Edge density scales as `1/c` under a uniform rescaling of a plan by `c`, since perimeter is linear and area quadratic. **That is not an invariance but a systematic scaling, and it is the whole of Section 4.1's argument.** The multiplier `1 + d/w` is scale-free and the seating and clearance floors are not; **the second is what stops the first proving too much.**

Head-turn geometry is invariant under table diameter. `psi = 90 − phi/2` depends only on the angular separation, so **the sightline result is identical for a 1.5 m and a 5.5 m round table** — which is why roundness buys equality and does not buy conversation, and why the acoustic constraint must be applied separately. **Centrality variance is likewise invariant under uniform scaling and under rotation of the whole layout, and is NOT invariant under the choice of head-turn threshold, which is why Section 6.3 reports it at three thresholds and why the hollow square's zero at 45 degrees is a coincidence rather than a symmetry.**

Unit rescaling of the storage law. With `Q' = cQ`, the law is invariant provided `eta`, `C` and `h` rescale and `delta`, `N`, `u`, `phi` and `a` do not. **The dimensionless group — `delta`, `u`, `N`, `a`, `phi`, `M`, `d/w`, `Gamma` — is comparable across systems; the unit-carrying group — `Q`, `eta`, `C`, `h` — is not, unless a common proxy is declared.**

How many scales this has been exercised at. Three constructed systems, at 42 m^2, 900 m^2 and one committee room; three table geometries computed and none built; one materials table computed and none measured. **That is one author, three constructed cases and no independent replication.** And **the three-way convergence of Section 6.4 is three calculations rather than three measurements, two of which share the proxemic input and the assumed speech level**, so it is weaker than three independent confirmations would be — a point stated here because the convergence is the section's strongest-sounding claim.

12.10.7 10.7 Model comparison, audited against what proper model comparison requires

This paper fits no model to data. All three worked systems are constructed with declared parameters, and no parameter is estimated by minimising anything. **Measured against the full requirement, the position is as follows, and three of the five items are not met.**

Requirement	Status in this paper
Out-of-sample rather than in-sample performance	**NOT APPLICABLE.** Nothing is fitted; there is no sample and no holdout
A matched null with the same free-parameter count	**NOT MET.** Each worked case specifies a matched control *design* — an equal-cost refurbishment with the mechanism absent — **but no alternative model of the outcome is specified or compared.** A design control is not a model comparison
The number of free parameters stated explicitly	**MET.** Section 8.1 fixes six (`Q`, `N`, `u`, `eta`, `delta`, `phi`) plus two measured cost inputs; 8.2 fixes six plus `phi`; 8.3 fixes six plus the alignment interval. **All are surveyed or stipulated, none is fitted, and none carries an interval except the alignment coefficient**
An information criterion, so the parameter count is paid for	**NOT MET.** No AIC or BIC was computed here, and none has been computed anywhere in this corpus, for any model

Requirement	Status in this paper
Effect sizes with intervals, not only p-values	**NOT MET.** No p-value is reported anywhere, and no interval accompanies any headroom, steady-state or parameter figure **except the alignment coefficient, which is reported as an interval precisely because a point estimate of it would be misleading**

The unmet items change how the headline figures should be read and are stated plainly. Section 8.1's fourfold headroom gain rests on six declared parameters and a declared calibration; **six declared parameters can produce almost any trajectory, and the case demonstrates that the procedure runs rather than that the model is right.** A reader who wants results from this paper should take the taper arithmetic, the edge yield, the comfort-model floor, the deference quartic and the centrality variance — **which are ARITHMETIC and CITED — and should not take the headroom trajectories, which are POSTULATED throughout.**

No scaling or heavy-tail claim is made anywhere here, so the distribution-fitting procedure of Clauset et al. [2009] has nothing to bite on. It does apply to the quadratic cost exponent used in Section 6.4, **which is defined by the model and not estimated**, and that status is recorded where the exponent is used and in Curzi [2026b]. Stumpf and Porter [2012] states the deeper problem — many mechanisms produce indistinguishable curves — and it applies to the underdetermination discussed in Section 9.3.

12.10.8 10.8 Scale type, analogy discipline, and the precision of the numbers

Scale type, quantity by quantity. Lengths, areas, volumes, times, temperatures, sound pressure levels and heat capacities are **ratio-scale physical quantities** with natural zeros, and every operation performed on them here is licensed. **Decibel quantities are interval-scale in the logarithmic domain**, so differences of decibels are meaningful and "twice as many decibels" is not, and no such statement is made.

The mismatch index is ordinal and it is treated as more than ordinal in two places. The eight-attribute character vector is a set of ordinal ratings; the maximum of a set of ordinal differences is defensible as a rank statement, **but `M_bar`, the mean of those differences, is not licensed by the scale of its inputs, and neither is the substitution of an ordinal difference for the impedance *ratio* the analogy actually uses (Section 10.6). Both operations are performed and both are stated here rather than defended.** Rule T-A is written on the maximum for exactly this reason.

Stored order and non-parallelism are treated as ratio-scale throughout and the conditions that would license that have not been tested. Michell [1997] argues that psychology systematically fails to test whether its attributes are quantitative at all before measuring them, **and that is the strongest single objection to this framework's founding move.** The formal remedy is conjoint measurement — the test for whether an attribute has additive quantitative structure [Luce and Tukey, 1964, Krantz et al., 1971] — or a Rasch demonstration [Rasch, 1960]. **Neither has been run for any quantity in this paper.** The alignment coefficient is worse placed than either: **it is estimated from a variance ratio of ordinal or interval self-reports, using a relation that follows from the postulate's linear form rather than from data, with a lower bound that depends on respondents reporting whether they can name what changed their mind.** The physical quantities in this paper are not exposed to that objection at all [Stevens, 1946], **and that asymmetry is the reason this paper leans on the geometry and the physics and reports the headroom trajectories as illustration.**

Analogy discipline, restated at the point of exposure. The transmission-line result is an **analogy**, and Section 4.2 states the exclusion. The first-order step response shared by the storage law and a low-pass section is a **shared mathematical form**. Sabine's equation, the diffusion depth and the effusivity contact temperature are **derivations** used within their own domains.

The failure mode is letting the first borrow the certainty of the third, and the concrete guard against it here is that no claim in Section 4 is certified by the analogy: the worked case measures `k` and `m` directly, and the analogy only motivated the design. Cartwright [1999] supplies the general escape — specify the arrangement within which the law is claimed to hold — and Anderson [1972] the reminder that a law true at one scale need not be informative at another.

Precision. The numbers here are of four kinds. *Derived-from-defined* — `1 + d/w`, `Gamma = 0.365974`, `ln 12 = 2.484907`, `D = 2.8966 m`, `psi = 76.15 deg`, `Var(V_i) = 2.0947` — are exact to the precision printed and may be recomputed further. *Physical measurements* — reverberation times, background levels, illuminances, operative temperatures — are quoted to the precision the stated method supports and no further. *Nominal or standard-practice inputs* — absorption coefficients, conductivities, heat capacities, effusivities, the illustrative life-cycle rates — **carry two or three figures that record a published typical value and not a measurement of anything that will be built**, and the effusivity column in particular is not comparable across sources without checking each source's convention. *Illustrative model output* — every headroom figure, every steady state, every `phi` — is the output of stipulated parameters and **carries no measurement uncertainty because there was no measurement**; four decimal places there record the arithmetic, not confidence. **Any application to real data must report fitted parameters with intervals, and the four-decimal presentation of Section 8 must not be carried over to a measured `eta`, where two significant figures with an interval would be the defensible form. The alignment coefficient is the one quantity in this paper reported as an interval, and it is reported that way because a point estimate of it would be the most misleading number the method can produce.**

12.11 11 Limitations

All three worked systems are constructed, not observed. No dataset was collected. Every number in Section 8 is the output of stated parameters under stated models, carried through so that a reader can re-derive it. **They demonstrate that the procedure runs and that it reports its own failures; they are not evidence that any building or committee behaves this way, and they must not be cited as such. Every figure there is an instance, not a constant: the method transfers and the numbers do not.**

The two load-bearing postulates have no external support. That a built threshold behaves like a matching section is an analogy with no theorem behind it and no measurement in this paper; **if it is false, Section 4 describes a suggestive picture and not a mechanism, and the entrance-sequence case is an expensive coincidence.** That deference acts as a common rotation with a single coefficient is this framework's own construction; **it appears in no literature, it is wrong in detail — deference is not uniform across members, private views are not orthogonal, and alignment varies by topic — and the entire quartic result and every number in Section 8.3 consumes it.**

The alignment coefficient is modelled rather than observed, and its estimator is weak. The relation `V_post/V_pre ~ 1 − a^2` follows from the postulate's linear form, not from data. Its upper bound is confounded with legitimate persuasion by evidence. **Its lower bound depends on the people being measured reporting whether they can name what changed their mind, which is a self-report about one's own reasoning and is exactly the class of judgement least reliably introspected** [Nisbett and Wilson, 1977]. The intervals are correspondingly wide — `[0.73, 0.93]` and `[0.25, 0.69]` — **and the interval before the intervention comes within 0.02 of the break-even alignment, which is the difference between a council that adds and one that destroys.**

A dimensional bridge in Section 8.1 is an identification, not an identity. `C_switch` is a fraction of a working day and `phi` is a fraction of the ceiling, and the paper adds them. **That step asserts that the share of available time lost to switching equals the share of the ceiling consumed by it, which requires stored-order production to be proportional to available working time at a rate independent of interruption. It is not defended anywhere here, and it carries**

Section 8.1's headline figures. Section 10.1 states it in full.

The mismatch index is ordinal and is used as more than ordinal. The mean `M_bar` is not licensed by the scale of its inputs, and substituting an ordinal *difference* for the impedance *ratio* the analogy actually turns on is unjustified within the analogy itself. **Both operations are performed.**

Nine claims in this paper carry no bibliography entry, and they are named rather than dressed with a citation that would not support them. *(i)* The 1984 window-view recovery study, described in Section 5.1 with its design and its sample size, is not in this corpus's bibliography; anyone quoting its numbers must read the paper. *(ii)* The field literature on interruption and resumption lag, on which Section 4.6 explicitly declines to supply a universal number. *(iii)* The communication-versus-distance regularity from research-and-development organisations. *(iv)* The predicted-mean-vote comfort model, its dissatisfaction curve and its clothing-insulation tables, all used as engineering-practice values. *(v)* The adaptive-comfort field result that perceived control widens the acceptance band. *(vi)* The ventilation standards whose per-person rates are referenced. *(vii)* The carbon-dioxide-and-cognition literature, whose contested state Section 5.4 summarises without citing either side. *(viii)* The last-speaks-first practice from aviation and clinical settings. *(ix)* The minority-influence result that authentic dissent outperforms an assigned devil's advocate. **Attaching a citation that did not actually support these sentences would be worse than leaving them uncited, because a reviewer will check.**

The collective-intelligence correlate is a laboratory finding extrapolated to standing bodies [Woolley et al., 2010], its replication record is mixed [Engel et al., 2014, Bear and Woolley, 2011], **and the causal step was preregistered, tested and not confirmed** [Curzi, 2026e]. The broader diversity-and-performance literature does not uniformly support a variety-raising programme [Mannix and Neale, 2005, Thompson, 2014, van Knippenberg and Schippers, 2007], and the formal diversity results are sensitive to their assumptions [Hong and Page, 2004, Singer, 2019, Grim et al., 2019, Kuehn, 2017].

The reflection problem outranks every before-and-after result reported here. Applied to a group whose members both influence and constitute the aggregate, the endogenous social effect is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011], and **the matched controls remove a confound without solving it.** The realistic repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001].

Every material value is nominal and no building in this paper exists. The absorption coefficients, conductivities, heat capacities and effusivities are generic published values; **Section 8.2's computed reverberation and contact temperatures are what a measurement would return if the nominal values were right, which is a stronger assumption than any other in the substrate section.** The effusivity table's `e` column depends on a convention that is not stated in the source and is not comparable across references.

`N_eff = 1 + (N-1)u` is not a Hill number and no external literature contains it. `1/HHI` and `exp(H)` are the grounded members of that family [Hill, 1973, Jost, 2006]; the affine count is this framework's own construction, adopted by design axiom [Curzi, 2026]. **The effective-speaker count used in Section 6.5 IS `exp(H)` and is grounded; the surplus law's effective count is not, and the two appear within pages of one another here** [Curzi, 2026]. Relatedly, **the variety measure travels under a word covering three incompatible constructs** — separation, variety and disparity [Harrison and Klein, 2007] — and the audited category counts here are variety while non-parallelism is closer to disparity, **and they are used in the same equation.**

The three-way convergence on table size is three calculations, not three measurements, and two of the three share the proxemic pitch and the assumed conversational level. **It is presented as the strongest result in Section 6 and it is weaker than three independent confirmations.**

The cost calibration was declared, not derived. All three cases express cost as `C = phi eta ln N`, which makes `phi` interpretable only relative to a ceiling that itself depends on the audited category count. **Two systems with different category audits are not comparable on `phi`, and none of the three is comparable with any system outside this paper.**

The framework's reflexivity is not applied to its own instruments. This paper prescribes measuring interruption counts, contested adjustments, addressee counts and speaking shares, and reporting them. **A measure adopted as a target ceases to measure what it names** [Goodhart, 1975, Campbell, 1979]; classifications of people interact with the people classified [Hacking, 1995]; and a framework can make its own assumptions true [Ferraro et al., 2005, Merton, 1948]. **A council told that its speaking-share evenness is scored can raise it without anyone being better heard, and nothing here detects that.** The position taken is the narrow one: parameters are treated as stable only over a declared window and only while the gauge is not itself a reported target [Lucas, 1976]. And the desire-line instrument carries the same hazard in physical form: **paving every trace destroys the measurement that produced it, so a building with no soft surfaces left has lost the ability to say it is wrong.**

No break-even probability was computed for any of the three interventions. Section 4.7 states the form the calculation should take and names the corpus's instrument for it [Curzi, 2026]; **it is not performed here, so the area-against-hours comparison is a point estimate under certainty where a decision under uncertainty was required.**

The surplus functional's form is underdetermined by the evidence. A sub-linear power law [Latané, 1981] and `n log n` growth [Briscoe et al., 2006] reproduce the same qualitative facts as `ln(1 + (N−1)u)`, and nothing assembled in this corpus discriminates between them [Stumpf and Porter, 2012]. **The logarithm is chosen for its axiomatic characterisation, not established by measurement**, and Peters and Gell-Mann [2016] is the strongest available warrant precisely because it needs no psychological premise.

Unmet rigour checks, printed rather than left to a reviewer. *(i) Model comparison.* No AIC or BIC here or anywhere in this corpus; no alternative model of any outcome specified; no out-of-sample test — see Section 10.7. *(ii) Effect sizes and intervals.* Nothing in Section 8 carries an interval except the alignment coefficient, because nothing in Section 8 was measured on a real system. *(iii) Scale type.* Stored order, non-parallelism and the mismatch index are treated as more than their scales license and the conjoint conditions were not tested [Michell, 1997, Luce and Tukey, 1964]. *(iv) Statistical control.* The controls specified are matched-design controls, not permutation or shuffle tests; **no false-positive rate was measured against nominal anywhere.** *(v) Independent replication.* One author, three constructed cases [Open Science Collaboration, 2015, Ioannidis, 2005]; the analysis path was not preregistered [Gelman and Loken, 2013, Simmons et al., 2011]. *(vi) Directional versus point prediction.* Meehl [1967] observes that directional predictions are nearly costless in the social sciences; **this paper does make point predictions with constants — 13.4 per cent, 38.3 per cent, 86.6 per cent, 0.9513, 2.095, 0.689 m — which is the right answer to that objection, and none of them has been put at risk against a real system.** *(vii) The discriminating observation.* Durlauf [2005] and Sobkowicz [2020] ask what observation would separate this account from a neighbouring one. **For the deference model there is one — measured disagreement should move quartically rather than linearly with independently estimated alignment — and it has not been run.**

What would falsify the account. H1 fails on interruption counts that do not fall after a threshold intervention meeting its mismatch targets. H2 fails on occupancy counts showing no edge preference where edge positions are otherwise comparable. H3 fails on measured satisfaction under personal control no higher than under an optimised fixed setpoint in a population with dispersion above 1.5 K. H4 fails on measured disagreement moving linearly rather than quartically with independently estimated alignment. H5 fails on speaking-share inequality uncorrelated with computed centrality variance across layouts.

Nothing in this paper is a human-subjects finding. No interventions were run, no participants recruited, no meetings recorded and no thermostat logs collected. **The consent requirement of D14, the unconditional pass of D13 and D17, and the declination and crossability constraints of T14 are design constraints on prospective work and are not reports of any study performed.**

12.12 12 Conclusion

Three levers in physical setting are given quantitative form and priced against the same gauge, `h = eta ln N - delta Q - C`, and in all three constructed cases the binding term was cost.

A threshold is a matching section. Reflection depends on the *ratio* of two zones' characters and not on their difference, and intermediate sections reduce the worst junction: **dividing a 1-to-100 change into six equal-ratio steps drops worst-junction reflected power from 96.1 per cent to 13.4 per cent**, which translates into the one-step rule that no threshold may change any attribute by more than one point on an eight-attribute ordinal scale. **A threshold at which people are expected to stop must be at least 2.0 m deep, because comfortable deceleration at 0.5 m/s^2 from 1.4 m/s takes 1.96 m; and a bent entrance is worth more than the metres it costs, because a 90-degree turn converts 1.5 m of path into about 2.1 s instead of 1.1 s while delivering two further duty items. Edge is the cheap variable and interior the expensive one: six thin islands add 99 per cent of a 10 x 10 m room's edge for 13 per cent of its floor, against 40 per cent for 16 per cent from one fat island.** In the worked floor, **interruptions fell from 22 to 6 per person-day at an unchanged 7-minute resumption lag, cutting the switching cost from 0.321 to 0.087 of the working day, raising headroom from `+0.0642` to `+0.2955` and the sustainable stored order from 5.185 to 9.041, for 68.8 m^2 — 7.6 per cent of net floor — with no change to the people, the work or the diversity of the group.**

Adjustability beats optimisation, and the argument is arithmetic. The standard comfort model predicts **5 per cent dissatisfied at its own theoretical optimum**, so the usual acceptance criterion accepts one person in ten uncomfortable by design in a building working exactly as specified. **At a 2.0 K dispersion of preferred operative temperature, a fixed setpoint satisfies 38.3 per cent and two degrees of personal authority satisfies 86.6 per cent**, and the case strengthens rather than weakens as the population becomes more varied. **A substrate retrofit took reverberation from 4.42 s to 0.51 s while retaining 60 per cent of the thermally coupled soffit — the acoustic and thermal requirements are compatible and are almost never coordinated — and moved headroom from `-0.0894` to `+0.2688` with a 3.7-fold rise in sustainable stored order.** And **at the same 20 C an aluminium handrail presents 20.7 C to the hand and a cork one presents 32.0 C: eleven degrees at the skin from a material choice alone, which no thermostat setting produces and none compensates for.**

Deference is quartic. Under the badged rotation postulate, `u = 1 - a^4`, so a twelve-member assembly retains **97.6 per cent of its ceiling at `a = 0.5`, 63.0 per cent at `a = 0.9` and 44.8 per cent at `a = 0.95`. Ordinary politeness is nearly free and strong deference is catastrophic, and nothing in the paperwork records the loss. Geometric equality has an exact computable definition** — zero variance in the number of other seats within a comfortable head turn — **and it is zero only for a rotationally symmetric arrangement at every threshold, against 9.06 for an eighteen-place boardroom table whose head seats command fifteen of the other seventeen. Three constraints that do not know about each other — proxemic pitch, direct-field speech level, and the quadratic communication count — converge on eight to fourteen seats**, with thirteen at 0.70 m pitch giving exactly the 2.90 m comfortable social distance. The worked council's **centrality variance went from 2.095 to 0.00, its effective-speaker ratio from 0.53 to 0.83, its estimated alignment from 0.83 to 0.47 and its headroom from `-0.0146` to `+0.0751`, with the sustainable stored order rising from 5.21 to 9.65 — and the entire gain came from non-parallelism, because the furniture and the protocols stopped rotating everyone's contribution toward one seat.**

The paper's counter-result is a refusal and it is stated as plainly as the results. The causal chain from turn-taking equality to group performance was preregistered and tested elsewhere in this series, and it did not confirm: the mediator moved decisively and the outcome did not [Curzi, 2026e]. **This paper therefore forbids reporting geometry or acoustics as a collective-intelligence intervention — it buys the measured mediator only — and applies the same restraint to air quality, where ventilation may be claimed and cognitive performance may not.** Two requirements were recorded as not met rather than relaxed: edge density reached 0.291 m/m^2 against 0.40 because no arrangement of islands fixes a 22 m plate, and

a 7.0 m deep room cannot be daylit at a 2.4 m window head. One was recorded as met with a 1.8 dB margin, **and a margin that thin is a finding, not a pass.**

These are the statements downstream papers should quote rather than paraphrase. **Whether any organisation is described by the storage law is a separate question, it is a postulate rather than a result, and the one preregistered confirmatory test of that law reported in this corpus did not meet its own declared margin** [Curzi, 2026i].

12.12.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the models developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. **The three systems worked in Section 8 are constructed examples with declared parameters, not field observations**; the survey and re-measurement figures reported there are the outputs those models return for the specified interventions and are not records of buildings that exist. **The figures are generated by the scripts named in each caption**, and those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 4 to 6.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. No meeting was recorded, no speaking share was measured from a real group, no thermostat log was collected and no occupancy count was taken. The consent requirement of requirement D14 — that no measurement of speaking share be made without the informed, renewable and revocable consent of every participant — the unconditional pass of D13 and D17, and the crossability and code-precedence constraints of T14 are **design constraints on prospective work and are not reports of any study performed.**

Preregistration

This paper reports no preregistered test of its own that was executed on a real system. The falsification conditions attached to each worked case in Section 8 are constructed instances showing the form such a registration would take, including the matched control each would require, and they are labelled as constructed there and here. **The preregistered test of the causal chain this paper declines to claim was run and reported elsewhere in this series, and it did not confirm** [Curzi, 2026e]. The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule

— a 2.8 per cent held-out advantage over a matched baseline against a declared margin of 10 per cent — is reported in Curzi [2026i], and any applied claim resting on this paper inherits that result.

12.13 Appendix A Measurement protocols

Protocol T1 — the desire-line survey. (1) Photograph every floor and ground surface from a taped, fixed camera position at the same time of day, weekly for six weeks, so the images register; record wear differentially — floor polish, carpet nap direction, grass, dust, and snow or dew, which are the best desire-line media in existence and free for a few days a year. (2) Photograph every room at end of day *before* it is tidied: chair positions are a desire-line medium, as are mugs, cables, coats and laptops left in situ. (3) Mark handle wear and scuffs at 0.9 m (bag corners) and 0.15 m (feet), and log door-propping — **a habitually propped door is a threshold whose crossing count is high enough that the occupants chose to pay in noise rather than in operations, and that is a datum.** (4) Overlay the six images: traces in all six are structural, traces in one or two are events.

Protocol T2 — acting on it. Pave the structural desire lines, which converts an observation into infrastructure and removes the maintenance cost of repaired grass and re-polished floor. **Honest caution: paving destroys the instrument that produced the trace.** Retain one unpaved surface beside every paved route.

Protocol T3 — measuring the resumption lag. For a task with a natural progress metric — lines written, cases cleared, tests passed — record it in five-minute buckets for at least ten person-days, logging every interruption's start and end. Take the mean rate in the twenty minutes before each interruption and find the elapsed time after it ends at which the rate returns to within 90 per cent of that baseline. **That is `m`. Report the median and the interquartile range: the distribution has a long right tail.**

Protocol T4 — measuring the switch count. A tally card taped to the desk, one mark per involuntary switch, for two weeks. **Self-report undercounts, but consistently, which keeps a before-and-after comparison valid even where the absolute level is not.** Do not use telemetry alone: **it misses the person leaning over the partition, which is usually the dominant channel.**

Protocol B1 — the thermal attrition audit. Collect individual preferred operative temperature by structured self-report — a seven-point sensation scale under measured conditions, at least ten occasions per person across a season. Rank occupants by distance from the delivered operative temperature, then measure by decile: hours present, voluntary attendance at optional gatherings held there, and twelve-month retention. **If distance from setpoint predicts none of the three, the category-count attrition claim of Section 5.3 is false in that building and must be dropped. Report either result.**

Protocol D1 — the written-then-spoken divergence. Before any discussion, each member writes a position on a scaled question — a numeric estimate, a rating, a rank order. Collect. Hold the discussion. Collect a second written position. Compute the variance of the first set, `V_pre`, and of the second, `V_post`. Under the deference postulate's linear form, `V_post/V_pre ~ 1 - a^2`, so `a_max = sqrt(1 - V_post/V_pre)`. **Badge: that relation follows from the postulate, not from data**, and legitimate persuasion by evidence also reduces post-discussion variance, so it is an **upper bound**. In the second collection, ask what changed the member's mind: a specific argument, or nothing they can name. With `f` the fraction of changed positions no member could attribute to an argument, `a_min = sqrt(f (1 - V_post/V_pre))`. **Report the interval and carry its midpoint as the working estimate. A point estimate without its interval is the most misleading number this method can produce.**

Illustrative instance. Thirteen members writing estimates `3, 7, 2, 8, 5, 6, 4, 9, 3, 7, 5, 6, 8` have mean 5.615 and variance 4.391. If the post-discussion standard deviation falls to 0.6, the variance ratio is 0.082 — **91.8 per cent of the group's independent variance has been destroyed.** If the members can point to the argument that did it, that is deliberation working. If they cannot, that is a cascade, and the estimator returns `a ~ sqrt(1 - 0.082) = 0.958`, **past**

the break-even point of Section 6.1.

Protocol D2 — the addressee count. During the meeting, log for each contribution whether the speaker's gaze and body orientation are directed at the chair or at the table. **A room in which over half of contributions are addressed to the chair is a room operating at high alignment.** One observer and a tally sheet.

Protocol D3 — the centrality audit. Take the furniture plan. Mark each seat position and its facing direction. For each ordered pair, measure the angle between the seat's facing direction and the bearing to the other seat, and count those within 45 degrees. **Report the vector `v`, its mean and its variance at 30, 45 and 60 degrees. A layout whose variance has not been computed is a layout whose governance has not been specified.**

12.14 Appendix B Failure-mode catalogue

FT1 — the cliff edge. A single door between zones with `M >= 3`, classically the street door opening onto working space. *Damages* cost, continuously and to everyone crossing. *Signature:* hesitation at the door, entries followed by exits within thirty seconds, over-corrected volume in the first sentences. *Fix:* T2's step limit.

FT2 — the corridor with no pocket. A route of uniform width with no recesses, so any pause is an obstruction. *Damages* the optional activity that is the conversion proxy: **two people who become an obstacle stop talking.** *Fix:* T4's pause-and-pass widths and three corridor widenings.

FT3 — the deep plan. Edge density below 0.2 m/m^2. *Damages* conversion, because the positions people select for do not exist. *Signature:* perimeter desks occupied at twice the rate of interior ones. *Fix:* T6 and T7, **and record the shortfall where the plate depth makes the requirement unreachable.**

FT4 — the reflected visitor. A threshold physically deep enough but delivering none of the duty items 4 to 7: nobody is seen arriving, nobody can assess the room before committing, and there is no way to wait without being conspicuous. *Fix:* design against the duty list, not the depth.

FT5 — the paved meadow. Every desire line paved and no soft surface left, **so the building has lost the ability to record a route it does not already have.** *Fix:* Protocol T2's retained surface.

FT6 — the open plan without impedance. All internal thresholds removed in the name of collaboration. *Damages* cost through the switch count and conversion through the loss of closable zones. *Signature:* headphone use as a proportion of the roster — **occupants privately funding the threshold layer the building did not supply.** *Fix:* T9, T10 and T11 together, **never T10 alone.**

FT7 — the fortified threshold. A threshold that has become a gate: crossing needs a third party's permission. **This is outside the framework's scope and is a prohibition rather than a failure mode.** *Fix:* remove the gate; the distinction is whether the choice stays with the crosser.

FT8 — the unmeasured switch. A threshold intervention justified, and later evaluated, on impressions rather than on `k` and `m`. *Fix:* T13, before and after, **with the control.**

FB1 — the air-temperature-only building. One controlled variable of six. *Damages* cost through persistent complaint and contested adjustment. *Signature:* complaints concentrated at particular seats rather than distributed. *Fix:* B6, measured at the seat.

FB2 — the cold window seat. A seat provided at the glazing, behind glazing that makes it uninhabitable in winter. *Damages* conversion by removing the position with the best light and view for half the year. *Fix:* B7.

FB3 — the horizontal-only lighting sign-off. 500 lux on the desk and 130 lux at the eye. *Damages* decay through the circadian route. *Fix:* B3 — **record both planes.**

FB4 — the permanently closed blind. A glare problem answered by the occupant with the only tool they were given. *Damages* the daylight asset entirely. *Signature:* count the blinds. *Fix:* B5, control glare at source.

FB5 — the sealed ceiling. Acoustic treatment that deletes the thermal-mass strategy. *Damages* cost through peak load, invisibly. **The material is still there; its coupling to the room air is not.** *Fix:* B11 — baffles and rafts absorb without sealing.

FB6 — the 5 per cent floor ignored. An operator treating residual thermal complaint as a personnel problem. **The model says the floor is 5 per cent by construction.** *Fix:* B8, personal channels.

FB7 — the dress code as thermal policy. A handbook clause disabling the free, personal, instantaneous adjustment channel and transferring the load onto a shared, slow, expensive one. *Fix:* recognise that clothing is a control, and stop.

FB8 — the carbon-dioxide overclaim. A ventilation business case built on the cognitive-performance literature. *Damages* the credibility of every other number in the specification. *Fix:* B10 — **claim ventilation only.**

FB9 — the cold handrail. Bare metal where skin meets building in an unheated space. *Signature:* computable in ten seconds from effusivity. *Fix:* B13.

FB10 — the laminate decade. Layered materials specified on first cost, with a step-function replacement stream that gets deferred whenever budgets are tight. *Damages* the appearance decay rate. *Fix:* B14, and price the stream rather than the first cost.

FD1 — the head of table. A seat with all others in its forward cone and the conventional right to open and close. *Damages* non-parallelism quartically. *Signature:* addressee count above 50 per cent to the chair. *Fix:* D1 and D9.

FD2 — the long boardroom table. The head-of-table failure in its most severe geometric form, with centrality variance of 9.06 at eighteen places. *Fix:* D1, D4 and D5.

FD3 — the oversized body. A deliberating group above sixteen. *Damages* cost quadratically while the ceiling grows logarithmically. *Fix:* D6, **and accept that the decision will be made elsewhere by fewer people if the body is not resized.**

FD4 — the inaudible far seat. A table wider than the room's noise floor supports. *Damages* non-parallelism by silencing the far members. *Signature:* speaking share correlating with distance from the table's midpoint. *Fix:* D4 and D7 together.

FD5 — the reserved seat. A round table with nameplates, reintroducing rank into a geometry built to remove it. *Fix:* D10.

FD6 — the cascade. Independent private judgements collapsing during discussion with no argument anyone can name. *Signature:* `V_post/V_pre < 0.25` with a high unattributed fraction. *Fix:* D11 and D12.

FD7 — the decorative minority. Members present, counted, and silent. **They are in the roster and not in the effective count, and the minute records twelve attendees.** *Signature:* `N_speak/n` below 0.7. *Fix:* D13's round-robin with an unconditional pass.

FD8 — the assigned advocate. A rotating devil's-advocate role standing in for real disagreement. **Better than nothing and not a substitute for recruiting someone who actually disagrees**, which is a recruitment problem and cannot be solved with furniture.

FD9 — the protocol that compels. A speaking-order rule with no unconditional pass, or a measurement taken without consent. **This is a prohibition, not a failure mode.** *Fix:* D13, D14 and D17.

FD10 — the unmeasured table. A round table installed and never instrumented, **which damages the ability to know whether any of this worked.** *Fix:* D2, D14 and D15, with the control.

Chapter 13

Turn-Taking, Complex Contagion, and the Critical Boundary-Cost Multiplier: Three Channels into the Surplus Law

Abstract. Three mechanisms that move realised non-parallelism are made numerical and coupled to the storage law. Turn-taking is treated as a spending efficiency rather than a source: realised interaction U = J u_pot, with J the normalised participation entropy, so that at N = 5 and u_pot = 0.60 a severely dominated meeting delivers 0.7450 nats against 1.2238 at equality, a 39% loss, while even perfect equality reaches only 76% of the ln 5 ceiling. A worked multidisciplinary meeting measured J = 0.52, S = 0.8879 nats (46% of ln 6), positive headroom of +0.0211 and a negative step of -0.2952; the surplus required for stability, U = 0.93, is infeasible on a roster whose capacity is 0.55, so protocol alone cannot repair it and only a cost cut from 0.42 to 0.20 produces growth. Contagion is treated as reinforcement-limited: seeding 10% of a population puts 57% within reach of one adopter but only 19% within reinforcing range, so clustered seeding dominates spraying. The silo is priced by a critical boundary-cost multiplier m*; at rho = 0.45 and eta = 0.34, m* = 3.17 while the case organisation operated at m = 8. A forced integration that genuinely raised contact from 0.03 to 0.45 raised surplus 121% and cost 279%, and destroyed order faster than inaction.

Keywords: participation entropy; complex contagion; clustered seeding; boundary cost; silo; critical multiplier; surplus ceiling; coordination cost

Series: B. Engineering the Surplus **Paper:** CCP-013

13.1 1 Introduction

The surplus functional `F(u) = ln(1 + (N−1)u)` prices the difference a roster carries. It says nothing about how much of that difference reaches the record. **This paper develops three mechanisms that stand between an available difference and a realised one, makes each numerical, and couples each to the storage law `Q_{t+1} = (1−delta) Q_t + eta S_t − C_t`.** The three are turn-taking, contagion, and the boundary between organisational units, and each fails in a different way that looks like a personnel problem and is not.

Turn-taking is a spending efficiency, not a source. Model realised interaction as `U_t = J_t u_pot`, with `u_pot` the non-parallelism the roster carries and `J = H/ln n` the normalised participation entropy of the speaking shares. At `N = 5` and `u_pot = 0.60`, a meeting with one voice at 80 per cent of the airtime delivers **0.7450 nats** against **1.2238** at perfect equality — **a 39 per cent loss purchased entirely by who was allowed to talk, on an identical roster, with nobody hired or fired.** And the ceiling is not reached even then: perfect equality still delivers only **76.0 per cent of `ln 5`**, because `u_pot` is 0.60 and not 1. **Equality spends what the roster carries; it does not create any.** The two-way duel is worse than the single dominant voice — 2.88 effective speakers against 3.32 — **and it is the most flattering of the failure modes, because it produces the appearance of vigorous debate while consuming the airtime the other three would need to enter.**

Contagion is reinforcement-limited, and the arithmetic is unforgiving of the intuitive plan. Under a mildest-possible complex-contagion rule — adopt when two of eight neighbours have — seeding 10 per cent of a population at random puts **57 per cent of everyone within one hop of the new practice and only 19 per cent within reinforcing range.** That gap is the whole distance between a launch that looks successful in week one and a practice that has vanished by month three. It is why clustered seeding dominates spraying even when spraying wins the first-period metric nine to one, and why the order parameter to report is largest connected adopter cluster rather than total adopters: **between mean degree 1.0 and 1.1 — a 10 per cent change in connectivity — the largest connected group in a 220-person firm goes from essentially nothing to 38.7 people.**

The silo is priced by a critical boundary-cost multiplier. Let `rho` be the fraction of cross-boundary pairs actually in contact and `m` the factor by which a cross-boundary exchange costs more than a within-boundary one. Differentiating the one-step increment with respect to `rho` gives

```
m* = eta (N−1) u_cross / [ (1 + (N−1) u(rho)) c_in x (cross pairs) ]
```

and **contact improves the system only while `m < m*`.** At `rho = 0.45` and `eta = 0.34` in the worked case, `m* = 3.17` while the organisation operated at `m = 8`. **Whether cross-boundary contact helps or harms is therefore determined by the boundary cost and not by the willingness, goodwill or collaborative disposition of the people crossing: enthusiasm does not appear in the expression.**

The paper's central counter-result follows directly and is the reason it is worth reading. A forced integration in the worked 60-person organisation raised realised non-parallelism from 0.1155 to 0.3465 — **a genuine, large, successfully executed increase in contact that more than doubled what it set out to double — and it destroyed stored order faster than doing nothing.** Surplus rose 121 per cent; cost rose 279 per cent; the step went from `−0.1953` to `−0.3714`, and 78 per cent of stored order was gone in twelve months against 63 per cent in twenty-four by inaction. **At the un-remediated boundary cost the step is monotonically worse at every level of contact up to complete integration: there is no value of `rho` at which that organisation benefits from more collaboration.** The same target contact, approached by lowering the boundary cost first — one shared instrument, one interface contract, two offered rotations — takes `m` from 8 to 2 and `eta` from 0.34 to 0.46, and the identical contact and identical surplus then grow the stock at `+0.0408` per month. **The entire difference between a destructive reorganisation and a working one is the boundary cost and the conversion rate, neither of which is about how much people collaborate.**

Two further results are worth stating in the introduction because they are what the arithmetic buys that exhortation cannot. First, **the diagnostic split**: in the worked deliberation group, headroom is `+0.0211` while the one-step increment is `−0.2952`. The gauge says the regime is *feasible* and the current geometry does not achieve it, **and confusing the two is why organisations despair when they should retune, or retune when they should stop.** Inverting the requirement shows the group would need realised `U = 0.93` on a roster carrying `u_pot = 0.55`, **so the requirement is infeasible under any conversational protocol whatsoever** — the largest available turn-taking intervention moved the step by 0.1139 and did not change its sign, and

only a cost cut from 0.42 to 0.20 produced growth. Second, **rotation dosage is computed rather than chosen**: at `m = 2` and `eta = 0.46` the step turns positive only just above `rho = 0.30`, so a one- or two-week cross-boundary rotation improves it by 0.012 to 0.023 and leaves it firmly negative. **A one-week rotation is tourism.**

Sections 2 and 3 state the hypotheses and the framework, including the identification problem. Section 4 develops turn-taking, Section 5 contagion, Section 6 the boundary. Section 7 collects the design specifications. Section 8 works three systems end to end. Sections 9 to 12 discuss, verify, limit and conclude. Appendix A gives the measurement instruments and Appendix B the failure-mode catalogue.

13.2 2 Hypotheses

Some results below are exact consequences of stated models and cannot be falsified by observation; they are labelled as derivations where they appear. Others claim that these models describe real groups, and those are stated here with what would defeat them.

H1 — Realised non-parallelism is the roster's available difference scaled by turn-taking equality: `U_t = J_t u_pot`. Predicted: an intervention that raises `J` with the roster held fixed raises measured disagreement dispersion and realised surplus proportionally; in the worked group, `J` from 0.52 to 0.86 takes `S` from 0.8879 to 1.2134 nats. **Falsified by:** measured surplus that does not track `J` at fixed roster, or that tracks it non-linearly in a way a linear interpolation cannot absorb. **The linear form is a modelling choice with no derivation behind it, chosen for its boundary behaviour — at `J = 1` the group realises everything on the roster, and at `J -> 0` a single voice has `u = 0` with itself and produces `ln 1 = 0` — and it should be replaced the moment anyone measures a better one.**

H2 — Average social sensitivity acts primarily on conversion rather than on surplus. What turn-taking governs is how much difference is *emitted*; what social sensitivity governs is how much of what is emitted is received, understood and retained. **Predicted:** groups matched on `J` and `u_pot` but differing in measured social sensitivity differ in the fraction of raised objections that survive into a durable record. **Falsified by:** objection survival uncorrelated with measured social sensitivity across groups matched on participation equality. **This is a badged assignment of a correlate to a parameter and nothing in this paper measures it.**

H3 — Costly practices require reinforced exposure, so clustered seeding dominates uniform seeding at equal budget. Predicted: under a 2-of-8 rule, a seeding budget concentrated into one unit past its own local tipping point produces a larger connected adopter cluster, and higher survival after sponsor withdrawal, than the same budget spread to maximise first-hop reach — even though the spread plan reports 44.5 people in reinforcing range against the clustered plan's five. **Falsified by:** a matched comparison in which the sprayed budget produces equal or greater largest-cluster size at six months, or equal survival through a one-month sponsor withdrawal.

H4 — Whether cross-boundary contact helps is determined by the boundary cost, not by disposition. Contact improves the one-step increment only while `m < m*`. **Predicted:** in an organisation measured at `m > m*`, raising `rho` lowers the step monotonically; in the same organisation after `m` is lowered below `m*`, raising `rho` raises it. The worked case gives `m* = 3.17` at `rho = 0.45`, `eta = 0.34` against a measured `m = 8`. **Falsified by:** an organisation measured above its own critical multiplier whose stored order nonetheless rises after contact is increased with the boundary cost untouched. **This is the paper's most exposed prediction and the one it most wants tested.**

H5 — A shared instrument lowers the boundary cost. The dominant component of cross-boundary cost is translation and disputed measurement, so a single measurement apparatus owned by neither side removes most of it. **Predicted:** median cross-boundary answer latency falls by at least half within four months of a shared instrument entering daily use; in the worked case, 14.6 hours to 3.6 hours, `m` from about 8 to about 2. **Falsified by:** `m` staying at its prior value while a well-built, well-used shared instrument is in daily use — **which would mean the boundary cost lives somewhere this paper did not look, in incentives, in status, in scheduling, and the recommendation to build instruments first is wrong for that system.**

Two claims in this paper are **not** hypotheses and are labelled accordingly. That the three reported correlates of a collective-intelligence factor map onto this framework's parameters — turn-taking onto realised non-parallelism, social sensitivity onto conversion, composition onto the category count — is a **modelling assignment** with no derivation and no test reported here; it is the whole engineering content of Section 4 and it is not proved. That an organisational domain can be described as a basin in a comfort landscape, with a barrier between it and a neighbouring domain, is an **analogy**; Section 6.1 states what it licenses and Section 11 states that it is not a measurement.

13.3 3 Framework

13.3.1 3.1 What is presupposed

The storage law and its gauge. The equation acted on throughout is

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t,     S_t = F(U_t) = ln(1 + (N−1) U_t)
```

with headroom `h_t = eta ln N − delta Q_t − C_t`, the maximum one-step increment `r_max = h_t`, the admissibility condition `C_t <= (1−delta)Q_t + eta S_t`, the sustainability ceiling `C_t <= eta ln N − delta Q_t`, the exact transient `Q_t = (1−delta)^t Q_0 + (1−(1−delta)^t) Q_inf`, and the steady state `Q_inf = (eta F(u*) − c*)/delta`, **which the result allows to be negative and does not hide when it is** [Curzi, 2026b]. Where headroom is negative, no interaction geometry prevents decline. The level–rate–delay vocabulary long predates this framework [Forrester, 1961], the tendency of people to misjudge such systems even under aligned incentives is documented [Sterman, 1989], and headroom is this framework's name for organisational slack [Cyert and March, 1963].

The surplus functional. `u(x,y) = 1 − (x.y)^2` in `[0,1]` and `f(u) = ln(1 + (N−1)u)`, characterised by four axioms, with `0 <= F(u) <= ln N`, `F = 0` exactly at parallel and `F = ln N` exactly at orthogonal [Curzi, 2026]. **The affine effective count `N_eff = 1 + (N−1)u` is a design axiom: chosen, not derived**, and its provenance, its bridge to a participation ratio and its measurement-error budget are developed in Curzi [2026c], whose worked case records that a hundred-person department at `u = 0.05` has an effective count of 5.95. **Concavity is what makes the second genuinely different member the largest single gain an assembly will ever buy**, and the logarithmic ceiling is what makes a bigger group a poor answer to a difference problem.

The decomposition. For a pure block structure the framework separates cross-block from within-block non-parallelism, `u = u_cross + u_div`, with the bound `max(f(u_cross), f(u_div)) <= f(u) <= f(u_cross) + f(u_div)`, and prices the two identically at the margin [Curzi, 2026d], whose institute case records `u_cross = 0.72`, `u_div = 0.03`, `u = 0.75` at `N = 6`, a balance index of 0.0206, ceiling utilisation of 0.8696 and **zero within-block dissents in forty decisions.** Section 6 is that case's structural sibling: **a roster rich in cross-block difference that realises none of it.**

Opposition is not difference. The extremality condition is stated on the *squared* alignment, so a pair in perfect opposition and a pair in perfect agreement both read `u = 0`, `N_eff = 1` and surplus zero [Curzi, 2026r]; the same identity in the frequency domain reads `u = 1 − rho^2`,

depending only on `|rho|`, so `rho = +1` and `rho = −1` give the identical result [Curzi, 2026]. **A group that has organised itself into two opposed camps has not preserved its difference; it has spent it, and the arithmetic does not distinguish that state from unanimity.**

Three effective counts appear in this paper and they are different objects. `N_eff = 1 + (N−1)u` is the surplus law's affine count and **it is not a Hill number** — it is a linear interpolation between 1 and `N`, belonging to no order of the family whose canonical members are `1/HHI` and `exp(H)` [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. `E = exp(H)`, the effective number of speakers of Section 4.2, **is** the Hill number of order one, the exponential of Shannon entropy [Shannon, 1948, Pielou, 1966], computed from participation shares. And `1/HHI`, the Hill number of order two, is the concentration instrument used elsewhere in this corpus, where a naive share vector gives 3.41 effective jurisdictions against a bloc-collapsed count of 1.00 [Curzi, 2026], and where the same instrument applied to reachable shares gives 4.96 effective compartments from six unequal ones and cuts maximum single reach from 100.0 per cent to 30.0 per cent [Curzi, 2026]. **The structural rhyme between them is that all three punish redundancy — a member who adds nothing distinct is not counted — and the rhyme is not an identity. They must not be substituted for one another, and `ln E` must never be reported as a surplus.**

The comfort construct. The framework's founding move is that comfort is the felt total of present costs, so the present state is a local minimum of the comfort landscape **by definition rather than by luck** [Curzi, 2026]. **Section 6 is that definition applied to an organisational domain**: a silo is not a failure of will but a position from which every direction out is uphill, and the method that follows from the definition is to lower the neighbouring valley rather than to push.

13.3.2 3.2 Identification: what no amount of measurement recovers

This is the most serious methodological problem in the paper and it belongs in the method. Every mechanism here runs through a group whose members both influence and constitute the aggregate: who speaks shapes what the group decides, what the group decides shapes who speaks next, and the group is made of its members. That is a linear-in-means reflexive specification, and Manski [1993] proves that in such a specification **the endogenous social effect is not identified from observational data** — it cannot be separated from contextual effects or from correlated unobservables however much data is collected. Shalizi and Thomas [2011] reinforce it for network data, and Lyons [2011] makes the same point about a widely cited contagion result: influence and selection are generically confounded in observational network data, **and the contagion sections of this paper are exactly where that confound bites hardest.**

What survives and what does not. The participation entropy, the binomial reinforcement arithmetic, the clustering coefficients, the percolation fixed point, the pair counts and the critical-multiplier derivation are combinatorics and elementary probability computed from stated models; no identification problem arises for any of them. **The interpretation of a measured change in `J`, in `u`, or in adoption as an endogenous social effect is what is not identified**, and no held-out comparison recovers it.

A partial remedy is adopted and its price is paid. Each worked case carries a **shuffled-input control**: the same surplus series randomly permuted across periods, held out and compared. That asks whether the *timing* of surplus predicts the *timing* of order, and it is the control that separates a mechanism from a period of managerial attention. Together with the matched autoregressive baseline it addresses the confound that measuring a group changes it [McCambridge et al., 2014, Rosenthal and Jacobson, 1968]. **It does not solve the reflection problem.** The route that would is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001]; the fixed rosters, declared category sets and declared participation rules of these surveys point toward it without taking it. **Until then, every applied claim in this paper about a group is a modelling position rather than an identified empirical result**, and Durlauf [2005] and Sobkowicz [2020] state the demand that remains open: name the obser-

vation that would distinguish this account from a neighbouring one fitting equally well. The general hazard of over-reading social-scientific prediction is documented [Lazer et al., 2014, Hofman et al., 2017, Watts, 2014, Salganik et al., 2020], and this paper inherits it.

13.3.3 3.3 Analogy discipline

The information-theoretic quantities are used as information theory and nothing more. `ln N` is a bound on an ensemble of `N` equiprobable categories [Shannon, 1948]; the requisite-variety tradition supplies the reason a variety term appears as a ceiling at all [Ashby, 1956]; and `E = exp(H)` is a descriptive diversity index. **Surplus is not identified with Shannon entropy or mutual information, and no thermodynamic entropy law is invoked anywhere.**

The percolation and threshold results are derivations within their own models and analogies outside them. `S = 1 − e^{−zS}` is exact for an Erdos–Renyi random graph [Erdős and Rényi, 1960, Newman, 2018], and the clustering and path-length expressions are exact for a ring lattice and its rewirings [Watts and Strogatz, 1998]. **Real organisational graphs are neither random nor regular**: they are degree-heterogeneous, correlated, and structurally diverse in ways that change both quantities [Barabási, 2016, Ugander et al., 2012], so the numbers here are **order-of-magnitude structure and not predictions for any organisation**, and Section 11 says so at length.

The comfort landscape and the escape-rate reading are analogies and are badged as such. A basin, a barrier, a ridge and an escape rate are borrowed vocabulary; **nothing about activation energy, temperature or Arrhenius kinetics is claimed to hold of a person deciding whether to learn a neighbouring domain's vocabulary.** What the analogy supplies is a hypothesis about the *shape* of a decision — that lowering the destination is different from raising the agitation — and Section 6.1 converts that into a testable statement about forward and reverse rates.

The logarithm has two warrants and this paper needs only the weaker. The Fechnerian warrant requires a contested perceptual story [Fechner, 1966]; Peters and Gell-Mann [2016] derives a logarithmic evaluation from multiplicative dynamics with **no psychological premise at all**. Mirowski [1989] is the standing warning against copying a physics without its conservation law, and Cartwright [1999] supplies the escape this paper takes: specify the arrangement within which the law is claimed to hold, which is the stated domain of Section 10.5.

13.3.4 3.4 Standing honesty clauses

- **As deployed, the surplus functional is a lower bound** on the ensemble's information [Curzi, 2026]. Every number in this paper is a floor.
- **`ln N` is a ceiling per interaction, not a typical value.** A group at 46 per cent of its ceiling is not 46 per cent of the way to a target; it is realising 46 per cent of what its own roster could carry in a single interaction.
- **Diversification benefit depends on covariance, not on count.** The point that a portfolio's risk reduction comes from the covariance structure and not from the number of holdings was stated formally in 1952 [Markowitz, 1952], **and this framework's insistence that `u` and not `N` is what pays is that result restated in another vocabulary.** It is not novel here.
- **A proxy for stored order must not be a repackaging of the interaction measure.** In all three worked cases the order proxy is built from downstream operational facts recorded by people who do not know the interaction measure, while the interaction measure comes from a disagreement audit. **A proxy that is secretly the input will fit beautifully and mean nothing**, and this is the most common measurement error in applying the law.
- **Nothing in this paper is mandated, and mandate is not a weaker version of adoption but a different thing.** No seeding programme, rotation, protocol or measurement here may be required, incentivised through evaluation, or used as a compliance criterion. **A method that works by removing resistance has no coercive failure mode, and its worst**

outcome is that someone declines to use it. The framework's own treatment of the case where a feedback loop runs through another person's will records that seam as unsettled and refuses to close it [Curzi, 2026], and this paper's mandate refusal in Section 5.7 is written against that refusal rather than around it.

- **Where a measurement becomes a target it ceases to measure what it names** [Goodhart, 1975, Campbell, 1979]. The participation index in particular must never be an individual performance target, and Section 11 records that this paper's own instruments are exposed to the hazard they warn about.

13.4 4 Turn-taking as a spending efficiency

13.4.1 4.1 What the collective-intelligence result supplies, and what it does not

Woolley et al. [2010] report a single statistical factor predicting group performance across varied tasks, not predicted by members' average or maximum individual ability, and correlating with three things: social sensitivity, **equality of conversational turn-taking**, and the proportion of women in the group. **The turn-taking correlate is the one an engineer should care about most, not because it is the strongest but because it is the one a room, a protocol and a piece of furniture can move.**

The honest limit is stated here rather than buried. The factor was measured in short-task laboratory settings with small groups; extrapolating it to a standing institutional committee is a modelling assumption and not a finding. The replication and extension record is mixed rather than uniformly supportive [Engel et al., 2014, Bear and Woolley, 2011], and the broader diversity-and-performance literature carries its own well-documented scepticism [Mannix and Neale, 2005, Thompson, 2014, van Knippenberg and Schippers, 2007] against formal results whose conclusions are sensitive to their assumptions [Hong and Page, 2004, Page, 2007, Singer, 2019, Grim et al., 2019, Kuehn, 2017].

The mapping this paper uses is a postulate and it is badged. Turn-taking equality is assigned to realised non-parallelism; social sensitivity to the conversion coefficient; composition to the audited category count. **That assignment is the whole engineering content of this section and it is not proved.** What follows from it is arithmetic; what precedes it is an assumption.

13.4.2 4.2 Turn-taking equality, made numerical

Let a group of `n` members produce speaking shares `p_1, ..., p_n` over an observation window, with `sum p_i = 1`. Define

```
H = - sum_i p_i ln p_i                  (nats)
E = exp(H)                               effective number of speakers
J = H / ln n                             equality index, in [0,1]
```

`J = 1` is perfectly even participation and `J -> 0` is one voice. `E` is an **effective count of speakers** — a headcount audited for the fact that a person who says nothing is not, for the purposes of the discussion, present. **BADGE: `E = exp(H)` is the Hill number of order one computed from participation shares; `N_eff = 1 + (N-1)u` is computed from geometric non-parallelism between category vectors. They are different quantities sharing the exponential-of-a-log-measure form and they must not be conflated.** The reason to notice the rhyme is that it says what kind of quantity is in hand: **both punish redundancy, and both say the same brutal thing — a member who adds nothing distinct is not counted.**

Computed for a five-person group, with `ln 5 = 1.6094`:

participation profile	shares	H (nats)	E = exp(H)	J = H/ln 5
perfectly equal	0.20 / 0.20 / 0.20 / 0.20 / 0.20	1.6094	5.0000	1.0000
mild skew	0.30 / 0.25 / 0.20 / 0.15 / 0.10	1.5445	4.6855	0.9596
one dominant voice	0.60 / 0.15 / 0.10 / 0.10 / 0.05	1.2014	3.3247	0.7465
two-way duel	0.45 / 0.45 / 0.04 / 0.03 / 0.03	1.0578	2.8800	0.6573
severe dominance	0.80 / 0.10 / 0.05 / 0.03 / 0.02	0.7420	2.1001	0.4610

A single person taking 60 per cent of the airtime in a five-person meeting reduces the effective number of speakers from five to 3.32: five salaries are being paid and three and a third people are being convened. At 80 per cent dominance the figure is 2.10 — a conversation between one person and a rounding error, **which everyone present knows without being able to say why.**

Read the fourth row carefully. The two-way duel scores worse than the single dominant voice, at 2.88 against 3.32. Two loud people arguing is not twice as good as one loud person talking; it is worse, because the argument consumes the airtime the other three would need in order to enter, and it does so **while producing the appearance of vigorous debate. The duel is the most flattering of the failure modes and one of the most expensive.** It is also the state in which two opposed positions can look like maximal difference while contributing none of it: the extremality condition is stated on the squared alignment, so perfect opposition and perfect agreement both read `u = 0` [Curzi, 2026r,?].

13.4.3 4.3 From equality to the storage law

The bridge, wearing its badge. A group has an *available* non-parallelism `u_pot` determined by who is on the roster — their training lineages, incentives and priors. It *realises* only some of that in any given interaction, and this paper models the realised value as

```
U_t = J_t * u_pot            J_t in [0,1] the turn-taking equality index
```

This is a modelling choice and not a derived result. It is chosen for its boundary behaviour: at `J = 1` the group realises everything on the roster, and at `J -> 0` only one voice reaches the record, and a single voice has `u = 0` with itself, so `F = ln 1 = 0`. **A monologue produces no surplus no matter whose monologue it is.** The linear interpolation between those endpoints is the simplest defensible form and **should be replaced the moment anyone measures a better one.** With `N = 5` categories and `u_pot = 0.60`:

profile	J	U = J u_pot	N_eff = 1 + 4U	S = ln(1+4U)	% of ln 5
perfectly equal	1.0000	0.6000	3.4000	1.2238	76.0%
mild skew	0.9596	0.5758	3.3031	1.1949	74.2%
one dominant voice	0.7465	0.4479	2.7915	1.0266	63.8%
two-way duel	0.6573	0.3944	2.5774	0.9468	58.8%
severe dominance	0.4610	0.2766	2.1065	0.7450	46.3%

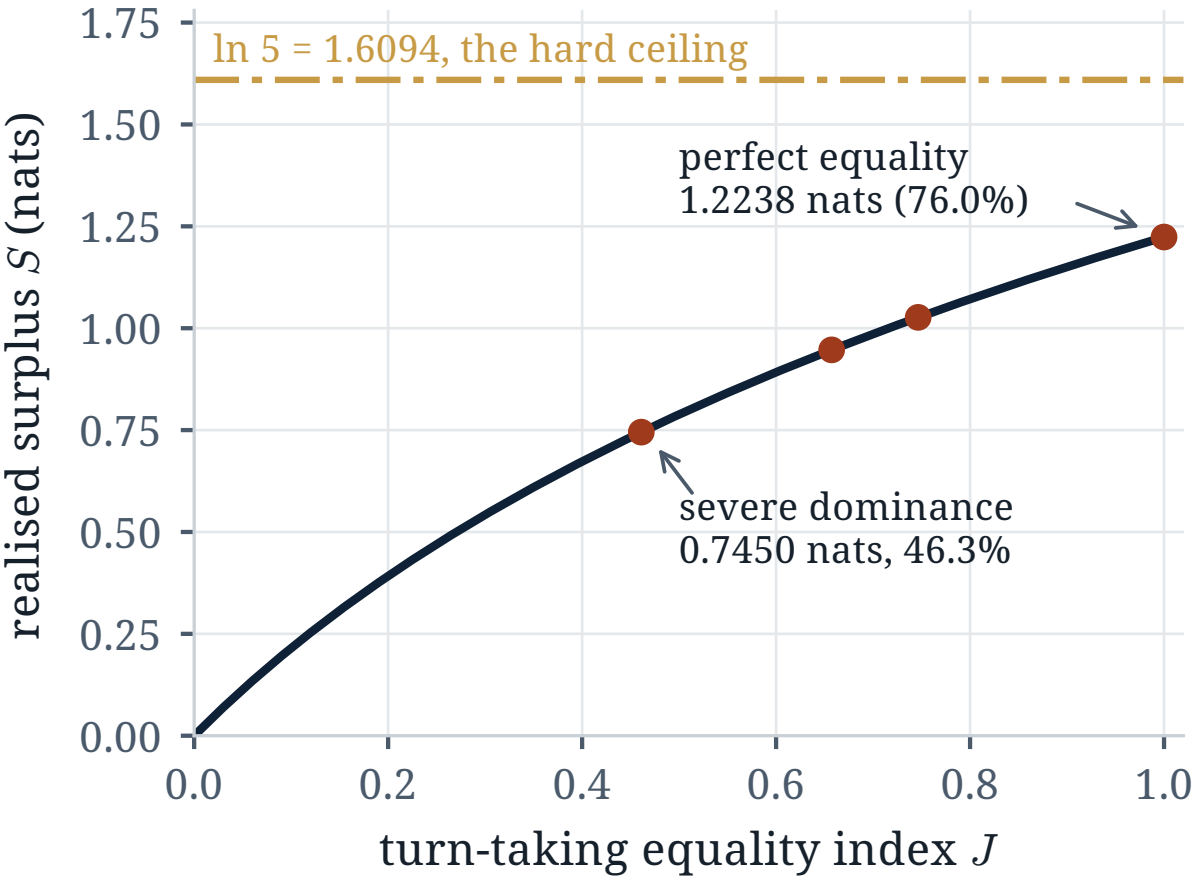

Figure 13.1: **Turn-taking spends what the roster carries and creates none of it.** Realised surplus `S = ln(1 + 4 J u_pot)` at `N = 5` and `u_pot = 0.60`: perfect equality delivers 1.2238 nats, 76.0 per cent of the `ln 5` ceiling, and severe dominance delivers 0.7450 nats, 46.3 per cent — a 39 per cent loss on an identical roster. Modelled: `U = J u_pot` is a badged modelling choice with no derivation behind it and `u_pot = 0.60` is stipulated; the arithmetic given them is exact. Generated by `figs/src/CCP-013_fig01.py`.

Between an even meeting and a dominated one, the same five people on the same roster deliver 1.2238 nats or 0.7450 nats — a 39 per cent loss purchased entirely by who was allowed to talk. Nobody was hired or fired, nobody's ability changed, the roster is identical: **the arrangement moved and the output moved with it.**

Notice what the table does not say. Even at perfect equality the group reaches only 76.0 per cent of its ceiling, because `u_pot = 0.60` and not 1. Equality is a spending efficiency, not a source. If the five are graduates of the same programme with the same incentives, `u_pot` is near zero, `J = 1` multiplies near zero by one, and the perfectly equal meeting produces `ln 1 = 0`.

13.4.4 4.4 Social sensitivity as a conversion parameter, and composition as a category count

Turn-taking governs how much difference is *emitted*. **Social sensitivity governs how much of what is emitted is received, understood and retained — and that is the definition of the conversion coefficient.** A contribution that is made, not understood, and not recorded has been emitted and not converted, and the storage law charges its cost either way. **That assignment is H2 and it is badged: nothing in this paper measures it, and a protocol that makes a signal**

explicit converts a compositional advantage into an architectural one, which is the practical reason to prefer protocol to selection.

The composition finding requires more care than any other line in the source literature, and it is stated exactly. Woolley et al. [2010] report that the proportion of women in a group correlates with the collective-intelligence factor, and that the relationship is **mediated by social sensitivity**. Four things follow and one emphatically does not.

Follows. **The mediation is the operative claim**: a mediated correlate is a marker of the mediating variable, so the design target is the mediator and not the marker. *Follows.* A group composed entirely of one type on any dimension has, by this framework's own argument, a lower audited category count than a mixed one, and the ceiling `ln N` falls accordingly. *Follows.* The finding is a result about a sample, in a laboratory, at one time, and its transfer to a standing institution is an assumption. *Follows.* Its replication record is mixed [Engel et al., 2014, Bear and Woolley, 2011].

Does not follow: that any individual's contribution can be predicted from their category. The result is a statement about group-level correlates and it licenses nothing about individuals. **Requirement CI-17 of Section 7 therefore forbids selecting individuals on any of the reported correlates**, and that prohibition is not a decoration on the argument — **a framework whose category count is its ceiling has an obvious and ugly failure mode if categories are used to sort people, and the prohibition is what keeps the arithmetic from licensing it.**

13.4.5 4.5 What the factor is not: not intelligence, not morale, not cohesion

It is not aggregate individual ability, which is the finding's whole point: the factor was not predicted by members' average or maximum. In this framework's terms, **individual ability sits in what each member brings and the factor sits in the effective count** — a room of highly able people all trained the same way has a high mean and a low `u`, and the surplus law prices the second.

It is not morale, and it is not cohesion — and cohesion is frequently the enemy. Cohesion drives non-parallelism toward zero, and non-parallelism is the quantity the ceiling is built on. A group that has converged is a group whose members' contributions have become parallel, and `f(0) = ln 1 = 0`. **A pleasant, aligned, mutually appreciative committee is, in this arithmetic, indistinguishable from a monologue.** Cohesion has a genuine benefit — it lowers coordination cost — so the question is a crossover rather than a prohibition: **compare the marginal cost reduction against the marginal surplus lost, annually, and record the comparison** (requirement CI-14). What makes it dangerous is that the cost saving is immediate and visible while the surplus loss is delayed by the time constant `1/delta`, **which is why a converged committee looks strong for years and then does not.**

Groupthink, priced. An over-framed group banks *more* stored order than a calibrated one, not less: it produces decisions faster, records them more confidently, and re-litigates them less. **What it loses is veridicality, and the storage law has no term for whether the stored order is correct.** That is a real limitation of the law and is stated here rather than in a footnote: **the law counts protocol, runbook, default and agreement; it does not check them against the world.** A group whose `u` has collapsed will show a healthy stock and a rising gauge while being systematically wrong, **and no amount of computing headroom will detect it.** The corpus's own analysis of reflexive runaways makes the same structural point from the other side — the loop terminates at the ceiling rather than diverging, and its time constant `1/(1−a)` goes tenfold at a loop gain of 0.90, **so the system slows before it destabilises and the slowing is what is observed** [Curzi, 2026ac]. **The detection instrument is not the gauge but the disagreement audit, run on a cadence.**

13.4.6 4.6 The room is part of it

Turn-taking equality is partly a property of the room. In a hard-surfaced reverberant space the loudest speaker wins by acoustics: the gap a following talker must leave for the previous

talker's tail to fall 15 dB is `t_15 = RT60/4`, which is 488 ms in an untreated 1.95 s room against a natural turn gap of about 200 ms, and 98 ms after treatment [Curzi, 2026e]. **A group in such a room will attribute the resulting silence to the people who are silent.** The geometric channel is the same: deference modelled as a common rotation toward one seat gives `u = 1 − a^4`, so an assembly keeps 97.6 per cent of its ceiling at an alignment of 0.5, 63 per cent at 0.9 and 45 per cent at 0.95 [Curzi, 2026f].

The correction that must travel with that claim is stated here in full. The step from raising turn-taking equality to raising the collective-intelligence factor requires a causal direction that the source literature does not establish, **and the preregistered test of it was run and did not confirm: the mediator moved decisively — turn-share evenness from 0.604 to 0.812 against a matched control room flat at 0.638 to 0.650 — and the group-performance outcome did not reach its threshold** [Curzi, 2026e]. **Wherever this paper buys turn-taking equality it is buying the measured mediator: reduced listening effort, recovered access to the ceiling for members the room was excluding, and a measured rise in the effective-speaker ratio. Those are worth having on their own account and require no causal claim. Reporting an acoustic or geometric change as a collective-intelligence intervention is forbidden here.**

13.4.7 4.7 Measuring the proxies

Six instruments are specified in full in Appendix A: participation shares, an interruption ledger, a disagreement audit for `u_pot`, an error-decorrelation measure that is harder and better, a conversion audit measuring objection survival into the durable record, and a cost tally. **What to do with the numbers is as important as taking them. Do not compute a single scalar and call it a group's collective-intelligence factor.** The factor is a laboratory construct measured by a specific battery; what these instruments give are **proxies for the parameters this framework prices**, and the badge is required on every report that uses them (requirement CI-20).

And the standing warning applies with unusual force here. The moment the participation index becomes a target it ceases to measure what it names [Goodhart, 1975, Campbell, 1979]; classifications of people interact with the people classified [Hacking, 1995]; and a framework that assumes the worst of people can make the assumption true [Ferraro et al., 2005, Merton, 1948]. **A meeting in which everyone speaks for exactly their share, because the share is scored, has a participation index of 1 and has learned nothing.** Requirement CI-19 forbids using it as an individual performance target, appraisal input or ranking criterion, **and that prohibition is load-bearing rather than decorative.**

13.5 5 Contagion: reinforcement, clustering, thresholds, and the order parameter

13.5.1 5.1 The reinforcement requirement, made numerical

A practice worth adopting is usually *costly* to adopt: it is worth doing only if others do it, and it is socially expensive to be the only person doing it. That is the definition of a **complex contagion**, in which adoption requires reinforcement from multiple independent contacts, as against a **simple contagion** which spreads on single exposure [Centola and Macy, 2007, Centola, 2010]. **The distinction is the whole of this section, because the seeding plan that is optimal for one is close to worst for the other.**

Model the requirement crudely and honestly: a person adopts when at least `a` of their `k` neighbours have already adopted. Take `k = 8` and `a = 2` — **the mildest possible complex contagion, requiring just one more contact than a virus.** Under *uniformly random* placement of seeds at population fraction `s`:

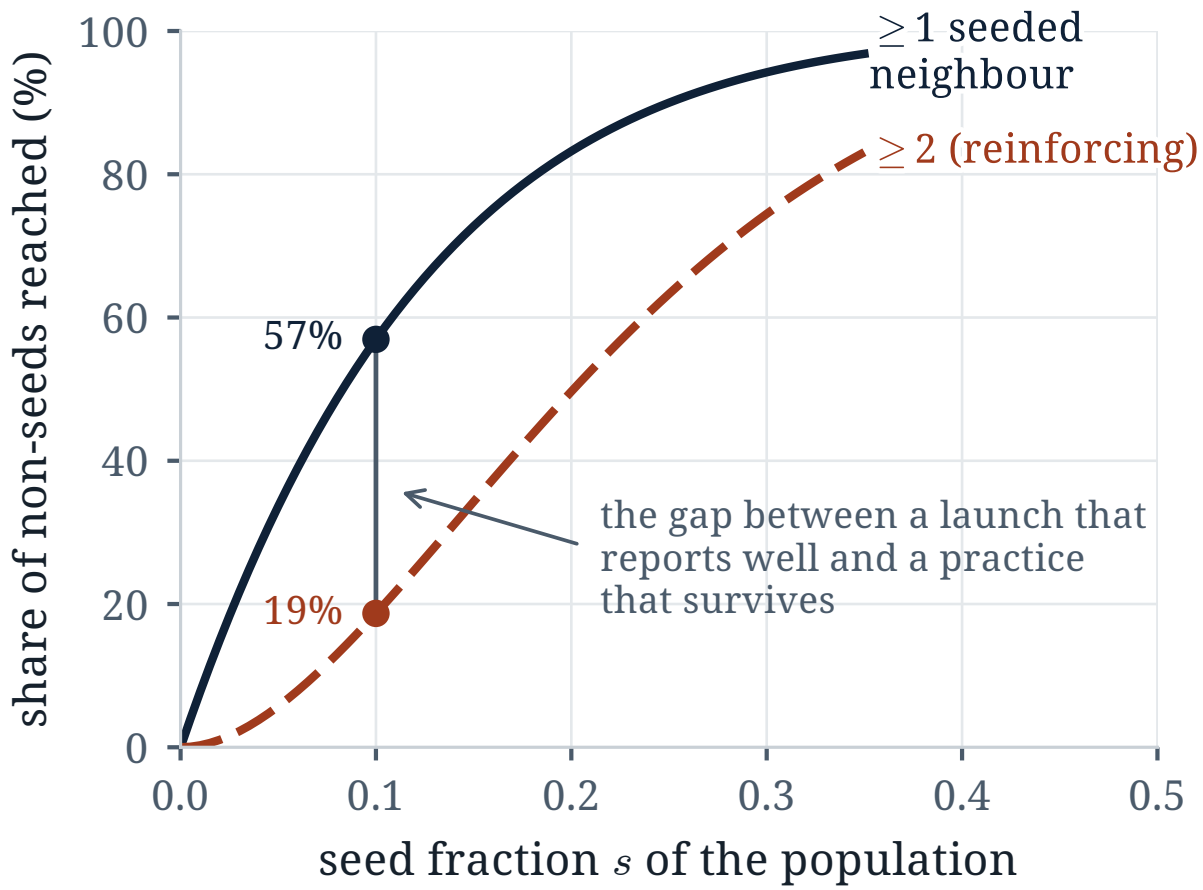

Figure 13.2: **A launch reports its first-hop reach and dies of its reinforcement gap.** Under a 2-of-8 reinforcement rule with uniformly random seed placement, a seed fraction of 0.10 puts 57 per cent of non-seeds within reach of one adopter and 19 per cent within reinforcing range. Exact binomial arithmetic; the 2-of-8 rule is a stipulated model of complex contagion and uniformly random placement is the worst case, which is what clustering improves on. Generated by `figs/src/CCP-013_fig02.py`.

seed fraction `s`	`P(>= 1 seeded nbr)`	`P(>= 2 seeded nbrs)`	ratio
0.05	0.3366	0.0572	0.170
0.10	0.5695	0.1869	0.328
0.114	0.6203	0.2294	0.370
0.15	0.7275	0.3428	0.471
0.20	0.8322	0.4967	0.597
0.25	0.8999	0.6329	0.703
0.30	0.9424	0.7447	0.790

Read the `s = 0.10` row. Sprinkling seeds across 10 per cent of a population puts 57 per cent of everyone within one hop of the new practice — magnificent coverage, and it will be reported as such. It puts 19 per cent within reinforcing range. The gap between 57 and 19 is the entire distance between a launch that looks successful in week one and a practice that has vanished by month three. And note the shape: **raising the requirement from one contact to two — the smallest possible step into complex contagion — cuts effective coverage by a factor of three at low seed density. The penalty is worst exactly where budgets force an operator to work.**

13.5.2 5.2 Clustering, and the trade the modern organisation has already made

The random-placement arithmetic above assumes the worst case: seeds scattered so that no two land adjacent. Real topology is not random, and the property that matters is the **clustering coefficient** — the probability that two of a person's neighbours are also neighbours of each other. Two structures with identical mean degree `k = 8` on `n = 220` people:

```
RING LATTICE (each node joined to its 8 nearest neighbours)
  clustering  C = 3(k−2) / (4(k−1)) = 3(6)/(4(7)) = 18/28 = 0.6429
  mean path   ~ n / (2k) = 220/16 = 13.75 hops

RANDOM GRAPH (same mean degree)
  clustering  C ~ z/n = 8/220 = 0.0364
  mean path   ~ ln n / ln z = 5.394/2.079 = 2.594 hops
```

The lattice is 17.7 times more clustered; the random graph has paths 5.3 times shorter. For a simple contagion the random graph wins overwhelmingly. For a complex contagion the lattice wins, and the mechanism is visible in the numbers: in the lattice, an adopter's neighbour has on average `8 x 0.6429 = 5.14` neighbours who are also neighbours of that adopter; in the random graph the same figure is `8 x 0.0364 = 0.29`. **The lattice hands each newly exposed person five potential reinforcing contacts. The random graph hands them a third of one.**

The rewiring parameter interpolates between them, with clustering falling approximately as `C(p) = C(0)(1−p)^3` [Watts and Strogatz, 1998]:

rewiring `p`	0.00	0.05	0.10	0.20	0.50	1.00
clustering `C`	0.6429	0.5512	0.4686	0.3291	0.0804	0.0000
reinforcing contacts among 8	5.14	4.41	3.75	2.63	0.64	0.00

The small-world regime — the one that makes information travel beautifully — is the regime in which behaviour stops travelling. At `p = 0.10` path length has already collapsed toward the random-graph value while clustering retains most of its lattice value; that is the celebrated sweet spot for *information*. Push to `p = 0.50` and the result is a superb rumour network in which no costly practice can establish, **because a person's neighbours no longer know each other and therefore cannot corroborate.**

The implication for the modern organisation is direct and unwelcome. Every tool that flattens communication — the all-hands channel, the company-wide forum, the cross-functional matrix, the open-plan floor that puts everyone within earshot of everyone — **raises the rewiring parameter.** Each is defended, correctly, on information grounds; each degrades the substrate that costly practices need. **An organisation optimised end to end for information flow has, without noticing, optimised itself against behaviour change.** This is not an argument for removing the tools; it is an argument for knowing which quantity each one moves, and requirement CN-19 requires the trade to be recorded rather than discovered.

13.5.3 5.3 Thresholds and the discontinuous aggregate

The threshold model of collective behaviour assigns each individual a number: how many others must act before they act [Granovetter, 1978]. Its consequence is that **aggregate sentiment is not a predictor of aggregate behaviour**, and three cases make the point.

Case A — thresholds 0, 1, 2, …, 99. One person with threshold 0 acts. That makes one actor, so the person with threshold 1 acts, and so on: **all 100 act.**

Case B — identical, except that the single person with threshold 1 instead has threshold 2. The zero-threshold person acts; nobody has threshold 1; the cascade halts. **1 acts.**

Case C — identical to A, except nobody has threshold 0. **Nothing happens at all: 0 act.**

One person's threshold moved by one unit is the difference between a movement of one hundred and a movement of one. Three consequences follow. **First, aggregate sentiment is not a predictor:** "most people are broadly in favour" tells an analyst nothing about whether anything will happen, because what determines the outcome is the *distribution* of thresholds and specifically whether it has gaps. **Second, the binding constraint is usually a gap rather than a shortage:** in Case B the population is overwhelmingly willing and one rung of the ladder is missing. **Third, the zero-threshold seed is structurally required** — Case C is a population in which every single person would act if someone else went first, and in which nobody ever does. **Requirement CN-8 therefore requires manufacturing the zero-threshold actor deliberately rather than hoping one appears**, and Appendix A gives the threshold survey that finds the gaps.

13.5.4 5.4 Percolation, and the only number worth reporting

The threshold model explains *whether* a cascade runs. Percolation explains **what it looks like from inside while it is running.** For a random graph on `n` nodes with mean degree `z`, the fraction `S` of nodes in the giant connected component satisfies `S = 1 − e^{−zS}` [Erdős and Rényi, 1960, Newman, 2018]:

mean degree z	0.5	0.8	0.9	1.0	1.1	1.2	1.5	2.0	3.0	4.0
giant component S	0.000	0.000	0.000	0.000	0.176	0.314	0.583	0.797	0.941	0.980
nodes of 220	0.0	0.0	0.0	0.0	38.7	69.0	128.2	175.3	206.9	215.6

Between `z = 1.0` and `z = 1.1` — a 10 per cent change in connectivity — the largest connected group goes from nothing to thirty-nine people. Below the threshold there is no giant component at any size; above it one appears and grows fast. **The population on either side of a phase transition experiences it very differently from how it appears in a table**, and the lived consequence is the reason so many good practices are killed.

Below threshold, every observation says failure, and the observation is correct. Adoption clusters stay small, isolated and stagnant; they do not merge; reports say "some enthusiasm in two teams, no broader traction"; a reasonable executive cancels the programme. **Just above threshold, the observations say the same thing for a while**, because the giant component exists and is still small in absolute terms. Then it grows, and the growth is fast, and everyone involved retrospectively constructs a narrative about the moment when people finally came around. **There was no such moment: the parameter crossed a threshold and the visible behaviour lagged it.**

This produces the single most expensive error in organisational change: cancelling at the point of maximum apparent failure, which is frequently the point just before the transition. The defence is not faith but instrumentation:

```
DO NOT MEASURE:  total number of adopters
DO MEASURE:      size of the LARGEST CONNECTED CLUSTER of adopters
                 number of distinct clusters
                 number of edges BETWEEN clusters
```

Total adopters rises smoothly and says nothing about which side of the transition a programme is on. Largest-cluster size is the order parameter and it is the only number that distinguishes "slow" from "stuck": two hundred isolated adopters is a failed programme, and forty adopters in one connected component is a programme about to work.

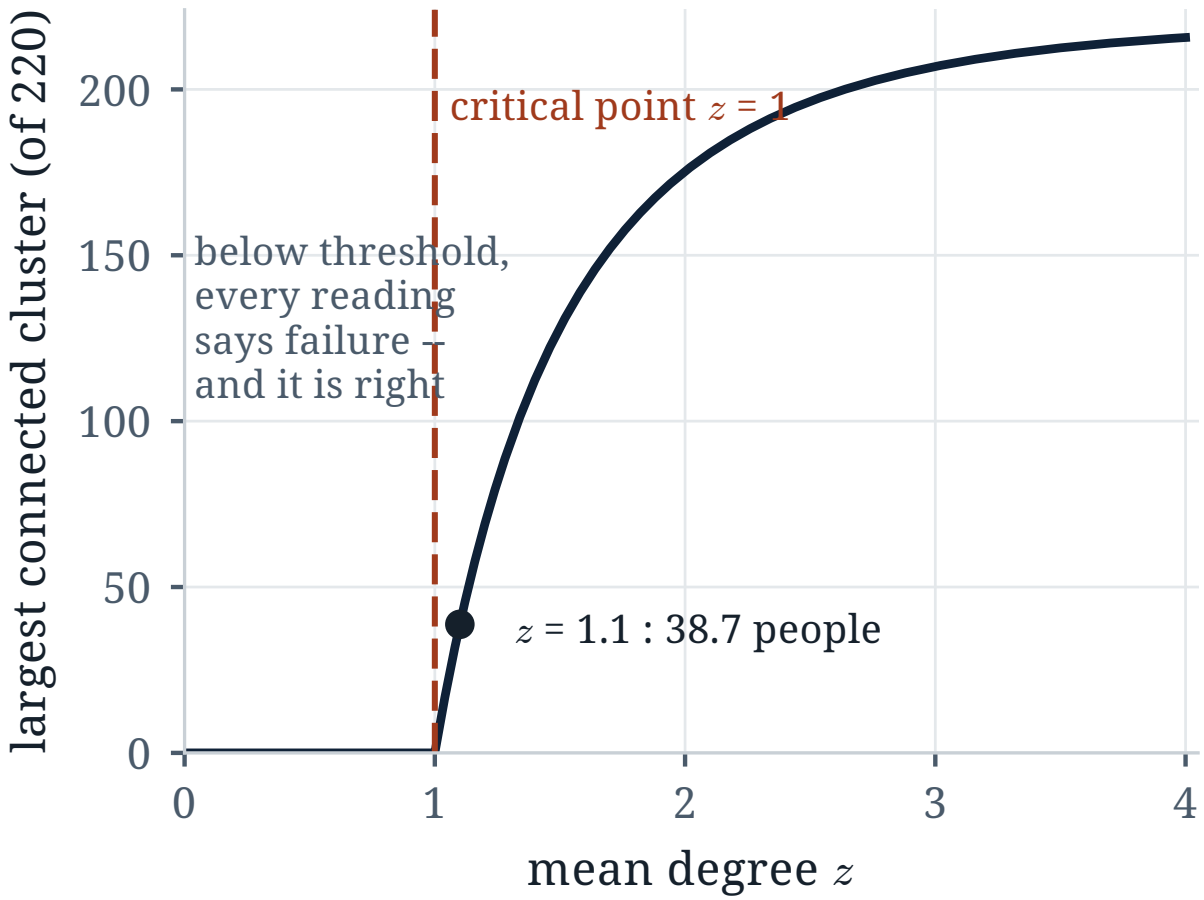

Figure 13.3: **The order parameter is the largest connected cluster, and it moves discontinuously.** Fraction of a 220-person population in the giant connected component of a random graph, solving `S = 1 − e^{−zS}`. Below `z = 1` there is no giant component at any size; between 1.0 and 1.1 the largest connected group goes from nothing to 38.7 people. Exact solution of the branching-process fixed point; the random-graph model is an analytical convenience and real organisational graphs are neither random nor regular. Generated by `figs/src/CCP-013_fig03.py`.

13.5.5 5.5 The tipping-point figure, and the discipline for using it

Centola et al. [2018] demonstrated experimentally that a committed minority below a critical size is absorbed with no residue while one above it flips a whole population, with the critical size measured at about 25 per cent in that setting. **Its value to an engineer is not the specific quarter. Its value is that it demonstrated experimentally that a tipping point exists at all** — before it, tipping points in social conventions were a theoretical prediction; after it, they are a measured phenomenon in at least one carefully constructed setting. **The honest limit: one experiment, one paradigm, online, with anonymous participants, on an arbitrary naming convention with no prior stakes, no status differences, no history and no cost of switching. Use 25 per cent to check whether a plan is off by a factor of ten. Do not use it as a target and never report it as a law** (requirement CN-20).

The practical value is as an order-of-magnitude check, and the table contains the most useful design move in the section:

organisation scope	population	25%	committed people needed
whole firm	220	55.0	55
one division	60	15.0	15
one unit	30	7.5	8
one team	12	3.0	3
one squad	6	1.5	2

SHRINK THE DENOMINATOR. A committed minority of 55 people is a political campaign requiring budget, sponsorship and eighteen months. A committed minority of 3 is a team lunch. **The threshold is a proportion, so the cheapest way over it is not to recruit more committed people but to narrow the population within which the convention must hold.** Establish the convention in one team of twelve with three committed members: that team is now internally past its tipping point, the convention there is self-sustaining rather than sponsored, and **it is also now a cluster in the sense of Section 5.2 — a dense region where anyone adjacent receives multiple reinforcing contacts.** The second team needs three more committed people and some are now available, because they are the first team's members who work partly with the second. **Sequential local tipping is cheaper than simultaneous global tipping by a wide margin, and it is the only version that produces clusters as a side effect rather than requiring them as a precondition.**

13.5.6 5.6 Cluster, do not spray: the calculation

A 220-person firm with a budget for 25 people's time to establish a new practice, mean degree `k = 8`, a 2-of-8 reinforcement rule.

PLAN A — SPRAY. Distribute the 25 across the organisation, roughly two per team, maximising reach: `s = 25/220 = 0.11364`.

```
P(a given non-seed has exactly 0 seeded neighbours) = 0.3811
P(exactly 1)                                        = 0.3907
P(exactly 2)                                        = 0.1753
P(exactly 3)                                        = 0.0449

P(>= 1 seeded neighbour)  = 0.6189     <- the number that gets reported
P(>= 2 seeded neighbours) = 0.2282     <- the number that matters

Expected non-seeds within reinforcing range = 195 x 0.2282 = 44.5 people
```

Note the second row: 39 per cent of the population has exactly one seeded neighbour, which is the worst-populated cell in the table. Those 76 people have encountered the practice,

formed an impression, and their impression is *one person on my team is doing an odd new thing.* **They are not neutral afterwards. A below-threshold exposure is not a free trial: it spends the practice's novelty and returns a null result, and the second attempt to introduce the same practice to the same person starts from a worse position than the first.**

PLAN B — CLUSTER. Put all 25 into a single 30-person unit; local seed fraction `25/30 = 0.8333`. Every one of the five non-seeds in that unit has at least two seeded neighbours with probability 1.0000, so five of five are activatable inside the unit and approximately none outside it in the first period.

Plan A's headline number — 44.5 people in reinforcing range — is nearly nine times Plan B's five, and any reasonable reading of a one-period comparison prefers Plan A. Plan A is the wrong choice, for three reasons a one-period comparison cannot see. *First, the 44.5 are at the exact margin*: they have precisely two contacts and the rule requires two, so any attrition among the 25 seeds — one on holiday, one reassigned, one quietly stopping because their two teammates did not join — drops many of them below threshold. **Plan A's coverage is brittle in exactly the way a two-of-eight rule is brittle.** *Second, Plan A's adopters are not connected to each other*: the order parameter is largest-cluster size, and Plan A maximises the number of clusters while minimising the size of each — **it is engineered, precisely, to sit below the percolation threshold.** *Third, Plan B's unit is past its own tipping point*: 25 of 30 is 83 per cent, far above the floor, so the convention inside that unit is not a programme but how things are done. **It survives the sponsor losing interest, which Plan A does not**, and it is a genuine cluster, so anyone in an adjacent unit who works with two or three people from the seeded unit receives multiple independent reinforcing contacts — **exactly the condition Plan A could not manufacture anywhere.**

Plan A optimises the first-period metric. Plan B optimises the order parameter. The first-period metric is what gets reported and the order parameter is what determines the outcome.

The seeding procedure that follows:

```
1. Pick the smallest population within which the practice makes sense standing alone.
   It must be able to work if NOBODY outside adopts. If it cannot, pick a different practice.
2. Seed that population past its own tipping point. Use 25% as a floor, not a target;
   the experimental figure came from perfectly committed confederates and yours are people.
3. Let it stabilise until the practice survives the removal of its sponsor.
   That is the test. Remove yourself for a month and see.
4. Seed the adjacent population using members of the first as the reinforcing contacts.
   Do not send an evangelist. Send two people who work there anyway.
5. Repeat outward along real working ties, not along the org chart.
```

Step 5 deserves its own emphasis: seed along the graph of who actually works with whom, which is not the graph of who reports to whom. Section 6.5 gives the structural reason. **Seeding along the org chart is seeding along a diagram.**

13.5.7 5.7 What "committed" must mean, and the refusal of mandate

The experimental minority was committed by construction — confederates instructed never to deviate. **Reproducing that property in an organisation is where this method could become something this framework refuses to be**, and the distinction is between two mechanisms that produce apparent commitment and are not equivalent. **Genuine commitment** is a person who has used the practice, found it better, and would continue without instruction. **Compliance** is a person who adopts because adoption is required, evaluated, or visible to someone who can affect their standing.

Mandating adoption defeats the purpose of adoption, and not for ethical reasons alone, though those are sufficient. **A mandated practice produces artefacts near review dates and decisions unchanged;** the measurement detaches from the thing it names [Goodhart, 1975, Campbell, 1979]; and, in this framework's own arithmetic, **mandate drives non-parallelism**

to zero across adopters, because everyone is doing the same thing for the same reason, so the spread practice's own surplus becomes `ln 1 = 0`. The consequence is stated plainly: **100 per cent compliance is a worse outcome than 60 per cent adoption with 40 per cent articulate declines.** The declines carry information about where the practice does not fit, and **recorded declines are the most valuable data a seeding programme generates and the data most often discarded.**

Requirements CN-12 to CN-15 make this operational: no seeding programme proceeds unless a member of the seeded population can decline without consequence; declines are recorded with reasons and reported alongside adoptions; adoption is never required, incentivised through evaluation, or used as a compliance criterion; and before expanding, the sponsor withdraws for a month and the practice must survive. **The framework's own treatment of cases where a feedback loop runs through another person's will records that seam as unsettled and declines to close it** [Curzi, 2026]. **This paper does not close it either. It draws the line where the line can be drawn — at whether declining is free — and states that the harder cases beyond it are not resolved here.**

13.5.8 5.8 Coupling contagion to the storage law

Two couplings are needed and both are badged as modelling choices. **First, the adoption dip.** Most practices worth adopting cost something during transition: the conversion coefficient rises with adoption share and the cost term falls with it, but the cost of adopting is paid before the benefit arrives, **so the stock falls before it rises.** Modelling both as linear in the adopted fraction — `eta(a) = eta_0 + (eta_1 − eta_0) a` and `C(a) = C_0 + (C_1 − C_0) a` — is a convenience with no support beyond tractability, and it is the form used in Section 8.2. **Second, partial adoption can be strictly worse than zero adoption.** If adoption stalls at a level where the organisation maintains two conventions at once, the cost of running both may exceed the benefit of either, and the dual-convention plateau is a stable and expensive place to stop (failure mode **FN5**).

The reachability structure that makes this work is itself measurable, and the corpus's instrument for it is the concentration index applied to reachable shares: six unequal compartments give 4.96 effective compartments and cut maximum single reach from 100.0 per cent to 30.0 per cent, worth 1.400 units a year against 0.110 of cost — **a 12.73 to 1 ratio with a break-even hazard of 0.157 per cent per year** [Curzi, 2026]. **That analysis prices compartmentation as protection against unwanted spread; this section prices the same structure as an obstacle to wanted spread. They are the same arithmetic read in opposite directions, and an organisation cannot have both at once** — which is the trade requirement CN-19 exists to record.

13.6 6 The silo and the critical boundary-cost multiplier

13.6.1 6.1 What a silo is, and why exhortation fails

A silo is a local minimum. The framework's founding definition makes the present state a minimum of the comfort landscape by construction [Curzi, 2026], and a silo is that definition applied to a domain of practice: a position that is **deep** — every direction out is uphill, because inside it a practitioner is fluent and competent and outside it they are a novice — and **narrow**, because it admits one vocabulary, so that a question posed in a neighbouring dialect does not merely go unanswered but is not recognised as a question. **Nothing about that description requires anyone to be territorial, defensive or uncooperative, and the diagnosis that reaches for those words has already misidentified the mechanism.**

The landscape is an analogy and is badged as one. A basin, a barrier and a ridge are borrowed vocabulary; nothing about activation energy or reaction kinetics is claimed. **What the analogy supplies is a hypothesis about the shape of a decision, and it makes one prediction that distinguishes it from exhortation.**

Exhortation fails in two independent ways. *First, exhortation is a tilt that is removed when the speech ends.* Declaring collaboration a value changes nothing about the landscape: the barrier is where it was, and the crossing rate rises during the campaign and returns afterwards. **The diagnostic signature is a forward rate that rises and falls with attention, and the measurement is to check the reverse rate three months after attention has moved on** (requirement SL-18). *Second, exhortation raises agitation, and agitation is undirected.* Pressure applied to a boundary raises the rate at which people cross it **and the rate at which they cross back, in the same proportion, so the forward-to-reverse ratio is unchanged at every level of pressure.** Building a lower valley next door changes the ratio; pushing does not. **A manager watching only the forward rate — how many people attended the cross-functional session — sees the two routes as identical, and they are not.**

The method that follows from the diagnosis is to build a lower valley next door: to make the cross-domain position genuinely cheaper to occupy, rather than to make the present position uncomfortable. **And the acid test is the safety property: if nobody moves, nothing has been done to anyone.** A method that works by removing resistance has no coercive failure mode, and **its worst outcome is that someone declines to use it.** That is not a concession the method makes; **it is the property that makes it safe to recommend**, and it is why requirement SL-16 makes every instrument in this section declinable.

What actually lowers the valley, in the order that the arithmetic of Section 6.3 puts them: **(1) a shared instrument** — one measurement apparatus, one dataset, one dashboard, owned by neither side and readable by both without specialist tooling, which terminates the large class of cross-boundary arguments that are really arguments about what is happening; **(2) boundary objects** — artefacts plastic enough to be read differently by each side while remaining recognisably the same object, which is the class named and analysed in the sociology of scientific work [Star and Griesemer, 1989, Star and Ruhleder, 1996]; **(3) a translator role**, timeboxed with a termination condition and a build list, because a permanent translator has paid the boundary cost rather than lowered it; **(4) rotation**, offered and never assigned; and **(5) co-located cross-function**, on shared output rather than adjacent output. **Instruments 1 and 2 move the boundary cost and the conversion coefficient at once, which is why Section 8.3 finds them outranking rotation by a wide margin.**

13.6.2 6.2 The double indictment, priced

Consider a 60-person organisation in two silos of thirty. Take `N = 6` categories with between-silo non-parallelism `u_cross = 0.55` and within-silo dissent `u_div = 0.0990`:

```
u_cross = 0.5500      f(u_cross) = ln(1 + 5(0.5500)) = 1.3218
u_div   = 0.0990      f(u_div)   = ln(1 + 5(0.0990)) = 0.4021
u       = 0.6490      f(u)       = ln(1 + 5(0.6490)) = 1.4457

decomposition bound: max(1.3218, 0.4021) = 1.3218 <= 1.4457 <= 1.3218 + 0.4021 = 1.7239  HOLDS
```

The silo condition is that `u_cross` is on the roster and is **realised at approximately zero**, because the interactions that would realise it do not occur:

```
Available  S = f(u_cross + u_div) = 1.4457 nats
Realised   S = f(u_div only)      = 0.4021 nats
Forgone                           = 1.0436 nats per interaction  =  72.2%
For reference, the hard ceiling is ln N = ln 6 = 1.7918 nats.
```

The organisation is discarding 72.2 per cent of the surplus its own roster can supply, and the discarded portion is the cross-category portion — the part that is expensive to hire and impossible to substitute. This is not a diversity-of-hiring failure. The difference was purchased. It sits in the building. It is not in contact. The structural sibling of this case is the institute

whose audit returns `u_cross = 0.72`, `u_div = 0.03` and **zero within-block dissents in forty decisions** [Curzi, 2026d]: the same shape from the other direction.

The cost side. On the same sixty people, `paths(30) = 435` and `paths(60) = 1770`, so within-silo pairs number `2 x 435 = 870` and cross-silo pairs `30 x 30 = 900`, and `870 + 900 = 1770` confirms the decomposition [Brooks, 1975]. **More than half of all pairs in this organisation — 900 of 1770 — are cross-boundary pairs.** Model the cost as `C = c_in x (within pairs in contact) + m c_in x (cross pairs in contact)`, with `m` the **boundary-cost multiplier**: how many times more expensive a cross-boundary exchange is than a within-boundary one. At `c_in = 0.00012` with all pairs in contact:

`m`	`C`	cross-boundary share of `C`
1	0.2124	50.8%
2	0.3204	67.4%
4	0.5364	80.5%
8	0.9684	89.2%
16	1.8324	94.3%

A correction to the source is recorded here rather than made silently. The manuscript this paper converts prints this table with the absolute cost column computed at `c_in = 0.0004` — giving 0.7080, 1.0680, 1.7880, 3.2280 and 6.1080 — while its text states `c_in = 0.00012`, and while its own critical-multiplier table and all three worked cases use 0.00012 consistently. **The column above is recomputed at the stated and internally consistent value. The share column is unaffected, because `900m/(870 + 900m)` does not depend on the scale of `c_in`**, and nothing in the argument turns on the absolute column.

At `m = 8` — a plausible figure where two domains share terms with different referents and no shared instrument exists — 89.2 per cent of the organisation's coordination cost is boundary-crossing cost.

Now put the two sides together, because this is where the silo's peculiar viciousness shows. The silo suppresses the interactions that would realise the cross-boundary difference, **and the reason it suppresses them is that `m` makes them expensive. So the organisation is simultaneously forgoing 72 per cent of its available surplus AND, to the extent that cross-boundary contact happens at all, paying a multiplied price for it. Every attempt to fix the first by mandating more contact makes the second worse**, which is why reorganisations aimed at collaboration so often produce a measurably worse system: **they raise contact without lowering `m`, and the arithmetic of that combination is unambiguous.**

13.6.3 6.3 The critical boundary-cost multiplier

Let `rho` be the fraction of cross-boundary pairs actually in contact. Model realised non-parallelism as `u(rho) = rho u_cross + u_div` — **a badged linear modelling choice** — and cost as `C(rho) = c_in x 870 + m c_in x rho x 900`. The one-step increment is `eta ln(1 + 5 u(rho)) − delta Q − C(rho)`; differentiating with respect to `rho` and setting the derivative to zero gives

```
d(step)/d(rho) = eta (N−1) u_cross / (1 + (N−1) u(rho))  −  m c_in x 900

m* = eta (N−1) u_cross / [ (1 + (N−1) u(rho)) x c_in x 900 ]
```

`m*` is the critical boundary-cost multiplier: more contact improves the system only while `m < m*`.

rho	u(rho)	m∗ at eta = 0.34	m∗ at eta = 0.46
0.00	0.0990	5.79	7.83
0.10	0.1540	4.89	6.62
0.20	0.2090	4.23	5.73
0.30	0.2640	3.73	5.05
0.45	0.3465	3.17	4.29
0.60	0.4290	2.75	3.72
0.80	0.5390	2.34	3.17
1.00	0.6490	2.04	2.76

> **Whether cross-boundary contact helps or harms is determined by m, the boundary cost — not by the willingness, goodwill or collaborative disposition of the people crossing.**

If m > m∗, increasing contact makes the system monotonically worse, and it does so no matter how enthusiastically people participate. Enthusiasm does not appear in the expression. This is the precise sense in which collaboration is not a virtue problem.

Two further readings. **m∗ falls as rho rises**, because surplus is concave in u while cost is linear in rho: **the first cross-boundary contacts are the ones that pay, full integration is rarely optimal, and the two policies that fail are "integrate everything" and "integrate nothing".** And **m∗ rises with the conversion coefficient** — at eta = 0.46 instead of 0.34 the tolerable boundary cost is about 35 per cent higher at every level of contact — **so raising conversion makes contact affordable that was not affordable before.** Since a shared instrument raises conversion *and* lowers boundary cost at once, **it moves both sides of the inequality in the favourable direction, which is why it ranks first among the instruments.**

13.6.4 6.4 The contact literature, in this vocabulary

The contact hypothesis holds that contact between groups reduces prejudice **under four conditions**: equal status within the situation, common goals, intergroup cooperation rather than competition, and **the support of authorities, law or custom** [Allport, 1954]. The meta-analytic record supports a general effect and finds the conditions to be facilitating rather than strictly necessary [Pettigrew and Tropp, 2006], while the broader literature on diversity and contact carries genuine contrary findings that must be cited alongside [Putnam, 2007, Abascal and Baldassarri, 2015]. **In this framework's vocabulary the fourth condition is the one that does the arithmetic work: institutional support is what lowers m.** A cross-boundary exchange that has a budget line, an owner, a time allocation and a shared instrument is cheap; one that is done in gaps by volunteers is expensive, **and it is the first thing dropped under load** (failure mode **FS8**). **Contact without institutional support is not a weak version of the intervention. It is the intervention with the term that pays for it removed**, and requirement SL-13 requires the four conditions to be checked explicitly and the absent ones recorded.

13.6.5 6.5 The structural cause, and why boundaries are legitimate

Organisations produce designs that mirror their own communication structures [Conway, 1968]. **Three consequences follow, and the third is the deepest.**

First, the silo is downstream of a structural decision and is not repairable upstream of it. If the organisation is partitioned by function, its outputs will be partitioned by function, and no amount of cross-functional exhortation changes the partition that produced them. **Second, boundaries are legitimate and necessary**: the cost arithmetic requires them, since coordination cost grows with the pair count [Brooks, 1975], and the corpus's roster ceiling states the same limit exactly — m(m−1) <= 2 eta ln(N)/kappa, with a constructed commons sitting at 30

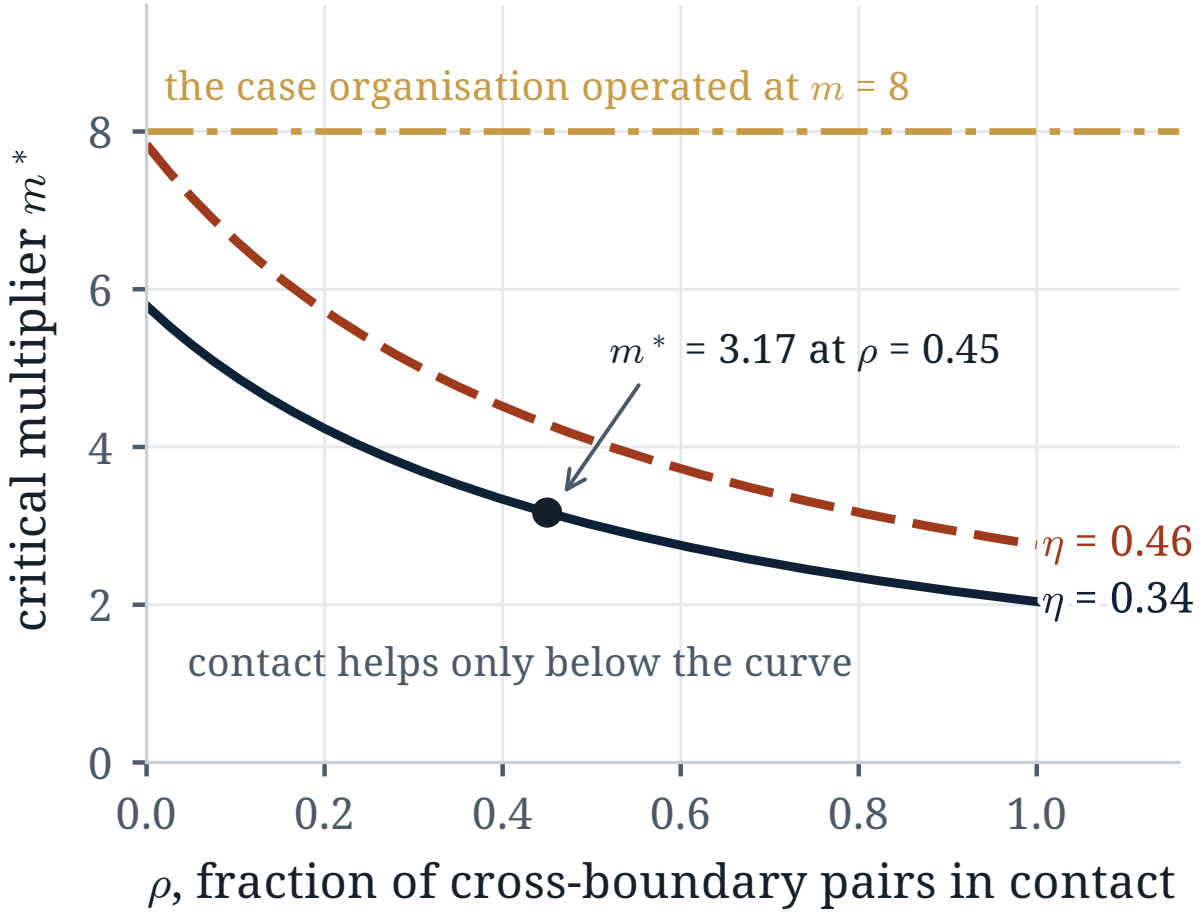

Figure 13.4: **Contact helps only below the curve, and the case organisation was above it before it started.** The critical boundary-cost multiplier `m* = eta (N−1) u_cross / [(1 + (N−1)u(rho)) c_in x 900]` at `N = 6`, `u_cross = 0.55`, `u_div = 0.0990`, `c_in = 0.00012` and 900 cross-boundary pairs. At `rho = 0.45` and `eta = 0.34`, `m*` = 3.17 against a measured `m` = 8. Modelled: linear `u(rho)` is a badged modelling choice and a single scalar boundary multiplier is crude; the qualitative result — that a critical cost exists — survives the crudeness and the exact value does not. Generated by `figs/src/CCP-013_fig04.py`.

against a bound of 30.7225 [Curzi, 2026]. **A boundary is a cost-control device. Removing it by default is not a fix; requirement SL-15 says so.**

Third, and this is the structural point: a strict hierarchy is the organisational form that drives non-parallelism toward zero. A tree gives every unit exactly one parent and forbids overlaps, so any two units at the same level receive their context through the same channel; **a semilattice lets a person belong to a function *and* a product *and* a guild, and the number of ways a person participates is the number of independent contexts they carry** [Alexander, 1965]. **Building a lower valley is, structurally, replacing a tree with a semilattice**, and failure mode **FS6** is the tree in its diagnostic form: cross-domain questions escalate before they are answered, the answer arrives via two managers, and nobody has a working relationship outside their branch.

13.7 7 Design specifications

The requirements below are stated in the form a specification would carry. **`CI-1` to `CI-20` govern deliberation, `CN-1` to `CN-20` seeding, and `SL-1` to `SL-20` the boundary.** A requirement is not a finding: the schedule is a design instrument derived from the results above, and **its numerical thresholds are chosen values rather than measured optima.**

13.7.1 7.1 Deliberation

CI-1 deliberative groups shall be sized `n <= 8` unless a specific argument is recorded. **CI-2** before convening, list the `N` genuinely distinct categories present and strike duplicates; two people from the same lineage count once. **CI-3** the participation index shall be measured on at least one session in four. **CI-4** target `J >= 0.85` for deliberative sessions. **CI-5** every decision meeting shall open with three to five minutes of silent written positions. **CI-6** before any decision is recorded, every member states a position in a go-around. **CI-7** the highest-status participant states their view after all others. **CI-8** every decision-log entry shall carry a dissent field, and an empty field on a contested item is itself a finding. **CI-9** deliberation rooms shall meet the acoustic specification for reverberation and background level [Curzi, 2026e]. **CI-10** seating geometry shall give every participant a direct sightline to every other [Curzi, 2026f]. **CI-11** where `J` is below its floor, run the interruption ledger. **CI-12** the available non-parallelism `u_pot` shall be measured on a stated cadence, **because it decays.** **CI-13** every standing group shall run at least one active maintenance practice for `u_pot`. **CI-14** annually, estimate the marginal cost reduction and the marginal surplus loss from cohesion and record the comparison. **CI-15** no deliberative session shall end without a durable artefact. **CI-16** quarterly, sample decisions and compute the fraction of raised objections surviving into the record. **CI-17 — no compositional screening.** Nothing here licenses selecting individuals on any reported correlate of the collective-intelligence factor. **CI-18 — right of abstention.** Every protocol here shall be declinable, unconditionally and without reason. **CI-19 — metric hygiene.** The participation index shall never be an individual performance target, an appraisal input, or a ranking criterion. **CI-20 — badge discipline.** Any report using this paper's mapping shall state that the mapping from the reported correlates to this framework's parameters is a postulate and not a finding.

13.7.2 7.2 Seeding

CN-1 before seeding, record whether the practice is simple or complex, and state the evidence. **CN-2** seed along the graph of who works with whom, evidenced by shared artefacts and threads, not along the org chart. **CN-3** estimate the clustering coefficient of the seeding region. **CN-4** pick the smallest population within which the practice works standing alone. **CN-5** seed past the local tipping point, taking 25 per cent **of that population** as a floor and not a target. **CN-6 — never spray.** Distributing a fixed budget uniformly across a large population

is prohibited. **CN-7** run the threshold survey before seeding and look for gaps rather than for a mean. **CN-8** manufacture the zero-threshold actor deliberately. **CN-9** programme reporting shall track largest connected adopter cluster, cluster count and between-cluster edges — **not headcount. CN-10 — declare the dip.** Before launch, state in writing that the order proxy is expected to fall first, with a predicted depth and timing. **CN-11** cancellation criteria shall be preregistered. **CN-12 — the decline test.** No seeding programme shall proceed unless a member of the seeded population can decline without consequence. **CN-13** declines shall be recorded with reasons and reported alongside adoptions. **CN-14 — no mandate.** Adoption shall not be required, incentivised by evaluation, or used as a compliance criterion. **CN-15 — sponsor-removal test.** Before expanding, the sponsor withdraws for a month and the practice must survive. **CN-16** the second population shall be seeded by people who already work there. **CN-17** where seeding through a high-degree individual, record the single-point-of-failure risk. **CN-18** do not plan for sustained partial adoption across a population that must share one convention. **CN-19** where an organisation is simultaneously introducing tools that flatten communication, record that they raise the rewiring parameter and degrade the substrate costly practices need. **CN-20 — badge discipline.** Any use of the 25 per cent figure shall carry the statement that it derives from one online experiment on an arbitrary convention with no prior stakes.

13.7.3 7.3 The boundary

SL-1 locate the boundary before diagnosing the behaviour; record what draws it. **SL-2** measure `u_cross` and `u_div` separately and report both. **SL-3** measure `rho`, the fraction of cross-boundary pairs actually in contact, from shared artefacts, meetings and threads. **SL-4** estimate `m` by timing a matched sample of within- and cross-boundary exchanges from question asked to answer usable. **SL-5 — compute `m*` before increasing contact. SL-6 — lower `m` before raising `rho`.** The sequence is shared instrument, then boundary objects, then rotation, then contact targets. **SL-7** build a shared instrument, readable by both sides without specialist tooling and owned by neither. **SL-8** specify boundary objects, not forms: the artefact must tolerate different interpretations on each side while remaining one object. **SL-9** time-box the translator role with a success condition and a build list. **SL-10 — rotation is offered, never assigned**, and declining shall carry no consequence to standing. **SL-11 — rotation dosage is computed, not chosen**, from the `m*` arithmetic. **SL-12** co-locate on shared work, not adjacent work. **SL-13** check the four contact conditions explicitly and record which are absent. **SL-14** prefer semi-lattice to tree. **SL-15** do not remove the boundary by default; it is a cost-control device. **SL-16** nothing in this section is mandated and every instrument shall be declinable. **SL-17 — no exhortation as intervention. SL-18 — predict the reverse rate** for any cross-boundary change, and measure it after attention has moved on. **SL-19** measure whether the cross-domain position is actually cheaper by asking the people who tried it. **SL-20 — badge discipline.** The landscape and escape-rate models are analogies and shall be labelled as such in any report.

13.8 8 Results: three systems worked end to end

All three systems are constructed. No dataset was collected for this paper. Every number below is the output of stated parameters under the models of Sections 4 to 6, carried through so that a reader can re-derive it. **They demonstrate that the procedure runs and that it reports its own failures; they are not evidence that any organisation behaves this way.**

13.8.1 8.1 A nine-person review group: the diagnostic split, and a protocol that cannot win

The system. A hospital discharge safety review group: nine people meeting fortnightly for ninety minutes to review discharge criteria, incidents and proposed protocol changes; four

years old, two membership changes. Audited categories, with two consultants in the same specialty counting once: acute medicine, nursing, pharmacy, physiotherapy and rehabilitation, data and audit, and a patient-experience representative. **`N = 6` and `ln 6 = 1.7918` nats is the hard per-interaction ceiling.** Parameters estimated over eight sessions:

```
n        = 9 people                    N       = 6 distinct categories
u_pot    = 0.55   dispersion of written pre-discussion positions
eta      = 0.35   objection survival into the durable record
delta    = 0.06   per fortnight, from decay of protocol adherence during a
                  10-week gap when the group did not meet
C_t      = 0.42   person-hours in room + preparation + rework attributable to
                  coordination failure, in the same normalised units as Q
Q_0      = 3.10   order proxy: composite of documented current criteria, staff
                  adherence audit score, and incident-review closure rate
J        = 0.52   two acute-medicine consultants hold 61% of speaking time;
                  the patient-experience representative holds 2%
```

Proxy justification. The order proxy is built from *adherence and closure* — downstream operational facts recorded by people outside the group who do not know its interaction measure — while the interaction measure is estimated from written position dispersion inside the group. **The two share no input. A proxy that is secretly the interaction measure will fit beautifully and mean nothing.**

Baseline.

```
Realised  U   = J x u_pot = 0.52 x 0.55 = 0.2860
N_eff         = 1 + 5(0.2860)           = 2.4300
S             = ln(2.4300)              = 0.8879 nats     (46% of ln 6)
eta S         = 0.35 x 0.8879           = 0.3108
delta Q_0     = 0.06 x 3.10             = 0.1860
C             =                           0.4200

Headroom h    = 0.35(1.7918) - 0.1860 - 0.4200 = 0.6271 - 0.6060 = +0.0211
One step      = 0.3108 - 0.1860 - 0.4200                        = -0.2952
```

This is the diagnostic pattern that makes headroom worth computing. Positive headroom says the regime is *feasible*: some interaction geometry grows order. The one-step calculation says the *current* geometry does not. Confusing the two is why organisations despair when they should retune, or retune when they should stop. Nine people convene fortnightly and produce the deliberative output of **2.43 effective participants**, with order falling at 0.295 units per period. Left alone:

period	0	4	8	12	16	17
`Q_t`	3.1000	2.0213	1.1791	0.5215	0.0081	**model breaks: -0.1015**

The steady state is `Q_inf = (0.3108 - 0.4200)/0.06 = -1.8206`, **a negative equilibrium, which the result does not hide: it means the regime is unsustainable or the linear model must be replaced.** At period 17 the admissibility condition fails (`0.4200 > 0.3185`) and the model stops applying. **In the building that is not a mathematical event. It is the group's documented criteria quietly becoming a folder nobody opens** — eight months of fortnightly meetings, the room booked, the minutes taken, **and the institution running a maintenance ritual on a declining asset while recording attendance as evidence of health.**

What surplus would be required. A non-decreasing step requires `S_t >= (delta Q_t + C_t)/eta`:

```
S_req = (0.1860 + 0.4200) / 0.35 = 1.7314 nats        ln N = 1.7918 nats
1 + 5 U = e^{1.7314} = 5.6495   ->   U = 0.9299
```

`S_req < ln N`, so the ceiling does not rule it out — the same fact as positive headroom. **But the group would need realised `U = 0.93` on a roster carrying `u_pot = 0.55`, and even at perfect equality `J = 1` gives `U = 0.55`. The requirement is infeasible on this roster under any conversational protocol whatsoever. The headroom gauge said feasible; the geometry says no**, and that discrepancy is exactly what a single-number dashboard hides.

Stage 1 — turn-taking only. Silent written positions first, a full go-around, consultants speaking last, ceiling absorption installed in the meeting room, and seating changed from a boardroom table to a ring with no head [Curzi, 2026e,f]. Measured over the next eight sessions, `J` rises to **0.86**.

```
U     = 0.86 x 0.55  = 0.4730       N_eff = 3.3650
S     = ln(3.3650)   = 1.2134 nats  (up from 0.8879, +36.7%)
eta S = 0.35 x 1.2134 = 0.4247
Step  = 0.4247 - 0.1860 - 0.4200 = -0.1813      STILL DECLINING
```

The largest available conversational intervention improved the step by 0.1139 units per period and did not change its sign. Effective participants rose from 2.43 to 3.37 — a real gain, honestly measured — **and the asset still shrinks, just more slowly**, from 3.1000 to 0.7627 over 24 periods, with `Q_inf = (0.4247 - 0.4200)/0.06 = 0.0783`. **The intervention bought survival at near-nothing rather than collapse.**

This is the result the section has been building toward and it is the reason it is not a list of meeting tips. A turn-taking intervention operates on `S`; `S` enters the storage law multiplied by `eta` and competes against `delta Q + C`. If the cost term is large, no achievable `S` wins, and running a better meeting is a real improvement inside a losing budget. Anyone stopping at Stage 1 would hold a genuine, measurable, publishable improvement in group process **and a department whose discharge criteria continued to decay** — and would also, quite reasonably, conclude that the collective-intelligence literature does not survive contact with practice.

Stage 2 — the cost term. The cost of 0.42 decomposes as 0.13 for the session itself, 0.06 for preparation, **0.15 for a standing weekly sub-meeting duplicating the fortnightly agenda**, and 0.08 for criteria re-litigated because prior decisions were not findable. Two moves, neither about conversation. **Retire the weekly sub-meeting** — it existed because the fortnightly meeting produced no findable record, so people met to re-establish what had been decided, **which is low conversion presenting as a cost** — saving 0.15. **Install the decision log** with an open-questions column and a required dissent field, saving 0.07 of the 0.08.

```
C: 0.4200 -> 0.2000        eta S unchanged at 0.4247 (Stage 1 protocols retained)

Headroom h = 0.6271 - 0.1860 - 0.2000 = +0.2411
Step       = 0.4247 - 0.1860 - 0.2000 = +0.0387      GROWING
S_req = 0.3860/0.35 = 1.1029  ->  U_req = 0.4026 ;  realised U = 0.4730   FEASIBLE
Q_inf = (0.4247 - 0.2000)/0.06 = 3.7450
```

period	0	4	8	12	16	20	24
Q_t	3.1000	3.2414	3.3518	3.4380	3.5053	3.5579	3.5989
h_t	+0.2411	+0.2326	+0.2260	+0.2208	+0.2168	+0.2136	+0.2112

Contrast the three trajectories: doing nothing, the model breaks at period 17 with the stock through zero; with the best available meeting protocol alone, 0.7627 at period 24 and falling toward 0.0783; with the protocol and the cost cut, 3.5989 and rising toward 3.7450. And observe the convergence: the stock climbs and slows as it goes, because headroom shrinks as

the stock grows. **Success consumes its own headroom** [Curzi, 2026b], and the fixed point is reached because `delta > 0` makes the map a contraction.

What the group should watch next. *The cohesion clock:* `u_pot = 0.55` was measured, not assumed, and it decays. At 5 per cent per fortnight it halves in about a year, and at `u_pot = 0.40` the step at `Q = 3.60` becomes `0.3502 − 0.2160 − 0.2000 = −0.0658` — **negative again, with nothing visibly changed and everyone getting on better than ever.** *The maintenance trap:* as the stock rises toward 3.745, the maintenance term rises from 0.1860 to 0.2247 and the budget tightens by 0.0387 **purely from success.** *The proxy:* the moment any component of the order proxy becomes a target it detaches from the thing it names [Campbell, 1979], **and the adherence audit is the most gameable.**

Preregistered falsification, declared before Stage 2. Fit `Y_{t+1} = a Y_t + b F(U_t) − C_hat_t + e_t` with `0 <= a <= 1` and `b >= 0` on periods `−16..0`, freeze, and predict periods `1..24` held out, against four baselines: persistence; direct input with raw `U` and no logarithm; a matched autoregressive model with no interaction term; and a **shuffled-input control** in which the same surplus series is randomly permuted across periods. **Falsified if** the shuffled control predicts held-out order as well as the ordered series, or the matched autoregressive baseline is not beaten, or the fitted persistence lies outside `[0,1]`, or the fitted gain is negative. **The shuffled control is the one most often omitted and the one that decides this case: a department that improved its meetings, cut two commitments, installed a decision log and got better may simply be a department that received attention. The shuffle asks whether the timing of surplus predicts the timing of order, and if it does not, the arithmetic described a coincidence in the vocabulary of a theorem.**

13.8.2 8.2 A 220-person firm: seeding a costly practice, and the dip

The system. A professional services firm, twelve teams, chronically losing decisions: the same questions re-litigated across engagements, nobody able to find why a prior call was made, senior staff spending a measurable fraction of the week reconstructing context. **The proposed practice is a decision log** — for every decision above a stated threshold, a short structured record of the decision, its alternatives, the dissent and the open questions. **It is a conversion device and a classic complex contagion: it is only worth writing if others read it, and it is socially costly to be the only person writing them.**

```
n = 220 people, 12 teams        N = 8 distinct practice categories, ln N = 2.0794
u = 0.50 from a disagreement audit -> S = ln(1 + 7 x 0.50) = ln 4.50 = 1.5041 nats
delta = 0.05 per month          C_0 = 0.55        eta_0 = 0.30        Q_0 = 4.00
```

with the order proxy built from reconstructibility, re-litigation rate and lookup latency — **all sampled from engagement files and sharing no input with the disagreement audit.** A two-team pre-pilot over four months estimates post-adoption values `eta_1 = 0.52` and `C_1 = 0.46`, **the latter net of the real cost of writing the logs.**

```
h_0  = 0.30(2.0794) − 0.2000 − 0.5500 = 0.6238 − 0.7500 = −0.1262      h < 0
step = 0.4512 − 0.2000 − 0.5500                          = −0.2988     DECLINING
```

Headroom is negative, and that is categorical: no choice of interaction geometry prevents order from decreasing. No amount of better meetings, better recruitment or higher non-parallelism fixes this firm, **because even at the ceiling the input `0.30 x 2.0794 = 0.6238` is less than `delta Q + C = 0.7500`. The binding constraint is conversion and cost, and the diagnosis is available before anyone is consulted about anything.** Post-adoption, if the practice fully lands:

```
h_1    = 0.52(2.0794) − 0.2000 − 0.4600 = 1.0813 − 0.6600 = +0.4213
step_1 = 0.52(1.5041) − 0.6600                            = +0.1221   GROWING
Q_inf  = (0.7821 − 0.4600)/0.05                           = 6.4424
```

So the practice is worth having. The remaining question is entirely a contagion question: does it arrive?

The seeding decision. Budget: 25 people's time. *Plan A, spray:* two seeds per team, 22.8 per cent of non-seeds in reinforcing range, 44.5 people, **zero teams past their local tipping point, largest adopter cluster 2.** *Plan B, cluster:* saturate one 30-person team, local committed fraction 83 per cent, **largest adopter cluster 25**, and the practice's value realised locally because that team's own decisions become reconstructible regardless of the other eleven teams. **Plan B is chosen, and what is given up is stated in advance: for roughly two months 195 people see no change at all and the programme's reportable reach is 14 per cent. Requirement CN-10 exists because a reach of 14 per cent at month two will otherwise be read as failure.**

The adoption trajectory, modelled logistically at `r = 0.55` per month with `K = 220` and `a_0 = 25/220`, coupled by the linear conversion and cost forms of Section 5.8 — `eta(a) = 0.30 + 0.22a` and `C(a) = 0.55 − 0.09a`:

month	adopters	share `a`	`eta`	`C`	`Q_t`	`h_t`	step
0	25.0	0.1136	0.3250	0.5398	4.0000	-0.0640	-0.2509
1	37.2	0.1690	0.3372	0.5348	3.7491	-0.0211	-0.2151
2	54.2	0.2463	0.3542	0.5278	3.5340	**+0.0320**	-0.1718
3	76.6	0.3484	0.3766	0.5186	3.3622	+0.0965	-0.1203
4	104.1	0.4732	0.4041	0.5074	3.2419	+0.1708	-0.0617
5	134.3	0.6103	0.4343	0.4951	3.1802	+0.2490	-0.0009
6	163.1	0.7412	0.4631	0.4833	**3.1793**	+0.3206	+0.0542
8	202.0	0.9181	0.5020	0.4674	3.3294	+0.4100	+0.1212
10	215.8	0.9808	0.5158	0.4617	3.5831	+0.4317	+0.1349
12	219.1	0.9960	0.5191	0.4604	3.8505	+0.4266	+0.1279
14	219.8	0.9992	0.5198	0.4601	4.1009	+0.4158	+0.1167

Read the stock column. It falls for six months, bottoms at 3.1793 — 20.5 per cent below where it started — and does not recover to its starting value until month 14. That is the adoption dip, computed rather than asserted. **Month five is the maximum danger point:** the step is `−0.0009`, essentially flat; the stock is at its worst; 61 per cent of the firm has adopted; and every visible operational indicator is at its lowest reading since before launch. **A cancellation at month five would be entirely defensible on the evidence available at month five and would destroy a programme one month from turning.**

Note the headroom column, which tells a different and earlier story. Headroom crosses zero at month two, four months before the stock turns. The gauge is the leading indicator and the order proxy is the lagging one: a firm watching headroom sees the regime become sustainable in month two, and a firm watching the stock sees nothing good until month six. **That is the strongest practical argument in this corpus for computing the gauge.**

A coincidence, labelled as one. At month 2 the adopted share is 0.2463, essentially the published tipping-point figure, and month 2 is also where headroom turns positive. **This is a coincidence.** The logistic parameters came from the pre-pilot, and headroom crossing zero at `a = 0.246` reflects the conversion and cost slopes, **not any tipping-point mechanism. Two arithmetic facts landing on the same month is not evidence that one caused the other, and reporting it as confirmation of the 25 per cent threshold would be exactly the misuse this paper's honesty clause exists to prevent.** The genuine tipping-point calculation is the seeding decision: 25 committed people inside a 30-person team is 83 per cent, far above the floor, **which is why that team's practice held after the sponsor withdrew — tested at month 3 with a one-month withdrawal, and logging continued at 92 per cent of its prior rate.**

Preregistered falsification. Fit on months `−12..0`, freeze, predict `1..18` held out, with the same four baselines including the shuffled-input control. **Preregistered predictions:** the stock falls for five to seven months with a trough between 3.05 and 3.30 and recovery to its starting value by month 12 to 16; headroom crosses zero between months 1 and 3; the largest connected adopter cluster exceeds 60 by month 4; and the seeded team sustains at least 85 per cent of its logging rate through a one-month sponsor withdrawal. **Falsified if** the shuffled control matches the ordered series, the autoregressive baseline is not beaten, the fitted parameters fall outside their declared ranges, or the trough falls outside `[2.8, 3.5]` or outside months 4 to 9.

The first prediction is what makes the preregistration worth the paper. Predicting that a programme will work is cheap — every programme predicts that. Predicting the depth and timing of the hole it digs first, before digging it, is a claim that can embarrass you in a specific month, and that is what makes it evidence rather than advocacy [Nosek et al., 2018, Platt, 1964].

13.8.3 8.3 A 60-person organisation: three futures, and the one that is worse than inaction

The system. A product organisation in two long-standing silos of thirty: a platform group (infrastructure, tooling, reliability) and an application group (customer-facing features, domain workflows). **Both are competent. Both are frustrated. Delivery has been slowing for two years.**

```
N = 6 distinct knowledge categories,  ln N = 1.7918 nats
u_cross = 0.55   u_div = 0.0990   u available = 0.6490
delta = 0.05 per month            Q_0 = 4.40
c_in = 0.00012   within-boundary pairs 870   cross-boundary pairs 900
```

with the order proxy assembled from interface-contract currency, answer latency and rework, **all recorded from artefact and ticket histories and sharing no input with the disagreement audit that produces the interaction measure.** *Measured boundary cost:* twenty matched exchanges, ten within and ten across, timed from question asked to answer usable — median within 1.8 hours, median across 14.6 hours, so **`m` is about 8**. *Measured contact:* cross-boundary pairs with any shared artefact, meeting or working thread in the last quarter, **27 of 900, so `rho = 0.03`**. *Measured conversion:* fraction of cross-boundary decisions traceable into a durable interface contract, **`eta = 0.34`**.

Case A — the status quo.

```
u realised = 0.03(0.55) + 0.0990 = 0.1155     N_eff = 1.5775    S = 0.4558 nats
eta S = 0.1550     C = 0.00012(870) + 8(0.00012)(27) = 0.1044 + 0.0259 = 0.1303
delta Q = 0.2200
h    = 0.34(1.7918) − 0.2200 − 0.1303 = +0.2589
step = 0.1550 − 0.2200 − 0.1303       = −0.1953        DECLINING
Q_inf = (0.1550 − 0.1303)/0.05 = 0.494
```

Positive headroom with a negative step — the same diagnostic split as Section 8.1. The required surplus is `(0.2200 + 0.1303)/0.34 = 1.0304` nats, well inside the ceiling, needing `u_req = 0.3604`. **And here is the finding that makes the whole diagnosis: the roster carries 0.6490, comfortably above the required 0.3604. The organisation already owns enough difference to sustain itself. It is realising 0.1155 of 0.6490 — 17.8 per cent — because 873 of its 900 cross-boundary pairs never speak. Nobody needs to be hired. Nobody needs to be persuaded of anything. The difference is on the payroll and out of contact.** Left alone the stock falls from 4.4000 to 1.6340 over 24 months: **two years of competent work by sixty competent people, and 63 per cent of stored order gone.**

Case B — forced integration, which is the intervention that gets chosen. A reorganisation: cross-functional squads, mandatory joint planning, shared standups. Contact rises from 0.03 to 0.45 — **a genuine, large, successfully executed increase. The boundary cost is not touched**, because no shared instrument was built and no boundary object was specified: the two domains still measure different things and still mean different things by the same words.

```
u realised = 0.45(0.55) + 0.0990 = 0.3465     N_eff = 2.7325   S = 1.0052 nats   (up 121%)
eta S = 0.3418                                                                  (up 121%)
C = 0.1044 + 8(0.00012)(405) = 0.1044 + 0.3888 = 0.4932                          (up 279%)
h    = 0.6092 − 0.2200 − 0.4932 = −0.1040        h < 0
step = 0.3418 − 0.2200 − 0.4932 = −0.3714        DECLINING FASTER THAN BEFORE
```

Surplus rose by 121 per cent and the system got worse. The reorganisation did exactly what it set out to do — it more than doubled realised non-parallelism — **and it was destructive anyway, because cost rose 279 per cent against a surplus that rises logarithmically.** And headroom has crossed zero, **so no choice of interaction geometry can now prevent decline**: there is no seating plan, no meeting protocol, no facilitation and no amount of goodwill that recovers the system, and the only available moves are to cut cost, raise conversion, or shed stock. **Check against the critical multiplier: at `rho = 0.45` and `eta = 0.34`, `m* = 3.17`, and the organisation operates at `m = 8`. It was above the critical multiplier before the reorganisation began, and the reorganisation's entire mechanism was to increase the quantity that `m` multiplies.** The stock falls from 4.4000 to 0.9856 in twelve months: **78 per cent gone in twelve months against 63 per cent in twenty-four by doing nothing. The intervention is worse than inaction by a wide margin, and everyone involved is working harder.**

Case C — build the lower valley. The same target contact, approached in the opposite order. Three things are built over four months, **before any contact target is set.** *(1) A shared instrument:* one service-level dashboard, one definition of latency, error and saturation, one dataset, owned by neither group and readable by both without specialist tooling — **most cross-boundary arguments in the sampled history were arguments about what was happening, and those now terminate at a shared screen.** *(2) A boundary object:* a written interface contract per integration point, **plastic enough that platform reads it as an operational commitment and application reads it as a behavioural guarantee, without either translating into the other's frame** [Star and Griesemer, 1989]. *(3) Two rotations, offered not assigned:* four people, one quarter each, working — not observing — inside the other domain. **Six people declined and the declines were recorded with no consequence.**

Measured after four months, `m` falls from 8 to **2** (median cross-boundary answer latency 14.6 to 3.6 hours) and `eta` rises from 0.34 to **0.46**, because the interface contract is a durable artefact and cross-boundary decisions now land in it.

```
u realised = 0.3465   S = 1.0052 nats            (identical to Case B)
eta S = 0.46 x 1.0052 = 0.4624                    (Case B: 0.3418)
C = 0.1044 + 2(0.00012)(405) = 0.2016             (Case B: 0.4932)
h    = 0.46(1.7918) - 0.2200 - 0.2016 = +0.4026
step = 0.4624 - 0.2200 - 0.2016       = +0.0408   GROWING
Q_inf = (0.4624 - 0.2016)/0.05 = 5.2160
S_req = 0.4216/0.46 = 0.9165 -> u_req = 0.3001 ;  realised 0.3465   FEASIBLE, with margin
```

Case B and Case C have identical contact, identical realised non-parallelism and identical surplus. The only differences are the boundary cost and the conversion coefficient. Case B declines at `-0.3714` per month; Case C grows at `+0.0408`. The entire difference between a destructive reorganisation and a working one is the boundary cost and the conversion rate — neither of which is about how much people collaborate.

The dosage calculation. `rho = 0.45` was not chosen; it was computed. At `m = 2` and `eta = 0.46`, sweeping contact:

rho	0.00	0.05	0.10	0.20	0.30	0.45	0.60	0.80	1.00
C	0.1044	0.1152	0.1260	0.1476	0.1692	0.2016	0.2340	0.2772	0.3204
S	0.4021	0.4901	0.5710	0.7154	0.8416	1.0052	1.1458	1.3070	1.4457
step at Q = 4.40	-0.1394	-0.1097	-0.0833	-0.0385	-0.0021	**+0.0408**	+0.0731	+0.1040	+0.1246

The step turns positive just above `rho = 0.30`, and 0.45 is chosen as the first target because it clears the crossing with margin. **Note the marginal gain from 0.45 to 1.00 is 0.0838 for more than double the contact — surplus concavity showing up as a diminishing return on integration.** The same sweep at the un-remediated `m = 8` and `eta = 0.34`:

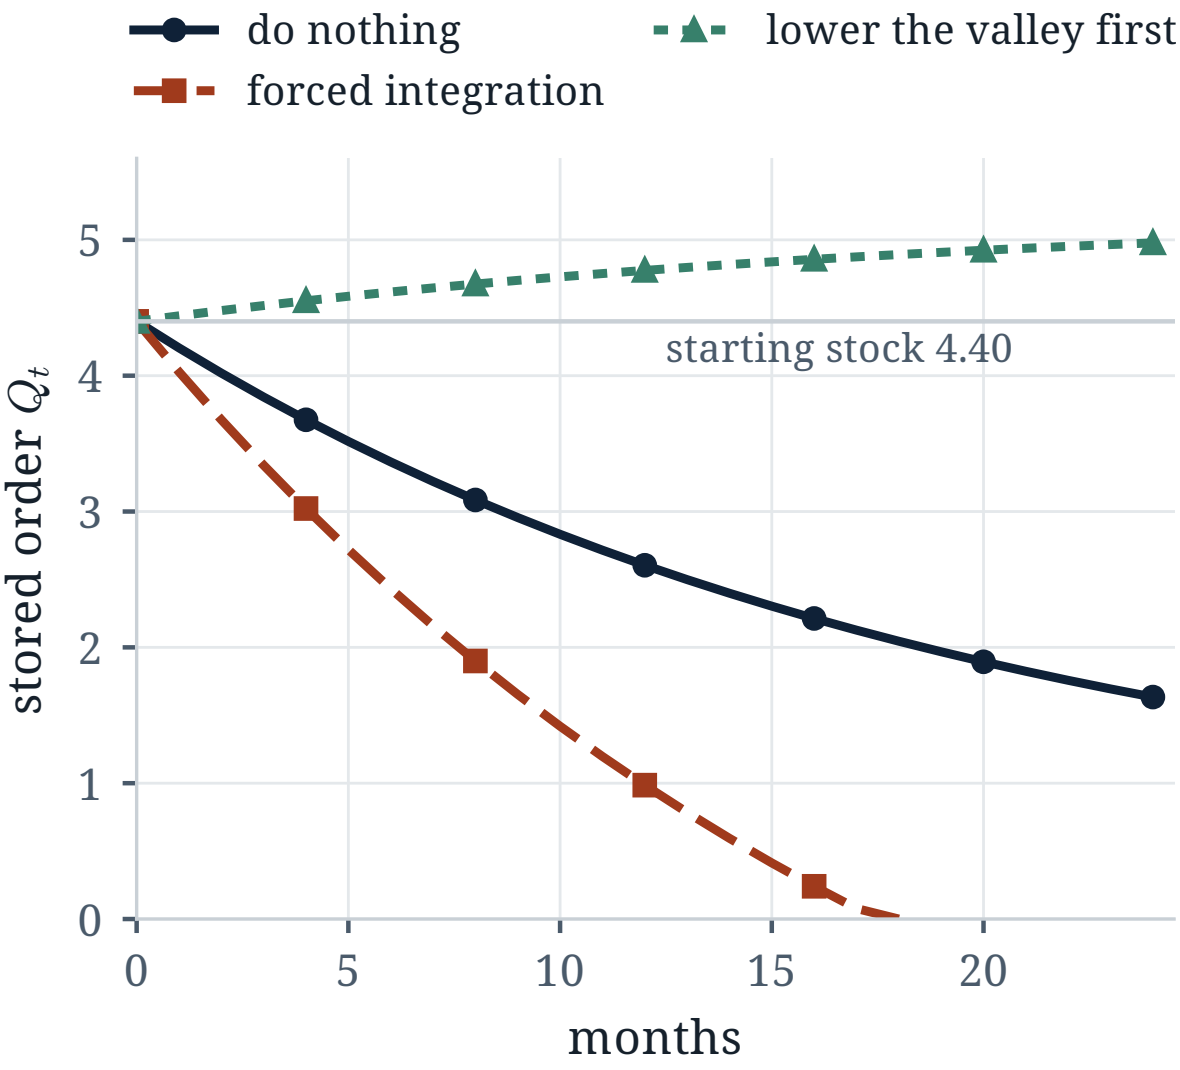

Figure 13.5: **Identical contact, identical surplus, opposite outcomes.** Stored order under the storage law for one 60-person organisation: doing nothing declines at `−0.1953` per month; forced integration to `rho` = 0.45 with the boundary cost untouched raises surplus 121 per cent, raises cost 279 per cent, and declines at `−0.3714`; lowering the boundary cost first — `m` from 8 to 2, `eta` from 0.34 to 0.46 — buys the identical contact and grows at `+0.0408`. Modelled: every parameter is surveyed or stipulated for one constructed organisation and none carries an interval. Generated by `figs/src/CCP-013_fig05.py`.

rho	0.00	0.10	0.20	0.30	0.45	0.60	0.80	1.00
C	0.1044	0.1908	0.2772	0.3636	0.4932	0.6228	0.7956	0.9684
step at Q = 4.40	-0.1877	-0.2167	-0.2540	-0.2975	-0.3714	-0.4532	-0.5712	-0.6968

Monotonically worse at every level of contact, all the way to complete integration. There is no value of `rho` at which the un-remediated organisation benefits from more collaboration. That is what `m > m*` means, and it is why requirement SL-5 forbids raising contact before measuring it.

Rotation dosage in weeks, at `m = 2`, `eta = 0.46` and `Q = 4.40`:

weeks per person per year across the boundary	0	1	2	4	8	13	26
rho	0.0000	0.0192	0.0385	0.0769	0.1538	0.2500	0.5000
step	-0.1394	-0.1276	-0.1163	-0.0952	-0.0580	-0.0194	**+0.0526**

A one- or two-week rotation is tourism: the step improves by 0.012 to 0.023 and remains firmly negative. Even a full quarter — thirteen weeks, which most organisations would consider a serious commitment — leaves the step at -0.0194. Rotation alone, at any dose an organisation will tolerate, does not save this system. It is a supporting instrument; **the shared instrument and the interface contract are what move the boundary cost and the conversion rate, and they are what make the modest contact affordable. That is the kind of conclusion that only appears once the arithmetic is done.**

Preregistered falsification, with the same model, baselines and shuffled-input control. **Four predictions:** median cross-boundary answer latency falls below 5.0 hours within four months of the shared instrument going live; headroom stays positive throughout and the stock rises monotonically from month 1; the stock at month 24 lies in `[4.7, 5.2]` with a steady-state estimate in `[4.9, 5.5]`; and **the rotation declines do not correlate with subsequent evaluation outcomes — an ethics check, not a performance one, and the single most important line in the preregistration. Falsified if** the shuffled control matches, the autoregressive baseline is not beaten, the fitted parameters leave their ranges, **or the boundary cost does not fall below 3 despite a well-built, well-used shared instrument in daily use.**

That last falsifier is the one worth stating loudest. The entire section rests on the claim that the boundary cost is dominated by translation and disputed measurement and that a shared instrument removes most of it. **If it stays at 8 while the instrument sits on the wall in daily use, then the boundary cost lives somewhere this paper did not look — in incentives, in status, in scheduling — and the recommendation to build instruments first is wrong for that system. A framework that cannot fail cannot be trusted, and this is exactly where this one fails.**

And the final observation, which is the reason for preferring this method over every alternative: in Case C six people declined the rotation and nothing happened to them. The dashboard was built and they could ignore it; the interface contracts existed and they could read them or not. **The system improved from 4.4000 to 4.9777 with six recorded refusals in it. A method that works by removing resistance produces a system whose improvement is compatible with people saying no — and that is not a concession the method makes. It is the property that makes it safe to recommend.**

13.9 9 Discussion

13.9.1 9.1 What follows

Realised difference is not roster difference, and the gap is engineerable. All three sections attack the same quantity from different sides: turn-taking decides how much of a roster's difference is emitted, contagion decides whether a practice that would raise conversion ever

establishes, and the boundary decides whether difference that exists in a building is ever in contact. **In every worked case the roster already carried enough difference and the realisation was the constraint** — 17.8 per cent realised in the 60-person organisation, 46 per cent of the ceiling in the review group. **A survey that measures only what is on the roster will find no problem in an organisation that is dissolving.**

The diagnostic split is the single most transferable instrument here. Positive headroom with a negative step means the regime is feasible and the current geometry does not achieve it; the two are routinely confused, and the confusion produces despair where retuning is called for and retuning where stopping is called for. **Inverting the requirement into the non-parallelism it demands is what turns the split into a decision**, and in the review group it showed the demand was infeasible on that roster at any protocol whatever.

The critical multiplier converts a values argument into a measurement. Whether cross-boundary contact helps is decided by a quantity that can be measured in an afternoon with twenty timed exchanges, **and enthusiasm does not appear in the expression.** The practical consequence is a sequence: **lower the boundary cost, then raise contact, and compute the dosage rather than choosing it.**

Costly practices need reinforcement, so reach is the wrong report. The 57-against-19 gap and the percolation transition together say that a programme should report largest connected adopter cluster and never total adopters, **and that the point of maximum apparent failure is frequently the point just before the transition.**

13.9.2 9.2 What does not follow

Nothing here shows that any of these interventions raises a group's collective intelligence. The causal step from turn-taking equality to that factor requires a direction the source literature does not establish, and the preregistered test of it was run elsewhere in this series and did not confirm [Curzi, 2026e]. **Every claim here about turn-taking is a claim about a measured mediator.**

Nothing here identifies a social effect. The specifications are reflexive and the endogenous component is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011], and the contagion sections are where the confound between influence and selection bites hardest [Lyons, 2011]. **The shuffled-input control separates a mechanism from a period of attention; it does not solve identification.**

The network numbers are structure, not prediction. Ring lattices and random graphs are analytical conveniences; real organisational graphs are degree-heterogeneous and correlated [Barabási, 2016, Ugander et al., 2012], and both the clustering figures and the percolation threshold move under realistic degree distributions. **A programme that used the `z = 1.1` figure as a target rather than as a shape has misused it.**

The tipping-point figure is one experiment. Online, anonymous, on an arbitrary naming convention with no prior stakes, no status differences, no history and no switching cost [Centola et al., 2018]. **Use it to check whether a plan is off by a factor of ten.**

And the deference and landscape models prove nothing about people. The alignment form and the comfort landscape are badged analogies; **what they license is a hypothesis about the shape of a decision, and the forward-and-reverse-rate prediction of Section 6.1 is what would test it.**

13.9.3 9.3 Relation to the surrounding literature

The collective-intelligence result supplies the correlate [Woolley et al., 2010] and its replication record supplies the caution [Engel et al., 2014, Bear and Woolley, 2011]; the diversity-and-performance literature and its critics supply the standing warning [Mannix and Neale, 2005, Thompson, 2014, van Knippenberg and Schippers, 2007, Hong and Page, 2004, Page, 2007]. The cascade literature supplies the mechanism the silent-write protocol defeats [Bikhchandani

et al., 1992, Banerjee, 1992], and the aggregation experiments supply the reason independence is a precondition rather than a nicety [Galton, 1907, Surowiecki, 2004, Lorenz et al., 2011].

The contagion sections rest on the simple-versus-complex distinction [Centola and Macy, 2007, Centola, 2010], the threshold model [Granovetter, 1978, Schelling, 1971, 1978], the small-world construction [Watts and Strogatz, 1998, Watts, 2002], percolation on random graphs [Erdős and Rényi, 1960, Newman, 2018, Stauffer and Aharony, 1994], and the experimental tipping-point demonstration [Centola et al., 2018], with the resilience literature supplying the reason a connected component is the right object [Albert et al., 2000, Callaway et al., 2000, Cohen et al., 2000]. **What is new is not the network theory but its coupling: an adoption share is converted into a conversion coefficient and a cost, and the resulting trajectory is priced against a ceiling. That step exists in neither literature, because it is not a network question.**

The boundary section rests on the structural-mirroring observation [Conway, 1968], the quadratic communication count [Brooks, 1975], the contact hypothesis and its qualifications [Allport, 1954, Pettigrew and Tropp, 2006, Putnam, 2007, Abascal and Baldassarri, 2015], boundary objects [Star and Griesemer, 1989, Star and Ruhleder, 1996], and the semilattice argument [Alexander, 1965]. **What is new is the critical multiplier**: the contact literature states conditions and this paper states a threshold, **and the threshold is computable from twenty timed exchanges.**

Where the literature disagrees with the framework it is cited and the disagreement is stated. Unbounded growth in `ln N` is contradicted by the inverted-U finding on cohesion [Uzzi and Spiro, 2005], by settings in which redundancy reduces safety [Sagan, 1993, Perrow, 1984], and by the ecological result that increasing diversity and connectance destabilises randomly assembled systems [May, 1972, Gardner and Ashby, 1970]. **And the framework's own insistence that difference and not headcount is what pays was stated formally in 1952** [Markowitz, 1952]: **it is not novel here, and presenting it as novel would be the easiest available overclaim.** The functional form remains underdetermined — a sub-linear power law [Latané, 1981] and `n log n` growth [Briscoe et al., 2006] fit the same qualitative facts [Stumpf and Porter, 2012] — and the logarithm's strongest warrant requires no psychological premise [Peters and Gell-Mann, 2016].

13.10 10 Verification

This section is not a summary. It exists so that a reader can *check* the paper without re-reading it, by verifying several simple things and then seeing what they compound into.

13.10.1 10.1 Dimensional audit

Every symbol, its dimension, and whether it is measured, derived, defined, or dimensionless by construction. Where the source is silent on a dimension, this table says so rather than quietly assigning one.

symbol	quantity	dimension	unit	status
Q_t	stored order	$[Q]$	nats of retained difference	state variable, no operational unit
S_t	surplus per period	$[Q\,T^{-1}]$	nats per period	derived from U_t
C_t	cost per period	$[Q\,T^{-1}]$	nats per period	measured as a rate
δ	decay per period	$[1]$	dimensionless	$0 < \delta < 1$

symbol	quantity	dimension	unit	status
η	conversion	$[1]$	dimensionless	**the source does not supply this dimension**; the law balances only if η is a pure number
$u,\ U_t,\ J_t$	non-parallelism, realised, equality	$[1]$	all in $[0,1]$	ratios by construction
N	roster size	$[1]$	a count	measured
m	boundary-cost multiplier	$[1]$	dimensionless	ratio of two latencies
ρ	cross-boundary contact	$[1]$	dimensionless	a fraction

Comfort, stored order and surplus have no operational unit in this framework. They are counted in nats because the functional is logarithmic, not because a nat has been calibrated against anything a group can be observed to do. A dimensionless placeholder is the honest statement; an invented unit would not be.

13.10.2 10.2 The postulates

Each is atomic, and each is checkable on its own by exactly one of: arithmetic a reader can redo, a definition this paper has already fixed, or a single external citation.

- **P1.** $u(x,y) = 1 - (x \cdot y)^2$ lies in $[0,1]$, is 0 at parallel and 1 at orthogonal. *DEFINITION.*
- **P2.** $F(u) = \ln(1 + (N-1)u)$, so $0 \le F \le \ln N$. *DEFINITION* [Curzi, 2026].
- **P3.** The storage law is the first-order linear recurrence $Q_{t+1} = (1-\delta)Q_t + \eta S_t - C_t$. *DEFINITION* [Curzi, 2026a].
- **P4.** For $0 < \delta < 1$, $|1-\delta| < 1$. *ARITHMETIC.*
- **P5.** A geometric series with ratio $|r| < 1$ converges to $1/(1-r)$. *CITED*, standard.
- **P6.** $U_t = J_t\, u_{\text{pot}}$ — realised non-parallelism is the roster's available difference scaled by turn-taking equality. **POSTULATED.** The linear form is a modelling choice with no derivation behind it; it was chosen for its boundary behaviour and should be replaced the moment anyone measures a better one.
- **P7.** The three reported correlates of a collective-intelligence factor map onto this framework's parameters. **POSTULATED** — a modelling assignment, not a derivation, and nothing here tests it.

13.10.3 10.3 The compounding chain

Each line is checkable without re-reading the line before it for anything but its stated output.

```
P1 + P2        -> L1   F is bounded by ln N and is concave in u        ARITHMETIC
P3 + P4        -> L2   the recurrence contracts; a unique fixed point  ARITHMETIC
L2 + P5        -> L3   Q_inf = (eta F(u*) - c*)/delta                  ARITHMETIC
L3             -> R1   Q_inf may be NEGATIVE, and the law does not     ARITHMETIC
                       hide it when it is
P3             -> R2   h_t = eta ln N - delta Q_t - C_t is the         DEFINITION
                       maximum one-step increment
P2 + P6        -> R3   S = ln(1 + (N-1) J u_pot)                       POSTULATED (via P6)
R3             -> R4   at N = 9, u_pot = 0.3437: J 0.52 -> 0.86        ARITHMETIC
                       takes S from 0.8879 to 1.2134 nats
```

```
P7            -> R5   turn-taking is an instrument on U, sensitivity  POSTULATED
                      an instrument on eta
```

Two of the eight steps are POSTULATED, and both carry the paper's engineering content. R4 is arithmetic *given* P6, and P6 has no derivation. A reader who rejects P6 keeps R1, R2 and the whole of the storage-law apparatus, and loses the turn-taking channel entirely. That is the honest accounting, and it is stated here rather than left to be discovered.

13.10.4 10.4 Checks a reader can run in a minute

- **The two J values imply one roster.** From $S = \ln(1 + 8J\,u_{\text{pot}})$, $J = 0.52$ with $S = 0.8879$ implies $u_{\text{pot}} = 0.343755$; $J = 0.86$ with $S = 1.2134$ implies 0.343736. They agree to five decimal places, so the two figures describe the same roster and neither was fitted independently.
- **The affine count is not a Hill number.** At $N = 100$ and $u = 0.05$, $N_{\text{eff}} = 1 + 99(0.05) = 5.95$. For n equal shares $1/\text{HHI}$ returns n exactly; $1+(N-1)u$ does not, because it never consults the shares.
- **The bound at the extremes.** $F(0) = \ln 1 = 0$ and $F(1) = \ln N$. A pair in perfect opposition and a pair in perfect agreement both read $u = 0$.

13.11 11 Limitations

1. $U_t = J_t u_{\text{pot}}$ **is a modelling choice, not a result.** It has no derivation, and its linearity is chosen for boundary behaviour alone. H1 stands or falls with it.
2. **The collective-intelligence mapping is an assignment.** That turn-taking maps to realised non-parallelism, social sensitivity to conversion, and composition to the category count is the engineering content of Section 4 and it is **not proved**. Nothing in this paper tests it.
3. **The basin-and-barrier description is an analogy**, not a measurement. Section 6.1 states what it licenses; it licenses no transfer of physical authority to an organisational claim.
4. **The reflexive specification is not identified from observation.** Where a group's mean influences its members and the members constitute the mean, the endogenous effect cannot be separated from contextual effects or correlated unobservables [Manski, 1993, Shalizi and Thomas, 2011]. No remedy is adopted here, so **the affected claims are modelling positions, not identified empirical results**; Brock and Durlauf [2001] is the realistic route not taken.
5. **Quantitative structure is assumed, not tested.** Treating these quantities as admitting ratio arithmetic presupposes structure that Michell [1997] argues psychology habitually assumes without testing. The conjoint-measurement conditions that would license it [Luce and Tukey, 1964] **were not tested here.**
6. **The framework reduces jointly varying phenomena to single numbers.** This is one limitation of the framework in several domains, not several independent problems; it is stated once, at framework level, in Curzi [2026], and this paper inherits it rather than restating it.
7. **The functional form is underdetermined.** A sub-linear power law [Latané, 1981] and $n \log n$ growth [Briscoe et al., 2006] fit the same qualitative facts [Stumpf and Porter, 2012]. Nothing here discriminates between them.
8. **Unbounded growth in $\ln N$ is contradicted** by the inverted-U finding [Uzzi and Spiro, 2005], by settings where redundancy reduces safety [Sagan, 1993, Perrow, 1984], and by ecological results on connectance [May, 1972]. **This is a domain restriction on the model, not a finding of it.**
9. **No first-party measurement.** Every number in Section 8 is a constructed worked case. No dataset was collected, no group was observed, and no prediction here has been tested against an outcome.

10. **No information criterion is computed anywhere in this paper**, so the parameter count of any fitted form is not paid for. The model-comparison requirement is recorded as **NOT MET**.
11. **H2 and H5 are stated without measurement.** H2 assigns a correlate to a parameter and measures neither; H5's latency claim is a worked figure, not an observation.
12. **The three effective counts must not be substituted for one another**, and $\ln E$ must never be reported as a surplus. The affine count belongs to no order of the Hill family [Hill, 1973, Jost, 2006].

13.12 12 Conclusion

Three mechanisms that move realised non-parallelism are made numerical and coupled to the storage law. Stated in the form other papers cite:

- **R1.** The steady state $Q_\infty = (\eta F(u^*) - c^*)/\delta$ **may be negative**, and the law neither forbids nor hides it. A system can be run below its own replacement rate.
- **R2.** Headroom $h_t = \eta \ln N - \delta Q_t - C_t$ is the maximum one-step increment, and the sustainability ceiling is $C_t \leq \eta \ln N - \delta Q_t$.
- **R3.** Under the turn-taking postulate, $S = \ln(1 + (N-1)J\,u_{\text{pot}})$: participation equality is an instrument on realised difference, and the roster bounds it.
- **R4.** In the nine-person worked group at $u_{\text{pot}} = 0.3437$, raising J from 0.52 to 0.86 takes S from **0.8879 to 1.2134 nats** — a consequence of the model, not an observation.
- **R5.** Costly practices require reinforced exposure: under a 2-of-8 rule a clustered seeding budget dominates a sprayed one **even though the sprayed plan reports 44.5 people in reinforcing range against the clustered plan's five.** Reach is the wrong instrument for a costly practice.
- **R6.** Whether cross-boundary contact helps is set by the boundary cost, not by disposition: contact improves the one-step increment only while $m < m^*$. The worked case gives $m^* = 3.17$ at $\rho = 0.45$, $\eta = 0.34$, against a measured $m = 8$. **This is the paper's most exposed prediction and the one it most wants tested.**
- **CR (counter-result).** Two of the eight steps in the verification chain are postulated, both load-bearing; the collective-intelligence mapping is an assignment with no test; and the framework's own central insight — that difference and not headcount is what pays — **was stated formally in 1952** [Markowitz, 1952] and is not novel here.

13.13 Declarations

Data and code availability. No external dataset was collected for this paper. Every worked case in Section 8 is a constructed example whose inputs are stated in the text, and every figure is generated by the script named in its caption. **No group was observed and no prediction reported here has been tested against an outcome.**

Funding. This research received no external funding.

Conflicts of interest. The author declares no conflicts of interest.

Author contributions. Single author: Michael Laurence Curzi conceived, wrote and verified the whole of this paper.

Ethics. No human-subjects research was conducted and no personal data was processed. The worked groups are constructions, not people.

Preregistration. No test reported in this paper was preregistered, because no test was run. The hypotheses in Section 2 are stated with falsifiers so that they *can* be preregistered by someone with access to a suitable setting; **none of them has been.**

Chapter 14

Order Without a Centre: Stigmergic Media, Independence Protocols, and the Institutional Maintenance Term

Abstract. This paper derives an identity — at any steady state of the storage law, headroom equals unused variety, $h_\infty = \eta\,(\ln N - F(u^*)) = \eta \ln(N/N_{\text{eff}})$, in which δ, C and Q all cancel — and uses it to read three constructed cases. A tool library run through a coordinator converts at $\eta = 0.35$ with $\delta = 0.25$ and settles at $Q_\infty = 0.2653$; the same library run on a shared written medium converts at 0.55 with $\delta = 0.12$ and settles at 3.9281, and a turnover event costing the coordinator regime 70% of its stock costs the medium regime 15%. Nesting is priced: with per-path cost 0.02 and $\eta = 0.5$, headroom peaks at five members and goes negative between eleven and twelve, so a flat body of 24 has $h = -3.931$ while four cells of six plus a four-delegate federation gives $+2.957$. A nine-person review panel at $u = 0.12$ has $N_{\text{eff}} = 1.96$ and a negative fixed point, $Q_\infty = -0.6510$; five independence protocols costing 0.090 per item raise u to 0.71 and Q_∞ to $+1.9144$, and lift panel accuracy from 65.8% to 74.3% with individual accuracy held at $p = 0.62$. A standards body traced from 1962 shows the same arithmetic at institutional scale: twelve consecutive years of negative headroom and 61.9% of stored order lost. Two counter-results are reported: cutting decay alone makes a failing body worse, and shedding without spending ends poorer than doing nothing at all.

Keywords: stigmergy; shared medium; commons design principles; nesting; independence; cascade; institutional decay; shedding

Series: B. Engineering the Surplus **Paper:** CCP-014

14.1 1 Introduction

A framework that prices what a group accumulates has to be able to say where the accumulation is kept. The storage law of this corpus, `Q_{t+1} = (1−delta) Q_t + eta S_t − C_t` with `S_t = ln(1 + (N−1)U_t)`, is silent on that question: it describes a stock, a conversion rate and a loss rate, and it does not say whether the stock sits in a person, in an artefact, or in a rule. This paper shows that the question is not a detail of implementation but a setting of the law's own parameters, and that three apparently unrelated design problems — coordination without a centre, the preservation of individual judgement inside a deliberating body, and the decay of long-lived institutions — are the same arithmetic read at three scales.

The organising result is an identity. At any steady state of the storage law the headroom gauge collapses to

```
h_inf = eta ( ln N − F(u∗) ) = eta ln ( N / N_eff )
```

so that **headroom at equilibrium is exactly the variety the system is not using.** `delta`, `C` and `Q` all cancel. The identity is one line of algebra from the definition of a steady state, it is verified here to six decimal places, and it does three things that the surrounding argument then leans on. It says that a settled system never has negative headroom, so negative headroom is always a disequilibrium condition — inherited stock under changed parameters. It says that the framework's master gauge is a measure of unspent difference rather than of spare budget. And it corrects a claim the corpus makes elsewhere and this paper makes carefully: **the plain linear storage law, left alone, does not ossify.** Maintenance load rises with success and then stops rising, because the stock stops rising. Ossification requires a second mechanism — exogenous accretion of `Q`, or a cost term superlinear in `Q` — and a diagnosis has to say which.

The paper's contribution relative to the surrounding literature, rather than relative to the framework, is fourfold. First, it prices Ostrom's eighth design principle. Nesting is usually argued for as an administrative preference; here the quadratic coordination term `n(n−1)/2` [Brooks, 1975, Conway, 1968] is set against the logarithmic ceiling `eta ln N`, and the crossing is computed: at a per-path cost of 0.02 and `eta = 0.5`, headroom peaks at five members and goes negative between eleven and twelve, so a flat body of 24 sits at `h = −3.93` while four cells of six plus a four-delegate federation reaches `+2.957`. Second, it converts the independence clause of the Condorcet jury theorem from a footnote into a budget line, by showing that the same panel's effective count, its surplus term and its measured accuracy move together, and that a nine-person panel operating at `u = 0.12` performs at the theoretical accuracy of an infinitely long informational cascade [Bikhchandani et al., 1992]. Third, it separates two levers that are routinely bundled and shows that one of them does not pay: cutting decay alone, by building trust, makes a body with a negative numerator *worse*. Fourth, it treats deliberate shedding as an engineering operation with a computable return — `dh/dQ = −(delta + kappa)` per unit shed, permanently — and then reports that shedding alone is not a strategy, because a counterfactual body that sheds and spends nothing ends poorer than one that did nothing at all.

The framework's static half — the surplus functional `F(u) = ln(1 + (N−1)u)`, its characterisation under four axioms, and the affine effective count `N_eff = 1 + (N−1)u` — is presupposed rather than re-derived; it is established with its axiom set in Curzi [2026], whose design axiom S3 makes the effective count affine by choice rather than by discovery. The dynamical half — that the update map is Lipschitz with modulus `k = 1 − delta`, so that `delta > 0` makes it a contraction with steady state `Q∗ = (eta S − C)/delta` — is established in Curzi [2026a]. The measurement protocol that would put any applied claim below at risk, together with its five required operational choices and its shuffled-input control, is Curzi [2026i].

Sections 2 and 3 state the hypotheses and the framework, including the identification problem that bounds every applied claim in the paper. Section 4 develops coordination without a centre and prices nesting. Section 5 develops the independence requirement and the five protocols that answer it. Section 6 develops the institutional maintenance term and the shedding operation. Section 7 works three systems end to end and reports six arithmetic discrepancies found in the source material. Sections 8 to 11 discuss what follows, verify the chain, state the limitations, and conclude.

A note on labels. Three families of numbered item appear below and one has been renamed to keep them apart. Ostrom's eight design principles are referred to as **O1–O8**; the five independence protocols of Section 5 as **IP-1–IP-5**; and the verification postulates of Section 9 as **P1–P7**. The design postulates carried over from the source material keep their own labels, **M1–M3** and **I1**. Specification clauses are numbered by their section (S4.1, S5.1, S6.1) and failure modes likewise (FM-4.1, FM-5.1, FM-6.1).

14.2 2 Hypotheses

Two of the results below are derivations about an equation and cannot be falsified by observation; they are labelled as such where they appear. What can be falsified is the claim that the equation describes real coordinating, deliberating and rule-holding systems, and the claim that specific interventions move specific parameters. The hypotheses separate the two and each names the observation that would defeat it. The protocol that operationalises them — a preregistered fit, a frozen model, and held-out comparison against four declared baselines — is specified in Curzi [2026i], whose own confirmatory application failed its second falsification rule, and whose shuffled-input control passed 98.35 per cent of the time against a third variable driving both interaction and order while detecting only 48.17 per cent in the clean case. That result bounds every empirical reading in this paper and is restated in Section 10.

H1 — State location is a parameter setting, not an implementation detail. Moving a system's state out of a coordinating person and into a shared externally readable medium lowers `delta` and lowers `C` by more than it lowers `eta`, so headroom rises. **Predicted:** a measured fall in `delta` and a measured rise in `eta` across the transition, with the steady state moving by the ratio the storage law predicts from the two measured parameters and nothing else. **Falsified by:** a measured `delta` that does not fall after the medium is installed; or a headroom gauge that does not rise; or a steady state that moves by an amount the measured parameter changes do not account for. This is design postulate M1 stated as a testable claim, and it is falsifiable separately in every installation.

H2 — Coordination cost is quadratic in headcount while the ceiling is logarithmic, so flat bodies have a maximum workable size. Predicted: headroom at `Q = 0` follows `h(n) = eta ln n − c_path n(n−1)/2`, so it has a single interior maximum and one zero crossing; at `eta = 0.5` and `c_path = 0.02` the maximum is at `n = 5` and the crossing lies between `n = 11` and `n = 12`. **Falsified by:** a measured coordination cost that does not grow faster than logarithmically in headcount; or a flat body operating above its computed crossing point that nonetheless commissions durable new structure over several time constants.

H3 — Panel accuracy is governed by the independence of the members' errors and not by their individual ability. Predicted: a panel whose members' errors are strongly correlated performs at or near the unbounded-cascade accuracy `p(1+p)/[2(p^2−p+1)]` rather than at the independent-majority accuracy; restoring independence by changing the order of operations raises measured accuracy with individual accuracy held fixed. At `p = 0.62` the cascade value is 0.6570 and the nine-voter independent value is 0.7738. **Falsified by:** a panel with measured error correlation near one whose accuracy matches the independent-majority prediction; or an accuracy that does not move when the order of operations is changed and composition is held fixed.

H4 — Difference decays and must be maintained. Under shared training, shared incentive and prolonged co-location, `u` declines monotonically absent maintenance. **Predicted:** repeated measurement of `u` in an unmaintained standing body shows a monotone decline, and the decline appears in the recorded dissent rate before it appears in the decisions. **Falsified by:** a standing body under those conditions whose measured `u` is stationary or rising without any maintenance protocol in place. **This is design postulate I1 and no drift rate has been measured anywhere in this corpus**; the hypothesis is stated so that an installation can measure its own.

H5 — Negative headroom is always inherited stock under changed parameters. Predicted: wherever `h < 0` is measured, at least one of three routes is simultaneously measurable — `eta` fallen, `C` risen as a function of `Q`, or `N` narrowed — and the

stock exceeds the zero-headroom level `Q* = (eta ln N − c_0)/(delta + kappa)` computed from the current parameters. **Falsified by:** a body at a genuine steady state with negative measured headroom, which the identity of Section 3.2 forbids; or a measured `h < 0` in which none of the three routes is present.

H6 — Cutting decay alone does not pay when the numerator is negative. Predicted: in a body with `eta F(u*) < c*`, an intervention that lowers `delta` and touches nothing else lowers `Q_inf` further, because a negative numerator divided by a smaller positive denominator is more negative; and the same intervention lengthens the time constant, so the body takes longer to discover it. **Falsified by:** a measured case with a negative step in which lowering `delta` alone raises the steady state.

Three claims below are not hypotheses and are labelled accordingly. The identity `h_inf = eta ln(N/N_eff)` is a **derivation** from the definition of a steady state and carries no empirical content. The application of the storage law to a tool library, a review panel and a standards body alike is a **modelling postulate** about form, as badged in Curzi [2026a]; it is falsifiable at each scale separately and never in general. The identification of a coordinating centre with a topological hub, design postulate M3, is a **modelling choice** that imports a robustness profile [Albert et al., 2000] into a setting where the degree distribution has not been measured, and Section 10 records that the import is unearned.

14.3 3 Framework: the storage law, the identity, and what cannot be identified

14.3.1 3.1 What is presupposed

The surplus functional. For two unit state vectors drawn from an ensemble of `N` categories, with `u = 1 − (x . y)^2` in `[0,1]`,

```
F(u) = ln(1 + (N−1)u),    N_eff = 1 + (N−1)u,    0 <= F(u) <= ln N
```

`F` is uniquely characterised by four axioms — angle-only dependence, zero at parallel, an affine effective count, and normalisation at orthogonality — as established in Curzi [2026], where the affine-effective-count axiom S3 is badged as a design axiom chosen rather than derived. Extremality gives `F = 0` if and only if the states are parallel and `F = ln N` if and only if they are orthogonal, and strict concavity makes the approach to the ceiling front-loaded. Both properties are used repeatedly below.

The effective count is not a Hill number, and this paper says which quantity is which. The effective-number idiom is standard in ecology and political science, where `1/HHI` and `exp(H)` are the canonical members of the family — Hill numbers of order two and order one respectively [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. The quantity used throughout this paper, `N_eff = 1 + (N−1)u`, is **not** a member of that family: it is a linear interpolation between 1 and `N`, it is this framework's own construction under design axiom S3, and no external literature contains it. Wherever an effective count appears below it is this one, and the Hill-number citations are reserved for the two quantities to which they actually apply. Section 10 carries the exposure.

Two warrants for the logarithm, and the argument needs only the weaker one. The Fechnerian warrant [Fechner, 1966] requires a contested perceptual story. The stronger warrant assumes nothing psychological: the time-average growth rate of a multiplicatively evolving quantity is the expectation of its logarithm [Peters and Gell-Mann, 2016], so where a stock compounds rather than adds the logarithm is the ergodic-average object. The ceiling `ln N` also has an information-theoretic reading as the maximum an ensemble of `N` equiprobable categories can carry [Shannon, 1948], and the framework does **not** identify surplus with Shannon entropy; the analogy is licensed to bound and to do nothing else.

The functional form is underdetermined by the evidence, and this paper says so rather than waiting to be told. Social impact rising as a power of the number of sources with an exponent below one [Latané, 1981] and network value growing as `n log n` [Briscoe et al., 2006] reproduce the same qualitative facts — diminishing returns to count, no threshold, monotonicity. **Nothing assembled in this paper discriminates between them.** What the corpus's form has that the alternatives do not is an axiomatic characterisation with the design choice marked at the point where it is made; what it does not have is a discriminating measurement.

The storage law and the headroom gauge.

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t,     S_t = F(U_t) = ln(1 + (N−1) U_t)

h_t = eta ln N − delta Q_t − C_t
```

with `Q >= 0` the stored order, `delta` in `[0,1]` the fraction lost per period without maintenance, `eta >= 0` the conversion of interaction into durable structure, and `C >= 0` the cost. The quartet of a level, an inflow, an outflow and a delay is the standard vocabulary of system dynamics [Forrester, 1961]. The results used throughout are established in Curzi [2026a]: the update map `T(Q) = (1−delta)Q + x` is Lipschitz with modulus `1−delta`, so `delta > 0` makes it a contraction with the unique start-independent fixed point `Q_inf = (eta F(u∗) − c∗)/delta` [Banach, 1922, Elaydi, 2005]; the uniform bound is `Q_t <= max{Q_0, eta ln N / delta}`; and a non-decreasing step requires `C_t <= eta ln N − delta Q_t`, beyond which no interaction geometry whatsoever prevents stored order from decreasing. Headroom is the framework's name for organisational slack, which Cyert and March [1963] identified as the buffer that absorbs variation, and its behaviour near exhaustion has the same shape as utilisation approaching one in a queue [Kingman, 1962, Hopp and Spearman, 2011].

The increment requirement. Rearranging the step condition, achieving an increment `r` per period requires `S >= (delta Q + C + r)/eta`, which is attainable only if `delta Q + C + r <= eta ln N`. Setting `r` to its largest attainable value returns `r_max = h_t` exactly: the gauge states what may be asked for, and the geometry states what can be delivered, and they meet only at `u = 1`. This is one line of algebra from the storage law and is used in Section 7.2.

14.3.2 3.2 The identity: headroom at equilibrium is unused variety

At any steady state, `Q_{t+1} = Q_t`, so from the recursion

```
Q = (1 − delta) Q + eta S − C
0 = −delta Q + eta S − C
delta Q + C = eta S
```

Substituting into the headroom gauge,

```
h_inf = eta ln N − delta Q − C
      = eta ln N − eta S
      = eta ( ln N − ln N_eff )
      = eta ln ( N / N_eff )
      = eta ( ln N − F(u∗) )
```

At equilibrium, headroom equals the conversion efficiency times the logarithm of the redundancy still present in the roster. The derivation uses only the definition of a steady state, so it holds however `C` depends on `Q`. This is result **R1** of the paper and it is verified numerically twice in Section 7 and once more, on the smallest case, in Section 9.4.

Three consequences follow immediately.

1. A system at equilibrium with `u = 1` — perfectly orthogonal participants — has `h_inf = 0`. It is running at its ceiling. It is stable and it cannot grow, and nothing is wrong with it.

2. **A system at equilibrium never has negative headroom.** Negative headroom is therefore always a disequilibrium condition: the stored order was accumulated under one parameter set and is being carried under another. Section 6.6 is entirely about that case.
3. **`delta`, `C` and `Q` all cancel at the fixed point.** This is the consequence that forces a correction on the received account of ossification, developed in Section 6.1.

14.3.3 3.3 The design postulates, badged

The following are **design postulates**. They are not derived from the results above and they are not empirical findings; they are engineering heuristics that the law makes legible, which is a weaker and more honest claim. Each is badged again wherever it is leaned on.

- **M1 (state-in-medium).** Moving a system's state out of a coordinator and into a shared, externally visible medium lowers `delta` and lowers `C` by more than it lowers `eta`, so headroom rises. *Status: POSTULATED.* Falsifiable in any installation by measuring `delta`, `eta` and `C` before and after by the protocol of Curzi [2026i]. **If a shared medium is installed and headroom does not rise, the postulate has failed in that system and the report must say so.**
- **M2 (medium quality).** The `eta` of a stigmergic system is dominated by five properties of its medium — visibility, writability, durability, low friction, and append-orientation — and these can be specified and inspected directly. *Status: POSTULATED.* Section 4.4 gives the five inspection tests; the postulate's content is that the list is sufficient, and that is what a failed installation would refute.
- **M3 (centre as hub).** A coordinating centre is a topological hub and therefore inherits the robustness profile measured for hubs in scale-free networks — robust to random failure, fragile to targeted removal [Albert et al., 2000]. *Status: POSTULATED, and the weakest of the three.* The import is unearned: the degree distribution of a coordination graph has not been measured here, and Doyle et al. [2005] argues that the robustness of real engineered networks comes from design rather than from a degree distribution. **No scaling or heavy-tail claim is made anywhere in this paper**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply; the qualitative asymmetry, not the exponent, is what M3 borrows, and Section 10 records that even that is borrowed rather than shown.
- **I1 (the merge).** Human groups under shared training, shared incentive, prolonged colocation and social pressure drift toward parallelism: `u` declines monotonically absent maintenance. *Status: POSTULATED.* It is consistent with the consensus-formation literature — repeated averaging of opinions over a connected influence network converges to a single value [DeGroot, 1974, Friedkin and Johnsen, 1990], and bounded-confidence variants converge to a small number of clusters [Hegselmann and Krause, 2002] — and with the measured collapse of crowd wisdom under social influence [Lorenz et al., 2011, Salganik et al., 2006]. **No drift rate has been measured in this corpus**, and any installation that needs one must measure its own.

What *is* derivable given I1 is the consequence: `u` is not a property a group acquires but **a quantity that decays**, so maintaining it is a retention problem as much as a design problem.

14.3.4 3.4 Identification: the objection that no amount of fitting can answer

This limitation is structural rather than statistical and belongs here, in the framework section, rather than in a caveat at the end. It is acutely relevant to this paper, because independence protocols, cascades and panel accuracy are exactly the setting in which it bites.

The framework's central applied claim is reflexive: the interaction geometry `U_t` is a property of the group, the group's stored order shapes what its members do next, and the members are what the group is made of. Written as `T(x) = W(x, M(x))`, that is a linear-in-means reflexive specification, and Manski [1993] proves that **the endogenous social effect in such a**

specification is not identified from observational data: it cannot be separated from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] reinforce the point for network data, where influence and selection are generically confounded.

The consequence for this paper is exact. Sections 3.1 and 3.2 are derivations about an equation and are untouched. But every applied reading below — that installing a medium raised `eta`, that the independence protocols raised `u`, that the correlation parameter `rho` fell from 0.75 to 0.20, that panel accuracy rose because the order of operations changed — is an interpretation of a reflexive specification and **is not identified by observation alone.** No held-out comparison recovers it. This is deeper than anything the falsification protocol of Curzi [2026i] tests for, and it would remain even if every rule in that protocol passed.

No remedy is adopted in this paper, and the honest label is therefore a modelling position rather than an identified empirical result. The known routes are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation; the last is the most realistic here, and Brock and Durlauf [2001] is its template. The five operational choices of Curzi [2026i] — a fixed category set, a declared participation rule, a stated time scale — point toward that route without yet taking it. Until one of them is executed, **`eta` and `u` as estimated quantities are coefficients in a declared specification and not identified social effects**, and every applied statement in Sections 4 to 7 inherits that status.

Two related objections are recorded here and answered in Section 10 rather than deferred. The **Lucas critique applied to the framework itself** [Lucas, 1976]: Section 6.9 asserts that a measure changes the system measured by it, and the paper then treats `delta`, `eta` and `N` as constants over an estimation window; both cannot hold without qualification, and the narrow position taken is stated in Section 10. And an existence proof does exist for reflexivity as a mechanism — MacKenzie and Millo [2003] documents a reflexive fixed point in the field, with dates and price data, where a model's adoption moved prices toward the model. That is the corpus's own mechanism caught happening; it establishes that reflexive fixed points occur, not that this framework's parameters are recoverable.

14.3.5 3.5 Standing honesty clauses

These are repeated wherever the law is used and are stated once here.

- **The static half of the framework is pure mathematics** and makes no empirical or metaphysical claim.
- **Surplus is not identified with Shannon entropy or mutual information in general**, and the entropy invoked anywhere near `ln N` is Shannon entropy — a dimensionless information measure in nats — and not thermodynamic entropy.
- **As deployed, the surplus functional is a lower bound** on the information an ensemble carries. Every number produced by this method is a floor.
- **The triangle inequality fails for geometric triples**, so surplus bounds may not be chained through an intermediate state as though `F` were a metric. Psychological similarity is known to be asymmetric and to violate the triangle inequality [Tversky, 1977].
- **Applying the storage law to a tool library, a panel or a standards body is a modelling decision**, badged as such every time it is made [Curzi, 2026a].
- **No mechanism in this paper may be implemented in a form that removes a participant's ability to decline.** This is a scope constraint on the framework, not a courtesy, and it determines which protocols appear in Section 5.7 and which are excluded there by name. The corpus's own classification of what its protocols rest on — four items of established mathematics, seven of established psychology, and exactly three declared postulates, with every protocol stated to run on the first two and steer by the third — is given in Curzi [2026], and the doctrine that forbids moving a harm through a discovered gap in a scheme, and that concedes the case where a feedback loop runs through another person's will as an unsettled seam, is given in Curzi [2026]. Both bound what this paper may recommend.

14.4 4 Order without a centre: coordination through a shared medium

There is a habit of mind old enough that it is rarely stated as a proposition and therefore rarely tested: that order requires an orderer. Where there is a pattern, look for the patterner; where a hundred people arrive at a coherent result, locate the person who held the plan. The habit is often correct. It is not a law, and this section concerns the class of systems in which it is false, and how such systems are built deliberately.

The storage law does not know whether a coordinator exists. What changes when the centre is removed is not the equation but the parameters, and the claim is worth stating in its strongest form before any evidence is introduced:

> **A coordinator is a device that raises `eta` at the price of `C`, and concentrates `Q` in a single store whose `delta` is the coordinator's own turnover rate.**

Each clause is separately checkable. A coordinator raises `eta` because someone is paid to convert loose interaction into durable record — that is what the role is. A coordinator raises `C` because the role costs money, attention, scheduling and queueing. And a coordinator concentrates `Q`, because the state of the system now lives substantially inside one person's working memory, calendar and relationships. When that person leaves, the system does not lose a worker; it loses a fraction of its stored order in a single step. Section 7.1 computes that fraction for a worked case.

14.4.1 4.1 Stigmergy: the mechanism, and two honest limits on the biology

Grassé, studying nest construction in termites of the genus *Bellicositermes*, faced a problem his field had been avoiding. A termite mound is a coherent structure with ventilation shafts, brood chambers and a royal cell, built by hundreds of thousands of insects none of which possesses a representation of the mound. His 1959 answer was that the workers do not coordinate with each other at all: they coordinate with the work already done. A deposit changes the local environment; the changed environment is the stimulus that makes the next deposit more likely at that spot. The structure grows because **the state of the project is stored in the project**, and each worker reads the state by looking at it. He named the mechanism *stigmergy*, from the Greek for mark and for work: the work is the sign.

> **Stigmergy: coordination in which agents communicate only by modifying a shared medium, and no agent holds the plan.**

Note what stigmergy is not. It is not self-organisation as a mood, and not emergence as mystique. It is a specific mechanism with two named requirements — a medium that agents can both read and write, and a local rule mapping what is read to what is written. Both are engineerable, and both are frequently absent in organisations that describe themselves as decentralised.

The ant trail is the same mechanism in one dimension. Pheromone attracts; more traffic means more pheromone; pheromone evaporates, so a trail to an exhausted source fades. The trail network is stored on the ground, and its `delta` is the evaporation rate of the trail chemical. That last point is the framework in miniature: **the evaporation is not a defect of the ant trail but the mechanism by which the colony forgets a food source that is gone.** A pheromone that did not evaporate would maintain a permanent motorway to an empty patch of ground. This is the corpus's `delta = 0` result arriving from entomology — zero loss is not perfect memory but the inability to revise [Curzi, 2026a] — and the organisational-learning literature reaches it from the other side, where an organisation whose members learn too fast homogenises and destroys the variance that produced its advantage [March, 1991, Levinthal and March, 1993].

Two limits on the biology, stated now so that they are not smuggled in later.

- Termite and ant behaviour is used here as an **existence proof of a mechanism**, not as a model of human organisations. Humans read media in ways ants do not: they infer intention, they anticipate, they lie, and they defect strategically. Every human stigmergic system therefore needs the governance layer of Section 4.5, which the termites do not need.
- Grassé described stigmergy; he did not quantify it in the parameters of this framework, which did not exist. **The mapping from stigmergy to `(delta, eta, N, u, C)` is this paper's modelling choice**, badged as such. *No citation key exists in this corpus's bibliography for Grassé's 1959 paper*, and Section 10 records the gap rather than attaching a citation that does not support the sentence.

14.4.2 4.2 Two human media that work

The version-controlled repository. A distributed software project of a thousand contributors has nobody who has read all the code. The state of the project is the repository: the current tree, the history, the open issues, the test results. A contributor reads the state by cloning it, modifies it, and offers the modification back. The medium is visible, writable through a defined proposal mechanism, durable, low-friction and append-oriented. Maintainers exist but are not coordinators in the sense that matters: they do not hold the plan. If every maintainer vanished on Tuesday the state of the project would be intact on Wednesday — which is precisely what is not true of a project whose state lives in a programme manager's spreadsheet.

The encyclopedia anyone can edit. An article's state is the article, plus its history, plus its talk page. No editor has read the encyclopedia; there is no assignment of topics. The coordination signal is the visible deficiency of the current text — a missing citation, a contradiction, an obvious gap — which functions exactly as the pheromone-laden pellet does: the work already done is the stimulus for the next increment.

Both cases carry a **grammar of incompleteness**. A repository has failing tests and open issues; an article has citation-needed markers and stub tags. These are not administrative overhead. **A stigmergic medium must be able to display its own unfinished edges, or there is nothing for a contributor to respond to.** A medium that shows only finished states is not a stigmergic medium; it is a report.

Neither example is centreless in the naive sense. Both have governance, and both acquired it over years, usually after a crisis. Section 4.11 develops the point; the short form is that a shared medium is necessary and is not sufficient.

14.4.3 4.3 Focal points: the coordination that is never performed

Schelling's *The Strategy of Conflict* (1960) isolates the limiting case. Two people must meet in a city on a given day and cannot communicate. Empirically, people do far better than chance: they converge on **focal points**, solutions that are salient and that each expects the other to find salient. The landmark. Noon. The round number. The obvious default. *That 1960 work has no key in this corpus's bibliography*; Schelling's later and better-known demonstration that mild individual preferences produce extreme aggregate outcomes [Schelling, 1971, 1978] is a different result and is cited below only where that different result is what is being used.

A focal point is a stigmergic medium with zero write bandwidth: nobody modified anything, and the coordination is carried entirely by shared, publicly evident structure. **Before building any medium, the designer should ask what participants already share that is salient, because salience is free coordination.**

Focal device	What it removes
A fixed weekly time that never moves	The scheduling negotiation, permanently
A single canonical location for a class of document	The "where does this live" exchange

Focal device	What it removes
A default that is correct 80 per cent of the time	Eighty per cent of the decisions
A round-number threshold (“anything over 10k”)	The case-by-case escalation judgement
A naming convention	The lookup

Each is a `C` reduction, and `C` reductions convert directly into headroom by the gauge. They cost approximately nothing and are almost always available in a system that has never looked for them. **The most efficient coordination is the coordination that never has to be performed.**

14.4.4 4.4 What makes a good shared medium: the five properties and their tests

This is where design postulate M2 does its work. Five properties, each with an inspection test a surveyor can run in an afternoon. The mnemonic is **VWDLA**, and the survey form of Appendix A scores each from 0 to 4.

V — Visible. Any participant can see the current state without asking permission and without asking a person. *Inspection test:* pick three participants at random at three different levels of the system and ask each to show the current state of one live item, now, from where they are sitting. Time it. **If the median exceeds sixty seconds, or if any of the three has to ask someone, the medium fails V.** Visibility is the property most often lost by accident: a medium starts open, acquires access controls for good reasons, and acquires so many that reading it requires knowing whom to ask. At that point the system no longer has a shared medium; it has a coordinator wearing a database costume. The security-engineering form of the same requirement is old and well established — a system’s design should not depend on its own obscurity [Kerckhoffs, 1883, Saltzer and Schroeder, 1975].

W — Writable. Any participant who observes something can record it, and the recording takes effect without adjudication. *Inspection test:* count the steps between a participant noticing something and the medium showing it. **Two steps or fewer passes; four or more fails.** Count review as a step only if it is blocking. Writability is where most organisational media die: read-only dashboards are extremely common and are not stigmergic media at all but broadcast, and broadcast has `eta` near zero for the receivers, because nothing a receiver learns can be deposited back. The subtlety is that writability does not mean unmoderated — it means the default is write-through and the correction is after the fact. An append-only log with revert is writable; a submission queue with a two-week approval cycle is not.

D — Durable. The state survives the departure of any individual, and survives the interval between uses. *Inspection test:* the **bus-count** — for each critical piece of state, count how many people would have to leave simultaneously for it to become unrecoverable. **A bus-count of 1 for any critical item is a failure.** Then the **fortnight test**: is state recorded two weeks ago still intelligible today to someone who was not present when it was written? Durability is the direct `delta` control, and it is the parameter a coordinator-centred system gets catastrophically wrong, because a person’s memory has a `delta` that looks small in the short run and equals 1.0 on the day they resign.

L — Low friction. The cost of one read and one write is small relative to the value of the increment. *Inspection test:* measure the seconds to complete one typical write end to end, including authentication, navigation and any required fields. **Under thirty seconds passes; over two minutes fails and will be routed around.** Then count required fields: every mandatory field is a tax on every write, forever. Friction is not a minor usability concern but the term that decides whether the medium is used at all, and an unused medium has `eta = 0` however well designed. The characteristic failure is the elaborate system that captures everything perfectly and is filled in by nobody, sitting beside a group chat that captures nothing and holds the real state.

A — Append-oriented. New information is added; old information is superseded rather than erased; the history is retrievable. *Inspection test:* can the state as of a named date last quarter be reconstructed? **If not, the medium is not append-oriented**, and every dispute about what was decided will be resolved by whoever speaks most confidently. Append-orientation is what makes the medium adjudicative. It is also what makes deliberate forgetting possible *as a decision* rather than as an accident: a rule can be retired explicitly, and the retirement is itself a record. Section 6.7 depends on this.

14.4.5 4.5 Ostrom's eight design principles, in full

Ostrom [1990] is the most directly engineerable document in the sociology of shared resources. Its method matters as much as its result: rather than theorising about whether commons must fail, Ostrom and her collaborators assembled and compared a large body of field cases of common-pool resources — Swiss alpine pastures, Japanese village forests, Spanish irrigation systems, Philippine irrigation federations, inshore fisheries, groundwater basins — and asked what distinguished the arrangements that persisted for centuries from those that collapsed. The polycentric extension [Ostrom, 2010] generalises the nesting result to overlapping jurisdictions.

A **common-pool resource** in this sense has two features: it is *subtractable* (what one person takes, another cannot) and it is *hard to exclude people from*. Grazing land, fish stocks, groundwater, a shared workshop, a shared codebase, a shared meeting-hour budget, the attention of a small team.

The eight principles are given below in full, referred to as **O1–O8**. **Ostrom did not claim these are sufficient and did not claim they are a recipe.** She characterised them as features found in the enduring cases and absent or weak in the failed ones. That is the claim this paper repeats and it is not a stronger one. The largest external audit of the principles [Cox et al., 2010] finds broad but uneven empirical support across ninety-one studies, and that qualification travels with every use of the list below.

O1 — Clearly defined boundaries. Individuals or households with rights to withdraw resource units must be clearly defined, as must the boundaries of the resource itself. *Why it matters:* if one cannot say who is in and what the resource is, one cannot say what over-use looks like, and every participant's estimate of every other's restraint is a guess. *Parameter:* `N` and `C`. Undefined boundaries make the effective category count unknowable and generate continuous boundary-dispute cost.

O2 — Congruence between appropriation and provision rules and local conditions. *Why it matters:* two congruences are required and are usually confused. The rules must fit the physical conditions — a rule written for a wet valley will destroy a dry one — and what may be *taken* must be proportionate to what is *put in*. A system in which extraction rights are detached from contribution obligations has instructed its members to free-ride. *Parameter:* `C` and `eta`.

O3 — Collective-choice arrangements. Most individuals affected by the operational rules can participate in modifying them. *Why it matters:* this is the principle most often violated by well-intentioned outsiders who write good rules for people who had no hand in them. Rules written by the users are better fitted, because the users hold the local knowledge, and better complied with, because compliance with a rule one helped write is not obedience. *Parameter:* `u` and `eta`. Participation in rule-making is exactly the mechanism that puts multiple distinct viewpoints into the rule, and a rule one helped write has already converted into one's own practice.

O4 — Monitoring. Monitors who actively audit resource conditions and appropriator behaviour are accountable to the appropriators or are the appropriators themselves. *Why it matters:* this is Ostrom's sharpest empirical finding and the one that overturns the standard framing. The enduring commons are not populated by unusually virtuous people but by ordinary people who **can see what everyone else is doing.** In the durable cases monitoring is mutual, cheap, and largely a by-product of the work itself — the irrigator who opens the gate

can see the level in the channel and can see who opened it last. *Parameter:* `C`, via the free-riding loss term. Section 4.8 computes the trade.

O5 — Graduated sanctions. Appropriators who violate operational rules are assessed graduated sanctions depending on the seriousness and context of the offence. *Why it matters:* graduation is the load-bearing word. A system with one severe sanction has in practice no sanction: the penalty is so disproportionate to a first small lapse that nobody applies it, everybody knows nobody applies it, and the rule becomes advisory. A first offence drawing a word, a second a small fine, a third exclusion, is a system in which the first step is actually taken. **Graduated sanctions are cheap precisely because they are mild, and effective precisely because they are used.** *Parameter:* `C`.

O6 — Conflict-resolution mechanisms. Appropriators and their officials have rapid access to low-cost local arenas. *Why it matters:* every rule is ambiguous at some boundary and every commons generates disputes; the question is never whether disputes occur but how expensive they are. *Rapid*, *low-cost* and *local* are all three doing work: a mechanism that takes six months, costs a lawyer, or requires travelling to a capital will not be used, and unresolved disputes compound. *Parameter:* `C`, and it is the term most likely to be omitted from a cost tally because it is nobody's line item.

O7 — Minimal recognition of rights to organise. The rights of appropriators to devise their own institutions are not challenged by external governmental authorities. *Why it matters:* self-governance that can be overridden at any moment is a delegation that will be revoked at the first inconvenience. The requirement is *minimal* recognition: Ostrom's cases did not need the external authority to endorse or fund the local institution, only to refrain from voiding it. *Parameter:* `eta`. If local decisions can be nullified from outside, interaction does not convert into durable structure. This is `eta` collapse by decree and is the most common way a head office destroys a functioning local commons while believing it is helping.

O8 — Nested enterprises. For common-pool resources that are parts of larger systems, appropriation, provision, monitoring, enforcement, conflict resolution and governance are organised in multiple layers of nested enterprises. *Why it matters:* it is the answer to scale. A single governance body for ten thousand people cannot monitor, cannot resolve disputes locally and cannot fit rules to local conditions. *Parameter:* `C`, decisively, and it is computable — which is the subject of the next subsection.

14.4.6 4.6 Nesting priced: the quadratic term against the logarithmic ceiling

The communication-path count `n(n−1)/2` grows quadratically in headcount [Brooks, 1975, Conway, 1968] while surplus grows as `ln N`. With a per-path cost of 0.02 and `eta = 0.5`, headroom at `Q = 0` is `h(n) = eta ln n − 0.02 n(n−1)/2`:

n	paths	C	eta ln N	h
4	6	0.120	0.6931	+0.5731
5	10	0.200	0.8047	**+0.6047**
6	15	0.300	0.8959	+0.5959
8	28	0.560	1.0397	+0.4797
10	45	0.900	1.1513	+0.2513
11	55	1.100	1.1989	+0.0989
12	66	1.320	1.2425	**-0.0775**
16	120	2.400	1.3863	-1.0137
24	276	5.520	1.5890	-3.9310

Headroom peaks at `n = 5` and goes negative between 11 and 12. A single flat body of 24 has `h = −3.93`: it cannot build anything, ever, at any interaction geometry.

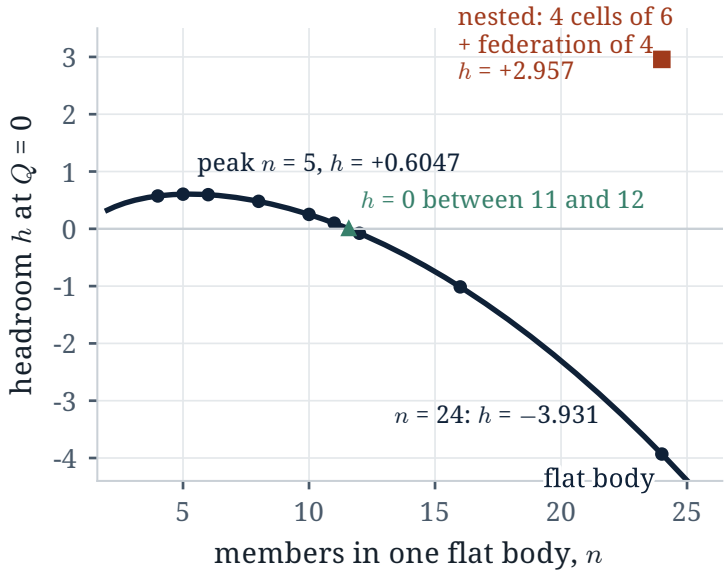

Figure 14.1: **Headroom has a single interior maximum in flat-body size and one zero crossing**: at a per-path cost of 0.02 and `eta` = 0.5, `h` peaks at `n` = 5 with +0.6047 and crosses zero between `n` = 11 and `n` = 12, so a flat body of 24 sits at −3.931 while four cells of six plus a four-delegate federation reaches +2.957. Modelled from the two stipulated parameters of Section 4.6; generated by `figs/src/CCP-014_fig01.py`.

Now nest it. Four cells of six, each at `h = +0.5959`, plus a federation layer of four delegates at `h = +0.5731`. *Modelling assumption, badged:* the law is stated per system, and summing headroom across cells assumes the cells are genuinely independent in their cost structure — if they are not, the sum overstates. Under that assumption the nested form reaches `4 x 0.5959 + 0.5731 = 2.957` against the flat form's `-3.931`. This is result **R3**.

O8 is not an administrative preference. It is the difference between a positive and a negative headroom budget, and the arithmetic is elementary. Note what the figure does *not* show: the crossing point is a function of the per-path cost, which is a stipulated parameter here and a measurable one in any installation. A body with a per-path cost of 0.005 crosses at `n = 34`, and a body at 0.05 crosses at `n = 6`. The shape is the result; the numbers belong to the parameters.

14.4.7 4.7 The install order, and a correction to naive practice

The eight principles are a set, not a sequence, and the temptation on reading them is to start with the one that feels most like community: build trust, and the rest will follow. **That is the wrong order, and in a system that is already losing it is actively harmful.**

The mechanism is the steady-state theorem and nothing more: `Q_inf = (eta F(u*) - c*)/delta` [Curzi, 2026a]. Trust acts on `delta` — a group that relies on unverified commitments loses less order between periods, and the mechanism by which it does so is retention: trust enters the storage law as a modification of the decay term, `delta_eff = delta_0 + (1-a)(1-v)`, giving a superlinear stock dividend as the trust parameter rises [Curzi, 2026s]. **But when the numerator is negative, dividing by a smaller positive denominator makes the result more negative.** Separating the moves in a worked consortium and computing them:

move	`Q_inf`
baseline	-0.0836
trust alone (`delta` 0.4300 -> 0.1700)	**-0.2114 — worse**
reciprocity alone (`eta` 0.1721 -> 0.4026)	+0.7394

move	`Q_inf`
both	+1.8701

Trust does not add order. It amplifies whichever sign the system already has. Halving `delta` on a negative numerator multiplied the loss by the same factor it would have multiplied a gain. This is the first half of counter-result **CR**, and it is stated as a result rather than a caveat because it reverses a widely recommended sequence.

The design rule that follows is exact: **fix the numerator first — raise `eta` through reciprocity, or cut `C` — until `eta F(u*) > c*`, and only then invest in trust.** Read against Ostrom's list, this puts O4 and O5 ahead of anything working by extended credit, because Section 4.8 shows both acting on the numerator; and it puts O8 ahead too, because Section 4.6 shows it changing the exponent on `C`. The failure signature to watch for is specific: **a trust programme in a body that converts nothing durable produces a slower, more polite decline, and survey results saying the intervention worked.** Self-report about the causes of one's own performance is exactly the measurement known to be unreliable [Nisbett and Wilson, 1977], which is why the signature is not self-correcting. The reciprocity literature supplies the mechanism the numerator-first rule actually needs — repeated interaction with reputation, rather than generalised goodwill [Axelrod, 1984, Nowak and Sigmund, 2005].

14.4.8 4.8 The two named failure modes of the commons, and the structural answers

The centreless case has two classical objections. Both are real, both have answers in the eight principles, and the answers are structural rather than moral.

The tragedy of the commons. The argument in its standard form [Hardin, 1968]: a shared pasture, herders each adding animals; the benefit of an extra animal accrues entirely to its owner while the cost of the extra grazing is spread across all herders; each herder therefore faces a private incentive to add animals until the pasture is destroyed. The arithmetic is correct for the situation described. **What the argument actually models is not a commons but an unmanaged open-access resource** — no boundaries, no rules, no monitoring, no sanctions, no communication. Ostrom's field cases are what happens when those things exist, and her central empirical point is that they very frequently do [Ostrom, 1990].

Mechanism of tragedy	Principle that addresses it
Anyone may take, so no restraint is credible	**O1** boundaries: define who may withdraw and from what
No limit on how much may be taken	**O2** congruence: appropriation limited and tied to provision
Restraint is invisible, so it is unrewarded	**O4** monitoring: restraint becomes observable
Over-use carries no consequence	**O5** graduated sanctions
Rules imposed from outside do not fit the pasture	**O3** collective choice, **O7** right to organise
Disputes over the boundary destroy the arrangement	**O6** low-cost local arenas
The pasture is bigger than any one village	**O8** nesting

The point to carry: **the tragedy is a property of a missing institution, not of human nature.** Where the eight features are present the tragedy is not observed; where they are absent it is. That is a claim about the world, from field data, and the meta-analytic audit of it is Cox et al. [2010].

Free riding. The narrower and more common problem: the resource is not destroyed, but a fraction of participants consume the shared order without contributing to it. Nothing collapses; everything costs more, degrades faster, and quietly demoralises the contributors. In the storage law free riding is unambiguously a `C` term — every unit of order consumed without replacement is a dissipation. Model it as `C = C_base + lambda phi`, with `phi` the free-riding fraction and `lambda` the loss per unit of it. Taking the tool library of Section 7.1, with `eta = 0.55`, `delta = 0.12`, `N = 8`, `u = 0.62`, `S = 1.6752`, `C_base = 0.40` and `lambda = 0.9`:

Without monitoring, at `phi = 0.35`:

```
C     = 0.40 + 0.9(0.35) = 0.7150
h(Q=0)= 0.55(2.0794) − 0.7150 = +0.4287
Q_inf = (0.55 x 1.6752 − 0.7150) / 0.12 = 1.7198
```

With O4 and O5 — mutual monitoring at a cost of 0.08, graduated sanctions bringing `phi` down to 0.06:

```
C     = 0.40 + 0.08 + 0.9(0.06) = 0.5340
h(Q=0)= 0.55(2.0794) − 0.5340 = +0.6097
Q_inf = (0.9214 − 0.5340) / 0.12 = 3.2281
```

Monitoring costs 0.08 and returns 0.261 in reduced free-riding loss. **Steady-state stored order nearly doubles — 1.72 to 3.23 — for a monitoring cost of eight hundredths of a unit.** That is an 87.7 per cent *increase* in the steady state and a 68.3 per cent recovery of what free riding had taken; the two figures are different quantities and Section 7.5 records that the source material conflates them. This is why O4 is the one to install first if only one can be installed: it has the best ratio in the list, and it is the one people are most squeamish about because it sounds like surveillance.

It is not surveillance when it satisfies Ostrom's actual condition: **the monitors are accountable to the appropriators, or are the appropriators.** Mutual visibility among peers who share the resource is a different object from observation by an authority that does not. The first raises `eta`; the second raises `C` and lowers `u`, because people watched by an authority converge on the behaviour the authority rewards.

14.4.9 4.9 Where central enforcement is absent, and where formal rules are not enough

Two field observations complete the picture and both are uncomfortable in ways that make them useful.

Private protection. Gambetta's study of Sicily asked what fills the gap when central enforcement of contracts is unreliable, and answered that a market in private protection emerges: a networked structure of obligation, reputation and guarantee that does, in a fashion, produce order. Contracts are honoured, disputes are settled, coordination occurs. *The 1993 monograph has no key in this corpus's bibliography*; the collection Gambetta edited on the making and breaking of cooperative relations [Gambetta, 1988] is the citable neighbour and is cited for the general claim rather than for the Sicilian case.

The lesson is deliberately double-edged. **Order without a centre is not automatically good order.** The mechanism recommended here — put the state in the medium, let obligation and reputation do the enforcement — is the same mechanism, structurally, that produces outcomes nobody would design. The difference is not in the topology. It is entirely in whether the governance features of Section 4.5 are present, and specifically O3, O5 and O6. A centreless system that fails O3, O5 and O6 is not a commons; it is a protection racket with good uptime. Carry this as a standing check: **centrelessness is a topology, not a virtue.**

Formal rules against stored order. Putnam et al. [1993] examined the divergent performance of regional governments in Italy after identical institutional reforms were applied

across the country. The same formal institutions produced markedly different results, and the difference tracked dense horizontal associational life and the norms of reciprocity that go with it. In this framework's terms: **identical formal structure, different `Q`.** The reform supplied a constitution; it did not supply stored order, and stored order cannot be legislated into existence in one step because the storage law integrates — `Q_t = (1-delta)^t Q_0 +` the driven terms, so if `Q_0` is low the transient is low and the driven term needs time at a positive step to accumulate.

Honesty note. Putnam's causal direction has been disputed at length — whether civic association produces good government or good government produces civic association is not settled by the data presented — and this paper does not need it settled. What is used is the narrow and well-supported observation that **formal rules and stored social order are different quantities, and installing the first does not install the second.** A further qualification is owed and is not comfortable for the framework: Putnam's own later finding is that diversity in the short run reduces trust and civic participation [Putnam, 2007], which cuts directly against the corpus's founding preference for raising `u`; the rebuttal literature qualifies but does not dissolve it [Abascal and Baldassarri, 2015], and contact across difference is known to produce value only under conditions rather than automatically [Allport, 1954, Pettigrew and Tropp, 2006].

14.4.10 4.10 The topology argument, and what it does not establish

Albert et al. [2000] measured the robustness of scale-free networks and found an asymmetry: such networks tolerate random node failure well and fail catastrophically under targeted removal of high-degree hubs. Under design postulate M3 a coordinator is a hub — by construction the highest-degree node in the coordination graph. The consequence is not that coordinators are bad. It is that a coordinated system has a **specific and predictable fragility profile**: it handles random absences well and the targeted loss of the coordinator very badly, and no amount of diligence by the coordinator removes it. Diligence makes it worse, because the more effectively the coordinator holds the state, the more of it is lost when they go.

Two engineering consequences follow.

1. **Coordinator loss is an architectural risk, not a personnel risk.** The mitigation is not a better succession plan; it is moving state out of the person and into the medium, so that the hub carries traffic and not storage.
2. **Measure hub concentration directly.** For each critical class of state, record the number of people who could reconstruct it. The distribution of that number across all state is the system's real robustness curve, and a system with many items at bus-count 1 is fragile however good its documentation policy claims to be.

What this argument does not establish, stated plainly. No degree distribution has been measured for any coordination graph in this paper; the scale-free label is borrowed [Barabási and Albert, 1999] and not demonstrated, and the robustness of real engineered networks is known to come substantially from design rather than from a degree distribution [Doyle et al., 2005]. Two further results in the same literature are more directly useful than the hub asymmetry and are used here for what they actually say: coupled systems are more fragile than either component alone, so a nested design whose layers share a failure mode is not nested in the sense that matters [Buldyrev et al., 2010]; and an unaudited count of participants is worthless where one party can present as many [Douceur, 2002], which is the pseudo-diversity problem stated as a theorem and is the network-security twin of the redundancy audit that produces `N_eff`. The count of genuinely independent parties required to tolerate `f` faulty ones is likewise a hard external number [Lamport et al., 1982], and the closest empirical analogue of an effective count in the social sciences measures adoption against the number of *distinct connected components* among a person's contacts [Ugander et al., 2012].

14.4.11 4.11 The honest limits of centrelessness

Four things a shared medium does not do, each stated because the literature on decentralisation routinely omits them.

It does not remove governance; it relocates it. The repository has maintainers and a merge policy. The encyclopedia has arbitration and protected pages. Every enduring commons in Ostrom's sample had rules, monitors and sanctions. A medium without governance is an unmanaged open-access resource, which is the case the tragedy argument correctly describes.

It does not remove cost; it changes its shape. Coordinator cost is concentrated, visible and budgeted. Medium cost is distributed, invisible and unbudgeted — everyone spending some minutes maintaining shared state. Distributed invisible cost is exactly the kind that goes unmeasured and therefore unfunded, which is the infrastructure problem of Section 6.8 [Star and Ruhleder, 1996] arriving early.

It is slower for genuinely novel decisions. Stigmergy excels at incremental work against an existing structure and is poor at the standing start — a decision with no precedent, no existing state to modify, and a deadline. For that class of decision a temporary centre is often correct, and the design question is whether it dissolves afterwards.

It requires a medium that can represent the work. Some work does not deposit a legible trace: a difficult conversation, a judgement call, an intuition about a person. Where the trace cannot be made, the mechanism does not apply, and pretending otherwise produces a medium full of ritual entries that nobody reads. **If the trace cannot be honestly deposited, the medium should not be built for that class of work.**

14.4.12 4.12 Specifications

S4.1 — Medium requirements (VWDLA). A shared medium **shall** satisfy all five properties, each scored 0–4 by the inspection tests of Section 4.4. A score of at least 3 on all five passes; any single score of 0 or 1 is a blocking defect.

#	Property	Requirement	Test	Pass
1	**V**isible	Current state readable by any participant without asking a person	Three-participant sixty-second test	median <= 60 s, 0 asks
2	**W**ritable	<= 2 non-blocking steps from observation to recorded state	Step count	<= 2
3	**D**urable	No critical state at bus-count 1; entries intelligible after 14 days	Bus-count census; fortnight test	0 items at bus-count 1
4	**L**ow friction	One typical write completes end to end in under 30 s	Stopwatch, 5 samples, median	median < 30 s
5	**A**ppend-oriented	State as of any past date reconstructible	Reconstruct a named date last quarter	success

S4.2 — The medium shall display its own unfinished edges. There **shall** exist a standing, visible representation of what is incomplete: open items, failing checks, known gaps, unanswered questions. **A medium that shows only finished states supplies no stimulus and is not stigmergic.** Requirement: the incomplete-edge view is reachable in one step from the medium's default view.

S4.3 — Ostrom conformance checklist. Score each principle 0 (absent) / 1 (partial) / 2 (present). This is the governance audit and it is mandatory before any centreless design is declared complete.

#	Principle	Evidence required	Score
O1	Clearly defined boundaries	A written list of who may withdraw, and a written definition of the resource	/2
O2	Congruence: rules to conditions, appropriation to provision	Rules reference actual local conditions; take is tied to contribution	/2
O3	Collective-choice arrangements	A named, used procedure by which affected users change operational rules	/2
O4	Monitoring	Monitors are the appropriators or accountable to them; monitoring is routine, not exceptional	/2
O5	Graduated sanctions	At least three distinct severity levels, with the mildest actually used in the last year	/2
O6	Conflict-resolution mechanisms	A local arena, resolution time measured in days, no external cost	/2
O7	Right to organise recognised	No external authority has voided a local rule in the review period	/2
O8	Nested enterprises (if part of a larger system)	Each layer's remit written; cell size within the headroom-positive band	/2

Total /16. Below 10, the arrangement is not a governed commons and the tragedy argument applies to it as written.

S4.4 — Cell sizing. Working cells **shall** be sized within the headroom-positive band computed for the system's own `eta` and per-path cost. For the reference parameters of Section 4.6 the band is `n <= 11` with peak at `n = 5`. **Each installation shall recompute the band with its own measured per-path cost rather than adopting these figures.**

S4.5 — Focal-point inventory. Before building any medium, the designer **shall** produce a written inventory of at least five focal points already available to participants (Section 4.3)

and **shall** adopt them as defaults. Every adopted focal point is a `C` reduction obtained at zero build cost.

S4.6 — Hub census. The designer **shall** record, for every class of critical state, the number of people who could reconstruct it from what exists outside their own memory. **Any class with a count of 1 is a blocking defect** and must be remedied by depositing that state in the medium before the design is signed off.

S4.7 — Deposit rule. Every participant-facing procedure **shall** specify, in one sentence, what it deposits in the medium. **A procedure that deposits nothing has `eta = 0` and shall be marked as such in the survey.** This applies to meetings, reviews, inspections, and conversations held for the purpose of alignment.

S4.8 — Declination gate. No mechanism in this section may be implemented in a form that removes a participant's ability to decline. Monitoring under O4 **shall** be mutual and peer-accountable, not unilateral; participation under O3 **shall** be an available right and not a compulsory duty; and withdrawal from the commons **shall** remain possible on stated terms. **A monitoring regime whose subjects cannot opt out of the commons is not Ostrom's Principle 4; it is surveillance, and it is outside the scope of this framework.**

14.4.13 4.13 Failure modes

FM-4.1 — The phantom centre. *Description.* The organisation has declared itself decentralised, removed the coordinator's title, and kept the coordination. State still lives in one person's head; they simply no longer have the authority or the budget that used to come with holding it. *Damages.* `C` unbudgeted, `delta` unchanged and high, `eta` falling because the person now has no mandate to convert. *Diagnostic signature.* The hub census returns a bus-count of 1 for most critical state despite an org chart with no centre. People still ask the same one person; their calendar is the busiest in the group. *Fix.* Either re-establish the centre honestly and budget it, or execute S4.6 properly: enumerate what that person holds and deposit each item in the medium, one at a time, until the census passes. There is no third option.

FM-4.2 — Broadcast mistaken for medium. *Description.* A read-only dashboard, status report or weekly digest is presented as the shared state. Participants can see it; they cannot write to it. *Damages.* `eta` near zero for all receivers; `u` falls, because observations that cannot be deposited are eventually not made. *Diagnostic signature.* Fails S4.1 test 2 outright. The tell is that corrections are sent to a person by message rather than made to the artefact. *Fix.* Make the artefact writable with after-the-fact review. If it genuinely cannot be made writable, stop calling it the shared state, identify what the actual shared state is — usually a chat thread — and apply VWDLA to that instead.

FM-4.3 — Ritual deposit. *Description.* Everyone writes to the medium because it is required. Nobody reads it. The entries are formally complete and informationally empty. *Damages.* `C` as pure dissipation — everyone pays the write cost, nobody collects the read benefit — and `eta` zero despite apparent activity. *Diagnostic signature.* High write volume, near-zero read volume. Ask three participants what changed in the medium last week; if none can answer, the deposits are ritual. Entries uniform in length and phrasing are the fingerprint of a required field being satisfied rather than a state being recorded. *Fix.* Delete required fields until writes become informative. Then make one visible consumer of the medium — a decision, a schedule, a rota — depend on it, so that a wrong deposit produces a visible wrong outcome. **A medium nothing depends on will be filled in wrongly forever and nobody will ever find out.**

FM-4.4 — Free-ride drift. *Description.* Contribution slowly concentrates in a shrinking fraction of participants. Nothing breaks. The contributors become quietly bitter and then leave, at which point something breaks all at once. *Damages.* `C` rises with `phi`, then `Q` takes a step loss when contributors depart. *Diagnostic signature.* Plot contribution share by participant over time and watch for the top-quartile share rising quarter on quarter. **This is measurable before it is felt**, which is the entire reason to measure it. *Fix.* O4 and O5 together: make contribution visible — not ranked, not gamified, merely visible — and install a gradu-

ated response that begins with a private word. Section 4.8 shows monitoring paying for itself many times over. Do not begin with the severe sanction; a severe sanction alone is FM-4.5.

FM-4.5 — Terminal sanction only. *Description.* The only available response to rule-breaking is expulsion or an equivalent. It is therefore never used, the rules become advisory, and everybody knows it. *Damages.* `C` rises because enforcement is impossible so violations accumulate; `Q` falls because rules that are not enforced are not stored order but stored text. *Diagnostic signature.* Ask when the sanction was last applied. If the answer is never, or once years ago and it was very ugly, this is the fault. Count the severity levels: one level is the fault. *Fix.* Build at least three graduated levels and use the mildest deliberately within the first month, so that its use becomes ordinary rather than an event.

FM-4.6 — Medium capture. *Description.* Access controls, mandatory fields, approval workflows and schema requirements accumulate on the medium — each individually justified — until reading requires permission and writing requires an intermediary. The medium has become a coordinator with a database interface. *Damages.* `C` rises, `eta` falls, `u` falls because the schema now dictates what can be said. *Diagnostic signature.* Compare today's V and L scores against the scores at installation. **Medium capture is only visible as a trend, which is why S4.1 must be re-run annually and the scores retained.** A second tell: a shadow medium has appeared — a chat channel or a spreadsheet where the real state now lives. *Fix.* A schema and permission budget: fix the maximum number of required fields and access tiers at installation, and require that adding one removes one. The shadow medium is not the problem, it is the diagnosis — whatever people fled to is telling you which property you lost.

FM-4.7 — Centreless and ungoverned. *Description.* The medium exists, VWDLA passes, and the Ostrom score is 4/16. Boundaries are vague, nobody monitors, there are no sanctions, and disputes go to whoever shouts. *Damages.* All of them, eventually, via free riding and boundary erosion. *Diagnostic signature.* S4.3 total below 10 with a good S4.1 score. This combination is common in new, enthusiastic, technically competent groups, and it is the standard prelude to the collapse later described as needing more structure all along. *Fix.* Install O1, O4, O5 and O6 first — boundaries, monitoring, graduated sanctions, and a cheap local arena. These four cover the bulk of the failure surface; O2, O3 and O8 can follow.

FM-4.8 — Nesting refused. *Description.* The body grows past the headroom-positive band and refuses to split, usually for reasons of unity, culture or fear of fragmentation. *Damages.* `C` quadratic, `h` negative, `u` falling because large bodies suppress dissent by fatigue long before they suppress it by policy. *Diagnostic signature.* Compute `n(n−1)/2 x` per-path cost against `eta ln N`. If `C` exceeds `eta ln N − delta Q`, the sustainability ceiling applies and **no arrangement of the people prevents decline** [Curzi, 2026a]. Observable proxies: meeting length rising with no rise in decisions; a growing tier of people who attend but do not speak; decisions made before the meeting and ratified in it. *Fix.* O8. Split into cells within the band, write each cell's remit, and give the federation layer only what cells genuinely cannot do. Expect the split to be resisted on grounds of culture; the arithmetic does not care about culture.

FM-4.9 — Evaporation refused. *Description.* Nothing in the medium ever expires. The trail to the exhausted food source is maintained in perpetuity, and new participants cannot tell live state from archaeology. *Damages.* `C` rises via search cost, `eta` falls as the medium's signal-to-noise degrades, and eventually `h` falls via the maintenance term of Section 6. *Diagnostic signature.* Ask a participant of under six months' standing to identify the current state of three items and count errors caused by stale entries. **More than one error in three is the fault.** *Fix.* Deliberate `delta` — the pheromone must evaporate. Expiry dates on entries, an archive tier that is retrievable but out of the default view, and a standing review that retires rather than accumulates. This is the shedding operation of Section 6.7 applied at the level of the medium.

14.5 5 Individuality as load-bearing structure

Every familiar argument for preserving individuality in a group is a moral argument, and moral arguments lose to schedule pressure. The manager who wants the meeting over, the committee that wants a clean recommendation, the department that wants alignment — none of them is a villain, and none of them is moved by an appeal to the dignity of the dissenter. What can move them is a demonstration that **the thing they are trying to produce cannot be produced by the method they are using.** That demonstration exists, and it arrives from four independent directions, in four separate literatures, using four unrelated formalisms.

14.5.1 5.1 The arithmetic of the merge

From the extremality result of the surplus functional [Curzi, 2026], `F = 0` if and only if the states are parallel and `F = ln N` if and only if they are orthogonal. Combined with the effective count `N_eff = 1 + (N−1)u`, the consequence is arithmetical and not negotiable. **When the members of a group become parallel, `u` goes to 0, `N_eff` goes to 1, and the surplus of their interaction is `ln 1 = 0` — exactly zero, regardless of how many of them there are, how able they are, or how hard they work.** Nine people who have converged are not nine people. They are one person, counted nine times, at nine times the cost.

This is a theorem about a mathematical object and makes no empirical claim. The empirical content of this section comes from elsewhere; the surplus law's contribution is that it prices the same phenomenon in the same units as everything else in the framework. Here is the price list for a nine-person panel, `N = 9`, `ln N = 2.1972`:

u	N_eff	S = ln N_eff	Fraction of ceiling
0.00	1.00	0.0000	0%
0.10	1.80	0.5878	27%
0.12	1.96	0.6729	31%
0.25	3.00	1.0986	50%
0.50	5.00	1.6094	73%
0.69	6.52	1.8749	85%
0.75	7.00	1.9459	89%
1.00	9.00	2.1972	100%

Two features are worth dwelling on. **First, the collapse at the left end is total, not merely severe.** At `u = 0` the surplus is not small; it is zero, because `ln 1 = 0` exactly. **Second, the recovery is front-loaded.** Going from `u = 0` to `u = 0.25` — a quarter of the way to orthogonality — buys half the available surplus. That is strict concavity arriving as a design fact: the first increment of genuine difference is worth more than all subsequent increments combined, which means the first honest dissenter in a converged room is the single highest-value intervention available in that room.

The same concavity governs headcount. At `u = 0.62`, the marginal surplus of the `N`-th genuinely distinct member:

N	2	3	4	5	6	8	10
S	0.4824	0.8065	1.0508	1.2470	1.4110	1.6752	1.8840
marginal	+0.4824	+0.3240	+0.2443	+0.1962	+0.1640	+0.1234	+0.0990

The second genuinely different person is worth roughly five times the tenth — 0.4824 against 0.0990. Concavity is merciful, in that it means a cast of thousands is not required, and unforgiving in the other direction, because it also means that adding people who are *not* different adds nothing at all while adding coordination cost quadratically (Section 4.6). The

marginal entries are single-step differences and are stated as such; the table's columns skip `N = 7` and `N = 9`, whose surpluses are 1.5518 and 1.7850.

A construct warning that the framework owes and rarely pays. Three incompatible constructs travel under the word diversity — separation, variety, and disparity — and they have different antecedents and different effects [Harrison and Klein, 2007]. **`u` is a variety construct**: it measures non-parallelism of epistemic states and nothing else. It is not separation on an attitudinal continuum and it is not disparity in a valued resource. The empirical literature reporting that surface-level diversity often hurts in the short run [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007] is measuring constructs `u` does not name, which is a defence of `u` only if `u` is actually measured rather than inferred from demography — and Section 5.9 excludes the inference by rule.

14.5.2 5.2 Independence is the load-bearing clause

Condorcet's jury theorem, published in 1785, has a setup worth restating exactly: a binary question with a correct answer; `n` voters, `n` odd; each voter correct with probability `p`, **independently of the others**; the group decides by simple majority. The theorem: if `p > 1/2`, the probability that the majority is correct exceeds `p`, increases monotonically in `n`, and tends to 1 as `n` tends to infinity. The probability that the majority of `n` is correct is

```
P(n, p) = sum over k from (n+1)/2 to n of  C(n,k) p^k (1−p)^(n−k)
```

No citation key exists in this corpus's bibliography for Condorcet's original, and the gap is recorded in Section 10; the aggregation tradition it founded is represented here by Galton [1907] and Surowiecki [2004].

`n`	`p = 0.55`	`p = 0.60`	`p = 0.70`
1	0.5500	0.6000	0.7000
3	0.5748	0.6480	0.7840
5	0.5931	0.6826	0.8369
9	0.6214	0.7334	0.9012
15	0.6535	0.7869	0.9500
25	0.6937	0.8462	0.9825
51	0.7641	0.9265	0.9986
99	0.8413	0.9781	1.0000

Ninety-nine people each barely better than a coin reach 84 per cent as a body. This is the most encouraging table in the sociology of groups and it is why democratic aggregation is a technique and not only a value.

Now the clause that is routinely quoted past: *independently of the others.* Every number in that table is conditional on it. And the theorem has a second half that is almost never taught: **if `p < 1/2` the same monotonicity runs the other way**, and the majority is worse than the individual and gets worse with `n`.

`n`	1	3	9	25	99
`P` at `p = 0.45`	0.4500	0.4253	0.3786	0.3063	0.1587

Ninety-nine people each 45 per cent accurate produce a body that is **16 per cent accurate.** Aggregation is an amplifier: it amplifies whatever sign the individual competence has. And at exactly `p = 0.5`, `P(n, 0.5) = 0.5` for every `n` — no amount of aggregation extracts signal from noise.

What correlation does

Independence is an idealisation. Real voters share training, share sources, share incentives, and talk to each other. Model this with the simplest possible correlation structure, **badged as a modelling choice and not as a result**:

> *Model C1 (shared-signal mixture).* With probability `rho`, all voters observe and follow a single common signal, itself correct with probability `p`. With probability `1 − rho` they vote independently at accuracy `p`. Then `P(n, p, rho) = rho p + (1 − rho) P_independent(n, p)`.

This is crude — a two-point mixture, not a general correlation model — but it is transparent and it is sufficient. With `n = 9` and `p = 0.60`, so that `P_independent = 0.7334`:

`rho`	0.0	0.2	0.4	0.6	0.8	1.0
`P`	0.7334	0.7067	0.6801	0.6534	0.6267	0.6000

At `rho = 1` the nine-person panel performs exactly as well as one person, because it *is* one person. That is the extremality result again, in probability rather than geometry: **`rho -> 1` is `u -> 0` is `N_eff -> 1` is `S -> 0`.** And scale does not rescue it: ninety-nine voters at `p = 0.60` with `rho = 0.30` give 0.8646 against 0.9781 under independence. **Correlation is not a discount on the benefit of scale; it is a ceiling on it.** The measured version of the same effect is that social influence demonstrably narrows the range of estimates in a crowd while leaving confidence intact, so the group becomes both less accurate and more sure [Lorenz et al., 2011].

Honesty note on the bridge. `rho` and `u` are measures of the same underlying thing — non-redundancy — in different formalisms, and no general identity between them is claimed. Converting one into the other requires a specific state encoder [Curzi, 2026i] and the conversion should be stated whenever it is made. What is claimed is the direction: **as correlation rises, effective count falls, by both accountings.**

14.5.3 5.3 Diversity against ability, and the critique of that result

Hong and Page [2004] model problem solvers searching a solution landscape using *heuristics* — internal representations plus rules for where to look next. A solver gets stuck at a point that is a local optimum *for that solver's heuristic*; a group works by passing the current best solution around until no member can improve it. Their result, informally: under stated conditions, a group of randomly selected problem solvers drawn from a large pool of able solvers outperforms a group formed by taking the individually highest-performing solvers.

The mechanism is entirely legible in this framework's terms. **A solver's ability determines how good their local optimum is. A solver's difference determines whether they are stuck at the same place as everyone else.** A group of the individually best tends to share heuristics — that is frequently *why* they are the best on the measured task — and a group that shares heuristics shares local optima. When such a group gets stuck, everyone is stuck at the same point, and there is nobody whose different representation makes the next move visible.

The conditions matter and are stated rather than elided: the problem is difficult, so no solver alone finds the global optimum; the solvers are individually capable, so their local optima are not trivially bad; the pool is large; and the group is large enough that random selection produces genuine heuristic variety.

Honesty note, and it is a substantial one. The theorem has been the subject of mathematical criticism [Thompson, 2014] arguing that the formal result depends heavily on the specific construction of diversity and does not support the broad interpretation often placed on it. The subsequent exchange is genuinely two-sided [Kuehn, 2017, Singer, 2019, Grim et al., 2019], with Singer [2019] offering a repair that survives the objection and Grim et al. [2019]

mapping the boundary conditions by simulation. **This paper's position is narrow and, it believes, untouched by the critique:** the mechanism — that shared heuristics produce shared local optima, and that a group stuck in one place needs someone standing somewhere else — does not require the strong version of the theorem. It requires only that different representations get stuck in different places, which is nearly a definition. Where this paper uses the result, it uses the mechanism, and the formal claim is left to the primary literature and its critics.

14.5.4 5.4 Cascades: how copying destroys the information it appears to use

This is the most important result in the section, because it explains why `u` collapses in groups that nobody is pressuring, composed of people who are individually behaving well.

Bikhchandani et al. [1992] analysed sequential decision-making under observation: agents decide one at a time, each has a private signal about which of two options is correct, and each can observe the *actions* of everyone before them but not their signals. Banerjee [1992] reached the same structure independently. Their finding: after a very small number of decisions, agents rationally stop using their private signals. An **informational cascade** forms — everyone thereafter copies the visible pattern regardless of what they privately know — and **from that moment on, no further private information enters the public pool.** The chain looks informative and is not: it contains, permanently, the information of the first two or three agents and nothing more.

The arithmetic

Take the standard symmetric setup. The true state is HIGH, so ADOPT is correct; each agent receives a private signal correct with probability `p > 1/2`; agents act in sequence; ties are broken by a fair coin.

- **Agent 1** has only their own signal, so adopts with probability `p`.
- **Agent 2** observes agent 1's action and their own signal. If the signals agree they follow; if they disagree the posterior is exactly balanced and they flip a coin. So given agent 1 adopted, agent 2 adopts with probability `p + (1−p)/2 = (1+p)/2`.
- **Agent 3** observes two actions. If both were the same, a single private signal cannot overturn two, so agent 3 copies regardless of their own signal — **a cascade.** If the first two actions differed they cancel, and agent 3 is in agent 1's position: the process restarts.

The probabilities are

```
P(up cascade starting)   = p (1+p) / 2
P(down cascade starting) = (1−p)(2−p) / 2
P(restart)               = 1 − [p(1+p)/2 + (1−p)(2−p)/2] = p(1−p)
```

and these sum to 1 identically, which is the first check a reader can run. Since a cascade eventually forms with probability 1, the probability that the cascade that forms is the *correct* one is the ratio of the up-cascade probability to the total cascade probability:

```
P(correct cascade) = [ p(1+p)/2 ] / [ p^2 − p + 1 ]
```

p	0.55	0.60	0.62	0.70	0.80	0.90
P(correct cascade)	0.5664	0.6316	0.6570	0.7532	0.8571	0.9396

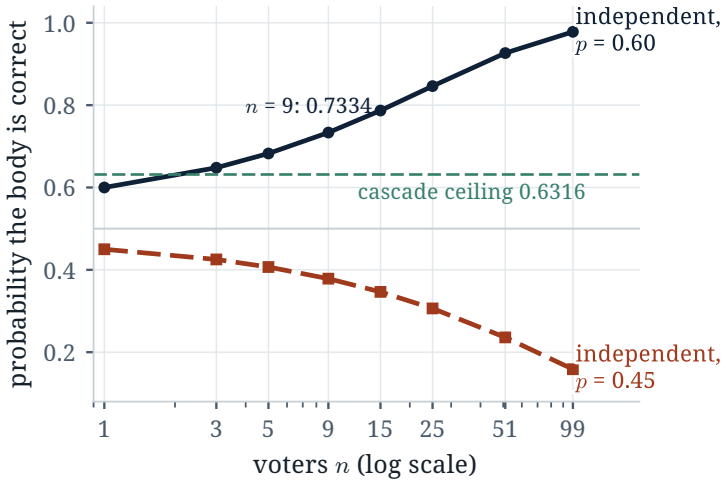

Figure 14.2: **Independence, not scale, is what aggregation runs on**: at `p` = 0.60 an unbounded informational cascade tops out at 0.6316 — below nine independent voters at 0.7334 and far below ninety-nine at 0.9781 — while at `p` = 0.45 the same majority rule drives accuracy down to 0.1587 at `n` = 99. Derived: exact binomial sums and the cascade formula of Section 5.4, both recomputable from the expressions printed there; generated by `figs/src/CCP-014_fig05.py`.

Verification. A Monte Carlo simulation of this process at `p = 0.60` over 400,000 trials returned 0.6323 against the analytic 0.6316 — within one standard error of the simulation (0.00076), which is what agreement looks like at that sample size. The simulation is reported as the source states it; no re-run was performed for this paper, and Section 10 records that.

The comparison, and the instruction it yields

At `p = 0.60`:

Arrangement	Accuracy
One person alone	0.6000
An unbounded cascade — a million observers	**0.6316**
9 independent voters, majority rule	0.7334
99 independent voters, majority rule	0.9781

An unbounded queue of rational, well-informed, honest people, each holding genuine private information, performs worse than nine of them who never looked at each other. The million observers contributed nothing. Their information exists; it simply never entered the pool, because each of them rationally deferred to a public record containing only the first two people's signals.

There is no villain in this story. Nobody is lazy, conformist or cowardly; every agent behaves optimally given what they can see. **The failure is structural: the observation of others' actions before the expression of one's own signal is sufficient to destroy the aggregation, all by itself.** The experimental demonstration that early visible choices lock in outcomes that were not determined by quality is Salganik et al. [2006], where parallel worlds seeded identically diverged and stayed diverged.

That is the design brief. If observation-before-expression destroys aggregation, then the fix is to **move expression before observation.** Everything in Section 5.7 is a variation on that single move.

14.5.5 5.5 The distribution of participation, not its peak

Woolley et al. [2010] had groups perform a battery of varied tasks and found that performance across the battery loaded onto a single statistical factor, `c`, analogous to the individual `g`. The findings that matter here, stated precisely: `c` was **not significantly predicted by average member intelligence, nor by the maximum**; `c` correlated with average social sensitivity of members, measured by a standard instrument whose construct validity has itself been examined [Engel et al., 2014]; `c` correlated with **equality in the distribution of conversational turn-taking**, groups in which a few members dominated having lower `c`; and `c` correlated with the proportion of women in the group, an effect largely mediated by social sensitivity [Bear and Woolley, 2011].

The turn-taking finding is the one this section builds on. Consider what unequal turn-taking *is* in the terms of Section 5.1. A group in which two people speak 80 per cent of the time is a group in which seven people's states are not entering the interaction at all. The nominal `N` is nine; the participating `N` is two. **Turn-taking inequality is `N_eff` suppression by airtime**, and it requires nobody to be silenced — the ordinary dynamics of a fast, unstructured conversation are sufficient.

Honest limits. Woolley's `c` was measured in short-task laboratory settings with ad hoc groups. Extrapolation to standing institutional bodies is a **modelling assumption** and is badged as such wherever it is used below. What transfers with confidence is the narrower claim: within the studied setting, the distribution of participation predicted performance and the peak of member ability did not. The general caution owed to any single psychological finding applies here too [Open Science Collaboration, 2015, Ioannidis, 2005].

14.5.6 5.6 Four results, one statement

Lay them side by side.

```
Condorcet    : aggregation works only if the inputs are independent
Hong & Page  : difference contributes what ability cannot
BHW 1992     : copying stops information from entering the pool
Woolley 2010 : equal participation predicts collective performance
```

Each is a statement about a different thing — probability, search, sequential inference, factor structure. Each was produced by people not working on the others' problems. And each reduces to the same instruction:

> **Keep the individuals individual, and keep them all in.**

The surplus law prices it. `S = ln(1 + (N−1)u)`. Merge the members and `u -> 0`, `N_eff -> 1`, `S -> 0`. Silence the members and the participating `N` falls, with the same effect. **Merge the individuals and the collective-intelligence factor falls, the cascade sets in, and the group becomes one mind with one blind spot** — a blind spot that is now nine times as confident as it was, because nine people agree.

The confidence is the cruellest part. A converged group does not experience itself as impoverished; it experiences itself as aligned, and alignment feels exactly like being right. There is no internal signal distinguishing a room that has converged on the truth from a room that has converged on the first speaker. **Only a protocol can distinguish them, and only if the protocol ran before the room started talking.**

14.5.7 5.7 The five independence protocols

Five, labelled IP-1 to IP-5. Each is specified with its mechanism, its cost, its expected effect, and — mandatorily — its decline path.

IP-1 · Independent estimate before discussion. *Mechanism.* Before any discussion of the item, every participant privately records their own judgement — an estimate, a rating, a recommendation, a probability — with a one-line reason. The records are sealed until all are in. Only then does discussion open, and the distribution of independent judgements is displayed *first*. *Why it works.* It is the direct structural answer to Section 5.4. The cascade requires observation before expression; this protocol inverts the order, so that every private signal enters the pool before any public signal exists to override it. **It is not a debiasing technique and does not depend on anyone being unbiased. It changes the order of operations.** *Cost.* Four to eight minutes per item; a `C` increment computed at 0.030 in Section 7.2. *Effect.* The distribution itself is the deliverable and is worth as much as the decision. A tight distribution before discussion is either genuine convergence or a symptom that convergence already happened elsewhere, and the two are distinguishable by asking whether the reasons given differ. **Identical conclusions with identical reasons is a `u = 0` reading. Identical conclusions with different reasons is the strongest evidence a committee can generate.** *Decline path.* A participant may record "no independent view" and the item proceeds. The record of a declined estimate is itself information: a member who declines on every item in their nominal area of expertise is reporting something about the panel that no survey will.

IP-2 · Anonymous-first elicitation. *Mechanism.* The first round of judgements is collected without attribution. Attribution is added in the second round, after the anonymous distribution is visible, and only for participants who choose to attach their names. *Why it works.* It removes rank from the first signal. In a group with any status gradient the junior member's private signal is systematically discounted by its own holder before it is spoken — a cascade driven by hierarchy rather than by sequence, with the same effect on the pool. *Cost.* A slip of paper and a box, or a form: effectively zero in money, three minutes in time; 0.010. *Effect.* The instrument to watch is the **anonymous-to-attributed drift**, the difference between the anonymous distribution and the attributed one. A large drift is a direct measurement of how much signal the group's status structure was suppressing, and it is one of the few `u`-suppression readings obtainable without a control group. *Decline path.* Participation in the anonymous round is optional and the option is stated aloud each time, not merely in the written procedure. Anonymity that participants do not believe in is worse than no anonymity, because it produces confident false readings. *Constraint.* Anonymity must be real. If the group is small enough that handwriting, phrasing or expertise identifies the author, the protocol is not anonymous and must not be described as such; say so and use IP-1 instead.

IP-3 · Dissent protection. *Mechanism.* A written, standing, published commitment that (a) a recorded dissent carries no consequence for standing, assignment or advancement; (b) dissents are entered in the record with the decision, not appended afterwards; and (c) the person who dissents is not the person then assigned to implement the majority position. *Why it works.* Under postulate I1, `u` decays. The largest driver of decay in an institutional body is not persuasion but anticipation of cost: a member who expects a recorded disagreement to be remembered at review time will not record it, and their private signal never enters the pool. **The protection is a retention intervention on `u`: it does not create difference, it stops the leak.** *Cost.* Near zero to write; substantial to honour, and the honouring is the whole protocol; 0.005. **A dissent protection that has never been tested is not known to exist.** *Effect.* The measurable quantity is the **dissent rate over time**. A body whose recorded dissent rate declines quarter on quarter is a body whose `u` is collapsing, and the decline is visible in the minutes long before it is visible in the decisions. *Decline path.* Nobody may be compelled to dissent, and nobody may be assigned the role of standing contrarian without explicit and revocable consent. Conscripted dissent is theatre; it produces a visible objection carrying no private signal, which is worse than silence because it looks like the protocol is working.

IP-4 · Minority report requirement. *Mechanism.* Any decision reached with less than unanimity must carry a written minority report: the strongest available statement of the rejected position, its evidence, and **the specific observation that would show the majority to be wrong.** The report travels with the decision permanently. Where a decision is genuinely unanimous, the requirement is met by an appointed **steelman** — a member tasked with writing the best case against, with that member's consent. *Why it works.* Three effects, of which the third is

the largest. (i) It preserves the minority's information in the durable record: dissent that is written down has `eta > 0`, dissent that is spoken and lost has `eta = 0`, so **a minority report is a conversion device applied to the most perishable and most valuable class of interaction in the system.** (ii) It makes the decision auditable later, when the world has supplied an answer. (iii) **It converts unanimity from an achievement into an obligation.** A committee that must produce a written minority report cannot use agreement as an exit, which removes most of the incentive gradient driving premature convergence, because the cheapest path is no longer for everyone to agree quickly. *Cost.* Twenty to forty minutes per non-unanimous decision: real, and the largest cost item in the list at 0.040. *Effect.* The falsification clause in (i) is the part usually dropped and the part that matters. A minority report saying "we disagree" is a mood; one saying "if the programme has not produced measurable X by month 18, the majority was wrong" is an instrument, and in eighteen months it will have paid for every minute it cost. This is the committee-scale form of the discipline that preregistration imposes on a study [Nosek et al., 2018, Platt, 1964]. *Decline path.* The steelman role is by consent and is rotated. If nobody consents, the record states that no steelman was appointed, which is itself the finding.

IP-5 · Turn-taking equalisation. *Mechanism.* Structural devices that flatten the airtime distribution without anyone policing it: round-robin on each item; the **last-speaks-first inversion**, in which the most senior person in the room speaks last; a hard first-round time box per speaker; and a table with no head. *Why it works.* It directly targets the turn-taking finding of Section 5.5 and simultaneously breaks rank-driven cascades: when the senior member speaks first, every subsequent contribution is a response to a public signal rather than an expression of a private one. *Cost.* Near zero; 0.005. **Furniture and speaking order are the cheapest governance instruments available, and they enforce continuously without anyone administering them.** *Effect.* Measure the Gini coefficient of speaking time, or more simply the share held by the top two speakers; the collective-intelligence finding predicts that flattening this distribution raises `c`. A physical precondition applies first: in a reverberant room the loudest voice wins by acoustics regardless of protocol, so the acoustic fix precedes the procedural one. *Decline path.* A participant in a round-robin may pass. Passing is recorded as passing, not as assent, and the distinction must be explicit in the record. **A protocol that reads silence as agreement has re-created the cascade inside the mechanism designed to prevent it.**

14.5.8 5.8 What the protocols cost and what they buy

Costs are in the normalised units of Section 7.2, per panel item.

Protocol	`C` per item	Primarily raises	Primarily protects
IP-1 independent estimate	0.030	`u`	against sequential cascade
IP-2 anonymous-first	0.010	`u`	against rank cascade
IP-3 dissent protection	0.005	`u` (lowers its decay)	against anticipatory self-censorship
IP-4 minority report	0.040	`eta`	against loss of the rejected case
IP-5 turn-taking	0.005	participating `N`	against airtime concentration
Total	**0.090**		

Nine hundredths of a unit. Section 7.2 shows this purchase moving `u` from 0.12 to 0.71 and taking a panel from a negative steady state to a positive one. **The protocols are cheap because they are procedural. They are effective because the failure they address is procedural.**

Note the split in the third column. IP-1, IP-2 and IP-3 raise `u` — they get more distinct signal into the room. IP-4 raises `eta` — it gets the signal that arrived into the durable record. **These are different parameters and neither substitutes for the other.** A panel with excellent elicitation and no minority report generates real difference every week and stores none of it. A panel with rigorous minority reports and no independent elicitation writes down, with great care, the objections of a group that has already converged.

14.5.9 5.9 The scope constraint, stated as engineering

The framework does not recommend any intervention that removes a person's ability to decline. It is worth being explicit about what this excludes, because the exclusions are not obvious and each has been proposed somewhere in good faith.

Excluded: compulsory disclosure of private judgement. IP-1 is powerful precisely because it captures what people actually think, and that power is exactly why it must not be mandatory. A required private estimate is not private, and a person who fears the record will write what is safe — which returns the body to the cascade with an extra step and a false sense of rigour.

Excluded: assigned permanent dissenters. Appointing someone the standing contrarian both conscripts them and defuses them: their objection is discounted by everyone, including themselves, as role-play. The steelman under IP-4 avoids this by being consensual, rotating, and about the argument rather than about the person.

Excluded: identity as instrument. Using a person's demographic or biographical characteristics as a proxy for their epistemic contribution is both an ethical failure and a measurement error: demographic difference without epistemic difference gives `u = 0` and buys nothing, which is precisely the separation-versus-variety confusion [Harrison and Klein, 2007]. **The quantity in the law is the non-parallelism of their states, and the only way to know it is to measure it.**

Excluded: mandatory participation. Every protocol above has a decline path, and it must be usable without explanation.

Included, and required: the right to be recorded as declining. This is the positive form of the same principle. A person who does not wish to give a view must be able to have that fact entered rather than being counted as assent. The alternative — silence read as agreement — is not a neutral default. It is a mechanism that manufactures unanimity out of absence, and a body that uses it will report high agreement and low `u`, which is the exact signature of the failure this section exists to prevent.

14.5.10 5.10 Specifications

S5.1 — Order of operations. Any deliberative body **shall** collect independent individual judgements on an item **before** opening discussion of that item. **Requirement: no participant observes another participant's position on the item before recording their own.** This is the single highest-value requirement in the section and the direct structural answer to the cascade result.

S5.2 — Distribution before conclusion. The distribution of independent judgements **shall** be displayed to the body before discussion begins, including its spread. **A body that sees only the mean has been shown a converged number and will converge on it.**

S5.3 — Reasons, not only conclusions. Each independent judgement **shall** carry at least one line of reasoning. Agreement of conclusions with agreement of reasons **shall** be recorded as a `u`-suppression indicator, not as corroboration.

S5.4 — Dissent record. Every non-unanimous decision **shall** carry a written minority report containing the rejected position, its evidence, and **a specific falsifier** — the observation that would show the majority wrong. Unanimous decisions **shall** carry a consented steelman statement, or an explicit note that none was appointed.

S5.5 — Dissent protection, published and tested. A written dissent protection **shall** exist, be published, and be exercised at least once per year. **An untested protection shall be recorded in the survey as absent.**

S5.6 — Participation measurement. Airtime **shall** be measured on a sample of sessions, at least quarterly. Recorded metric: share of speaking time held by the top two speakers. Threshold for intervention: **above 60 per cent in a group of eight or more.**

S5.7 — u maintenance schedule. Because u decays under postulate I1, the body **shall** remeasure u at least annually by the disagreement-and-error-decorrelation protocol of Curzi [2026i], and **shall** record the trend. A declining trend across two consecutive measurements **shall** trigger a composition review.

S5.8 — Decline paths, mandatory. Every protocol in this section **shall** be implemented with an explicit decline path, stated aloud at the time of use and not only in the written procedure. **Silence shall never be recorded as assent; a pass shall be recorded as a pass.** A protocol without a decline path is outside the scope of this framework and shall not be installed under its authority.

S5.9 — Anonymity truthfulness. Where anonymity is claimed, the designer **shall** verify that the group size and the response format do not identify authors. Where they do, the protocol **shall** be relabelled and the anonymity claim withdrawn.

14.5.11 5.11 Failure modes

FM-5.1 — The cascade collapse. *Description.* Discussion opens with a senior or confident member stating a position; everything subsequent is a response to that position. The panel reaches high agreement quickly and reports it as confidence. *Damages.* u to near zero within a single session, and through it S and Q. *Diagnostic signature.* Order-of-speaking correlates with the final position; time-to-consensus is short and falling; members can state the conclusion but cannot state a reason differing from the first speaker's. *Fix.* S5.1. There is no soft version of this fix: independent recording before discussion, or the cascade continues. Debiasing training does not address it, because the agents in the cascade model are not biased.

FM-5.2 — Unanimity reported as strength. *Description.* The body's minutes show near-total agreement across all items and this is presented as evidence of quality. *Damages.* u, and the credibility of the whole record. *Diagnostic signature.* Dissent rate below 5 per cent of decisions over a year. **Cross-check against outcomes: a body that agrees on everything and is wrong at the base rate is a body whose agreement carries no information.** *Fix.* S5.4 — the minority report requirement converts unanimity from an exit into an obligation. Expect resistance framed as efficiency; the arithmetic of Section 5.4 is the reply.

FM-5.3 — The token dissenter. *Description.* One member reliably objects; everyone knows they will object; the objection is heard, noted, discounted, and the decision proceeds unchanged. *Damages.* u in effect though not on paper — the record shows dissent while the pool receives none. *Diagnostic signature.* The same name in every minority position; decisions never change following a dissent; other members' dissent rate is zero. *Fix.* Rotate the steelman role so that objection is a function rather than a person. Measure **decision change rate following dissent**; if it is zero over a year, the dissent channel is decorative and the body should stop claiming it.

FM-5.4 — Anonymity theatre. *Description.* The first round is nominally anonymous in a group of six, where everyone can identify every author from phrasing and expertise. *Damages.* u, plus a false measurement — the group now believes it has an anonymous baseline and draws conclusions from it. *Diagnostic signature.* Ask three members to attribute the anonymous responses. **If they are right more than half the time, the protocol is not anonymous.** *Fix.* S5.9. Withdraw the anonymity claim and use IP-1's sealed independent estimates instead, which do not depend on anonymity for their effect.

FM-5.5 — Silence read as assent. *Description.* The chair asks whether there are any objections, hears none, and records consensus. Non-response is tallied as agreement. *Damages.*

`u` and `N_eff` — participants who did not speak are counted as if they had. *Diagnostic signature.* Minutes record consensus for items where airtime measurement shows several members never spoke. **This is detectable purely from records, retrospectively, and almost nobody checks.** *Fix.* S5.8. Record passes as passes; replace the negative call with a positive round.

FM-5.6 — The correlated panel. *Description.* Nine reviewers, all trained in the same three institutions, reading the same journals, funded by the same body. Their agreement is read as convergence on truth. *Damages.* `u` structurally, from the moment of appointment. *Diagnostic signature.* Measure error decorrelation, not opinion diversity: give the panel a set of items with known outcomes and check whether their *errors* are independent. **Correlated errors are the definitive reading; correlated opinions are only suggestive.** Then compute `N_eff` and compare with headcount. *Fix.* This is a composition problem and no protocol repairs it — the protocols of Section 5.7 extract the signal present, and if the signals are duplicates there is nothing to extract. Recruitment across training lineages, incentive structures and trades is the only remedy.

FM-5.7 — Protocol without storage. *Description.* Excellent elicitation. Real independent estimates, honest disagreement, a genuine distribution. None of it written down beyond the final number. *Damages.* `eta` — the surplus was generated and not converted. *Diagnostic signature.* Ask for last quarter's pre-discussion distributions. If they do not exist, `eta` for this body's most valuable output is zero. *Fix.* S5.2 and S5.4. Retain the distributions, the reasons and the falsifiers; the storage cost is trivial and the audit value compounds.

FM-5.8 — Conscripted difference. *Description.* A member is assigned to represent a perspective — demographic, disciplinary, regional — that they did not volunteer to represent and may not hold. *Damages.* `u`, because the represented perspective is performed rather than held; and it breaches the declination constraint. *Diagnostic signature.* The member's recorded positions do not differ from the majority except on the items where they are expected to differ. *Fix.* Withdraw the assignment. Recruit for genuine difference and let people speak for themselves, which is both the ethical and the measurable option. **Difference that has to be assigned was not present, and assigning it does not create it — it only makes it unmeasurable.**

14.6 6 Institutions as storage: the maintenance term

An institution, in this framework, is not a building, a charter, a payroll or a mission. It is a **device for holding `Q` against `delta`** — a mechanism whose function is to make stored order survive the departure of the people who made it. That is the whole definition, and every recognisable institutional form is a special case of it.

Form	What it stores	Against what `delta`
Constitution	Decision procedures and constraints on power	The turnover of every officeholder
Archive	Records of what happened and what was decided	Human memory, at roughly 100% per generation
Curriculum	The transmissible portion of a body of skill	Death of practitioners
Profession	Standards of competence and conduct	Individual variation and market pressure
Standards body	Interface agreements between independent parties	Divergent local optimisation
Maintenance regime	The physical plant and its working order	Wear, corrosion, degradation

Each is `Q` in a different substrate; each obeys the same recursion with different parameters. **That is a claim about model form and not about physics**, badged here as it is everywhere it is

made [Curzi, 2026a].

14.6.1 6.1 Why institutions ossify — the equation, and the correction it forces

Read the headroom gauge with the eyes of an institution that has been successful for sixty years.

```
h_t = eta ln N  −  delta Q_t  −  C_t
      ^^^^^^^^     ^^^^^^^^^     ^^^
      ceiling      maintenance   operating
      fixed        grows with    cost
                   success
```

The first term is a **hard ceiling**. `eta ln N` cannot be raised without limit: `ln N` grows logarithmically, so doubling the number of genuinely distinct categories adds `ln 2 = 0.693` and nothing more, whether the move is from 4 to 8 or from 400 to 800; and `eta` is bounded above by 1 in any sensible normalisation. **The ceiling is essentially fixed for a mature institution.** The second term is `delta Q_t`, and `Q_t` is the institution's accumulated achievement: every rule that worked, every precedent that settled a dispute, every procedure that prevented a past disaster, every standard that made two systems interoperate. All of it is `Q`, and all of it requires maintenance at rate `delta` per period, forever. **Therefore, as an institution succeeds, its own stored order consumes an increasing share of a fixed budget.** No malice, no decadence, no failure of nerve. Arithmetic.

> **Ossification is not moral failure. It is a headroom equation.**

Diagnostically this matters, because the standard response to ossification — replace the leadership, exhort the staff, run a culture programme — addresses a cause that is not operating. **If `delta Q_t + C_t` exceeds `eta ln N`, the sustainability ceiling applies and no arrangement of the people prevents decline** [Curzi, 2026a]. Not a better chief executive, not a more committed workforce, not a clearer strategy. The constraint is on the budget and must be relieved on the budget. The general form of the diagnosis is old: the accumulation of a legible order can destroy the local variety that made the system work in the first place [Scott, 1998].

And here the identity of Section 3.2 forces a correction on that account, which should be read carefully, because the account is the one this section is named for. Written with the surplus law substituted in, the identity is `h_inf = eta(ln N − F(u*))`, and the striking feature is what has vanished: **`delta`, `C` and `Q` all cancel at the fixed point.** So `delta Q_t` does grow with success — but under the plain linear law it grows toward a fixed point at which headroom is a *positive constant* that does not depend on `delta`, `C` or `Q` at all. **The plain linear model, left alone, never ossifies.** Maintenance load rises and then stops rising, because `Q` stops rising.

Ossification is therefore not a consequence of accumulation as such. It requires one of two further things, and a diagnosis should say which:

1. **Exogenous `Q` accretion** — obligations added from outside the loop faster than the loop's own fixed point would settle them: statute, merger, inherited estate, external mandate. `Q` is being pushed past its equilibrium by something that is not `eta S`.
2. **Superlinear cost** — `C` rising faster than linearly in `Q`, which breaks the cancellation. A correction load proportional to a rule stock is one instance; the `n(n−1)/2` coordination term of Section 4.6 is another.

The claim stands — but the equation names two specific mechanisms, and neither of them is age. Section 6.6's three routes are exactly the ways a real institution leaves the linear case.

14.6.2 6.2 Two identities that structure the section

Identity 1 — the uniform bound is the zero-headroom line. The uniform bound gives `Q_t <= max{Q_0, eta ln N / delta}` [Curzi, 2026a]. Setting `C = 0` in the headroom gauge and solving `h = 0` gives `Q = eta ln N / delta`. **The uniform bound on stored order is precisely the level at which headroom reaches zero in a costless system.** These are not two facts but one fact stated twice: an institution cannot exceed its storage ceiling because at the ceiling it has no budget left to add anything. Every unit of `Q` it holds is a unit of budget it has committed to holding. For a mature body with `eta ln N = 0.8349` and `delta = 0.015`, the bound is `Q <= 55.66` — the absolute maximum stored order the body could hold with no operating cost whatsoever. With any real `C` the practical ceiling is far lower, and Section 7.3 computes it at 13.73 for the same body.

Identity 2 — headroom at equilibrium is unused variety, derived in Section 3.2. Its consequences for institutions specifically: a settled institution's headroom equals the difference it is failing to use, and nothing else; and **a settled institution never has negative headroom**, so negative headroom is always a disequilibrium condition. **An institution in the red on headroom is always an institution living in a changed world with an inherited balance sheet.**

14.6.3 6.3 What the gauge does not contain, and the four levers

Look at the gauge again and note an absence that decides most institutional strategy:

```
h_t = eta ln N − delta Q_t − C_t
```

`u` does not appear. Non-parallelism enters the storage law only through `S_t = ln(1 + (N−1)U_t)` — the *input* term. It is not in the budget. The consequence is a hard rule contradicting a great deal of received practice:

> **Raising `u` does not raise headroom. It raises the input that fills headroom.**

An institution with `h < 0` that responds by recruiting for difference has bought a larger tap for a tank leaking faster than any tap can fill it. `S` can rise all the way to `ln N` and the step `eta S − delta Q − C` remains negative, because `eta ln N − delta Q − C` — which is exactly `h` — is negative by assumption. **Difference is the right move at `h > 0` and the wrong move at `h < 0`, and the gauge says which regime the body is in before anything is spent.**

The four levers that *do* move `h`, in order of their usual cost:

1. **Raise `eta`.** Usually cheapest. Capture what already happens.
2. **Cut `C`.** Usually available. Remove coordination overhead, friction, unresolved conflict.
3. **Raise `N`.** Expensive and logarithmically rewarded. Rarely the answer.
4. **Shed `Q`.** The one nobody considers, the subject of Section 6.7, and frequently the only one with enough range at institutional scale.

14.6.4 6.4 The fifth lever, and why it is not fifth by accident

The lever missing from that list is the one every institution reaches for first: **lower `delta`.** Build trust, build institutional memory, stop losing what is known. It is absent from the four because it behaves differently from all of them, and the difference is a correction to standard practice rather than a technicality.

Trust does act on `delta`; the mechanism by which it does so is retention, and it enters the law as a modification of the decay term [Curzi, 2026s]. But `delta` sits in the *denominator* of the steady state, and **when the numerator is negative, dividing by a smaller positive denominator makes the result more negative.** The worked separation of Section 4.7 gives the arithmetic: baseline `−0.0836`, trust alone `−0.2114`, reciprocity alone `+0.7394`, both `+1.8701`. **Trust does not add order. It amplifies whichever sign the system already has**, and a failing institution that

invests in trust first buys a slower, better-mannered decline — together with survey results reporting that the programme worked.

The design rule is therefore an ordering: fix the numerator first. Raise `eta`, or cut `C`, until `eta F(u*) > c*`; only then spend on trust, where the same division now multiplies a positive number. Note also what a lower `delta` does to the diagnosis: it lengthens the time constant `tau = 1/delta`, so the institution takes longer to find out. Section 6.10 records the same property working in the other direction, where the `delta` that slows the loss also slows the involuntary return of headroom.

14.6.5 6.5 The maintenance term at institutional scale

Institutions are distinguished from teams and rooms by one parameter above all: **their `delta` is small and their `Q` is large.** That is the point of them; a constitution with `delta = 0.3` per year is not a constitution. But `delta Q` is a product, and a small number times a large number is not small.

Take a fixed ceiling `eta ln N = 1.50` and ask what fraction of the annual budget the maintenance term alone consumes:

Q	delta = 0.005	delta = 0.01	delta = 0.02	delta = 0.03	delta = 0.05
10	3%	7%	13%	20%	33%
25	8%	17%	33%	50%	83%
50	17%	33%	67%	**100%**	**167%**
75	25%	50%	**100%**	**150%**	**250%**
100	33%	**67%**	**133%**	**200%**	**333%**

Every cell at or above 100 per cent is an institution that cannot fund its own maintenance out of its own surplus, before paying a single unit of operating cost. Reading across the `delta = 0.02` row: at `Q = 10` maintenance is a rounding error; at `Q = 50` it is two-thirds of the budget; at `Q = 75` it is the entire budget. This is result **R6**.

The same institution, doing nothing differently, moves from the first row to the last row simply by continuing to work. This is the maintenance-versus-growth transition, and every institution that survives long enough reaches it. It is not a phase to be avoided but a phase to be *recognised*, because the correct behaviour on either side of it differs and the behaviour that got the institution to the transition is wrong after it.

	Before the transition	After the transition
Dominant term	`eta ln N`	`delta Q_t`
Correct posture	Build. Accumulate. Say yes.	Maintain. Curate. Shed.
Success metric	New things established	Old things still working
Typical error	Under-building from caution	Over-building from habit
What “more resources” buys	More `Q`	A slower decline, briefly
Career incentive	Aligned with the correct posture	**Opposed to it**

The last row is where institutions actually die. **After the transition, the correct organisational behaviour is maintenance and shedding, and no individual career has ever been advanced by maintenance or shedding.** The incentive gradient and the headroom gradient point in opposite directions, and the incentive gradient is the one people can feel.

14.6.6 6.6 The three routes to negative headroom

Since a steady state cannot have `h < 0` by Identity 2, negative headroom always means the parameters changed under an inherited `Q`. There are exactly three routes and they are diagnosable apart.

Route A — `eta` falls. Interaction stops converting into durable structure. The meetings still happen; the deliberation is as long as ever; nothing lands. *Mechanisms.* Ritualisation, where the procedure survives its purpose and is performed rather than used. External override, where a higher authority can void local decisions so that deliberation produces nothing durable — which is the failure of O7. Legal review as a filter that removes anything consequential. Output formally produced and never adopted. *Signature.* Deliberation hours flat or rising; durable artefacts per hour falling. Ask what last quarter's meetings deposited (S4.7). **An institution whose meetings deposit nothing has `eta = 0` and is generating no order at any `u` whatsoever.**

Route B — `C` rises. Operating cost grows, usually as a function of `Q` itself, and usually for defensible reasons: each accumulated rule requires interpretation, each precedent must be checked, each standard must be maintained against its dependents. *Mechanisms.* Compliance load proportional to the rule stock. Coordination cost by `n(n−1)/2` as the body grows [Brooks, 1975]. Unresolved conflict, which compounds. Litigation and appeal. The secretariat that grows to service the archive. *Signature.* Model `C_t = c_0 + kappa Q_t` and estimate `kappa` by regression across periods. **A significant positive `kappa` means the institution's own stored order is buying its operating cost**, and it changes the shedding calculation decisively, because shedding `Q` then cuts both the maintenance term and the operating term at once.

Route C — `N` narrows. The categorical variety the institution spans contracts. A body founded to arbitrate between fourteen genuinely distinct constituencies now serves nine, because five merged, exited or were absorbed. *Mechanisms.* Industry consolidation. Professional narrowing. Scope creep in reverse, where the institution defends a shrinking core. Membership criteria that filter for similarity. *Signature.* Count the genuinely distinct categories, not the seats — the redundancy audit of Curzi [2026k], whose five-parameter survey reproduced each of five systems' observed decline, predicting `−0.250474` against an observed `−0.250` at one scale and `−0.996371` against `−1.000` at another, with residuals under 1.4 per cent of the ceiling term. `N` falling from 14 to 9 cuts the ceiling from `eta(2.6391)` to `eta(2.1972)` — **a 17 per cent reduction in the maximum possible input, permanently, and it is almost never noticed because the number of *seats* did not change.**

All three routes usually run together, which is why the diagnosis must be quantitative. Section 7.3 works a case with all three operating simultaneously over thirty-six years.

14.6.7 6.7 Shedding `Q` deliberately

This is the lever nobody reaches for, and at institutional scale it is often the only one with enough range. The reason for the neglect is not mysterious. `Q` is achievement: every unit of it was a solved problem, a settled argument, a prevented disaster. Shedding `Q` means deliberately unlearning something that once worked, and the case for keeping each individual unit is always stronger than the case for keeping the aggregate — because the individual case is concrete and the aggregate case is a division.

The arithmetic is unmoved by this. With `C_t = c_0 + kappa Q_t`,

```
dh/dQ = −(delta + kappa)
```

Every unit of `Q` shed returns `delta + kappa` units of headroom, permanently, every period. With `delta = 0.015` and `kappa = 0.0225`, shedding 8 units of `Q` returns `8 × 0.0375 = 0.30` units of headroom per period thereafter. Against a ceiling of 0.8349 that is 36 per cent of the entire budget, recovered by deletion.

The shedding instruments

Sunset clauses. Every rule carries an expiry date; renewal requires an affirmative act — a positive case, made by someone, at a scheduled time. The mechanism's power is entirely in the default. Without a sunset the default is "keep", and keeping requires no case, no advocate and no attention; with a sunset the default is "lapse", and the burden falls on continuation. **A sunset clause does not delete anything. It changes which side of the argument has to do the work**, and that is sufficient, because the scarce resource in every institution is not judgement but attention. Design notes: stagger expiries so review load is level rather than lumpy; make renewal genuinely possible in one step, or the clause becomes a hostage device; and require the renewal case to state what would make the rule unnecessary.

Term limits. Sunset clauses applied to roles rather than rules. Their storage function is double-edged and both edges should be stated: they raise `delta` on role-bound `Q`, which is a cost, because experience genuinely leaves; and they prevent role-bound `Q` from becoming permanent, which is the benefit. **A role held for thirty years accumulates a `Q` whose `delta` is zero until the day the holder leaves, and then it is 1.0.** Term limits convert a single catastrophic loss into a series of small scheduled ones, which is precisely the trade a well-designed system makes everywhere else.

Planned demolition. The physical form, and the honest one, because it is visible. A building scheduled for removal at a stated date. A programme with a defined end. A committee constituted for a task and dissolved on delivery. The discipline is that the end date is fixed *at the beginning*, when nobody yet has an interest in extending it.

Forgetting by design. The archive tier: records are retained but moved out of the default view, so that search cost — a `C` term — does not grow without bound with the archive. This is the evaporation requirement of FM-4.9 at institutional scale; the pheromone trail to the exhausted source must fade, or the colony maintains a motorway to an empty patch of ground.

Deletion budget. The most useful and least used instrument. Fix a rate — for every new standard adopted, one is withdrawn — and enforce it structurally rather than by intention. The one-in-one-out constraint keeps `Q` bounded by construction rather than by discipline, which matters because discipline is exactly what fails under schedule pressure.

What must not be shed

Shedding is a scalpel and not a policy. Two classes are excluded.

Anything load-bearing for a current dependent. A standard with live implementations is not overhead; it is the interface. Withdrawing it does not shed `Q`, it destroys `Q` elsewhere — usually more than it recovers, and on someone else's balance sheet. The formal version of the warning is that coupled systems fail together in ways neither would alone [Buldyrev et al., 2010].

Anything constituting the ability to decline. Procedural protections, appeal rights, dissent records, exit provisions and consent requirements are `Q` that specifically preserves people's capacity to refuse. **They may be simplified; they may not be shed for headroom.** An institution that buys headroom by removing the mechanisms through which people can say no has not improved its parameters; it has changed what it is, and this framework does not recommend it. The practical form: maintain an explicit **protected set**, written down before any shedding exercise begins, and exclude it from the deletion budget by rule rather than by argument.

14.6.8 6.8 Why the maintenance term is never funded

Star and Ruhleder [1996] characterised infrastructure relationally rather than as a class of object. Something is infrastructure *for* a given practice, and among its properties: it is embedded, transparent in use, learned as part of membership, linked to conventions, and — the property this section turns on — **it becomes visible upon breakdown.** Weiser's 1991 formulation is the same observation from the other side: the most consequential technologies are the

ones that disappear, weaving themselves into everyday practice until they are indistinguishable from it. *That paper has no key in this corpus's bibliography*, and the gap is recorded in Section 10.

Now put that next to the budget:

```
h_t = eta ln N − delta Q_t − C_t
                ^^^^^^^^^
                the maintenance term:
                large, growing, and invisible while it is being paid
```

The `delta Q` term is the cost of keeping infrastructure working. Infrastructure that is working is invisible. **Therefore the largest and fastest-growing term in an institution's budget is the one with no visible advocate, no constituency and no photograph.**

The consequences are predictable and are observed everywhere.

- **Maintenance is deferred first** under budget pressure, because deferring it produces no immediately visible effect. That is not a failure of judgement; it is a correct read of the visible evidence, and the evidence is systematically wrong. The general finding that people systematically misjudge stocks with delays, in a controlled setting where the correct answer is known, is Sterman [1989].
- **Maintenance is measured in avoided events**, and avoided events do not appear in any record. A maintenance regime that works perfectly generates a record indistinguishable from one that was never needed.
- **Maintenance funding is restored only after breakdown**, at which point the cost is the replacement cost rather than the maintenance cost, typically an order of magnitude higher, and the restoration is attributed to the crisis rather than to the neglect. The organisational study of how repeated uneventful deferrals become an accepted baseline until a catastrophic one is Vaughan [1996].
- **The maintainers cannot describe their contribution** in the vocabulary the institution uses for achievement, because their output is the absence of an event.

The engineering response is to make the invisible term visible *by construction*, since it will never become visible by attention.

Instrument	What it makes visible
A named budget line for `delta Q` — separately reported, not merged into operations	That maintenance has a magnitude
A stated `delta` per asset class, published and revised	That decay has a rate
Scheduled visible failure: a planned outage, a fire drill, a restore-from-archive exercise	That the thing is being held up by something
Deterioration reporting: what got worse this period	That neglect has a direction
Maintenance-to-new-build ratio, reported alongside `h`	That the two compete for one budget

Scheduled visible failure is the strongest of these and the least used. If infrastructure becomes visible on breakdown, the engineering inversion is to *cause a small breakdown on purpose, on a schedule*, so that visibility is obtained at a chosen cost rather than at an unchosen one. A quarterly exercise in which a system is restored from the archive tells the institution, in one afternoon, exactly what its `delta` has been doing.

14.6.9 6.9 Why measuring institutional health corrupts it

When a measure becomes a target it ceases to be a good measure [Goodhart, 1975]; and the more a quantitative indicator is used for social decision-making, the more subject it is to corruption pressures and the more apt it is to distort the processes it was meant to monitor [Campbell, 1979]. Institutional health is an unusually soft target and the corruption is unusually complete, because `Q` is not directly observable. What is observable is a proxy `Y`, and every proxy for stored order has a cheap counterfeit.

Proxy for `Q`	The counterfeit	What it does to the real parameters
Standards published	Publish more, thinner standards	`Q` looks up, `C` genuinely up, `eta` unchanged
Members enrolled	Lower the bar	`N_eff` down (new members duplicate old), `C` up
Procedures documented	Document what nobody does	`Q` flat, `C` up, search cost up
Meetings held	Hold more meetings	`C` up, `eta` down (dilution)
Compliance rate	Narrow the rule until compliance is automatic	`Q` down, measured `Q` up
Archive size	Retain everything	`C` up via search, `delta` masked

Every one of these raises the measured proxy and lowers real headroom. **The counterfeit is not usually fraud. It is the natural drift of an organisation optimising a number in good faith**, and it is fast: the corruption is a function of how much weight the indicator carries, not of anyone's intent [Campbell, 1979]. The methodological literature gives the same phenomenon inside research itself, where undisclosed flexibility in analysis produces confident findings from nothing [Simmons et al., 2011, Gelman and Loken, 2013].

Three defences, in order of strength.

First — measure `h`, not `Q`. Headroom is a difference of three quantities pulling in opposite directions and is therefore far harder to counterfeit than any of them. Inflating `Q` *lowers* `h` through the maintenance term; inflating activity raises `C` and lowers `h`. There is no cheap move that raises measured headroom, because the cheap moves all cost something that `h` subtracts. **A gauge built from a difference resists capture in a way a gauge built from a total never can.**

Second — measure `delta` directly, under zero input. Suspend input to a subsystem, observe the decay of `Y`, and compute `delta = 1 − Y_1/Y_0` [Curzi, 2026a]. This is expensive and disruptive and it is nearly impossible to game, because it measures what happens when nobody is trying.

Third — rotate the proxy. Announce that `Y` will be re-specified on a schedule and that the new specification will not be disclosed in advance. This does not prevent optimisation of the current proxy; it prevents the *investment* in optimising it, which is where most of the distortion lives.

And a standing honesty requirement: publish the proxy, publish its known counterfeits, and publish the falsification rules alongside every reported figure [Curzi, 2026i]. **A framework that cannot fail cannot be trusted** — which is the demarcation position the corpus adopts, in the qualified form that treats its own badged postulates as the protective belt around the programme rather than as tested claims [Lakatos, 1970].

14.6.10 6.10 The two ways headroom returns

Here is the structural fact that organises Section 7.3, and it is this section's thesis.

An institution in negative headroom does not stay there forever; the storage law will not permit it. If `h_t < 0` then `eta S_t < delta Q_t + C_t` for every attainable `S_t`, so `Q_{t+1} < Q_t`:

stored order falls. And as `Q` falls, `delta Q` falls, and `h` rises. Eventually `h` crosses back above zero.

Headroom always returns. The only question is whether the `Q` spent to buy it back was chosen or surrendered.

	Involuntary	Deliberate
Mechanism	Decay: the surplus does not cover maintenance, so things quietly stop working	Shedding: rules sunset, programmes end, roles rotate
Timing	Set by `delta` and by the size of the gap	Chosen
What is lost	Whatever was weakest, least defended, or least visible	Whatever was chosen, by stated criteria
Experienced as	Decline, drift, irrelevance	A decision, with an argument attached
Duration in `h < 0`	Years to decades	Zero
Protected set	Not protected — decay does not read the exclusion list	Protected by construction
Attribution	To the current leadership, who did not cause it	To the decision, correctly

The third row is the one to hold on to. **Involuntary shedding does not shed the least valuable `Q`.** It sheds whatever had the fewest defenders — which correlates with invisibility, which by the infrastructure result correlates with *working well* [Star and Ruhleder, 1996]. The archive that never failed loses its funding before the committee that meets monthly and produces nothing, because the committee has members and the archive has none.

Deliberate shedding is the same arrival, chosen, earlier, and with control over what is lost. That is the entire case for sunset clauses, term limits and deletion budgets, and it does not require anyone to believe that the shed rules were bad. It requires only that the budget is finite and that someone should choose.

14.6.11 6.11 The institutional survey, in brief

The full protocol is Curzi [2026i]; the institution-specific points are these.

`Q` proxy. For a rule-holding institution the natural proxy is the count of live rules weighted by dependency. **Weighting is not optional:** an unweighted count treats a foundational standard with two hundred implementations as equal to a procedural note nobody has read, and will therefore recommend shedding the wrong things.

Justify that `Y` is not the input restated. For a standards body, `U` is the disagreement structure among member organisations and `Y` is the live weighted rule stock. These are plainly different observables — a year of intense disagreement producing no adopted standard scores high `U` and zero change in `Y`, which is the required test. **This is the test the corpus's own empirical audit found it could not enforce**: the shuffled-input control passed 98.35 per cent of the time against a third variable driving both interaction and order while detecting only 48.17 per cent in the clean case, so the audit cannot see repackaging [Curzi, 2026i]. The justification therefore has to be made on the observables, in advance, and cannot be recovered statistically afterwards.

`delta` estimation. Institutions rarely permit a zero-input period, so use natural experiments: a dormant working group; a subsystem that lost its staff; the period after a merger when a function was unattended. `delta = 1 − (Y_1/Y_0)` over the dormant interval, annualised.

`C` tally. Include the items nobody budgets: unresolved dispute load, search cost across the archive, compliance interpretation, and the coordination cost `n(n−1)/2` of the governing body itself. These are typically the majority of real `C` and typically absent from the accounts.

`N` audit. Count genuinely distinct constituencies, not seats, and expect the honest `N` to be materially below the headcount [Curzi, 2026k]. The security-engineering form of the same requirement is that an unaudited count of participants is worthless wherever one party can present as many [Douceur, 2002].

A cheaper instrument, with its two conditions. Of the three terms in the gauge, only `C` depends on configuration, so the gradient of headroom is the negative of the gradient of cost: `grad h = −grad C`. **Therefore a habit survey is a headroom measurement.** Where do people actually route their requests; which form gets filled and which gets worked around; which meeting is attended and which is dialled into from a corridor; where has the paving been worn through the grass. Those recurring choices point down the cost field, which is to say up the headroom field. The practical consequence is that **the full survey is not always required to locate the direction of steepest improvement**, only to price it. Two conditions, both binding: the identity holds only where `eta`, `N`, `delta` and `Q` do not themselves move with the configuration — a workaround that destroys a distinction moves `N`, and the identity fails there — and the tally recovers cost *differences*, not absolute costs, so it ranks candidate moves and does not budget them.

Reporting. Report `h` with its three components separated, every period, with the maintenance term shown as a percentage of the ceiling. **That single percentage predicts institutional behaviour better than any strategy document.**

14.6.12 6.12 Specifications

S6.1 — Report headroom, decomposed. The institution **shall** report, each period: `eta ln N`, `delta Q_t`, `C_t`, and `h_t`. The maintenance term **shall** be reported as a percentage of the ceiling. **Reporting `Q` alone is prohibited under this specification**, because `Q` alone is the capturable quantity.

S6.2 — Named maintenance line. `delta Q_t` **shall** appear as a distinct, named budget line, not merged into operations, and **shall** be defended separately in every budget cycle.

S6.3 — Published decay rates. For each asset class holding `Q`, the institution **shall** publish an estimated `delta` and the method used to estimate it, and **shall** revise it at least every three years.

S6.4 — Sunset by default. Every new rule, standard, procedure or programme **shall** carry an expiry date at adoption. Renewal **shall** require an affirmative case, made at a scheduled time by a named advocate. Expiries **shall** be staggered so that review load is level.

S6.5 — Deletion budget. A withdrawal rate **shall** be fixed and enforced structurally. The default requirement is **one-in-one-out by dependency-weighted volume**. The rate may be varied only by an explicit decision recorded with its headroom justification.

S6.6 — Protected set. Before any shedding exercise, a written protected set **shall** be produced, containing at minimum (a) rules with live external dependents and (b) all procedural provisions that constitute a person's ability to decline, appeal, dissent or exit. **The protected set is excluded from the deletion budget by rule and not by argument.**

S6.7 — Term limits with handover deposit. Where term limits apply, the outgoing holder **shall** deposit role-bound `Q` in the shared medium of Section 4 before departure, and the handover **shall** be verified by the successor's ability to reconstruct the state without the predecessor present. **A term limit without a handover deposit converts a slow leak into a scheduled catastrophe.**

S6.8 — Scheduled visible failure. At least annually, the institution **shall** conduct an exercise in which a piece of working infrastructure is deliberately made visible: a restore from archive, a planned outage, a reconstruct-from-record drill. Findings **shall** be reported against the published `delta` estimates of S6.3.

S6.9 — The `h < 0` rule. When measured `h_t < 0`, the institution **shall not** commission new durable structure. Permitted actions are exactly: raise `eta`, cut `C`, shed `Q`. **Recruiting for difference is explicitly not a permitted response to negative headroom** (Section 6.3), because `u` does not appear in `h`.

S6.10 — Proxy honesty. Every reported proxy **shall** be published together with its known counterfeits (Section 6.9) and with the falsification rules of Curzi [2026i], including the shuffled-input control.

14.6.13 6.13 Failure modes

FM-6.1 — The maintenance trap. *Description.* `delta Q_t` has grown to consume the entire budget. The institution maintains and cannot build; every proposal is met with an assertion that there is no capacity, which is precisely correct and is mistaken for a cultural problem. *Damages.* `h` to zero or below, and then `Q` involuntarily. *Diagnostic signature.* `delta Q_t / (eta ln N) >= 0.9`. Corroborating symptoms: no new durable output for several periods despite unchanged staffing; strategy documents that repeat across years; a rising share of effort in interpretation and support of existing structure. *Fix.* Shed `Q` (S6.5) and cut `C`. **Do not attempt to raise the ceiling** — `ln N` is logarithmic and will not deliver. This is the failure mode for which deliberate shedding was invented.

FM-6.2 — The unshed `Q`. *Description.* Rules, programmes and roles accumulate without any withdrawal mechanism. Nothing has been removed in living memory. The rule stock is a stratigraphy in which nobody can tell live from fossil. *Damages.* `delta Q` rises toward the uniform limit; `C` rises through search and interpretation cost; `eta` falls because new work must be reconciled against everything. *Diagnostic signature.* Count withdrawals over the last five years. **Zero is the fault.** Second test: sample ten rules at random and count how many have a live dependent; a hit rate below half means most of the stock is fossil. *Fix.* S6.4 and S6.5. Begin with the sample: withdrawing ten rules that have no dependents is uncontroversial and establishes that withdrawal is possible, which is the actual barrier.

FM-6.3 — Invisible infrastructure. *Description.* Maintenance is unfunded because working infrastructure is invisible. The budget is cut, nothing happens for two years, the cut is judged a success, and the cut is repeated. Then something fails completely. *Damages.* `delta` effectively rises because unmaintained order decays faster; `Q` takes a step loss at breakdown; `C` is paid at crisis prices. *Diagnostic signature.* Maintenance budget falling in real terms across periods with no measured rise in `delta` — because nobody is measuring `delta`. **The absence of the measurement is the signature.** *Fix.* S6.2, S6.3 and S6.8. The scheduled visible failure is the one that changes minds, because it converts an argument into an observation.

FM-6.4 — Proxy capture. *Description.* A proxy for institutional health became a target. The proxy now rises reliably while the institution declines. *Damages.* All parameters, and the measurement system that would have detected the damage. *Diagnostic signature.* The reported metric improves monotonically across periods — real institutional quantities are noisy, and **a smooth monotone series is evidence of management of the series, not of the thing.** Cross-check: does an independent outcome measure move with the proxy? *Fix.* S6.1 — report `h` rather than any total. Rotate the proxy on an undisclosed schedule. Publish the counterfeits.

FM-6.5 — Ossification diagnosed as culture. *Description.* An institution with `h < 0` is treated to a leadership change, a values programme, a restructure, or an exhortation to be more innovative. None of it works. The next leadership is blamed and the cycle repeats. *Damages.* `C`, since the interventions are themselves expensive; morale; and time, while the real constraint continues to bind. *Diagnostic signature.* Compute `h`. If `delta Q_t + C_t > eta ln N`, the sustainability ceiling applies and **no arrangement of the people prevents decline** [Curzi, 2026a]. The signature is that successive leaderships of differing style produce indistinguishable results, which is exactly what a budget constraint predicts and a culture theory does not. *Fix.* Relieve the budget: shed `Q`, cut `C`, raise `eta`. Then, and only then, is a leadership or composition question worth asking.

FM-6.6 — Difference recruited into a deficit. *Description.* An institution with negative headroom responds by broadening its membership and recruiting for difference. `u` rises. Nothing improves. The failure is then attributed to the new members or to resistance from the old. *Damages.* `C`, since a larger body costs quadratically more to coordinate; and the credibility of `u`-raising interventions for a generation. *Diagnostic signature.* `h < 0` before the intervention; `u` measurably higher after; `Q` still falling. *Fix.* Sequence correctly, per S6.9: bring `h` above zero by shedding and by `eta` and `C` work, and *then* raise `u` to fill the budget that has been created. **The intervention is not wrong; it was administered in the wrong order.**

FM-6.7 — The sunset that never sets. *Description.* Sunset clauses exist and every renewal is automatic. The review is a formality, the advocate is the secretariat, and no rule has ever lapsed. *Damages.* `C`, since the review process is pure overhead; plus a false sense that FM-6.2 has been addressed. *Diagnostic signature.* Renewal rate at or near 100 per cent. **A functioning sunset regime lapses things; a renewal rate above roughly 90 per cent means the mechanism is decorative.** *Fix.* Require the renewal case to be made by a named beneficiary who is not the secretariat, and require it to state a live dependent. Pair with S6.5, which forces a withdrawal whenever an adoption occurs and therefore cannot be satisfied by universal renewal.

FM-6.8 — Term limits without deposit. *Description.* Rotation is enforced. Nothing was written down. Each rotation loses the role's accumulated judgement entirely. *Damages.* `Q` takes a step loss per rotation; `delta` is effectively raised to the rotation rate on all role-bound order. *Diagnostic signature.* Performance sawtooth synchronised with the rotation cycle; bus-count of 1 on role-bound state (S4.6). *Fix.* S6.7. Term limits and shared media are complements, not alternatives: **rotation without deposit is not a shedding strategy, it is a leak with a calendar.**

FM-6.9 — The protected set raided. *Description.* Under headroom pressure, the shedding exercise reaches appeal rights, dissent procedures, consultation requirements and exit provisions, because they are procedurally expensive and have no organised defenders. *Damages.* It breaches the declination constraint; and in the model's own terms it destroys the `u`-preserving structure of Section 5 and therefore the input term, so it does not even deliver what it promises. *Diagnostic signature.* The shedding list contains items whose function is to let someone say no. *Fix.* S6.6, enforced structurally: the protected set is written before the exercise begins and is excluded by rule. **Headroom bought by removing people's ability to decline is outside the scope of this framework, and no arithmetic in it licenses that trade.**

14.7 7 Results: three systems worked end to end

All three systems below are constructed cases with declared parameters, not measured organisations. Every number is computed from the stated parameters under the model of Section 3, and every table can be re-derived from the equations and parameter values printed beside it. They demonstrate that the procedure runs, that it reports its own failures, and that it produces counter-results as readily as confirmations; **they are not evidence that any organisation behaves this way and must not be cited as such.** Section 7.5 reports six places where the source material's arithmetic or its description of its own arithmetic does not hold up, and prints them rather than correcting them silently.

14.7.1 7.1 A neighbourhood tool library: coordinator against medium

A tool library with 48 member households, a shared inventory of hand and power tools, a converted garage, and a shared obligation to maintain both. It is a textbook common-pool resource — subtractable, since one person has the mitre saw and another does not, and hard to exclude from.

7.1.1 Encoding

The five operational choices of Curzi [2026i] are fixed and stated before any number is computed.

Choice	Setting
State encoder	Each member household's activity assigned to one of `N = 8` craft categories: woodwork, metalwork, garden, automotive, textiles, electronics, masonry, cycle repair
Interaction observable	Cross-category tool loans and joint working sessions per month
Order observable `Y`	Composite: tools in working order and correctly located, live maintenance skills held by more than one member, documented repair procedures
Time scale	One month = one period
Cost observable	Volunteer hours plus consumables plus loss and breakage, normalised to the same units as `Y`

The requirement that the order proxy not be a repackaging of the input holds here: `Y` is measured from a physical inventory audit and a skills census conducted independently of the loan log that produces `U`. A month with heavy borrowing and no repairs scores high `U` and flat `Y`. **The two observables can and do move in opposite directions, which is the test.**

7.1.2 Parameters

`N = 8`, so `ln N = 2.0794`. Non-parallelism from the disagreement-and-decorrelation protocol: `u = 0.62`.

```
N_eff = 1 + (N−1)u = 1 + 7(0.62) = 5.34
S     = ln(N_eff)  = ln(5.34)    = 1.6752
```

Forty-eight households, eight categories, and an effective count of 5.34. The redundancy audit removed a third of the categorical variety — 5.34 against 8, a 33.3 per cent reduction — before any surplus was credited, and 19.4 per cent of the available surplus with it, since `1.6752/2.0794 = 0.8056`. Both reductions are stated because they are different quantities and Section 7.5 records that the source conflates them.

7.1.3 Regime A — the coordinator

The library's first two years ran on a part-time paid coordinator holding the loan ledger, the maintenance schedule, the key rota and the membership list.

```
eta   = 0.35     interaction converts only via the coordinator's records
delta = 0.25     the coordinator's own turnover and forgetting rate
C     = 0.52     stipend, scheduling, queueing on one person's availability
```

Headroom at the start, `Q_0 = 0`:

```
h_0 = eta ln N − delta Q_0 − C = 0.35(2.0794) − 0 − 0.52 = 0.7278 − 0.52 = +0.2078
```

Positive but thin. Steady state:

```
eta S = 0.35 x 1.6752 = 0.5863
Q_inf = (eta S − C) / delta = (0.5863 − 0.52) / 0.25 = 0.2653
```

t (months)	0	2	4	6	8	10
Q_t	0.000	0.116	0.181	0.218	0.239	0.250

The library reaches a steady state of `Q_inf = 0.265` and stays there. It works. It never gets better. Check the identity of Section 3.2:

```
h at Q_inf      = 0.35(2.0794) − 0.25(0.2653) − 0.52 = +0.1415
eta ln(N/N_eff) = 0.35 x (2.0794 − 1.6752) = 0.35 x 0.4042 = +0.1415     [agrees]
```

Then the coordinator moves house. Their successor inherits the ledger but not the relationships, not the knowledge of which drill has the intermittent fault, not the informal understandings about who gets priority in spring. The hub census had a bus-count of 1 on most critical state. Estimated loss: **70 per cent of `Q` in a single step**, so `Q` drops from 0.239 to 0.072 at month 8. Recovery to the pre-shock level takes 6.9 months under the model. **The library did not lose a volunteer. It lost most of its stored order, because that is where the order was stored.**

7.1.4 Regime B — the medium

State is moved out of the coordinator and into two physical artefacts and one digital one:

- A **peg board** with a hook per tool: the tool's presence or absence, the borrower's tag and the return date, all readable from the doorway in three seconds. Visible 4/4.
- A **bound logbook** on a chain by the door: date, tool, member, condition on return, one line for anything odd. Writable in under fifteen seconds with a pen. Writable 4/4, low-friction 4/4, append-oriented 4/4.
- A **shared spreadsheet** mirrored weekly from the logbook by whoever is on rota, holding the membership list, maintenance schedule and repair procedures. Durable 3/4.

VWDLA total 19/20; passes S4.1. The unfinished-edge display required by S4.2 is a red tag hung on the peg for any tool needing attention, plus a chalked list of outstanding work on the garage wall. **The board displays its own defects, which is what makes it a stimulus rather than a report.**

Revised parameters, over the following year:

```
eta   = 0.55     every loan and every fault deposits directly into durable record
delta = 0.12     state survives departures; loss is physical wear and slow drift
C     = 0.45     no stipend; rota cost and write-cost distributed across members

h_0   = 0.55(2.0794) − 0 − 0.45 = 1.1437 − 0.45 = +0.6937
eta S = 0.55 x 1.6752 = 0.9214
Q_inf = (0.9214 − 0.45) / 0.12 = 3.9281
```

t (months)	0	2	4	6	8	10	12
Q_t	0.000	0.886	1.572	2.104	2.515	2.834	3.081

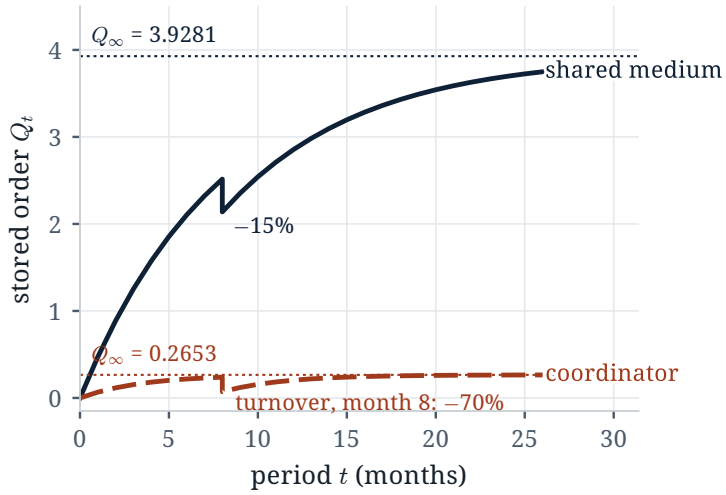

Figure 14.3: **The same turnover event costs 70 per cent of the stock under a coordinator and 15 per cent under a shared medium**, and the two regimes settle 14.8-fold apart — `Q_inf` = 0.2653 against 3.9281 — on a change of `eta` from 0.35 to 0.55 and `delta` from 0.25 to 0.12, with no change of people. Modelled from the parameters stipulated in Sections 7.1.3 to 7.1.5; generated by `figs/src/CCP-014_fig02.py`.

t (months)	0	2	4	6	8	10	12
`h_t`	+0.694	+0.587	+0.505	+0.441	+0.392	+0.354	+0.324

Identity check again:

```
h at Q_inf      = 0.55(2.0794) − 0.12(3.9281) − 0.45 = +0.2223
eta ln(N/N_eff) = 0.55 x 0.4042 = +0.2223     [agrees]
```

Time constant `tau = 1/delta = 8.33` months; half-life of stored order under zero input is `ln 2 / (−ln(1−0.12)) = 5.42` months.

Regime B holds 14.8 times the stored order of Regime A — 3.928 against 0.265 — at lower total cost. The mechanism is not effort: nobody in Regime B works harder than the coordinator did. The mechanism is that `eta` rose from 0.35 to 0.55, because every act of borrowing now deposits, and `delta` fell from 0.25 to 0.12, because the deposit is not in a person. This is result **R2**.

7.1.5 The turnover test, repeated

Regime B's most active member also leaves, at month 8. The hub census now shows no critical state at bus-count 1; what is lost is relationship and judgement, not record. Estimated loss: **15 per cent**, so `Q` drops from 2.515 to 2.138. Recovery to the pre-shock level takes 1.7 months under the model, against Regime A's 6.9. **Same event, same organisation, same people. Different location for the state.**

7.1.6 Free riding and the monitoring decision

Twenty months in, the contribution-share plot required by FM-4.4 shows the top quartile of households supplying 71 per cent of maintenance hours, up from 58 per cent. Estimated free-riding fraction `phi = 0.35`, loss coefficient `lambda = 0.9`, base cost 0.40. The arithmetic is computed in Section 4.8: without monitoring `Q_inf = 1.7198`, and with mutual monitoring at 0.08 and graduated sanctions bringing `phi` to 0.06, `Q_inf = 3.2281`.

Stored order had been more than halved by free riding — 3.93 down to 1.72 — without a single visible failure. Nothing broke; it simply cost more than it did. **Eight hundredths of a unit of monitoring cost bought back 1.508 units of steady-state stored order**, an increase of 87.7 per cent on the free-ridden level and a recovery of 68.3 per cent of what free riding had taken. Level 1 of the sanction ladder was used eleven times in the first year, level 2 twice, level 3 never. That distribution is the signature of a working graduated system and is the direct answer to FM-4.5.

7.1.7 Ostrom conformance audit

Principle	Evidence	Score
O1 boundaries	Written membership roll; inventory list defines the resource	2
O2 congruence	Borrowing limits set by tool scarcity; borrowing rights tied to rota participation	2
O3 collective choice	Rules changed at the quarterly members' meeting; sanction ladder was written there	2
O4 monitoring	Peg board and logbook are mutual and by-product; no external monitor	2
O5 graduated sanctions	Three levels; mildest used 11 times this year	2
O6 conflict resolution	Any two members may call a meeting within seven days; no cost	2
O7 right to organise	Independent association; no external authority has voided a rule	2
O8 nesting	Four craft circles of 8–14 households, plus a delegate council of 4	1

Total 15/16. O8 scores 1 because two of the four craft circles exceed the headroom-positive band and the delegate council's remit is not written down. **The band cannot be recomputed here, because the case never states this system's own per-path cost** — a parameter the specification S4.4 requires and the worked case omits. Section 7.5 records the omission; under the reference per-path cost of 0.02 the band is `n <= 11`, so circles of 12 to 14 exceed it, but that band is borrowed and not this system's.

7.1.8 Falsification, declared in advance

1. If, after installing the medium, measured `delta` did not fall below 0.20, **postulate M1 failed in this system** and the redesign should be reported as unsuccessful regardless of how good the board looks.
2. If `Q` under Regime B did not exceed Regime A's steady state within 12 periods, the modelling of `eta` is wrong.

3. If the monitoring intervention did not reduce measured `phi` within two quarters, O4 does not transfer to this setting, and that should be reported as a negative result, not explained away.
4. The shuffled-input control [Curzi, 2026i] must be run: if `Y` predicts as well from shuffled `U` as from real `U`, the model is fitting a trend and nothing more.

7.1.9 The rule extracted

The redesign changed no personnel, no funding and no rules of membership. It changed where the state lived. That single move raised `eta` by 57 per cent, cut `delta` by 52 per cent, and multiplied steady-state stored order fifteenfold. Then a monitoring regime costing 0.08 units recovered most of what free riding had quietly removed. **Put the state in the medium, not in a coordinator. Then govern the medium by the eight principles, or the tragedy argument applies as written.**

14.7.2 7.2 A nine-person review panel: independence priced

A standing panel of nine reviewers assessing proposals against a fixed rubric, meeting monthly. Decisions are consequential and outcomes are eventually observable, which makes the panel measurable in a way most committees are not.

7.2.1 Encoding

Choice	Setting
State encoder	Each reviewer's judgement vector across `N = 9` rubric dimensions
Interaction observable	Cross-reviewer disagreement per item, measured pre-discussion
Order observable `Y`	Panel's calibrated accuracy against realised outcomes at 24 months, plus the durable rubric refinements the panel produces
Time scale	One month = one period
Cost observable	Reviewer hours, meeting time, secretariat, appeals

`Y` is measured from realised outcomes 24 months downstream, entirely independently of the panel's own disagreement record, which satisfies the requirement that the order proxy not be a repackaging of the input.

7.2.2 Baseline

Standing parameters, over eight periods:

```
N     = 9        ln N = 2.1972
eta   = 0.45     proportion of panel deliberation that becomes durable rubric or precedent
delta = 0.18     turnover of two members a year plus drift in rubric interpretation
C     = 0.42     reviewer time, meeting, secretariat, appeals
Q     = 1.80     accumulated calibrated rubric and precedent
u     = 0.12     by the disagreement-and-error-decorrelation protocol
```

Seven of the nine reviewers were trained in three institutions; six sit on at least one other panel together; their pre-discussion ratings agree within one rubric point on 86 per cent of items.

```
N_eff = 1 + 8(0.12) = 1.96
S     = ln(1.96)    = 0.6729
```

Nine reviewers with an effective count of 1.96. The panel is, in the law's accounting, slightly less than two people.

7.2.3 The diagnosis

```
h = eta ln N − delta Q − C
  = 0.45(2.1972) − 0.18(1.80) − 0.42
  = 0.9888 − 0.3240 − 0.4200 = +0.2448
```

Headroom is positive, and this is important and counter-intuitive: **the panel is not overcommitted. It has budget. It is simply not collecting the input to use it.** Check the step:

```
eta S       = 0.45 x 0.6729 = 0.3028
delta Q + C = 0.3240 + 0.4200 = 0.7440
step        = 0.3028 − 0.7440 = −0.4412
```

The panel is losing 0.44 units of stored order per period, and

```
Q_inf = (eta S − C) / delta = (0.3028 − 0.4200) / 0.18 = −0.6510
```

A negative equilibrium means the regime is unsustainable as modelled — the storage law reports its own domain of breakdown rather than concealing it [Curzi, 2026a]. The panel's accumulated rubric and precedent will erode at a rate governed by `tau = 1/delta = 5.6` months, and the erosion will be attributed to turnover, workload, or the declining quality of applications. None of those is the cause. The cause is that `u = 0.12`.

7.2.4 What is required

By the increment requirement of Section 3.1, achieving an increment `r` per period requires `S >= (delta Q + C + r)/eta`, feasible only if `delta Q + C + r <= eta ln N`.

target `r`	required `S`	required `u`	feasible?
0.00 (hold)	1.6533	0.5280	yes
0.05	1.7644	0.6048	yes
0.10	1.8756	0.6906	yes
0.2448 (`= h`, the maximum)	2.1972	1.0000	yes, at orthogonality exactly

Read the first row before anything else. **To merely stop losing ground, this panel needs `u >= 0.528`; it currently has 0.12.** Every month spent below that threshold is a month of erosion, and no amount of reviewer diligence substitutes, because diligence does not appear in the equation. The last row is `r_max = h = 0.2448` arriving as a hard fact, and it requires `u = 1`, perfect orthogonality, which is not attainable with real people. **The gauge says what may be asked for; the geometry says what can be delivered; they meet exactly at the ceiling and not before.** Target: `r = 0.10`, requiring `u >= 0.6906`.

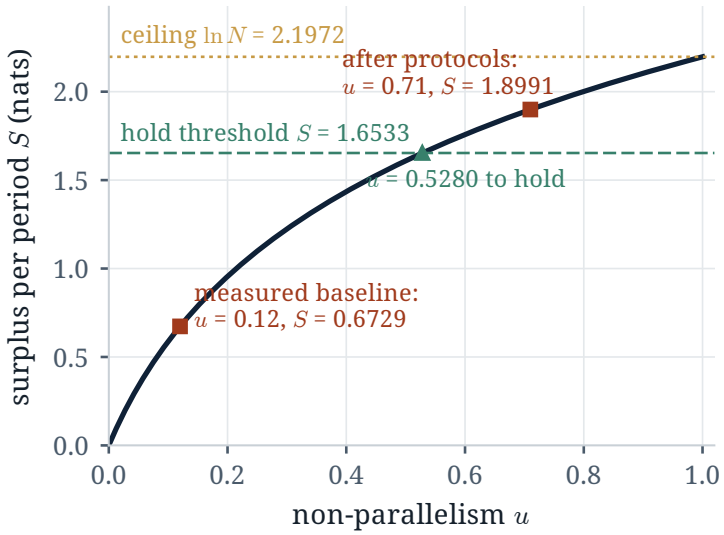

Figure 14.4: **The panel's deficit is an input deficit, not a budget deficit**: at `u` = 0.12 the nine-person panel generates `S` = 0.6729 nats against a hold threshold of 1.6533 and a ceiling of `ln 9` = 2.1972, and the five independence protocols move it to `u` = 0.71 and `S` = 1.8991. Modelled from the parameters stipulated in Section 7.2; generated by `figs/src/CCP-014_fig03.py`.

7.2.5 The intervention

All five protocols of Section 5.7, installed together, at a total cost increment of 0.090, so `C` rises from 0.420 to 0.510.

Protocol	Implementation at this panel
IP-1	Each reviewer submits a sealed rating with one line of reasoning 48 hours before the meeting; the distribution is displayed first for each item
IP-2	The sealed round is unattributed; names attach in round two, optionally
IP-3	Published dissent protection, signed by the commissioning body; dissent is not visible to the appointing authority at reappointment
IP-4	Minority report with a named falsifier on every split decision; consented rotating steelman on unanimous ones
IP-5	Round-robin on each item; the chair speaks last; the table replaced with a round one

Composition change, per FM-5.6, because protocols cannot extract signal that is not present: two retiring members replaced by a practitioner from an adjacent field and a reviewer from outside the three dominant training lineages. Measured after four periods: `u = 0.71`.

7.2.6 The result

```
N_eff = 1 + 8(0.71) = 6.68
```

```
S     = ln(6.68)    = 1.8991
eta S = 0.45 x 1.8991 = 0.8546

h     = 0.9888 − 0.3240 − 0.5100 = +0.1548
step  = 0.8546 − 0.3240 − 0.5100 = +0.0206
Q_inf = (0.8546 − 0.5100) / 0.18 = 1.9144
```

From a negative equilibrium to `Q_inf = 1.9144`. Confirm with the identity:

```
h at Q_inf      = 0.45(2.1972) − 0.18(1.9144) − 0.5100 = +0.13415
eta ln(N/N_eff) = 0.45 x (2.1972 − 1.8991) = 0.45 x 0.2981 = +0.13415     [agrees]
```

Note honestly what happened to headroom: it *fell*, from 0.2448 to 0.1548, because `C` rose by 0.09. **Headroom went down and the system got better.** This is not a contradiction; it is the correct reading of the gauge. Headroom is capacity to build, and the panel spent some of it on the mechanism that lets it build at all. A large unspent headroom in a system with `u = 0.12` is not health. It is a budget nobody can draw on.

7.2.7 Accuracy, computed

Take individual reviewer accuracy on the binary question of whether a proposal would have succeeded as `p = 0.62`, from the 24-month outcome record. Under full independence, nine reviewers by majority give `P_independent(9, 0.62) = 0.7738`. Under Model C1 — badged as a two-point mixture chosen for transparency, not a general correlation model — with the baseline correlation `rho = 0.75`:

```
P = 0.75(0.62) + 0.25(0.7738) = 0.6584
```

and after the intervention, with `rho` estimated at 0.20:

```
P = 0.20(0.62) + 0.80(0.7738) = 0.7430
```

Panel accuracy rises from 65.8 per cent to 74.3 per cent with no change in the individual ability of any reviewer. Seven of the nine are the same people, reading the same proposals, using the same rubric. The change is entirely in the order of operations and the composition of the pool. This is result **R4**.

Compare against the cascade bound. If the panel deliberated by open sequential discussion with no independent round, Section 5.4 gives, at `p = 0.62`:

```
P(correct cascade) = [0.62(1.62)/2] / [0.62^2 − 0.62 + 1] = 0.5022 / 0.7644 = 0.6570
```

65.70 per cent, against the panel's baseline of 65.84 per cent — a gap of 0.14 percentage points. **The panel of nine was performing at the theoretical accuracy of an unbounded cascade**, which is what a nine-person cascade should do, and is the strongest single corroboration available that the baseline diagnosis was right. **It is a corroboration and not a test**: the baseline `rho = 0.75` was chosen, not measured, and a different choice would break the coincidence. Section 10 records this.

7.2.8 Falsification, declared in advance

1. If measured `u` does not exceed 0.53 within six periods, the intervention has failed to reach even the hold threshold and must be reported as unsuccessful.
2. If the pre-discussion distributions show the same spread as post-discussion positions did under the old regime, IP-1 is not working and postulate I1's mechanism is wrong in this body.

3. If 24-month outcome accuracy does not rise above the 0.658 baseline within two full outcome cycles, the accuracy model is wrong and should be discarded rather than defended.
4. The shuffled-input control is mandatory: if Y is predicted as well by shuffled U as by real U, the entire causal story is a trend and must be reported as such.
5. If the dissent rate rises but decision-change-following-dissent stays at zero, the panel has acquired FM-5.3 and the apparent improvement in u is theatre.

7.2.9 The rule extracted

The panel was not short of ability. Its members were individually accurate at 62 per cent, above the Condorcet threshold, and its headroom was positive throughout. It was failing because nine reviewers had an effective count of 1.96, and because the order of operations in the room guaranteed a cascade before the second item. Ninety thousandths of a unit of procedural cost, two composition changes and a round table moved it from a negative equilibrium to a positive one and lifted its accuracy by 8.5 points. **Individuality is not a value the group tolerates. It is the structure the group's function rests on.**

14.7.3 7.3 A technical standards body, 1962 to 2026

A standards body founded in 1962 to publish interface standards for a manufacturing sector, with sixty-four years of continuous operation. All figures are computed; the parameter values are a constructed case rather than a measured organisation, and are stated as such.

7.3.1 Encoding

Choice	Setting
State encoder	Member organisations grouped into distinct constituencies by manufacturing role
Interaction observable	Cross-constituency working-group participation and recorded technical disagreement
Order observable Y	Live standards weighted by number of external implementations
Time scale	One year = one period
Cost observable	Secretariat, working-group time, interpretation requests, appeals — normalised to Y units

Y, the dependency-weighted live standard stock, is independent of U, the disagreement structure among members: a year of intense committee disagreement producing no adopted standard registers high U and zero change in Y.

7.3.2 Era 1 — 1962 to 1990

Founding parameters, estimated from the archive:

```
N     = 14        fourteen genuinely distinct constituencies    ln N = 2.6391
u     = 0.60      constituencies with materially different interests
eta   = 0.62      working groups produced adopted standards at high rate
delta = 0.030     standards decay slowly; technology drift and disuse
```

```
C     = 0.320     small secretariat, low interpretation load
Q_0   = 0         nothing stored at founding

N_eff    = 1 + 13(0.60) = 8.80
S        = ln(8.80)     = 2.1748
eta ln N = 0.62 x 2.6391 = 1.6362      <- the ceiling
eta S    = 0.62 x 2.1748 = 1.3483      <- the input
```

Year	Q_t	h_t
1962	0.000	+1.3162
1967	4.842	+1.1709
1972	9.001	+1.0462
1976	11.900	+0.9592
1982	15.638	+0.8471
1990	**19.669**	**+0.7261**

Twenty-eight years of accumulation, with headroom positive throughout and falling steadily — **success consuming its own headroom.** Steady state for these parameters would be `Q_inf = (1.3483 − 0.320)/0.030 = 34.28`, with `h_inf = eta(ln N − S) = 0.62(0.4643) = 0.2879` by Identity 2. The body never reached it. Maintenance share at 1990: `delta Q / (eta ln N) = 0.030 x 19.669 / 1.6362 = 36` per cent — substantial and not yet critical.

7.3.3 Era 2 — the parameters change, the `Q` does not

Between roughly 1985 and 1992 the sector consolidated, and all three routes of Section 6.6 operate at once.

Route C — `N` narrows. Fourteen constituencies become nine through merger and exit; the ceiling falls from `eta(2.6391)` to `eta(2.1972)`.

Route A — `eta` falls, 0.62 to 0.38. Standards now require legal review, patent clearance and a formal objection period. Working-group output that once became a standard in eighteen months now takes four years, and a growing share never completes.

Route B — `C` becomes a function of `Q`. With 19.7 units of live dependency-weighted standards, interpretation requests, conformance disputes and revision maintenance scale with the stock: `C_t = c_0 + kappa Q_t` with `c_0 = 0.320` and `kappa = 0.0225`.

And `delta` is deliberately driven down, 0.030 to 0.015, by a policy that no standard is ever withdrawn — which the body regards, reasonably, as a service to its implementers. Also `u` falls from 0.60 to 0.28: the surviving members are large integrated firms with substantially aligned interests.

```
N     = 9         ln N = 2.1972
u     = 0.28  ->  N_eff = 1 + 8(0.28) = 3.24,   S = ln(3.24) = 1.1756
eta   = 0.38  ->  eta ln N = 0.8349,   eta S = 0.4467
delta = 0.015
C_1990 = 0.320 + 0.0225(19.669) = 0.7626

h = 0.8349 − 0.015(19.669) − 0.7626 = 0.8349 − 0.2950 − 0.7626 = −0.2227
```

Negative. The body did nothing wrong in 1990. It inherited a `Q` of 19.669 accumulated under a ceiling of 1.6362 and is now carrying it under a ceiling of 0.8349. **Negative headroom is inherited order under changed parameters**, which is Identity 2's corollary in the flesh. The zero-headroom stock level for the new parameters is

```
Q* = (eta ln N − c_0) / (delta + kappa) = (0.8349 − 0.320) / 0.0375 = 13.73
```

The body holds 19.669. **It is 5.94 units of stored order over the line its current parameters can support**, and every one of those units was a solved problem.

7.3.4 Path A — do nothing

The body continues. Standards are neither withdrawn nor renewed; working groups meet; adoption is slow. `Q` decays because `eta S = 0.4467` does not cover `delta Q + C`.

Year	`Q_t`	`C_t`	`h_t`	Maintenance + operating as % of ceiling
1990	19.669	0.7626	**-0.2227**	127%
1995	16.835	0.6988	**-0.1164**	114%
2000	14.495	0.6461	**-0.0286**	103%
2005	12.561	0.6026	+0.0439	95%
2007	11.885	0.5874	+0.0692	92%
2010	10.964	0.5667	+0.1038	88%
2015	9.644	0.5370	+0.1533	82%
2020	8.554	0.5125	+0.1942	77%
2026	**7.494**	0.4886	+0.2339	72%

Twelve consecutive years of negative headroom, 1990 through 2001. The map is `Q_{t+1} = 0.9625 Q_t + 0.126717`, so the stock crosses `Q* = 13.73` at `t = ln(10.3516/16.2899)/ln(0.9625) = 11.87` years — that is, during 2002 — which is exactly twelve completed years at or below zero headroom, 1990 to 2001 inclusive. Twelve years in which the body could not, by the sustainability ceiling, commission any durable new structure at any interaction geometry whatsoever. During those twelve years the body appointed three directors-general, ran two strategic reviews and one culture programme. This is FM-6.5 in its natural habitat.

Headroom did return, in 2002, and by 2026 it stands at +0.2339. Read the price:

```
Q: 19.669 (1990)  ->  7.494 (2026)
Lost: 12.175 units = 61.9% of everything accumulated in twenty-eight years
```

The body bought back its headroom by losing 61.9 per cent of its stored order, over thirty-six years, without choosing a single unit of what was lost. What lapsed was whatever had the fewest defenders — which correlates with whatever was working quietly. This is result **R5**.

7.3.5 Path B — deliberate sunset in 1990

Counterfactual. In 1990 the body computes `h`, finds `−0.2227`, and applies S6.4 through S6.6: a protected set is written — standards with live implementations, all appeal and objection procedures — and 40 per cent of dependency-weighted stock is sunset in a single scheduled exercise.

```
Q: 19.669 -> 11.801
C: 0.320 + 0.0225(11.801) = 0.5855
h = 0.8349 − 0.015(11.801) − 0.5855 = +0.0724
```

Positive immediately.

Year	Q_t	h_t
1990	11.801	+0.0724
1995	10.336	+0.1273
2000	9.126	+0.1727
2010	7.301	+0.2412
2026	5.507	+0.3084

Zero years of negative headroom. But note the honest result, and it is the reason this path is not the recommendation: **Path B ends in 2026 with `Q = 5.507`, which is *less* than Path A's 7.494.** Shedding alone bought thirty-six years of positive headroom and then spent none of it. `eta` was still 0.38 and `u` still 0.28, so `eta S` was still 0.4467 and still insufficient. The body was solvent and idle. This is the second half of counter-result **CR**.

> **Shedding buys headroom. Headroom unspent is headroom wasted. Shedding is not a strategy; it is the precondition for one.**

7.3.6 Path C — shed, then spend

The full intervention, sequenced per S6.9: stabilise first, then grow.

1. **Shed 40 per cent** of dependency-weighted stock, protected set excluded: `Q: 19.669 -> 11.801`.
2. **Raise `eta` from 0.38 to 0.60.** Working-group output is captured directly into draft standards with a standing editor; the objection period runs concurrently with drafting rather than after it; every working group deposits to the shared medium (S4.7). This is `eta` work — the cheapest lever — and it does not require any change in what anyone is trying to do.
3. **Raise `u` from 0.28 to 0.55** — *only now*, with `h` positive. Membership is opened to integrators, testing laboratories and two adjacent-sector bodies, and the protocols of Section 5.7 run in every working group.

   eta ln N = 0.60 x 2.1972 = 1.3183 N_eff = 1 + 8(0.55) = 5.40 S = ln(5.40) = 1.6864 eta S = 0.60 x 1.6864 = 1.0118 h_1990 = 1.3183 - 0.015(11.801) - 0.5855 = +0.5558

Year	Q_t	C_t	h_t
1990	11.801	0.5855	+0.5558
1995	12.958	0.6116	+0.5124
2000	13.913	0.6330	+0.4766
2010	15.354	0.6655	+0.4226
2026	**16.770**	0.6973	**+0.3695**

Steady state and identity check:

```
Q_inf = (eta S − c_0) / (delta + kappa) = (1.0118 − 0.320) / 0.0375 = 18.449
h_inf = eta ln(N / N_eff) = 0.60 x (2.1972 − 1.6864) = 0.60 x 0.5108 = +0.3065
```

The trajectory converges on `Q_inf = 18.449` with `h_inf = +0.3065`, consistent with the table. Time constant `tau = 1/(delta + kappa) = 26.7` years — institutions are slow, and the slowness is the same property that makes them worth having.

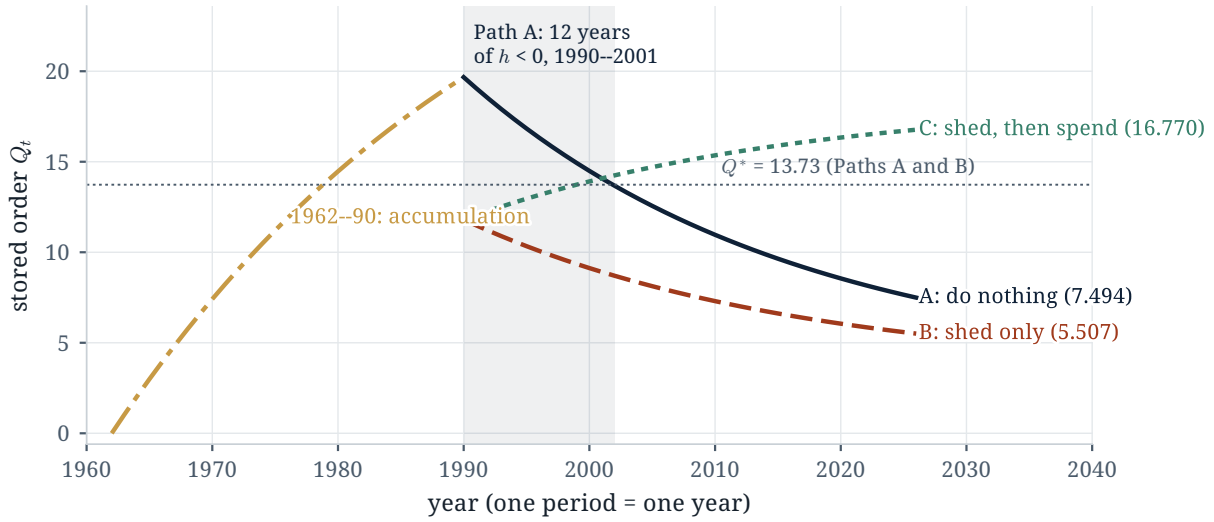

Figure 14.5: **Headroom returns either way; the only choice is whether the stock spent to buy it back was chosen**: the body accumulates to `Q` = 19.669 by 1990 under a ceiling of 1.6362, then carries it under a ceiling of 0.8349, and doing nothing costs 61.9 per cent of the stock over twelve negative-headroom years, while shedding 40 per cent on purpose and then raising `eta` and `u` ends at 16.770. Modelled from the parameters stipulated in Sections 7.3.2 to 7.3.6; generated by `figs/src/CCP-014_fig04.py`.

7.3.7 The three paths compared at 2026

At 2026	A: do nothing	B: shed only	C: shed, then spend
Years with `h < 0`	**12**	0	0
`Q` in 2026	7.494	5.507	**16.770**
`h` in 2026	+0.2339	+0.3084	+0.3695
`Q` lost from 1990 peak	61.9%	72.0%	**14.7%**
`Q` vs post-shed base	—	-53.3%	**+42.1%**
Loss chosen?	No	Yes	Yes
Protected set honoured?	No	Yes	Yes

Path A lost more than Path C and chose none of it. Path B was disciplined and inert. **Path C ends with 2.24 times Path A's stored order and higher headroom, having deleted 40 per cent of its rule stock on purpose in a single year.**

7.3.8 Falsification, declared in advance

1. If the dependency-weighted stock `Y` does not decay at approximately `delta = 0.015` per year during a period of suspended adoption, the `delta` estimate is wrong and every projection above is void.
2. If `C_t` does not regress significantly on `Q_t` — that is, if `kappa` is not distinguishable from zero — then Route B is not operating in this body and the shedding case loses most of its arithmetic force. **`kappa` must be estimated, not assumed.**
3. If, after the `eta` intervention, adopted standards per working-group hour does not rise, `eta` did not move and the intervention failed regardless of what the process documents say.

4. If measured `u` rises after the membership change but `Y` does not, then either `eta` is lower than estimated or the new members are duplicating existing constituencies — run the redundancy audit before concluding either.
5. The shuffled-input control is mandatory: if `Y_{t+1}` is predicted as well from a shuffled `U` series as from the real one, the model is fitting a trend and the entire analysis must be reported as unsupported.

7.3.9 The rule extracted

The standards body of 1990 was not badly run. It was a successful institution carrying the stored order of a world that had changed. Its ceiling had fallen by 49.0 per cent — from 1.6362 to 0.8349 — and its maintenance and operating load had not. Nobody in the building could see it, because `Q` is invisible while it works and the maintenance term has no advocate. What they could see was that everything took longer, that proposals stalled, and that morale was poor. They diagnosed culture. They were looking at arithmetic.

14.7.4 7.4 Results summary

Result	Statement	Status
R1	At any steady state, headroom equals unused variety: `h_inf = eta(ln N − F(u*))`. At `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55`, `C = 0.42`: `Q_inf = 2.840970` and `h_inf = 0.164501`, agreeing to six decimals	DERIVED, checked ARITHMETICALLY
R2	Coordinator to medium: `eta` 0.35 to 0.55 and `delta` 0.25 to 0.12 move the fixed point from `Q_inf = 0.2653` to 3.9281, a factor of 14.8; a turnover event costs 70 per cent of stock against 15 per cent	ILLUSTRATIVE MODEL OUTPUT from stipulated parameters
R3	At per-path cost 0.02 and `eta = 0.5`, headroom peaks at `n = 5` and goes negative between 11 and 12, so a flat body of 24 has `h = −3.931` while four cells of six plus a four-delegate federation gives `+2.957`	ARITHMETIC from two stipulated parameters
R4	A panel at `u = 0.12` has `N_eff = 1.96` and `Q_inf = −0.6510`; protocols raising `u` to 0.71 give `Q_inf = +1.9144` and lift accuracy from 65.8 to 74.3 per cent at unchanged individual accuracy `p = 0.62`	ILLUSTRATIVE MODEL OUTPUT; the accuracy figures depend on the stipulated `rho`

Result	Statement	Status
R5	The standards body: `Q` peaked at 19.669 as the ceiling fell from 1.6362 to 0.8349, giving `h = −0.2227`; doing nothing bought headroom back only by losing 61.9 per cent of stored order over twelve negative-headroom years	ILLUSTRATIVE MODEL OUTPUT from stipulated parameters
R6	At a fixed ceiling `eta ln N = 1.50`, a body with `delta = 0.02` and `Q = 75` spends 100 per cent of its surplus on maintenance before any operating cost	ARITHMETIC
CR	Two levers that do not pay: cutting decay alone by raising trust moves a failing body from `Q_inf = −0.0836` to `−0.2114` while reciprocity alone gives `+0.7394`; and a deliberate 40 per cent sunset without any conversion work ends in 2026 with less stored order (5.507) than doing nothing at all (7.494)	ILLUSTRATIVE MODEL OUTPUT; both are counter-results against the paper's own recommendations

14.7.5 7.5 Six discrepancies in the source material, printed rather than corrected

The worked cases above were re-derived from their stated parameters before being reported. Every trajectory reproduced to the printed precision. Six statements *about* the arithmetic did not, and they are listed here rather than quietly repaired, because a reader checking the corpus will find them.

1. **The free-riding recovery is described as 88 per cent and is 68.3 per cent.** Monitoring moves `Q_inf` from 1.7198 to 3.2281. That is an increase of 87.7 per cent *on the free-ridden level*, and a recovery of `(3.2281−1.7198)/(3.9281−1.7198) = 68.3` per cent *of what free riding had taken*. The source reports the first number under the second description. Section 4.8 and Section 7.1.6 state both quantities separately.
2. **The redundancy audit is described as removing "a quarter" of the categorical variety and removes a third.** `N_eff = 5.34` against `N = 8` is a 33.3 per cent reduction in effective count; the reduction in *surplus* is 19.4 per cent. Neither is a quarter. Section 7.1.2 states both.
3. **Regime A's recovery from the turnover event is given as approximately six months and is 6.9 months.** From `Q = 0.072` under `Q_{t+1} = 0.75Q + 0.066329`, the pre-shock level 0.239 is regained at `t = ln(0.026316/0.193316)/ln(0.75) = 6.93` periods.
4. **Regime B's recovery is given as under one month and is 1.7 months.** From `Q = 2.138` under `Q_{t+1} = 0.88Q + 0.471374`, the stock is 2.353 after one period and 2.542 after two, so the pre-shock 2.515 is regained between the first and second period. The qualitative contrast survives and is in fact a factor of four rather than a factor of six.
5. **A rounding inconsistency at the fourth decimal in the panel's identity check.** The source prints `h at Q_inf = +0.1342` against `eta ln(N/N_eff) = +0.1341`, which reads as a 0.0001

disagreement in an identity that holds exactly. Carried without intermediate rounding both sides are 0.134148. The identity is exact; the discrepancy is an artefact of rounding `S` to four decimals in one expression and not the other.

6. **A parameter the source never supplies.** The tool library's O8 score is justified by two craft circles exceeding the headroom-positive band computed with "its own per-path cost", and that per-path cost is never given anywhere in the case. The band quoted is the reference band from the stipulated 0.02, which S4.4 explicitly forbids adopting. Section 7.1.7 records the gap; the O8 score of 1 is therefore not recomputable from the case as stated.

Two further points of arithmetic are correct and are noted because they look wrong. The headroom at 1990 under the Era 2 parameters is `−0.222735`, printed in the source as `−0.2226`; the fourth decimal differs because `0.8349` and `0.7626` are themselves rounded, and the unrounded computation gives `−0.2227`, which is what is printed above. And the identity check in Path C returns `h_inf = +0.3065` against a 2026 headroom of `+0.3695`; these differ because the trajectory has not yet converged at 2026, the time constant being 26.7 years.

14.8 8 Discussion

14.8.1 8.1 What follows

Three design problems are one problem. The tool library, the review panel and the standards body differ in scale by three orders of magnitude and in subject matter entirely, and the same five parameters describe all three. What differs is which parameter is binding. The library's fault was `delta`, held high by storing state in a person. The panel's fault was `u`, held low by an order of operations that guaranteed a cascade. The standards body's fault was `Q` itself, inherited under a ceiling that had fallen by 49 per cent. **Naming the binding parameter is the whole of the diagnosis, and the gauge names it before any money is spent.**

The identity turns headroom into a difference measure. `h_inf = eta ln(N/N_eff)` says that a settled system's spare capacity is exactly the redundancy it is carrying. That has an uncomfortable corollary for anyone reporting a healthy headroom figure: **at equilibrium, high headroom is not a sign of health but a measure of unused difference.** The panel of Section 7.2 is the instance — headroom `+0.2448`, and a negative steady state, because the budget was there and nothing was arriving to spend it on.

Repetition cannot fix a fixed point. The steady state contains no time index, so no amount of doing the same thing better moves it; only a parameter change does. That result is stated sharply elsewhere in this corpus — refinement cannot move the fixed point, since `Q_inf = (eta F − c)/delta` contains no `t`, and the refinement ladder is silent in pitch because the relative frequency depends only on `u` and `N` [Curzi, 2026]. Every "try harder" response to a negative headroom reading is an attempt to move a fixed point by iteration, and it fails for a reason that can be written in one line.

Cost can be moved between participants without changing the total drive. The nesting argument of Section 4.6 splits a body's coordination cost across cells, and the natural objection is that the cost has only been relocated. The relevant invariance is exact: the sum of drives `b_i = eta_i F − c_i` is invariant under any transfer of cost among participants, verified in a different domain at `+0.643688229683` and `+1.268940530229` with residual `0.000e+00` [Curzi, 2026]. **Nesting does not work by moving cost; it works by removing paths**, which is why the arithmetic of Section 4.6 turns on `n(n−1)/2` and not on who pays.

The negative fixed point has a frequency reading. A body whose numerator is negative has a `Q_inf < 0`, and the corresponding statement in the frequency formulation of this corpus is a trichotomy: contact above, at, or below a minimum sustainable frequency `f_min = k e^(2c/eta)` corresponds exactly to `Q_inf` positive, zero or negative, with `k = 0.483425732988414` a **defined** constant [Curzi, 2026]. The two readings are the same inequality in different coordinates, and the second is more useful where contact is episodic rather than continuous

— a working group that meets twice a year is a frequency problem before it is a conversion problem.

14.8.2 8.2 What does not follow

Nothing here shows that any organisation obeys the storage law. All three worked systems are constructed. The one preregistered confirmatory test of the law reported in this corpus did not meet its own declared margin [Curzi, 2026i], and that result — not the arithmetic above — is the current evidential status of every applied claim in this paper.

Centrelessness is not shown to be better. It is shown to have a different parameter profile. Section 4.9 gives the case where the same topology produces outcomes nobody would design, and Section 4.11 gives four things a shared medium does not do. **A structure can answer real problems and still add nothing to the quantity the framework cares about**: the corpus's own worked case of a governance vehicle that answers ownership recording and succession, gives no protection against arbitrary state action, and **adds nothing to the effective count** is the clearest available warning [Curzi, 2026], and it bounds what Section 4 may claim for any structural move.

Raising the effective count is not the same as raising a related exposure measure, and the two can move in opposite directions. A worked case elsewhere in this corpus reports a move that lowered perimeter exposure to 13.6 per cent while *lowering* the effective bloc count from 2.94 to 2.34, and reports a printed computation of its own found wrong and corrected rather than silently amended [Curzi, 2026]. Another reports three legs of a diversification argument each failing against itself: an operating leg that lowered the effective count it was proposed to raise, a leg that fails outright once its maintenance cost reaches 0.38, and a funding gain cut from 3.175 to 2.410 effective blocs by a correlation adjustment applied against the argument [Curzi, 2026]. **Both bound this paper directly.** The second bounds Section 6.5: a maintenance cost of 0.38 is enough to destroy a positive case, and the maintenance table there is not a licence to assume the term is small. The third bounds Section 5.2: a correlation adjustment is exactly what Model C1 performs, and the honest expectation is that it *reduces* the count, not that it leaves it intact.

Zero decay is not the safe end of the range. Section 4.1 gives the entomological form and Section 6.7 the institutional one, but the underlying result belongs to the contraction: a map with gain exactly one is an isometry that orbits without arriving, and a map with gain at or above one is an amplifier whose corrections, sized to delayed feedback, arrive as new errors [Curzi, 2026]. The standards body's decision to drive `delta` from 0.030 to 0.015 — reasonable, and taken as a service to implementers — is a step in that direction, and Section 7.3.4 prices it: the same `delta` that slowed the loss also slowed the recovery, stretching twelve negative years out of what a larger `delta` would have compressed.

The independence protocols do not manufacture difference. They extract the signal present. FM-5.6 states the limit: where the signals are duplicates there is nothing to extract, and the composition change in Section 7.2.5 is doing work the protocols cannot do. Reported gains from elicitation in a homogeneous body should be read as measurement artefacts until composition is audited.

14.8.3 8.3 Relation to the surrounding literature

The commons literature supplies what this paper's arithmetic cannot: evidence that the arrangements exist. Ostrom [1990] is a comparative field study, and its principles are propositions about which features co-occur with endurance, audited across ninety-one subsequent studies with broad but uneven support [Cox et al., 2010]. **This paper adds a price and not a proof:** it computes what O8 is worth in headroom units under stated parameters, and computes the monitoring trade of O4 and O5. Where Ostrom's list says nesting helps at scale, Section 4.6 says at what size and by how much, conditional on a per-path cost that any installation must measure for itself.

The aggregation literature is where the framework's u finds its sharpest external counterpart. The independence clause of the jury theorem, the cascade result [Bikhchandani et al., 1992, Banerjee, 1992], the measured collapse of crowd wisdom under social influence [Lorenz et al., 2011], and the experimental demonstration that early visible choices lock in [Salganik et al., 2006] all say the same thing about the same quantity. The diversity-and-ability result [Hong and Page, 2004] and its critique [Thompson, 2014] are used here only for the mechanism, and the subsequent exchange [Kuehn, 2017, Singer, 2019, Grim et al., 2019] is cited so that a reader is not left with the impression that the formal result is settled. The construct warning [Harrison and Klein, 2007] is the one the corpus most needs and least often pays.

The institutional half draws on three separate literatures that do not usually meet. The infrastructure result [Star and Ruhleder, 1996] explains why the maintenance term has no advocate. The measurement-corruption results [Goodhart, 1975, Campbell, 1979] explain why any proxy for Q will be gamed and why a difference gauge resists it better than a total. And the organisational-learning results [March, 1991, Levinthal and March, 1993, Cyert and March, 1963] supply the mechanism by which a successful body loses the variance that made it capable — which is postulate I1 arriving from the other direction, in a literature that measured it.

Two places where the surrounding literature cuts against the corpus are stated rather than buried. Putnam [2007] reports that diversity in the short run reduces trust and civic participation — a result from a scholar who did not want it, and the largest single piece of contrary evidence for the corpus's preference for raising u; the rebuttal [Abascal and Baldassarri, 2015] qualifies it without dissolving it. And the empirical work on surface-level diversity harming short-run performance [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007] is not answered by pointing out that u is a different construct, unless u is actually measured rather than inferred — which is why Section 5.9 excludes the inference by rule and why S5.7 requires the measurement annually.

14.9 9 Verification

The results of this paper compound from seven postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped**; what remains is what the chain actually consumes.

14.9.1 9.1 Dimensional audit

The equations must balance before anything else about them is worth checking. `[Q]` denotes the dimension of stored order and `[T]` the dimension of time; the period is the unit of `[T]` and every rate below is *per period*, which is why no explicit `[T^-1]` appears once the recursion is written in discrete steps.

Symbol	Dimension	Unit	Status
`Q_t`	`[Q]`	proxy units (tools in order, rubric points, dependency-weighted standards)	**measured**, in whatever unit the declared order proxy counts
`U_t`, `u`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2` with `x`, `y` unit vectors
`N`	`[1]`	a count	**measured** as a count of genuinely distinct categories

Symbol	Dimension	Unit	Status
`N_eff`	`[1]`	a count	**derived** from `N` and `u`; **not a Hill number**
`S_t = F(U_t)`	`[1]`	nats	**derived** dimensionless: a logarithm of an effective count
`eta`	`[Q]` per nat per step	proxy units per nat per period	**measured**; *not* dimensionless in this framework
`delta`	`[1]`	per period	**measured** dimensionless fraction per step
`C_t`, `c_0`	`[Q]` per step	proxy units per period	**measured**
`kappa`	`[1]` per step	per period	**derived** from a regression of `C_t` on `Q_t`; dimensionless per step, since `kappa Q` must carry `[Q]` per step
`h_t`	`[Q]` per step	proxy units per period	**derived**
`Q_inf`, `Q*`	`[Q]`	proxy units	**derived**: `[Q]`/step divided by `[1]`/step returns `[Q]`
`tau`	`[T]`	periods	**derived**: `1/delta` or `1/(delta+kappa)`
`n`	`[1]`	a headcount	**measured**
`c_path`	`[Q]` per step per path	proxy units per period per communication path	**assumed**; the source stipulates 0.02 and never measures it
`phi`	`[1]`	a fraction	**measured** free-riding fraction
`lambda`	`[Q]` per step	proxy units per period per unit of `phi`	**assumed**
`p`, `rho`	`[1]`	probabilities	`p` **measured** from outcomes; `rho` **assumed**

Do the equations balance? The storage law balances if and only if every term on the right carries `[Q]`. The retention term does, since `delta` is dimensionless. The cost term does by construction. The drive term does only if `eta S_t` carries `[Q]`, and since `S_t` is a dimensionless count in nats, **`eta` must carry `[Q]` per nat per step**; it is therefore not dimensionless, and every `eta` quoted in this paper as a bare number — 0.35, 0.55, 0.45, 0.62, 0.38, 0.60 — is quoted with its unit suppressed. **That is a silence in the source and it is recorded here rather than quietly filled**: the tool library's `eta = 0.55` should read 0.55 proxy units per nat per month.

The headroom gauge balances because `ln N` is dimensionless, so `eta ln N` carries `[Q]` per step and is commensurable with `delta Q_t` and with `C_t`. **A headroom calculation in which `C` is denominated in hours or currency while `Q` is denominated in rules is dimensionally malformed however arithmetically tidy it looks**, which is the denomination requirement the survey protocol imposes [Curzi, 2026i]. The nesting expression `h(n) = eta ln n − c_path n(n−1)/2` balances only if `c_path` carries `[Q]` per step per path, which is what the audit assigns it; the source states 0.02 with no unit at all.

The cost-in-stock model `C_t = c_0 + kappa Q_t` balances only if `kappa` is dimensionless per step. It follows that `delta + kappa` is a per-step dimensionless rate and that `tau = 1/(delta + kappa)` carries `[T]` — which is why the two can be added at all, and the addition is not a convenience but a dimensional requirement that the model happens to meet.

Where the framework has no operational unit, it is said here. `Q` is stored order, and stored order has no natural unit: it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. Comfort itself, the underlying construct of the corpus, has **no operational unit at all** and is treated as a dimensionless magnitude by stipulation rather than by measurement.

A symbol collision, disclosed. `phi` denotes the free-riding fraction throughout Sections 4.8 and 7.1.6 and has no relation to the golden ratio, which appears only in the defined constant `k = (9/8)^2 / varphi^2` in Section 8.1 and is written `varphi` there for that reason.

14.9.2 9.2 The postulates

P1 — The recurrence is linear and first order. `Q_{t+1} = a Q_t + x_t` with `a = 1 − delta` and `x_t = eta S_t − C_t` not depending on `Q`. *Status:* **DEFINITION** — the model form adopted by the framework. It carries no empirical weight on its own, and Section 10 records that its application to any real system is a postulate.

P2 — `0 < delta <= 1` implies `0 <= a < 1`. *Status:* **ARITHMETIC.** Subtracting a number in `(0,1]` from 1 gives a number in `[0,1)`.

P3 — A contraction on a complete metric space has exactly one fixed point, reached from any start. *Status:* **CITED** — [Banach, 1922], with the elementary difference-equation route in [Elaydi, 2005].

P4 — Surplus per period is bounded: `0 <= S_t <= ln N`, with `S = ln N` if and only if the states are orthogonal. *Status:* **CITED** — the range and extremality results of the surplus functional [Curzi, 2026], following from `F(u) = ln(1+(N−1)u)` on `u` in `[0,1]`.

P5 — The number of distinct communication paths in a body of `n` participants is `n(n−1)/2`. *Status:* **ARITHMETIC**, and **CITED** for the claim that this count is what organisational coordination cost actually tracks [Brooks, 1975, Conway, 1968].

P6 — Under a shared-signal mixture with weight `rho`, majority accuracy is `rho p + (1−rho) P_ind(n,p)`; and under sequential observation of actions rather than signals, the probability that the cascade which forms is correct is `p(1+p)/[2(p^2−p+1)]`. *Status:* the mixture is a **MODELLING CHOICE** made in this paper, transparent and crude; the cascade expression is **CITED** [Bikhchandani et al., 1992] and its arithmetic is **ARITHMETIC**, checkable from the three branch probabilities, which sum to 1 identically.

P7 — Operating cost may be affine in the stock: `C_t = c_0 + kappa Q_t` with `kappa >= 0`. *Status:* **POSTULATED** — this is an assumption about how institutions charge overhead. It has no external support in this bibliography, it is used at exactly two places (R5 and the shedding return `dh/dQ`), and the falsification rule of Section 7.3.8 requires `kappa` to be estimated rather than assumed. **Every result not involving shedding or Path A/B/C holds with `kappa = 0`.**

14.9.3 9.3 The compounding chain

```
P1 + P2        -> L1   T(Q) = aQ + x has |T(Q)−T(Q')| = a|Q−Q'| with a < 1,
                       so T is a contraction.                          ARITHMETIC

L1 + P3        -> L2   T has exactly one fixed point
                       Q_inf = x/(1−a) = (eta S − C)/delta.            CITED (banach1922operations)

L2             -> R1   at the fixed point delta Q + C = eta S, so
                       h_inf = eta ln N − eta S = eta ln(N/N_eff)
                         = eta (ln N − F(u*)).                         ARITHMETIC
```

```
R1 + P4        -> R1a  h_inf >= 0 always, with equality iff u* = 1;
                       therefore h < 0 is never a steady state.        ARITHMETIC

R1             -> R1b  delta, C and Q are absent from h_inf, so a
                       linear system with constant parameters settles
                       at positive constant headroom and does not
                       ossify.                                         ARITHMETIC

P5 + P4        -> R3   h(n) = eta ln n - c_path n(n-1)/2 has
                       dh/dn = eta/n - c_path(n - 1/2), one interior
                       maximum and one positive zero; at eta = 0.5,
                       c_path = 0.02 the maximum is n = 5 and the zero
                       lies in (11,12).                                ARITHMETIC

L2             -> R6   the maintenance share is delta Q /(eta ln N),
                       which reaches 1 at Q = eta ln N / delta; at
                       eta ln N = 1.50 and delta = 0.02 that is
                       Q = 75.                                         ARITHMETIC

L2 + P7        -> R5a  with C affine in Q the map is
                       Q_{t+1} = (1 - delta - kappa) Q_t + eta S - c_0,
                       so Q* = (eta ln N - c_0)/(delta + kappa) is the
                       zero-headroom stock and tau = 1/(delta+kappa).  ARITHMETIC

R5a + P7       -> R5b  dh/dQ = -(delta + kappa): every unit shed
                       returns delta + kappa units of headroom
                       per period, permanently.                        ARITHMETIC

L2             -> CR1  for eta F(u*) < c*, dQ_inf/d(delta) > 0, so
                       lowering delta alone lowers Q_inf.              ARITHMETIC

P6             -> R4a  P(correct cascade) tends to a constant in n,
                       and at p = 0.62 equals 0.6570, which is below
                       P_ind(9, 0.62) = 0.7738.                        CITED (bikhchandani1992theory)

R4a + P6       -> R4b  a mixture at rho = 0.75 returns 0.6584 and at
                       rho = 0.20 returns 0.7430, so accuracy moves
                       8.5 points with p held at 0.62.                 ARITHMETIC on a MODELLING CHOICE
```

Every line is checkable from its own inputs. **R1, R1a, R1b, R3, R5a, R5b, R6 and CR1 are arithmetic consequences of one definition (P1), two arithmetic facts (P2, P5), one cited theorem (P3) and one cited range result (P4).** Only R5a and R5b consume P7, the one postulate with no external support, and the falsification rule of Section 7.3.8 puts it at risk. R4a is cited; R4b consumes a modelling choice and is labelled as such wherever it is quoted.

What this chain does not establish. It does not establish that any organisation obeys P1. That is the modelling postulate of Section 3.5, it is not verified here, and the one preregistered confirmatory test of it reported in this corpus did not meet its own declared margin [Curzi, 2026i]. **A chain whose steps are ARITHMETIC and CITED delivers the mathematics with certainty and delivers nothing whatever about institutions.**

One further line, separated because it is a stronger claim than the one before it. The constant `k = (9/8)^2 / varphi^2` is **DEFINED**: `(9/8)^2 = 1.265625` exactly, `varphi^2 = varphi + 1 = 2.618033988749895`, and the quotient is `k = 0.483425732988414` — three checks a reader can perform in a minute, and the fifteen figures are legitimate because the quantity is exact rather than measured. **Attaching the unit Hz to k, as the minimum-sustainable-frequency result does**

[Curzi, 2026], is a separate and much stronger claim, and its status is POSTULATED. Nothing in the definition of `k` supplies a time scale; the unit is asserted. And because `varphi` appears at all, the sceptical literature belongs beside it: claims of golden-ratio structure in natural and designed systems are frequently unsupported on inspection [Markowsky, 1992], and this paper uses `k` only as a defined reference constant in a cross-reference, never as evidence.

14.9.4 9.4 The identity, checked on the smallest case

The single most useful check a reviewer can perform is the identity of Section 3.2 on a case small enough to do by hand. Take `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55`, `C = 0.42`.

```
N_eff = 1 + 5(0.55)      = 3.75
S     = ln(3.75)         = 1.321755839982320
eta S = 0.35 x 1.321755839982320 = 0.462614543993812
Q_inf = (0.462614543993812 − 0.42) / 0.015 = 2.840969599587455
```

By the gauge, directly:

```
h_inf = 0.35 x ln 6 − 0.015 x 2.840969599587455 − 0.42
      = 0.35 x 1.791759469228055 − 0.042614543993812 − 0.42
      = 0.627115814229819 − 0.462614543993812
      = 0.164501270236007
```

By the identity:

```
h_inf = eta (ln N − S) = 0.35 x (1.791759469228055 − 1.321755839982320)
      = 0.35 x 0.470003629245735
      = 0.164501270236007
```

The two agree to fifteen figures, which is machine precision, and they agree because the second is an algebraic rearrangement of the first and not an approximation to it. Rounded to the six decimals quoted in R1: `Q_inf = 2.840970` and `h_inf = 0.164501`. **ARITHMETIC.**

The equilibrium can be confirmed independently by summing the series rather than solving for the fixed point. With `x = 0.042614543993812` and `a = 0.985`, the running total `x(1−a^t)/(1−a)` gives 0.042615 at `t = 1`, 0.084590 at `t = 2`, 0.398502 at `t = 10`, 1.506594 at `t = 50`, 2.214226 at `t = 100`, 2.702704 at `t = 200` and 2.840954 at `t = 800`, converging on `x/delta = 2.840970`. **The equilibrium is not an assertion; it is the sum of a geometric series, and the sum can be checked by hand.**

14.9.5 9.5 Four secondary checks

The nesting crossing. `h(n) = 0.5 ln n − 0.01 n(n−1)`. At `n = 11`, `0.5 x 2.397895 − 0.01 x 110 = 1.198948 − 1.100 = +0.098948`; at `n = 12`, `0.5 x 2.484907 − 0.01 x 132 = 1.242453 − 1.320 = −0.077547`. The crossing is therefore in `(11, 12)`; the continuous extension has its root at `n = 11.577`, and linear interpolation between the two integer values gives 11.561, which is the accuracy that interpolation is worth here. And `h(5) = 0.804719 − 0.200 = +0.604719` exceeds both `h(4) = +0.573147` and `h(6) = +0.595880`, so the maximum is at `n = 5` among integers. **ARITHMETIC.**

The cascade branch probabilities sum to one. `p(1+p)/2 + (1−p)(2−p)/2 + p(1−p) = (p + p^2 + 2 − 3p + p^2)/2 + p − p^2 = (p^2 − p + 1) + p − p^2 = 1`, identically in `p`. This is the check that establishes the denominator of the correct-cascade expression, and it can be done in two lines. **ARITHMETIC.**

Twelve negative-headroom years. Path A's map is `Q_{t+1} = 0.9625 Q_t + 0.126717` with fixed point 3.3791, so `Q_t = 3.3791 + 16.2899 x 0.9625^t` from `Q_0 = 19.669`. Setting `Q_t = Q* =`

13.7307 gives 0.9625^t = 0.63546 and t = 11.87. **The stock is above the zero-headroom line for the whole of years 0 to 11 and crosses during year 12**, so the count of completed years at h <= 0 is exactly twelve, 1990 to 2001 inclusive, and headroom is positive from 2002. **ARITHMETIC.**

The shedding return. With h = eta ln N − delta Q − c_0 − kappa Q, dh/dQ = −(delta + kappa) = −(0.015 + 0.0225) = −0.0375, so shedding 8 units returns 0.30 per period, which against the ceiling 0.8349 is 0.30/0.8349 = 35.9 per cent of the budget. **ARITHMETIC**, conditional on P7.

14.9.6 9.6 Limits, asymptotics, and the model's valid domain

delta −> 0 with kappa = 0. tau −> infinity, the fixed point diverges, and at exactly delta = 0 it does not exist: the map is an isometry, every point is fixed, and the uniform bound degrades to Q_0 + t eta ln N, linear in t. **The limit is singular and the two statements are different** — divergence and non-existence are often conflated. This value is outside the model's valid domain and is the failure mode FM-4.9 names.

delta −> 0 with kappa > 0. The fixed point survives, because the effective rate is delta + kappa > 0. **This is a substantive difference the affine-cost model introduces**: an institution with a cost proportional to its stock cannot lose its attractor by driving decay to zero, which is a mathematically reassuring result and an operationally miserable one, since the attractor it retains is (eta S − c_0)/kappa.

delta + kappa −> 1. The system has no memory: Q_{t+1} −> eta S − c_0, an input-output map with no state. **At that boundary the storage law is not a storage law**, and any claim about accumulation is vacuous there.

eta −> 0. The drive vanishes and Q_inf = −C/delta <= 0. **Zero conversion decouples the input from the stock entirely**, so no interaction geometry of any quality changes the outcome. This is Route A taken to its limit and it is why S4.7 exists.

u −> 0. N_eff −> 1, S −> 0, and h_inf −> eta ln N, its maximum. **The maximally redundant body has the maximum equilibrium headroom and the minimum equilibrium stock**, which is exactly the panel of Section 7.2 and is the sharpest single statement the identity makes. **u −> 1.** N_eff −> N, S −> ln N, h_inf −> 0: the ceiling is attained and no further gain is available from geometry.

N −> 1. ln N = 0 and F(u) = 0 for every u. **A single category has zero available surplus, not a small amount**, so Q_inf = −C/delta <= 0 at any positive cost. This is the boundary that makes the redundancy audit consequential.

N −> infinity. ln N −> infinity, so the ceiling grows without bound but only logarithmically, with marginal gain ln N − ln(N−1) ~ 1/N. Against this, coordination cost grows as n(n−1)/2. **The two curves cross, and beyond the crossing additional categories cost more than the ceiling they buy** — which is Section 4.6, and is the reason N is the most expensive and least rewarding of the four levers.

rho −> 1. Model C1 returns P = p exactly: the body performs as one member, which is u −> 0 in the other formalism. **n −> infinity under a cascade.** Accuracy does not tend to 1 but to p(1+p)/[2(p^2−p+1)], a constant less than the nine-voter independent value for every p in (0.5, 1). **Aggregation without independence has a ceiling, and the ceiling is independent of n.**

Stated domain. The results of this paper are valid for delta + kappa in (0, 0.5], eta > 0, N >= 2, u in [0,1], p in (0.5, 1) for the aggregation results, rho in [0,1], and C_t <= (1−delta)Q_t + eta S_t each period. Outside that domain the equations still have solutions and those solutions should not be interpreted as statements about a stock.

14.9.7 9.7 Invariance, and how far the scale claim has been tested

The claim that the same equations describe a 48-household library, a nine-person panel and a sixty-four-year standards body is an **invariance of form under a change of unit and a change of system size**, and it is worth stating as one. Let Q be rescaled by a positive constant c. The law

is invariant provided `eta`, `C` and `lambda` rescale with it — `eta' = c eta`, `C' = cC` — while `delta`, `kappa`, `N`, `u`, `p` and `rho` are unchanged, since `delta` and `kappa` are dimensionless per-step rates and `S` is a dimensionless count. **`delta`, `kappa`, `u`, `N`, `p` and `rho` are therefore the unit-free quantities of this paper, and `Q`, `eta`, `C`, `c_path` and `lambda` are the unit-carrying ones.** Two systems may be compared directly on the first group and not on the second unless they share a proxy.

The identity `h_inf = eta ln(N/N_eff)` is **not** scale-invariant in this sense: it carries `[Q]` per step through `eta`, so a headroom figure of `+0.164501` means nothing without the proxy that denominates it. **The dimensionless part of the identity is `ln(N/N_eff)`, and that is the quantity two systems can actually be compared on.** This is worth stating because headroom figures are quoted across the corpus as though they were commensurable and they are not.

What would break the invariance: a `delta` that varies with `Q`, which would make the transformation non-linear; an `eta` that saturates at large `S`; a `c_path` that is not constant across paths, which is the realistic case and which the nesting result assumes away; or a proxy whose counting unit is not extensive.

How many scales it has been tested at. Within this paper: three, and all three are constructed rather than observed. Elsewhere in this corpus the same five-parameter survey has been applied from a single desk to a 22-household block, reproducing each system's observed decline with residuals under 1.4 per cent of the ceiling term [Curzi, 2026k]. **That is a small number of systems, one corpus, one author, and no independent replication.** The invariance is a claim about form that has been exercised, not an invariance that has been established.

14.9.8 9.8 Analogy discipline, and the precision of the numbers

Stigmergy is used as an existence proof of a mechanism, not as a derivation. The termite mound and the ant trail establish that coordination through a modified shared medium occurs and is sufficient to build a structure. Nothing about insect physiology, pheromone chemistry or colony genetics is claimed to hold of a tool library, and no biological result's authority transfers. **This is category three in the analogy taxonomy — a suggestive correspondence used as motivation and never as evidence** — with one exception: the identification of trail evaporation with `delta` is category two, a shared mathematical form, because both are first-order exponential decay of a stored signal, and that identity is exact.

The topological fragility argument is category three and is the weakest thing in the paper. Section 4.10 states what it does not establish. No degree distribution was measured; the scale-free label is borrowed; and no power-law or heavy-tail claim is made anywhere, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply — but neither does the authority of the result being borrowed from.

The storage law itself is category two. It is the same difference equation that governs a first-order low-pass section, and every theorem about first-order discrete systems applies [Curzi, 2026a]. Nothing about charge, capacitance or energy is claimed to hold of an institution.

The entropy invoked near `ln N` is Shannon entropy, a dimensionless information measure in nats [Shannon, 1948], not thermodynamic entropy, which carries `[energy][temperature]^-1`. They are different objects and the framework identifies surplus with neither.

Precision. The numbers in this paper are of four kinds and are quoted accordingly.

- *Defined, and exact.* `k = 0.483425732988414`, `(9/8)^2 = 1.265625`, `varphi^2 = 2.618033988749895`. Fifteen figures are legitimate because these are exact ratios of exact quantities. **They are labelled defined wherever they appear at that precision.**
- *Derived from defined inputs.* `ln 8 = 2.0794`, `ln 9 = 2.1972`, `ln 14 = 2.6391`, every binomial sum in the Condorcet tables, the cascade probabilities, `h_inf = 0.164501`. These are exact to the precision printed and may be recomputed to any further precision.
- *Illustrative model output.* Every trajectory entry, every `Q_inf`, every headroom figure in Section 7. These are the output of stipulated parameters and carry **no measurement uncertainty because there was no measurement.** Four decimal places there record the arithmetic and not the confidence.

- *Measured or fitted.* **None appear in this paper**, because nothing in it was measured. Any application of this framework to real data must report fitted parameters with intervals, and Section 10 records that the corpus's one such report gives an interval on the retention coefficient and none on several other quantities.

14.10 10 Limitations

The three worked systems are constructed, not observed. No dataset was collected for this paper. Every number in Section 7 is the output of the stated parameters under the stated model, carried through so a reader can re-derive it. They demonstrate that the procedure runs and that it reports its own failures; **they are not evidence that any organisation behaves this way and must not be cited as such.**

Which parameters were chosen rather than measured. In all three systems the whole parameter vector is stipulated: `(N, u, eta, delta, C)` in every case, plus `c_path = 0.02` and `eta = 0.5` in the nesting result, `lambda = 0.9` and `phi = 0.35` and the monitoring cost 0.08 in the free-riding result, `kappa = 0.0225` in the institutional case, and `rho = 0.75` before and 0.20 after in the accuracy result. **The accuracy result is the most exposed of these**: the coincidence in Section 7.2.7 between the panel's 65.84 per cent baseline and the unbounded-cascade value of 65.70 per cent is produced by the choice `rho = 0.75`, and a different choice breaks it. It is a corroboration of internal consistency and not a test of anything.

The correspondence between the equations and any social system is a postulate, and its one preregistered confirmatory test did not meet its declared margin. Curzi [2026i] specifies the protocol and applies it; the fit landed inside the admissible box and its parameters agreed with independent measurement, but it beat a matched autoregression by 2.8 per cent on held-out error against a preregistered requirement of 10 per cent, so the verdict was parameters corroborated, predictive advantage not demonstrated. That is the current evidential status of every applied claim in this paper.

The audit cannot see repackaging, and this paper leans on the very justification the audit cannot enforce. The shuffled-input control passed 98.35 per cent of the time against a third variable driving both interaction and order, while detecting only 48.17 per cent in the clean case [Curzi, 2026i]. Sections 7.1.1, 7.2.1 and 7.3.1 each argue that `Y` is not a repackaging of `U`, on the observables and in advance, because that argument cannot be recovered statistically afterwards. **In a real installation those arguments would be the weakest joint in the whole chain**, and no amount of subsequent testing repairs them.

The reflection problem, and why it outranks everything else here. Section 3.4 states it in full. Applied to a group whose members both influence and constitute the aggregate, the specification is reflexive, and Manski [1993] proves the endogenous social effect is not identified from observational data; Shalizi and Thomas [2011] show the same confounding for network data. **No fit recovers the parameter.** This paper adopts no remedy, so every applied reading — that the medium raised `eta`, that the protocols raised `u`, that `rho` fell — is a **modelling position rather than an identified empirical result**. The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001]. Reflexive fixed points demonstrably occur [MacKenzie and Millo, 2003, Merton, 1948]; that they occur does not make this framework's parameters recoverable.

The Lucas critique applied to this framework's own parameters. Section 6.9 asserts that a measure changes the system measured by it and prescribes rotating the proxy in response; the paper then treats `delta`, `eta`, `N` and `kappa` as constants over an estimation window. **Both cannot be true without qualification** [Lucas, 1976]. The position taken is the narrow one: the parameters are treated as stable only over a declared window and only while `Q` is not itself a reported target, which is exactly why S6.1 prohibits reporting `Q` alone. Where `Q` is reported upward, the framework's own reflexivity applies to it and the constancy assumption fails. That is a real restriction on where the model may be used.

`N_eff = 1 + (N−1)u` is not a Hill number and no external literature contains it. `1/HHI` is the

Hill number of order two and `exp(H)` the Hill number of order one, and both are fully grounded [Hill, 1973, Jost, 2006]; `1 + (N−1)u` is a linear interpolation between 1 and `N` and is this framework's own construction, adopted by design axiom S3 [Curzi, 2026]. **A reviewer reaching for the Hill-number literature as support will find that it does not apply.** Every effective count in this paper is the affine one, and the repair is to derive its properties in the framework's own terms rather than to borrow.

`u` has not been shown to be a quantity, and this is the strongest objection to the framework. The whole of Section 5 treats non-parallelism as a measurable magnitude on which differences, ratios and logarithms may be taken. Michell [1997] argues that psychology routinely fails to test whether its attributes are quantitative at all before measuring them, and that the failure is systematic rather than incidental [Michell, 1999]. **The remedy is conjoint measurement — the formal test for additive quantitative structure [Luce and Tukey, 1964, Krantz et al., 1971] — or a Rasch demonstration [Rasch, 1960], and neither has been run for `u` anywhere in this corpus.** Until one is, the ratio-scale treatment of `u` throughout Sections 5 and 7 is a stipulation and not a licensed operation, and the paper concedes it rather than defending it. Relatedly, if `u` is read as a similarity measure over people it cannot be assumed to behave metrically [Tversky, 1977].

The construct question is unresolved. `u` is declared a variety construct in Section 5.1, but three incompatible constructs travel under the word diversity [Harrison and Klein, 2007] and the declaration is a definition rather than a validation. The literature reporting harm from surface-level diversity [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007] and the finding that diversity reduces trust in the short run [Putnam, 2007] are not dismissed by the declaration; they are set aside pending the measurement that S5.7 requires and that no worked case here performs.

The functional form is underdetermined. Section 3.1 gives the alternatives — a sub-linear power law [Latané, 1981] and `n log n` [Briscoe et al., 2006] — and records that nothing assembled here discriminates between them. **The logarithm is chosen for its axiomatic characterisation, not established by measurement**, and Peters and Gell-Mann [2016] is the strongest available warrant precisely because it needs no perceptual claim.

Postulate P7 is the one load-bearing assumption with no external support. The affine cost model `C_t = c_0 + kappa Q_t` produces R5, the shedding return, and the whole of the institutional case. It is plausible and it is asserted. If `kappa = 0` the standards body's Path A and Path B collapse toward each other and the shedding case loses most of its force, which is why the falsification rule of Section 7.3.8 requires `kappa` to be estimated. **A significant positive `kappa` has not been demonstrated anywhere in this corpus.**

Postulate M3 borrows an authority it has not earned. No degree distribution was measured; the robustness asymmetry is imported [Albert et al., 2000] into a setting where the contrary argument [Doyle et al., 2005] applies at least as well. The engineering advice that follows from M3 — deposit state in the medium, run a hub census — survives without it, because the bus-count argument needs no network model at all. **The topological framing is decoration on a sound recommendation and is labelled as such.**

Five works this paper needs and cannot cite. Grassé's 1959 paper on stigmergy, Schelling's *The Strategy of Conflict* (1960) on focal points, Condorcet's 1785 essay on the jury theorem, Gambetta's 1993 study of Sicily, and Weiser's 1991 formulation of disappearing technology are each named in the text and **have no key in this corpus's bibliography.** Rather than attach a citation that does not support the sentence, each is named in prose and the gap is recorded here. The neighbouring works that *are* cited — [Schelling, 1971, 1978, Gambetta, 1988, Galton, 1907, Surowiecki, 2004] — are cited only for what they actually say, which is not the same claim in any of the five cases.

The Monte Carlo verification was not re-run. Section 5.4 reports a simulation of the cascade process at `p = 0.60` over 400,000 trials returning 0.6323 against the analytic 0.6316. The analytic value was recomputed for this paper and is exact; **the simulation is reported as the source states it and was not reproduced.** The agreement is within one standard error, which is consistent but is not an independent check.

No model was fitted, so no model comparison applies — and the corpus's one fit reports none. Nothing in this paper is estimated, so no information criterion, no out-of-sample comparison and no matched null is owed by it. The corpus's one applied fit reports held-out error against baselines and **no AIC or BIC** [Curzi, 2026i], so the parameter count was never paid for. Where the framework is applied to real data, all of it is owed [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013].

No independent replication of anything. Every system in this paper and every system in the corpus's applied papers was constructed or surveyed by one author. The reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005], and Meehl [1967] observes that directional predictions are nearly costless in the social sciences. This framework does make point predictions with constants, which is the right answer to that objection, but only Curzi [2026i] has so far put one of them at risk.

Six discrepancies in the source material are printed in Section 7.5 rather than corrected, including a percentage described as a recovery that is an increase, a fraction described as a quarter that is a third, two recovery times understated, a fourth-decimal rounding inconsistency in an identity that holds exactly, and a parameter that a specification requires and the worked case never supplies. Those are disclosed because a reader checking the corpus will find them.

What would falsify the account. H1 fails if a measured `delta` does not fall after a shared medium is installed, or if headroom does not rise. H2 fails on a measured coordination cost that does not grow faster than logarithmically in headcount. H3 fails if a panel with strongly correlated errors matches the independent-majority prediction, or if accuracy does not move when the order of operations is changed at fixed composition. H4 fails on a standing body whose measured `u` is stationary or rising with no maintenance protocol. H5 fails on a body at a genuine steady state with negative measured headroom. H6 fails on a measured case with a negative step in which lowering `delta` alone raises the steady state. **The scale claim of Section 9.7 is falsifiable at each scale separately and is not falsifiable in general, which is a genuine weakness of that claim and is stated as one.**

Nothing in this paper is a human-subjects finding. No interventions were run and no participants were recruited. The declination constraint of S4.8 and S5.8 is a design constraint on prospective work, not a report of past practice.

14.11 11 Conclusion

At any steady state of the storage law, headroom equals unused variety:

```
h_inf = eta ( ln N − F(u*) ) = eta ln ( N / N_eff )
```

`delta`, `C` and `Q` all cancel. At `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55` and `C = 0.42` the stock converges to `Q_inf = 2.840970` and the identity returns `h_inf = 0.164501` by both routes, agreeing to machine precision (**R1**). Three consequences follow and are the statements downstream work should quote rather than paraphrase: a settled system at `u = 1` has zero headroom and is running at its ceiling; **a settled system never has negative headroom, so negative headroom is always inherited stock under changed parameters**; and **the plain linear model, left alone, does not ossify** — maintenance load rises with success and then stops, so ossification requires either exogenous accretion of `Q` or a cost term superlinear in `Q`, and a diagnosis must say which.

Where state is kept is a parameter setting. The same tool library run through a coordinator converts at `eta = 0.35` with `delta = 0.25` and settles at `Q_inf = 0.2653`; run on a shared written medium it converts at 0.55 with `delta = 0.12` and settles at 3.9281, a factor of 14.8, at lower total cost and with no change of people. A turnover event costs the coordinator regime 70 per cent of its stock and the medium regime 15 per cent (**R2**).

Nesting is priced, not preferred. With a per-path cost of 0.02 and `eta = 0.5`, headroom at `Q = 0` peaks at five members (`+0.6047`) and crosses zero between eleven and twelve, at `n = 11.577`

on the continuous extension. A flat body of 24 sits at `h = −3.931` and cannot build anything at any interaction geometry; four cells of six plus a four-delegate federation reaches `+2.957` under the stated independence assumption (**R3**).

Independence is a budget line. A nine-person review panel at `u = 0.12` has `N_eff = 1.96` and a negative fixed point, `Q_inf = −0.6510`; it needs `u >= 0.5280` merely to hold. Five procedural protocols costing 0.090 per item, plus two composition changes, raise `u` to 0.71 and `Q_inf` to `+1.9144`, and lift panel accuracy from 65.8 to 74.3 per cent **with no change in the individual accuracy of any reviewer**, which stays at `p = 0.62` (**R4**). At that individual accuracy an unbounded informational cascade tops out at 0.6570 — below nine independent voters at 0.7738 — so the panel's baseline was the accuracy of an infinite queue of people who never looked at each other's signals.

The maintenance term is the bill for past success. At a fixed ceiling `eta ln N = 1.50`, a body with `delta = 0.02` and `Q = 75` spends 100 per cent of its surplus on maintenance before any operating cost (**R6**). A standards body traced from 1962 accumulates to `Q = 19.669` by 1990 under a ceiling of 1.6362, then carries it under a ceiling of 0.8349 after its constituencies consolidate and its conversion rate falls, giving `h = −0.2227`. Doing nothing returns headroom in 2002 — **twelve consecutive negative-headroom years, 1990 to 2001 — at a cost of 61.9 per cent of everything accumulated in twenty-eight years, none of it chosen** (**R5**).

Two levers do not pay, and both are reported (CR). Cutting decay alone by building trust moves a failing body from `Q_inf = −0.0836` to `−0.2114` — worse — while reciprocity alone gives `+0.7394` and both together `+1.8701`: **trust does not add order, it amplifies whichever sign the system already has.** And a deliberate 40 per cent sunset with no conversion work ends in 2026 with less stored order (5.507) than doing nothing at all (7.494), while the sequenced intervention — shed, then raise `eta`, then raise `u` — ends at 16.770. **Shedding buys headroom; headroom unspent is headroom wasted. Shedding is a stabiliser, not a cure.**

All of this is arithmetic. **Whether any organisation is described by these equations is a separate question, it is a postulate rather than a result, the applied readings are not identified from observational data, and the one preregistered confirmatory test of the underlying law reported in this corpus did not meet its own declared margin.**

14.11.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the model developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The three systems worked in Section 7 are constructed examples with declared parameters, not field observations. The five figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 to 6. The Monte Carlo figure quoted in Section 5.4 is reported from the source material and was not re-run for this paper, which is stated again in Section 10.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The three worked systems are constructed. The declination constraint stated in S4.8 and S5.8 — that no mechanism which removes a participant's ability to decline is within the framework's scope — is a design constraint on prospective work and is not a report of any study performed. The monitoring arrangements described in Sections 4.5 and 4.8 are analysed as they appear in the field literature on common-pool resources and are specified here only in the mutual, peer-accountable form that S4.8 permits.

Preregistration

This paper reports no preregistered test of its own; its results are derivations and worked examples. The falsification rules declared in advance for each worked system are stated in Sections 7.1.8, 7.2.8 and 7.3.8 and are **declarations of what would count as failure, not reports of a test performed**. The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out advantage over a matched autoregression against a declared margin of 10 per cent — is reported in Curzi [2026i]. Any applied claim resting on this paper inherits that result.

14.12 Appendix A — The medium survey and governance audit forms

A.1 VWDLA score sheet. Score each property 0–4 by the inspection test of Section 4.4. Record the date and the assessor; the instrument's value is in the trend, because medium capture (FM-4.6) is visible only as a trend.

Property	Inspection test	Observation recorded	Score /4
Visible	Three participants, three levels, one live item each; median time to display; count of times a person had to be asked	median seconds; asks	
Writable	Steps from observation to recorded state, counting blocking review only	step count	
Durable	Bus-count census over critical state classes; fortnight intelligibility test	count of classes at bus-count 1; pass/fail	

Property	Inspection test	Observation recorded	Score /4
Low friction	Five stopwatch samples of one typical write, end to end; count of mandatory fields	median seconds; field count	
Append-oriented	Reconstruct the state as of a named date last quarter	pass/fail	

Pass condition: at least 3 on all five. Any single score of 0 or 1 is a blocking defect regardless of the total.

A.2 Hub census sheet. One row per class of critical state. The count is of people who could reconstruct the item **from what exists outside their own memory**, which is the count that matters and is not the count usually given.

Class of critical state	Where it is held	Reconstructible by (count)	Blocking?

A.3 Ostrom conformance score. The eight-row form of S4.3, scored 0/1/2, total out of 16, with the threshold at 10. Record the evidence, not the judgement: a score of 2 on O5 requires naming the three severity levels and the date the mildest was last used.

A.4 Focal-point inventory. At least five entries, each naming the coordination event it removes and the cost saved per occurrence. Required by S4.5 before any medium is built.

14.13 Appendix B — The independence protocol schedule

Each protocol is listed with the item it is run against, its cost in the normalised units of Section 7.2, and — mandatorily — its decline path stated in the form it is to be read aloud. **A protocol appearing in this schedule without a decline path is not installed under this framework's authority** (S5.8).

Protocol	Run when	Cost per item	Decline path, as stated to participants
IP-1 independent estimate	Before any discussion of the item opens	0.030	"You may record 'no independent view'; the item proceeds and the fact is recorded."
IP-2 anonymous-first	First round of every elicited judgement	0.010	"The anonymous round is optional. If the group is small enough that you can be identified, say so and we will use sealed estimates instead."

Protocol	Run when	Cost per item	Decline path, as stated to participants
IP-3 dissent protection	Standing; exercised at least annually	0.005	“Nobody is required to dissent, and nobody is assigned to. A recorded dissent has no consequence for standing, assignment or advancement.”
IP-4 minority report	Every non-unanimous decision; steelman on unanimous ones	0.040	“The steelman role is by consent and rotates. If nobody consents, the record states that no steelman was appointed.”
IP-5 turn-taking equalisation	Every item	0.005	“You may pass. A pass is recorded as a pass and never as assent.”
Total		**0.090**	

B.1 The measurement schedule that goes with them. IP-2 yields the anonymous-to-attributed drift; IP-3 yields the dissent rate over time; IP-5 yields the share of speaking time held by the top two speakers, with the intervention threshold at 60 per cent in a group of eight or more (S5.6). None of these requires a control group, and all three are recorded on the same sheet, at the same cadence, so that a declining u is visible as a trend across three instruments rather than as a single reading.

B.2 What the schedule cannot do. Where the panel’s signals are duplicates, the protocols extract nothing, because there is nothing to extract (FM-5.6). The annual u re-measurement of S5.7 is what distinguishes a body whose difference is being suppressed from a body that has none, and **only the second is repaired by recruitment.**

Chapter 15

Surveying and Preregistering the Storage Law: A Measurement Protocol, and a Confirmatory Fit That Failed Its Own Baseline Test

Abstract. This paper specifies an end-to-end measurement protocol for the storage law and then submits it to a preregistered test that it fails. The survey fixes five operational choices, supplies estimators for each parameter, and adds a participation-ratio identity, $N_{\text{eff}} = N + 1 - N/\text{PR}$, verified against random ensembles to better than 10^{-12}, that makes a redundancy audit computable from a Gram matrix. Applied to a county development-review office, the survey returned $N = 5$, capacity $U = 0.6972$ against a realised 0.6019 (a realisation deficit of 0.1823 nats caused by 32.7% of sessions running short-handed), $\delta = 0.003090$ per week from a 33-week zero-input episode, $\eta = 0.5015$ rules per nat, headroom $h = -0.1720$, and a negative steady state $Q_\infty = -17.3$, reported as negative. The preregistered confirmatory fit at an eight-week block scale returned $a = 0.97439$ and $b = 0.5859$, both interior to the admissible box, with implied decay within 4.8% and implied conversion within 16.8% of independently audited values. **It nevertheless beat a matched autoregression by only 2.8% on held-out error against a declared requirement of 10%, so the verdict is parameters corroborated, predictive advantage not demonstrated.** A repackaged order proxy passed all four baselines decisively and was caught only by structural tests.

Keywords: survey protocol; preregistration; held-out skill; shuffled-input control; order proxy; participation ratio; zero-input episode; falsification rules

Series: B. Engineering the Surplus **Paper:** CCP-015

15.1 1 Introduction

A framework that cannot fail cannot be trusted. This paper specifies the procedure by which the Creature Comforts storage law is made to face a real system on terms declared in advance, applies that procedure to one system, and reports that **the model failed its own second falsification rule.**

The question is narrow and answerable. The storage law `Q_{t+1} = (1−delta) Q_t + eta S_t − C_t` is a proved result about a difference equation [Curzi, 2026a], whose update map is

a contraction with modulus `1−delta` and whose steady state is `Q* = (eta S − C)/delta`. Nothing in that derivation says anything about an organisation. Turning it into a claim about an organisation requires five operational choices, six estimated parameters, and a commitment — made before the data are examined — about what result would count as a refutation. This paper supplies all three, and then reports what happened when the commitment was honoured.

The contribution has four parts. **First**, an end-to-end measurement protocol: five declared choices, an estimator for each of `delta`, `eta`, `N`, `u`, `C` and `Q`, and a one-page output format in which every number carries its provenance. **Second**, an identity that makes the redundancy audit computable from a Gram matrix, `N_eff = N + 1 − N/PR`, where `PR` is the Rényi-2 participation ratio of the encoded ensemble; the identity is exact and was verified against random ensembles at `K = 3, 5, 8, 12` to better than 1e-12. **Third**, a structural account of the single most common measurement failure in this area — an order proxy that is a repackaging of the interaction input — together with four tests, two of which must be run before any measurement is taken, and a demonstration that the statistical controls alone cannot catch it. **Fourth**, a preregistered confirmatory fit, reported in full including its failure.

The headline result is negative and is stated here in the same words used in Section 9. Applied to a county development-review office, the survey returned `N = 5`, capacity `U = 0.6972` against a realised `U = 0.6019` — a realisation deficit of 0.1823 nats traced to 32.7 per cent of sessions running short-handed — `delta = 0.003090` per week from a 33-week zero-input episode, `eta = 0.5015` rules per nat, headroom `h = −0.1720`, and a steady state `Q_inf = −17.3`, reported as negative. The preregistered confirmatory fit at an eight-week block scale returned `a = 0.97439` and `b = 0.5859`, both strictly interior to the admissible box, with implied decay within 4.8 per cent and implied conversion within 16.8 per cent of independently audited values. **It nevertheless beat a matched autoregression by only 2.8 per cent on held-out error against a declared requirement of 10 per cent.** The verdict is therefore *parameters corroborated, predictive advantage not demonstrated*, and the storage law is **not** corroborated as a predictive model of that system at that time scale.

Two secondary results are reported because they bear on how much the passing tests were worth. A deliberately repackaged order proxy — a rolling index of the board's own disagreement score, which stores nothing — **passed all four baselines decisively**, beating persistence by 89.4 per cent and the matched autoregression by 89.2 per cent at `p = 0.0005` against the shuffled-input control, and was caught only by structural tests: a fitted decay implying a 1.97-week half-life against a measured 224 weeks, and a single-week jump 38.5 times the maximum admissible increment. And the shuffled-input control, on which the empirical audit most depends, has been measured elsewhere in this corpus at a false-rejection rate of 0.108 against a nominal 0.05 [Curzi, 2026u] — it is **anti-conservative**, so the `p = 0.0005` reported here is optimistic by an unknown but non-trivial factor.

Preregistration in the sense used here is the standard remedy for undeclared analytic flexibility [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013], and the reason it is necessary in this setting is not suspicion of the analyst but arithmetic: with enough freedom in the analysis any series can be made to support any conclusion, and the person with the most freedom is the person who most wants the conclusion. It is also, and separately, an administrative countermeasure to measure corruption [Goodhart, 1975, Campbell, 1979], because it fixes the definition of the measure at a time when nobody yet has a reason to distort it.

Sections 2 and 3 state the hypotheses — including the falsification rules and their declared margins, *before* any result — and the estimation framework. Sections 4 and 5 give the survey and the order-proxy tests. Section 6 gives the preregistration procedure and the four baselines. Sections 7 and 8 collect the specifications and the named failure modes. Section 9 reports the worked office end to end, including the failed rule. Sections 10 to 13 discuss, verify, limit and conclude. The two operational instruments — the survey worksheet and the preregistration form — are reproduced as Appendices A and B.

15.2 2 Hypotheses and preregistered falsification rules

This paper is partly a protocol specification and partly a confirmatory test. The protocol sections advance no hypothesis and are labelled as specification where they appear. The hypotheses below are what the worked application put at risk, and each carries what would defeat it. **The falsification rules and their numerical margins are stated here, in advance of any result, because that is the order in which they were fixed**; Section 9 reports the measured values against them without adjustment.

15.2.1 2.1 Hypotheses

H1 — The storage law describes a real institutional stock. The count of live precedent rules in a municipal review office evolves as a leaky accumulator driven by the surplus of its review board. **Predicted:** an unconstrained least-squares fit of `Y_{k+1} = a Y_k + b F(U_k) − C_hat_k + eps_k` lands strictly inside `0 <= a <= 1, b >= 0`; the frozen model beats persistence, direct input, a matched autoregression and a shuffled-input control on held-out data by the declared margins; and the fitted `a` and `b` agree with independently measured `delta` and `eta` within the declared tolerance. **Falsified by:** failure of any one of those three rules. *(Result: **partially falsified** — see Section 9.5.)*

H2 — Timing carries information, not merely volume. The order in which interaction arrives predicts subsequent stored order beyond what the input's average level predicts. **Predicted:** the real fit's held-out RMSE lies below the null distribution obtained by permuting the input series in time, at `p <= 0.05`. **Falsified by:** a real fit that sits inside the shuffle null. *(Result: **not falsified** — `p = 0.0005`; see Section 9.4 and the calibration caveat in Section 12.)*

H3 — The mean pairwise aggregator is the participation-ratio effective count. For `K` unit vectors with Gram matrix `G`, the mean pairwise non-parallelism `U` satisfies `N_eff = 1 + (N−1)U = N + 1 − N/PR` with `PR = K^2/||G||_F^2`. **Predicted:** exact agreement in double precision between the two computations for any ensemble. **Falsified by:** any ensemble on which the two disagree beyond floating-point tolerance. *(Result: **not falsified** — agreement better than 1e-12 at `K = 3, 5, 8, 12`; this is a derivation, and the numerical check is a check on the implementation, not on the world.)*

H4 — Structural tests catch what statistical tests cannot. An order proxy that is a filtered copy of the input will pass every held-out baseline including the shuffle, and will be caught only by a parameter-agreement test or an arithmetic ceiling test. **Predicted:** a constructed filtered proxy passes all four baselines and fails independent-parameter agreement and the ceiling check. **Falsified by:** a filtered proxy that the four baselines detect on their own. *(Result: **not falsified** — see Section 9.7.)*

Two claims here are not hypotheses and are labelled as what they are. That stored order in a real institution is adequately summarised by a single non-negative scalar `Y_t` is a **modelling postulate**; nothing in the framework proves it, and Section 6 is the procedure by which reality is allowed to reject it. That the mean pairwise non-parallelism is the right aggregator over the encoded categories is a **declared modelling choice**, badged as such, which must appear in the preregistration; H3 is a derivation about that choice and not a defence of it.

15.2.2 2.2 The falsification rules, with their margins declared in advance

Three rules, each catching a different disease. The tolerances are those that must be fixed before the holdout is examined and may not be moved afterwards.

FR1 — THE ADMISSIBLE BOX. The unconstrained least-squares optimum must lie inside `0 <= a <= 1, b >= 0`. If it lies outside, the storage law is rejected for that system. No constrained refitting rescues it; a constrained fit sitting on the boundary is reporting that the data wanted to leave the box.

FR2 — BASELINE DOMINANCE. The frozen model must beat **all four** required baselines on held-out data by a declared margin: persistence, direct input, matched autoregressive, and the shuffled-input control. Failure against any one of the four is a failure of the rule. **The margins declared for the application in Section 9 were a 10 per cent reduction in held-out RMSE against each of the first three baselines, and `p <= 0.05` against the shuffle distribution.**

FR3 — INDEPENDENT-PARAMETER AGREEMENT. The fitted `a` and `b` must agree with the independently measured `delta` and `eta` from the survey, within a tolerance declared in advance; **the tolerance declared for Section 9 was ±25 per cent on each.** Additionally, no observed one-period increase in `Y` may exceed the ceiling `eta ln N` by more than the declared conversion-lag allowance.

FR1 catches a system that is not an accumulator at all. FR2 catches a model that adds nothing over inertia, trend, or the input's mere average level. FR3 catches a model that fits beautifully with parameters that are not the system's — the signature of the order-proxy trap of Section 5, and the only rule that reliably catches its most dangerous form.

15.3 3 Framework: the law, the five choices, and the estimation model

15.3.1 3.1 The equation being surveyed

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t        S_t = F(U_t) = ln(1 + (N−1) U_t)

Q_t      stored order            delta   retention loss per period, in [0,1]
S_t      surplus input           eta     conversion efficiency, >= 0
C_t      cost / dissipation      N       number of categories
U_t      interaction geometry in [0,1],  S_t in [0, ln N]
```

This is the storage law, and it is proved mathematics under its own assumptions [Curzi, 2026a]: the exact solution, the one-step growth condition, the uniform bound, the sustainability ceiling and the steady state are all derivations. **They are derivations *about the equation*.** They become statements about an organisation only if the equation is a faithful model of it, and whether it is a faithful model of it is exactly what the survey and the preregistration exist to decide. The contraction that supplies the fixed point is Banach's theorem, stated exactly — a contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass [Curzi, 2026]. The surplus functional `F(u) = ln(1 + (N−1)u)`, uniquely characterised by angle-only dependence, zero at parallel, an affine effective count and normalisation, is established in Curzi [2026].

The master gauge:

```
h_t := eta ln N − delta Q_t − C_t

h_t <  0    unsustainable in this model. No interaction geometry saves it.
h_t =  0    maintenance only. Hold; do not build.
h_t >  0    growth available; any requested increment must satisfy r_t <= h_t.
```

The gauge is the headroom result: `h_t = eta ln N − delta Q_t − C_t`, with three regimes, a maximum one-step increment `r_max = h_t`, and the separate constraints of admissibility `C_t <=`

`(1−delta)Q_t + eta S_t` and sustainability `C_t <= eta ln N − delta Q_t` [Curzi, 2026b]. At equilibrium the same quantity has an interpretation that the survey will need: headroom at equilibrium is unused variety, `h_inf = eta(ln N − F(u*))`, verified to six decimals — at `eta = 0.35`, `delta = 0.015`, `N = 6` and `u* = 0.55`, `Q_inf = 2.840970` and `h_inf = 0.164501` [Curzi, 2026h].

15.3.2 3.2 The five required operational choices

The storage law may not be applied to a real system by analogy. Before any number is taken, five choices must be written down in advance, in language specific enough that a second analyst could take the same measurements and obtain the same numbers.

#	Choice	What it fixes	Symbol produced
1	**State encoder**	how each participant, discipline, or category becomes a vector	`x_i`
2	**Interaction observable**	how the encoded states become a single geometry number per period	`U_t`
3	**Order observable**	what durable thing is counted as stored order	`Y_t` (proxy for `Q_t`)
4	**Time scale**	how long one period is	`t`
5	**Cost observable or cost model**	how dissipation is counted, in the same units as `Y`	`C_hat_t`

These five choices are the entire empirical content of the framework. The mathematics is fixed. Everything that can be wrong about an application of it is in these five lines. An analyst who writes them down badly has not produced a bad estimate; they have produced no estimate at all. The demand is the same one measurement theory makes of any construct before it is quantified — that the operations be specified well enough for another investigator to repeat them [Krantz et al., 1971, Cronbach and Meehl, 1955].

15.3.3 3.3 The estimation model

```
Y_{k+1} = a Y_k + b F(U_k) − C_hat_k + eps_k

subject to      0 <= a <= 1        b >= 0

identification  a = 1 − delta      b = eta
```

This is the storage law written as something a computer can fit. `Y_k` is the order observable; `F(U_k) = ln(1 + (N−1) U_k)` is the surplus input computed from the interaction observable; `C_hat_k` is the cost observable, denominated in `Y`-units, entering with a **fixed coefficient of one** — a measured offset, not a free parameter; `eps_k` is the residual.

Two free parameters. That is all the specification permits. The temptation to add a third — an intercept, a lag, a seasonal term, a second input — is the temptation to make the model unfalsifiable, and every such addition must be declared in advance or not made at all. The parameter count is not a stylistic preference: it is what makes the comparison against a matched two-parameter autoregression in Section 6.4 a fair one, and Section 11.5 records that the corpus did **not** compute an information criterion, which is the standard instrument for paying for parameters and which would have made the comparison sharper still.

The constraint box is the empirical content of the claim rather than regularisation. `a = 1 − delta` with `delta` in `[0,1]` says the system is a **leaky accumulator**: it keeps some fraction

of what it had and loses the rest. If the unconstrained best fit wants `a > 1`, the system is not accumulating with loss — it is compounding, and the storage law is the wrong model. If it wants `a < 0`, the system is oscillating period to period, which a stock does not do. If it wants `b < 0`, then interaction *destroys* order in that system, which is a coherent thing for a system to do and an incoherent thing for this model to describe. **The unconstrained fit is therefore computed first, and where its optimum lands is FR1.**

15.3.4 3.4 Badged postulates

POSTULATE (badged): scalar adequacy. The survey assumes that the stored order of a real system — a body of practice, a trained staff, a furnished room, a working institution — is adequately summarised by a single non-negative scalar `Y_t`, and that this scalar moves according to the storage law up to noise. Nothing in the framework proves this. The static half is pure mathematics and makes no empirical claim; the dynamic half proves properties of a recursion and does not prove that any organisation obeys it.

POSTULATE (badged): linearity. The storage law is linear in `Q` and in `S`. Real institutional stocks may saturate, may have thresholds, may exhibit hysteresis. The linear model is chosen for tractability and for the fixed-point guarantee, not derived from observation of organisations. A held-out failure may mean the storage law is wrong for a system, or it may mean the storage law is right and the linearity is wrong; the procedure below does not distinguish them, and it must not be presented as if it did.

POSTULATE (badged): constant parameters. The model treats `delta`, `eta` and `N` as constant over the estimation window. In an organisation with turnover, reorganisation, or a change of leadership they are not. The window must be declared and checked for a structural break; a fit spanning a regime change is fitting an average of two systems, neither of which exists.

POSTULATE (badged): well-behaved noise. `eps_k` is assumed additive, independent and homoscedastic. Audit error on a register is usually none of these — audits taken by different people, in different weeks, under different pressure. Residual autocorrelation must be reported; where it is large, held-out intervals are narrower than the truth.

The corpus's own classification of its claims puts three items in the postulate drawer against four items of established mathematics and seven of established psychology, with every protocol stated to run on the first two and steer by the third [Curzi, 2026]. The four postulates above are where that drawer bears on measurement.

15.3.5 3.5 Identification: the objection that no fit can answer

This belongs in the method rather than in a caveat, because it limits what the method can deliver before any data are collected.

The specification being fitted is reflexive. `U_k` is a property of the group; the group's stored order shapes what its members do in the next period; and the members are what the group is made of. That is a linear-in-means reflexive structure, and Manski [1993] proves that in such a structure **the endogenous social effect is not identified from observational data**: it cannot be separated from contextual effects — properties of the group that act on members without being produced by them — or from correlated unobservables acting on everyone at once. Shalizi and Thomas [2011] establish the same confounding for network data, where influence and selection cannot generically be told apart from observation.

The consequence for this paper is exact and it is not repaired by anything in Section 6. The falsification rules test whether the fitted model predicts out of sample better than declared baselines. They do not, and cannot, establish that `b` measures the conversion of interaction into structure rather than a contextual effect, a common driver, or selection into the board. A fit that passed all three rules would still not have identified that parameter. **The identification problem is therefore a deeper limitation than the one the confirmatory test found**, and it would have applied equally had the test passed.

No remedy is adopted here, so the honest label is a modelling position rather than an identified empirical result. The four known routes are randomisation, an instrument, partial-population variation, and stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]. The last is the most realistic in this setting, and the survey's fixed category set, declared merge and drop rules, and explicit participation rule are the machinery a defended stipulation would need — but stipulating the reference group and *defending* it are two different acts, and only the first has been performed. **Until a remedy is executed, the fitted `b` is a coefficient in a declared specification and not an identified social effect**, and every applied statement in this paper inherits that status. Section 9.8's licence list should be read accordingly.

15.3.6 3.6 Standing honesty clauses

- The triangle inequality **fails** for geometric triples; subadditivity holds on the parameter `u` only. Surplus may not be composed across three groups by adding distances.
- As deployed, the surplus functional is a **lower bound** on the ensemble's information, not the information itself. A survey reporting `F(u)` is reporting a guaranteed minimum, and the true richness of the interaction may be higher. This matters in Section 9.6: a fitted conversion slightly above the audited one is not automatically an error.
- Surplus is **not** identified with Shannon entropy or mutual information in general, so entropy intuitions must not be imported into the cost accounting.
- **No thermodynamic negentropy law is proved.** Higher static surplus does not imply higher canonical concentration.
- `0 <= F(u) <= ln N`. **`ln N` is the hard ceiling on surplus per interaction**, which is why `h` is defined with `ln N` rather than with `F(U_t)`.
- **The model is only a claim about the world if `Y` is not a repackaging of `U`.** If the order observable is computed from the same records, by the same instrument, at the same moment as the interaction observable, then `Y_{k+1} = a Y_k + b F(U_k) - C_k` can fit beautifully and mean nothing: it will have measured an algebraic relationship between two encodings of one measurement. Section 5 gives the four tests that prevent this, and Section 9.7 shows a repackaged proxy passing every statistical baseline.

15.4 4 The survey: instruments and estimators

15.4.1 4.1 What a survey is, and what it is not

A survey in this sense is not an audit, an assessment, a maturity model or a culture questionnaire. It produces six numbers and one verdict, it has a fixed output format, and it is finished when the format is full and every entry has a stated provenance.

It is also not a diagnosis. The survey reports the state of the accumulator; it does not report whether the accumulator should be full. **An institution with a low `Q` may be young or may be hollowed out, and a snapshot cannot distinguish them — only the trajectory can.** That is why the survey requires a series rather than a snapshot. The minimum deliverable:

```
SURVEY OUTPUT (one page)
-----------------------------------------------------------------
System ............. name, boundary, and what is excluded
Period ............. one period = ______ ; series length ______
Encoder ............ how x_i was formed
N .................. ______   ln N = ______
U (capacity) ....... ______   from ______ instrument
U (realised) ....... ______   from ______ instrument
F(U) realised ...... ______   = ln(1 + (N−1) U)
```

```
delta ............... ______ /period   half-life ______ periods
eta ................. ______ Y-units per nat
C_hat ............... ______ Y-units/period  (denominated in Y)
Q (= Y at survey) ... ______ Y-units
-----------------------------------------------------------------
eta ln N  = ______
delta Q   = ______
h         = ______        VERDICT: [ h<0 | h=0 | h>0 ]
one-step  = eta F(U) - delta Q - C_hat = ______
Q_inf     = (eta F(U) - C_hat)/delta   = ______
-----------------------------------------------------------------
```

Everything in this section exists to fill that page defensibly.

15.4.2 4.2 Choice 1 — the state encoder

The state encoder turns each *category* into a unit vector. It is the choice that determines what *different* means for a system, and therefore the choice with the largest downstream effect on `u`. Three encoders are practical in the field.

Encoder A — the disposition vector (recommended default). Assemble a fixed probe set of `m` real cases the system must handle. Each category — each discipline, role or site — records its disposition on each case as `+1` or `−1`. The category's vector is that list of `m` signs divided by `sqrt(m)`, so it is a unit vector. For two categories `i` and `j` that agree on `m − k` cases and oppose on `k`:

```
x_i . x_j = (agreements − disagreements) / m = 1 − 2 d_ij      where d_ij = k/m

u_ij = 1 − (x_i . x_j)^2
```

This encoder is exact rather than approximate: for a plus/minus encoding the inner product *is* one minus twice the disagreement rate.

Encoder B — the error vector. For systems producing forecasts or judgements with later ground truth, encode each category by its vector of signed errors over the last `m` resolved cases, mean-centred and normalised. This is the strongest encoder available, because decorrelated error is the operational meaning of independent judgement — the condition that Condorcet's theorem requires, that the diversity-prediction literature identifies as the source of the ensemble gain [Hong and Page, 2004, Page, 2007], and that the collective-intelligence factor tracks [Woolley et al., 2010]. The corresponding sceptical literature must be read alongside it: Thompson [2014] shows that the celebrated diversity-trumps-ability result is a mathematical artefact of its parameterisation rather than an empirical finding, and Harrison and Klein [2007] shows that three incompatible constructs travel under the word *diversity*. The encoder must therefore declare which construct it is measuring; Encoder B measures **disparity of error**, and nothing else.

Encoder C — the practice vector. For systems with no shared probe set, encode by observable practice: which tools, which sources, which sequence of steps, which vocabulary. Score each category on `m` binary practice items. This is the weakest of the three, because two people can share every practice and still disagree, and can share no practice and still agree.

An encoder warning that catches most beginners. `u = 1 − cos^2` is the squared *sine* of the angle between the encoded categories, and the sine rises steeply near alignment. Under Encoder A, a disagreement rate of only 1 case in 12 already gives

```
d = 0.0833 -> cos = 0.8333 -> u = 1 − 0.6944 = 0.3056
```

and a disagreement rate of 3 in 12 gives `u = 0.75`. **The encoder is generous: modest observed disagreement produces large `u`.** This is not an error in the mathematics but a property

of the geometry, and it has two consequences. The encoder must be declared before measurement, because a different encoder gives a different `u` for the same organisation. And a low measured `u` under Encoder A is a very serious finding: it means the categories are near duplicates of each other rather than merely similar.

15.4.3 4.3 Choice 2 — the interaction observable

From `N` unit vectors the framework requires one scalar `U_t` in `[0,1]` per period. It does not say which aggregator to use, so **the aggregator is a declared modelling choice, badged as such, and it must appear in the preregistration.** The recommended aggregator is the mean pairwise non-parallelism over all ordered pairs actually present in the period:

```
U_t = mean over i != j of ( 1 − (x_i . x_j)^2 )
```

There is a reason to prefer it beyond convenience. Let `G` be the Gram matrix of the `K` unit vectors, so `G_ij = x_i . x_j` and `tr G = K`. The participation ratio of the Gram spectrum — the standard Rényi-2 effective count [Rényi, 1961] — is

```
PR = (tr G)^2 / ||G||_F^2 = K^2 / ||G||_F^2
```

Since `||G||_F^2 = K + sum_{i != j} G_ij^2 = K + K(K−1)(1 − U)`, a line of algebra gives

```
K / PR = 1 + (K−1)(1 − U)        hence        U = 1 − (K/PR − 1)/(K−1)
```

and therefore, for the effective count of the surplus law,

```
N_eff = 1 + (N−1) U = N + 1 − N/PR
```

The mean pairwise aggregator is not an arbitrary average. It is exactly the participation-ratio diversity of the encoded ensemble, reparametrised into the effective-count form the surplus law uses. The identity is exact in double precision and was verified numerically for `K = 3, 5, 8, 12` on random ensembles with agreement to better than 1e-12; it is re-verified independently over six random correlation matrices elsewhere in this corpus, where `N = 8` and `u_bar = 0.783801` return 6.486606017883 by both routes [Curzi, 2026]. Declaring the mean pairwise aggregator therefore commits the analyst to a standard and well-understood diversity measure rather than to an improvisation.

Two limiting cases belong on the survey form. At `PR = N` — a Gram matrix with no off-diagonal mass — `N_eff = N`: roster and effective count coincide, and that happens only at exact mutual orthogonality. At `PR = 1` — every vector the same — `N_eff = 1`, and the size of the roster has left the arithmetic entirely. **Everything the survey reports about `N` lives between those two poles, and the participation ratio is the coordinate that locates it.** Where a sponsor asks why disagreement is averaged pairwise rather than some other way, the identity is the answer, not a plausibility argument.

One caution about what the identity does and does not import. `1/HHI` and `exp(H)` are Hill numbers of order two and one respectively [Hill, 1973, Jost, 2006], and the concentration instrument built on `1/HHI` is a separate construction with its own worked results [Curzi, 2026]. `N_eff = 1 + (N−1)u` is a linear interpolation between 1 and `N` and is **not** a Hill number of any order; it is this framework's own construction, and Section 12 states that plainly. What the participation-ratio identity establishes is that the chosen aggregator coincides with a recognised effective count *for this encoding*, which is a narrower and defensible claim.

Two distinctions must be kept separate, because collapsing them is the second most common survey error after the proxy trap. **Capacity `u` versus realised `u`:** the probe set measures what the category set is *capable* of — how non-parallel the disciplines are when all of them

speak — while the period-by-period observable measures what actually happened, which categories were present, which spoke, which were overruled before speaking. These are different numbers, and the gap between them is among the cheapest things an organisation can fix. The worked office of Section 9 has capacity `U = 0.6972` and realised `U = 0.6019`, and the entire difference comes from sessions run with fewer than the full board present. **Present versus counted:** a category in the room but silent contributes to nothing. Under Encoder A the survey must define in advance what counts as participation — a recorded disposition, a spoken objection, a signed line. Attendance is not participation and must never be encoded as it.

15.4.4 4.4 Choice 3 — the order observable

This is the choice that decides whether a survey is worth anything. The order observable `Y_t` is a countable, durable quantity standing in for `Q_t`. A valid `Y` has five properties, and each is tested explicitly with the answer recorded.

Property	Test	Why it matters
Durable	Does it persist for many periods with no input?	A stock, not a flow
Countable	Can two auditors independently produce numbers within a declared tolerance?	Otherwise `delta` and `eta` are noise
Decaying	Does it measurably decline under zero input?	If it never decays, `delta = 0` and the model has no fixed point
Independent of `U`	Different instrument, different record, different time?	the order-proxy condition — see Section 5
Denominable	Can cost be expressed in the same units?	Otherwise `h` cannot be computed at all

Candidate order observables that satisfy them, by system type:

System	Candidate `Y`	Units
Review office / standards body	live precedent rules in the standing manual	rules
Research group	reproducible protocols in the group handbook	protocols
Software organisation	modules with a named owner and a passing test suite	modules
Library reading room	seat-hours of optional occupancy per week	seat-hours
Maintenance regime	assets with a current, executed maintenance record	assets
Co-housing block	standing agreements in force and observed	agreements
Manufacturing cell	validated work instructions in use on the floor	instructions

And observables that do not, with the reason. **Headcount** does not decay in the right way, is not produced by interaction, and is an input to `N` — it is on the wrong side of the equation. **Revenue** is a flow rather than a stock and is driven by exogenous demand. **Engagement scores** are not durable; they are measured, not held. **Meeting count** is the support of `U`, not `Q`; counting meetings as order is the purest form of the trap in Section 5. **Any index the organisation reports upward** is exposed to measure corruption from the moment it is known to be counted [Goodhart, 1975, Campbell, 1979].

15.4.5 4.5 Choice 4 — the time scale

One period is the unit of the recursion. Choosing it wrongly does not bias the estimates; it destroys the ability to detect anything. Three constraints bound the choice.

The period must be at least as long as the conversion lag. If a decision made in a meeting takes six weeks to reach the standing manual, a one-week period puts cause and effect in different rows and the fit will find nothing.

The period must be short enough that `delta` per period is small — as a practical rule, `delta <= 0.3` per period, so that the linear approximation of a decaying stock is not being asked to cover a near-total loss in one step.

The period must be long enough that the input term is visible above measurement noise. This is the constraint nobody considers, and it has a precise structure. Audit error on a *level* does not accumulate: re-counting the stock twice as far apart leaves the error at the endpoints the same size while the accumulated input doubles. **Coarsening the time scale raises the signal-to-noise ratio of the input term roughly as the square root of the block length, and costs degrees of freedom linearly.** There is an optimum, and it must be chosen before the answer is seen (Section 6.7).

The period, the calendar alignment — which day the audit is taken — and the rule for handling periods with no interaction at all must all be declared. Periods with `U_t = 0` are not missing data; they are the most informative periods available, because they are where `delta` is identified.

15.4.6 4.6 Choice 5 — the cost observable, and the denomination rule

`C` must be denominated in the same units as `Y`. Where it cannot be denominated, headroom cannot be computed and the survey has failed. This is the most frequently botched line in a real survey, because cost arrives naturally in money and hours while `Y` arrives naturally in rules, protocols or modules. The requirement is dimensional rather than stylistic: every term in `h = eta ln N − delta Q − C` must carry the same dimension, and Section 11.1 gives the audit.

There are exactly two honest routes. **Route 1 — direct destruction accounting.** Count the `Y`-units destroyed or made unusable per period: rules struck by appeal reversal, rules orphaned because the only person who could apply them left, rules rendered unusable by contradiction with a newer rule. These are already in `Y`-units and require no conversion. **Route 2 — a declared conversion rate.** For dissipation that is real but not directly destructive — coordination overhead, rework, interruption, emotional labour, compliance reporting — measure it in its natural unit and convert at a rate declared in advance and justified. The honest way to set the rate is by *displacement*: measure how many `Y`-units the system produces per staff-hour of productive capacity, then charge dissipated hours at that rate. **A declared conversion rate is a badged modelling choice; an undeclared one is a fabrication.**

Cost categories to enumerate, with their usual `Y`-denominated form:

Category	Natural unit	Denomination route
Coordination overhead (Brooks, `n(n–1)/2` paths)	hours	Route 2
Rework and re-decision	items	Route 1 if it strikes `Y`, else Route 2
Conflict and appeal	cases	Route 1
Turnover loss	departures	Route 1 (orphaned units)
Maintenance and compliance	hours	Route 2
Rent, commute, physical friction	money, minutes	Route 2
Interruption / context switching	switches	Route 2

Two rules prevent the usual mistakes. **Do not double-count turnover.** Turnover appears in `delta` as decay of stored order *and* in `C` as a one-off destruction; each departure is assigned to one or the other and the assignment is written down. The convention that works: routine attrition at the historical rate sits in `delta`, while departures above that rate, and any departure that orphans a specific `Y`-unit, sit in `C`. **Do not omit the cost the organisation does not book.** The attention tax — the hours spent by people who are not in the meeting, reading about the meeting — is almost never in anyone's ledger and is often the largest single line. Omitting it makes `h` optimistic and the eventual intervention fail for a reason that was never measured. The coordination component has a known form: communication paths grow as `n(n–1)/2`, and the cost of bringing new arrivals up on person-borne stored order is charged against the same budget [Brooks, 1975, Conway, 1968].

15.4.7 4.7 Estimating `delta`

`delta` is the fraction of stored order lost per period with no maintenance and no input.

Method D1 — the zero-input episode (best). Find a stretch of `n` periods in which `U_t = 0` and `C_t = 0`: a shutdown, a hiring freeze, a suspended committee, a closed season, a strike, a vacancy. Over that stretch the law reduces to `Q_{t+n} = (1 − delta)^n Q_t`, so

```
delta = 1 − (Y_end / Y_start)^(1/n)
```

This is the only clean estimator, and finding such an episode in the record is the single highest-value hour of the whole survey. Institutions have more of them than they admit: budget freezes, closures, leave-of-absence gaps, the six months between an outgoing and an incoming director.

Method D2 — the cohort decay curve. Tag a cohort of `Y`-units created in one period and count how many are still live after 1, 2, 4, 8, 16 periods. Fit `ln(survivors)` against time; the slope is `ln(1 − delta)`. This is more work than D1, works without a zero-input episode, and additionally reports whether the decay is exponential at all. If the survival curve is not straight in log space, the constant-`delta` assumption is wrong for that system and the survey must say so.

Method D3 — the maintenance ledger (fallback). Where the organisation records maintenance effort per `Y`-unit, `delta` is approximately the fraction of units that would lapse in one period if that effort stopped. This is an estimate from testimony rather than measurement and must be labelled as such.

`delta` is then converted into the two numbers a non-technical reader can use:

```
half-life  t_half = ln 2 / ( −ln(1 − delta) )       periods
time constant  tau = 1 / delta                       periods
settling to 95% of a new equilibrium: about 3 tau    periods
```

delta	half-life (periods)	tau (periods)	3 tau (periods)
0.003	230.7	333.3	1000
0.005	138.3	200.0	600
0.01	69.0	100.0	300
0.02	34.3	50.0	150
0.05	13.5	20.0	60
0.10	6.6	10.0	30
0.20	3.1	5.0	15
0.30	1.9	3.3	10
0.50	1.0	2.0	6

A low `delta` is not unambiguously good. It buys durability and charges latency: a system with `delta = 0.003` per week takes a thousand weeks to settle to a new equilibrium. That is the reason an intervention protocol promises increments and never promises equilibria, and it is the same trade-off — doubled stock against doubled settling time — established for the storage law itself [Curzi, 2026a].

15.4.8 4.8 Estimating `eta`

`eta` is `Y`-units of durable order created per nat of surplus input. It is the parameter most organisations have never considered and the one most often closest to zero.

Method E1 — the attribution audit (recommended). Choose a window of `w` periods in which the system was operating normally. For each `Y`-unit created in that window, ask a single question with a written answer: which interaction produced this, and is that interaction in the record? Count only the units with an affirmative, documented answer. Then

```
eta_hat = (attributable Y-units created in the window) / (sum of F(U_t) over the window)
```

The denominator is in nats, the numerator in `Y`-units, so `eta` is `Y`-units per nat. The audit is deliberately strict: a unit created by one person alone at a desk is not attributable to interaction and does not count, and a unit whose origin nobody can name does not count. **The strictness is the point. `eta` is meant to measure the fraction of interaction that becomes structure, and a permissive audit measures the fraction of structure that had a meeting nearby.**

Method E2 — the capture-rate decomposition. Where the attribution audit is too expensive, decompose:

```
eta ~= (fraction of interactions that produce a written decision)
     x (fraction of written decisions that reach the durable medium)
     x (Y-units per decision that arrives)
```

Each factor is separately observable and each names its own repair. A meeting culture with excellent minutes and no publication path has a high first factor and a near-zero second.

Method E3 — the natural experiment. Where the organisation changed its capture practice at a known date — introduced a decision log, hired a technical writer, mandated a template — estimate `eta` separately before and after. This is the cheapest way to learn what a conversion intervention is worth in a given system.

15.4.9 4.9 Estimating `N`

`N` is the number of genuinely distinct categories the system spans. It appears in the ceiling `ln N` and therefore in every design inequality. The procedure has four steps. **Enumerate candidate**

categories — disciplines, training lineages, functions, sites, tenures, client types, whatever the system itself treats as a kind. **Merge duplicates**: two candidates merge if their encoded vectors have `u_ij < 0.10`, that is, if they disagree on less than about 2.6 per cent of probe cases under Encoder A; two categories that never disagree are one category with two names, and counting them twice inflates `ln N` while contributing nothing. **Drop non-participants**: a category with no route into the interaction is not in `N`, and a discipline consulted after the decision is not in `N`. **Count what survives**, recording the merge and drop decisions with reasons.

The marginal value of `N` is unforgiving and should be shown to anyone proposing to hire their way out of a headroom problem:

N	ln N	gain over N-1
2	0.6931	0.6931
3	1.0986	0.4055
4	1.3863	0.2877
5	1.6094	0.2231
6	1.7918	0.1823
8	2.0794	0.1335
10	2.3026	0.1054
12	2.4849	0.0870
16	2.7726	0.0645
20	2.9957	0.0513
30	3.4012	0.0339
50	3.9120	0.0202
100	4.6052	0.0101

Against the growth of communication paths, `n(n−1)/2` [Brooks, 1975]:

n	paths	paths added by the n-th member
3	3	2
4	6	3
5	10	4
6	15	5
8	28	7
10	45	9
12	66	11
15	105	14
20	190	19
26	325	25

Surplus grows logarithmically and coordination cost grows quadratically. That is the whole team-sizing problem in one line, and the survey's job is to find where a system sits on it. Two independent literatures reach the same shape from different directions: waiting time diverges as utilisation approaches one, so reserve is not prudence but the only thing keeping response finite [Kingman, 1962, Hopp and Spearman, 2011]; and cohesion buys creative success up to a point and then costs it, an inverted U rather than a monotone gain [Uzzi and Spiro, 2005].

15.4.10 4.10 Estimating `u`

With the encoder fixed and the aggregator declared, `u` is arithmetic. What takes judgement is the instrument that feeds it.

Instrument U1 — the probe set (capacity). Eight to sixteen real cases chosen to span the system's actual workload, each with a forced binary disposition, administered independently and in writing *before* any discussion — because discussion is exactly the mechanism by which informational cascades collapse `u` [Bikhchandani et al., 1992, Banerjee, 1992, Lorenz et al., 2011]. Administer annually: `u` is not a property a system acquires but a quantity that decays.

Instrument U2 — the disagreement audit (realised). From the decision record, count for each period the pairs of categories that registered opposed positions before the decision closed. This is a weaker signal than the probe set — a category can be silent because it agrees or because it has learned not to speak — but it is available for every period retrospectively, which the probe set is not.

Instrument U3 — error decorrelation (strongest, where available). Where the system makes resolvable predictions, compute the correlation of signed errors between categories. Decorrelated error is the operational definition of independent judgement, and it is the only instrument that cannot be gamed by disagreeing performatively.

Instrument U4 — the collision test (fast). Ask each category, independently and in writing, for the three things that would most change their mind, then count the distinct answers. A category set returning the same three answers has `u` near zero, whatever its demographics.

The effective-count table for `N = 5` is the arithmetic that makes `u` legible to a manager:

u	N_eff = 1 + 4u	F(u) = ln N_eff
0.00	1.000	0.0000
0.10	1.400	0.3365
0.20	1.800	0.5878
0.30	2.200	0.7885
0.40	2.600	0.9555
0.50	3.000	1.0986
0.5715	3.286	1.1897
0.60	3.400	1.2238
0.6972	3.789	1.3320
0.80	4.200	1.4351
0.90	4.600	1.5261
1.00	5.000	1.6094

Five reviewers at `u = 0` are one reviewer. The survey's job is to report the effective count, not the roster. This is the same instruction the concentration instrument gives in a different domain, where four jurisdictions with shares 40.9 / 27.3 / 18.2 / 13.6 read as 3.41 effective jurisdictions naively and as exactly 1.00 once the bloc structure is collapsed [Curzi, 2026], and where four US states with shares 40.0 / 25.0 / 20.0 / 15.0 read as 3.508772 naively and 1.00 after collapse, with a surplus term of exactly zero [Curzi, 2026].

15.4.11 4.11 Estimating `C`, `Q`, and the instruments that take the readings

Cost. Follow the denomination rule and build the tally as a line-item table, one line per category, each with its measurement method and its conversion where Route 2 applies. The tally is the only part of the survey the organisation will actively contest, because every line is somebody's work. Four disciplines keep it honest. Every line has a source document — appeal register, exit interviews, ticket system, time records, the minutes. Every Route 2 line shows its conversion rate and the justification for it, in the tally. **The tally is reconciled against the series**: where the line-item `C_hat` differs from the cost implied by the observed trajectory by more than the declared tolerance, one of them is wrong; in the worked office the line-item tally came to 0.63 `Y`-units per week against a series-implied 0.6275, agreeing to 0.0025, which is well inside tolerance and is the only reason the tally may be used. And **slack is not cost**:

queueing theory is unambiguous that utilisation near one makes waiting time explode [Kingman, 1962], so unused capacity is a cost-control device rather than a dissipation, and booking it as `C` inverts the design conclusion.

Stock. `Q` is `Y` at the survey date, once the count has been satisfied to be the count. Two corrections are almost always needed and they differ in kind. The **liveness audit** removes units that are formally in the register but which nothing and nobody has used in the last `k` periods; `k` is defined in advance. **Striking units that were already inert is not shedding `Q`; it is correcting the measurement** — a distinction that matters enormously downstream, because correcting the measurement changes the number and not the world, whereas shedding `Q` is an intervention with real effects. The **applier audit** removes units that survive but which no remaining person can apply; orphaning is a real loss and belongs either in `delta` if routine or in `C` if caused by a specific departure, but the unit itself comes out of `Y` either way. The pre-correction count, both corrections, and the post-correction `Q` are all recorded, so that a second analyst can see what was removed and why.

Instruments. Five take the readings. *Direct observation*: Whyte's method for physical systems — go, sit, watch, count, and record what people actually do rather than what they say they do [Whyte, 1980]. For an organisation the equivalent is attending the interaction without a role in it and tallying who spoke, in what order, for how long, who was interrupted, what was written down, and by whom. Whyte's finding that people sit where there is something to sit on generalises: **systems do what their fixtures make easy** — the same observation Jacobs [1961] and Gehl [1971] make about streets. An hour of direct observation routinely overturns a month of interviews. *The unglamorous record*: Whyte used time-lapse film because occupancy patterns are invisible at human tempo; the organisational equivalents are the commit log, the calendar export, the ticket system, the door-badge record, the room-booking data — the only sources in most organisations that were not written to be read by management. *The decision log*: the single most useful artefact to install if it does not exist and to read if it does, with each entry recording date, question, who was present, positions recorded before discussion, decision, and the durable artefact produced; a decision log yields `U_t` and `eta` at once, and a system that has kept one for two years can be surveyed in a week. *The disagreement audit*: a structured pass over the decision record coding each decision for whether any category recorded an opposed position and whether that position survived to the written outcome — the ratio of the second to the first is one of the best single diagnostics available, since an organisation where dissent is recorded and never survives has a governance problem that `u` alone will not reveal. *Turnover and tenure records*: these feed `delta` directly and `C` through orphaning, and the distribution rather than the average is what matters, since a department with a stable core and a churning periphery has a very different `delta` profile from one with uniform tenure.

A structural warning attaches to all five. Star and Ruhleder [1996] establish that infrastructure becomes visible only on breakdown, which has a specific consequence for surveying: **everything that is working will be systematically under-measured.** The maintenance regime that never fails has no tickets, no incidents, no records and no budget line. For each `Y`-unit class the survey must ask explicitly what keeps it alive, and expect the answer to be a person rather than a process.

15.4.12 4.12 Computing headroom and reading the verdict

With the six numbers in hand:

```
eta ln N        the best case: what conversion could deliver at the ceiling
delta Q         the maintenance draw: what the existing stock costs to hold
C_hat           the dissipation draw
h = eta ln N - delta Q - C_hat
```

Read as a budget: `eta ln N` is the income at maximum geometric efficiency, `delta Q` the

mortgage on what is already owned, `C_hat` the operating expense, and `h` what is left. Then compute the *realised* one-step change, which is a different and equally important number:

```
one-step = eta F(U_realised) - delta Q - C_hat
```

`h` uses the ceiling `ln N`; the one-step uses what actually happened. The gap between them is the **realisation deficit** — headroom that exists and is not being collected — and both must be reported, because they call for different classes of intervention.

One correction on `F(U_realised)` that most surveys get wrong. `U` is not constant across the periods of a series; it is a distribution. What the accumulator integrates is `sum of eta F(U_t)`, so the operative quantity is the **mean of `F`**, not `F` of the mean. Because `F` is strictly concave [Curzi, 2026], Jensen's inequality fixes the direction:

```
mean of F(U_t)  <=  F( mean of U_t )        with equality only if U is constant
```

Compute `F` period by period and average the results; never average `U` and then take `F` once. The gap is the concavity penalty and it is not small: in the worked office it is 0.0761 nats against an `F(mean U)` of 1.2262 — **6.2 per cent of the surplus, lost purely to the variability of the geometry.** A survey reporting `F(mean U)` overstates realised surplus by that much, and every downstream number inherits the error. Both figures belong on the output page, with the difference labelled as the concavity penalty, and the test runs against the mean of `F`.

Finally compute the steady state `Q_inf = (eta F(U) - C)/delta`. **Where `Q_inf` is negative, the result does not hide the failure mode: the regime is unsustainable, or the linear model must be replaced.** A negative `Q_inf` in a survey output is not a rounding artefact and must never be reported as approximately zero. It is the model reporting, in its own terms, that the system as configured is being driven to the boundary of its own validity.

One further prediction is available at no cost and should be made every time. `u` decays. Holding the other quantities constant and letting `u` decay geometrically at rate `lambda` per period, the doctrine-to-data ratio crosses 1 at

```
t* = ln(u*/u_0) / ln(1 - lambda)          periods
```

`t*` has no free parameters. Every quantity in it — the current `u_0`, the crossing level `u*`, the decay rate `lambda` — is already on the survey form, and nothing has to be fitted, tuned or assumed. In the corpus's worked case it comes to about 8.4 quarters. That makes it the most decisive and least expensive falsification available anywhere in this protocol: write the date down, wait, and look. A system that sails past `t*` with the ratio still below 1 has falsified either the decay estimate or the model, and either finding is worth more than another season of fitting. This is exactly the kind of point prediction with a constant that Meehl [1967] identifies as the appropriate response to the charge that social-science predictions are directional and nearly costless.

And a hard rule about combining surveys, because the arithmetic is unforgiving. The ratio must not be aggregated across sites, divisions or cohorts. Distortion does not average. Two sites distorted in opposite directions — one over-framed, one under-framed — produce an aggregate in which the two errors cancel, and the cancellation is not a reconciliation but a deletion. In the corpus's two-site example the aggregate **overstated bankable input by 4.26 times** while each site taken alone was correctly diagnosed. **Survey each site to its own ratio and report the vector, never the mean.** An organisation with one site at 2 and one at 0.5 does not have an organisation at 1; it has two different pathologies and no healthy site at all.

15.5 5 The order-proxy trap, and why the statistical controls cannot catch it

Everything in Section 4 is craft. This section is the part that decides whether the craft was worth anything.

The model is a claim about the world only if the order proxy `Y` is not a repackaging of the input `U`. Where it is, the estimation model of Section 6 will appear to fit — often superbly — and will have measured nothing about the world.

Why it happens is not stupidity. It happens because the most available records are the interaction records: the minutes exist, the attendance list exists, the ticket system exists. So an analyst in a hurry defines `Y` as *items dispositioned per session* or *decisions logged per month* or *a weighted index of board activity* — and every one of those is a function of the interaction rather than a store left behind by it. The equation then reads, in effect, `U = a U + b U`, and the fit recovers an identity.

There are two species and they need different tests. **Species 1 — contemporaneous repackaging:** `Y_t` is computed from the same records as `U_t`, at the same time; for example `Y` = items dispositioned this session against `U` = disagreement observed this session, both functions of how busy the board was. **Species 2 — filtered repackaging:** `Y_t` is a smoothed or accumulated version of `U` itself; for example a rolling index of the board's disagreement score, published weekly by the clerk who writes the minutes. **The second species is far more dangerous, because a filtered input is *genuinely* predicted by the input, so the model fits almost exactly and passes every statistical baseline including the shuffled-input control** — demonstrated with numbers in Section 9.7.

15.5.1 5.1 The four tests

All four are run and their answers recorded. Two are structural and must be run before a single measurement is taken.

Test 1 — the algebraic derivation test (structural). Write out, as a formula, how `Y_t` is computed from source fields, and how `U_t` is computed. Compare the source fields. If any field appears in both, or if `Y`'s formula contains `U`'s formula, there is repackaging. Declared tolerance: **zero shared fields.** The test costs ten minutes and catches most cases.

Test 2 — the instrument-independence test (structural). `Y` must be recorded by a different person, into a different medium, on a different schedule, from `U`. In the worked office, `U` comes from the board's minutes and `Y` from the code administrator's register, and the code administrator does not attend the board. Where the same clerk produces both, the test fails regardless of how the formulas look, because the two numbers will share the clerk's judgement. This is the multitrait–multimethod requirement in miniature: a construct measured by one method cannot be distinguished from the method [Campbell and Fiske, 1959].

Test 3 — the zero-input persistence test (empirical, decisive). Find a period with `U = 0` and look at `Y`. **A stock persists and decays slowly; a repackaged input collapses to zero and springs back.** This is the strongest empirical test available and it uses the same episode the `delta` estimate needed. In the worked office the true proxy went 206 to 186 across a 34-week freeze and continued from 186 when the board resumed, while the repackaged proxy fell from 82.1 to 0.1 and returned to 31.6 in a single week.

Test 4 — the ceiling test (arithmetic, decisive). The law itself bounds how fast a genuine stock can grow: the largest possible one-step increment is `eta ln N − delta Q − C <= eta ln N` [Curzi, 2026b]. In the worked office that ceiling is `0.5015 x 1.6094 = 0.8071` `Y`-units per week, and the repackaged proxy's single-week jump of 31.1 units is **38.5 times the theoretical maximum**. A quantity that can move faster than the conversion capacity of the system that allegedly produced it is not stored order. **The law is not only a model; it is a consistency check on the instrument.**

Two further tells do not prove repackaging but reliably accompany it. **A fitted `a` implying an implausible half-life**: in the worked office the fitted `a` for the filtered repackaging was 0.7038, implying a half-life of 1.97 weeks against a directly measured half-life of 224 weeks — a discrepancy of 114-fold, and an institutional stock with a two-week half-life is not an institutional stock. **A fitted `b` far outside the audited `eta`**: the same fit returned `b = 20.2` against an attribution-audited `eta = 0.5015`, a factor of 40. `b` is supposed to *be* `eta`; when the two are not in the same order of magnitude they are not measuring the same thing.

15.5.2 5.2 Three measured reasons the shuffle will not save the analysis

The four-baseline suite of Section 6.4 ends with the shuffled-input control, and analysts reach for it as the general-purpose guarantee that a fit means something. **It is not one.** Its behaviour has been measured by simulation rather than asserted [Curzi, 2026u], and it fails in three distinct ways, two of which can only be repaired at design time.

(1) It is anti-conservative as ordinarily run. Against a nominal `alpha` of 0.05 across 500 null trials the measured false-rejection rates were **0.108 for iid permutation (2.2 times nominal), 0.120 for circular shift (2.4 times nominal), and 0.060 for block permutation** (near nominal) [Curzi, 2026u]. A surrogate test taken off the shelf roughly doubles the false-positive rate, and the block variant — the one most often skipped as fussy — is the only one that behaved. **The remedy is not to abandon it but to calibrate it by simulation on the study's own design** — its series length, its autocorrelation, its block structure — and to preregister the calibrated threshold rather than the nominal one. In the same exercise the matched autoregressive baseline evaluated *alone* false-passed 35.8 per cent of the time, which is the arithmetic behind the requirement that all four baselines be read together.

(2) It cannot see repackaging. The filtered repackaging of Section 9.7 passed all four baselines, the shuffle included, at `p = 0.0005`. It was caught by Test 4 above and by nothing else. **Repackaging is a structural fault and only a structural test detects it.**

(3) It cannot see confounding by a shared slow driver. Where `U` and `Y` are both driven by a third slow variable — a funding cycle, a hiring wave, a market season — a 4,000-trial simulation found the shuffled-input control **passing 98.35 per cent of the time**, while the same simulation reports the control working honestly in the clean case at 48.17 per cent detection [Curzi, 2026u]. The contrast is what makes the 98.35 per cent figure a measurement rather than a complaint.

The consolidated rule: more surrogates do not fix any of this; design controls do. Blinding, channel separation, prospective sampling and a yoked control are the instruments that answer (2) and (3), and every one of them is a decision made among the five operational choices, before a single number exists. **This is why the repackaging tests sit in the survey section and not in the statistics section: by the time columns are being permuted, the instrument is already built.** It is the same lesson the garden-of-forking-paths literature reaches about analytic flexibility [Gelman and Loken, 2013, Simmons et al., 2011] — the damage is done at design time, and no amount of subsequent computation undoes it.

15.6 6 Preregistration and the four baselines

The survey produces six numbers. It does not produce a licence to use them. Six numbers arranged into an equation are a hypothesis about how a real system behaves over time, and a hypothesis that has not been given a chance to fail is not a hypothesis. This section is the procedure that gives the storage law a fair chance to be wrong about an organisation — and, when it is wrong, the procedure that makes the analyst say so.

15.6.1 6.1 What preregistration is for

Preregistration is the practice of writing down, in advance and in a form that cannot be silently edited, exactly what will be measured, exactly how it will be modelled, exactly what result would count as success, and exactly what result would count as failure [Nosek et al., 2018].

It is neither bureaucracy nor modesty. It solves a specific, mechanical problem: with enough freedom in the analysis, any series can be made to support any conclusion, and the person with the most freedom is the person who most wants the conclusion [Simmons et al., 2011]. In organisational work that person is usually the analyst, hired by someone with a preferred answer, working on a system whose staff will read the report. Three freedoms must be

surrendered, in order of the damage they do. **Freedom over the outcome** — choosing `Y` after seeing which candidate proxy moved. **Freedom over the time scale** — trying weekly, monthly and quarterly and reporting the one that worked; this is especially seductive because, as Section 6.7 shows, the time scale genuinely matters, which is exactly why choosing it after the fact is fatal. **Freedom over the specification** — adding a lag, an intercept, a control, or a dropped outlier until the fit clears. Preregistration surrenders all three in a dated document, before the holdout is examined.

15.6.2 6.2 The freeze

The freeze is the moment every choice becomes read-only. It has a date, a signature, and a copy held by someone other than the analyst.

Frozen item	Source
The five operational choices	Appendix A, Form A
The repackaging audit results	Appendix A, Form B
`N`, and the merge/drop decisions	Appendix A, Form C
The estimation window and the train/holdout split	Section 6.3
The time scale and its block alignment	Section 6.7
The model specification, including that `C_hat` has coefficient 1	Section 3.3
The four baselines and their exact definitions	Section 6.4
The three falsification rules and their numerical tolerances	The Law, above
The pre-declared handling of missing periods, outliers, and structural breaks	Section 6.3
The stopping rules and harm criteria for any intervention that follows	Section 6.10

What is *not* frozen, because it must not be: the holdout data. The training data may be examined as much as required before the freeze — that is what training data is for. **The holdout is not examined until after the freeze, and it is examined once.**

Where something must change after the freeze, it may — and the change converts the entire analysis from confirmatory to exploratory, permanently, and must be labelled as such in every sentence that reports it. This is not a punishment. Exploratory analysis is how new hypotheses are found. It is simply not evidence [Platt, 1964].

15.6.3 6.3 Train, holdout, and the fitting procedure

Split the series by time, never at random. Random splits leak: a randomly held-out period sits between two training periods and its level is nearly determined by them. The recommended split is the last 20 to 30 per cent of the series by calendar, with the exact boundary period declared in the preregistration. Three rules are violated constantly. **One look**: the held-out numbers are computed once, and any refitting after looking must be declared and the analysis relabelled exploratory. **No holdout in the estimation of anything**, including `delta` from the zero-input episode and `eta` from the attribution audit; where the zero-input episode falls in the holdout, either the split moves or the independent measurement of FR3 is no longer independent, and the report says which. **Report the holdout size**: a holdout of four blocks is not a holdout but an anecdote with a standard deviation, and Section 9.6 shows what that costs.

The awkward cases are declared in advance. **Periods with `U_t = 0` are kept** — they are the most informative periods available — with `F(0) = ln(1) = 0` stated explicitly, which is exact and requires no special-casing. **Missing audits** follow a declared rule, either carry-forward with a flag or drop-the-pair with a count; a stock is never interpolated, because interpolation manufactures the smoothness the analysis is trying to test for. **Outliers** follow a rule that does not reference the residual, because a rule that drops large residuals guarantees a good fit; the admissible rule references the *record* — a period in which the register was migrated, recounted or restated may be excluded, documented at the freeze if known and reported as exploratory if discovered later. **Structural breaks** that are known — a merger, a new director, a legal change — are declared, along with whether the window spans them and whether the fit will be run separately on each side; discovering a break after the fact and splitting on it is exploratory. And **the ceiling check** is declared: any observed single-period increase exceeding `eta ln N` plus the conversion-lag allowance is investigated before the analysis proceeds.

The fitting procedure is numbered so that it can be executed without judgement.

1. **Assemble the pair set.** For each period `k` in the training window for which both `k` and `k+1` are observed, form the row `(Y_k, F(U_k), C_hat_k, Y_{k+1})`.
2. **Move the cost to the left.** Define `z_k = Y_{k+1} + C_hat_k`. Because `C_hat` has a fixed coefficient of one, it is an offset and not a regressor.
3. **Fit unconstrained.** Solve the ordinary least-squares problem `z_k ~ a Y_k + b F(U_k)` with no intercept, and record `(a_unc, b_unc)`. **This is FR1's test; it is performed before the constrained fit and the answer is written down.**
4. **Fit constrained.** Solve the same problem subject to `0 <= a <= 1`, `b >= 0`, and record `(a, b)`.
5. **Translate.** `delta_fit = 1 − a`; `eta_fit = b`. Convert `delta_fit` to a half-life and a time constant so it is comparable with the survey's directly measured `delta`.
6. **Report the profile interval on `a`.** Refit `b` on a grid of fixed `a` values, record the sum of squared errors, and take the set of `a` within the declared confidence threshold. On slow stocks this interval is wide, and showing that it is wide is part of the report.
7. **Freeze the fitted coefficients.** They are now constants.
8. **Predict the holdout, once.** `Y_hat_{k+1} = a Y_k + b F(U_k) − C_hat_k`, one step ahead, using the *observed* `Y_k` at each step rather than the model's own previous prediction. One-step-ahead is the honest evaluation for a stock; free-running multi-step prediction of a near-unit-root series tests patience rather than the model.
9. **Compute held-out RMSE** for the model and for each of the four baselines.
10. **Run the shuffled-input control** (Section 6.5).
11. **Evaluate FR1, FR2 and FR3 against the frozen tolerances.** Record each as PASS or FAIL. They are not averaged and not weighted.
12. **Write the verdict sentence.** One sentence of the form: *the storage law is / is not corroborated as a model of `Y` in this system at the preregistered time scale, and the rule it failed is ___.*

The metric throughout is one-step-ahead held-out RMSE in `Y`-units. Raw RMSE is reported for every model, not only skill scores, because a skill score of 40 per cent means something completely different when the RMSE is 0.5 rules and when it is 50 rules. The skill convention is `skill = 1 − RMSE_model / RMSE_baseline`, so positive is better and a skill of 0.40 means the model's error is 60 per cent of the baseline's.

15.6.4 6.4 The four required baselines, and the distinct failure each one catches

Each baseline is a specific accusation against the model, and all four must be answered.

Baseline 1 — PERSISTENCE. `Y_hat_{k+1} = Y_k`. No parameters. *The accusation:* the model adds nothing over the observation that stocks are sticky. *What it catches:* the commonest and most embarrassing failure, and the reason a stock is treacherous to model. A quantity with a

four-year half-life barely moves period to period, so *it will be what it was* is an excellent forecast, and any model of a slow stock that cannot beat persistence has learned nothing about the stock. Persistence gets easier to beat as the period lengthens, because more happens between observations, so a large skill against persistence at a coarse time scale is not impressive on its own and must be read together with baselines 3 and 4.

Baseline 2 — DIRECT INPUT. `Y_hat_{k+1} = c_0 + c_1 F(U_k)`, with `c_0, c_1` fitted on the training data. No memory term. *The accusation:* `Y` is not a stock at all but a function of the input, and the memory term is decoration. *What it catches:* contemporaneous repackaging, species 1 of Section 5. If `Y` is an affine function of the interaction then the input alone predicts it and the accumulator adds nothing. For a genuine stock this baseline is hopeless, because the input carries no information about the *level* — in Section 9.4 it has a held-out RMSE of 79.4 rules against the model's 1.85, a skill of 97.7 per cent. **A direct-input baseline that performs well is not good news. It is the alarm for the order-proxy trap.**

Baseline 3 — MATCHED AUTOREGRESSIVE. `Y_hat_{k+1} = a_0 + a_1 Y_k`, with `a_0, a_1` fitted on the training data: two free parameters, matching the storage model's two. *The accusation:* the model is trend-following with extra steps, and the input term earns nothing that memory plus drift did not already give. *What it catches:* the failure that matters most for institutional work, and by far the hardest of the four to beat. An AR(1) with an intercept can represent any exponentially-approaching trend, and a declining institution *is* an exponentially-approaching trend. **Where a storage model cannot beat a matched autoregression, what has been measured is that the system is drifting — which was already known — and not that interaction is driving it, which is the entire claim.** The matching is essential: a baseline with fewer free parameters than the model is not a fair comparison, and the AR(1)-with-intercept has exactly two, as the storage model does. This is the baseline the confirmatory fit of Section 9 failed.

Baseline 4 — THE SHUFFLED-INPUT CONTROL. Refit and re-evaluate the *same* storage model with the input series `F(U_k)` randomly permuted in time, leaving `Y_k`, `C_hat_k`, the constraints and the split unchanged; repeat many times to build a null distribution of held-out RMSE, and locate the real fit within it. *The accusation:* `b` is not fitting the input's dynamics but its average level, and any series with the same distribution would have done as well. *What it catches:* the failure no other baseline can see. **It is the baseline most often omitted and most often decisive** — omitted because it is the only one requiring a loop rather than a formula, and decisive because it is the only test that asks whether the *timing* of interaction matters, which is the only thing distinguishing a driven accumulator from a bucket with a tap running at a constant average rate.

15.6.5 6.5 The shuffled-input control in detail

The procedure has five steps. Take the training pair set and permute the `F(U_k)` column, leaving `Y_k`, `C_hat_k` and `Y_{k+1}` in their original order. Refit the constrained model on the permuted training data, obtaining `(a*, b*)`. Permute the `F(U_k)` column of the *holdout* independently and compute held-out RMSE with `(a*, b*)`. Repeat at least 1,000 times; 2,000 is better and costs nothing. Report the mean and fifth percentile of the null RMSE distribution, the count of permutations achieving an RMSE at least as good as the real fit, and the resulting `p = (count + 1)/(n + 1)`.

Three details are commonly got wrong. **Refit under the permutation**: keeping the real `b` and permuting the input only at prediction time builds a much weaker null, because it tests whether the input helps *given a coefficient fitted to the true alignment*, which is nearly circular. **Permute the holdout independently**, or the holdout retains the alignment the null is supposed to destroy. **Do not permute `C_hat`**: the control isolates the input term, so cost stays aligned and stays at coefficient one, holding its explanatory contribution constant between the real fit and the null. That is what makes the test specific.

What the shuffle can and cannot detect has already been stated in Section 5.2 and is repeated here because this is where the suite is specified: **it detects that the input's timing carries**

information; it does not detect that `Y` is a filtered copy of `U`, because a filtered input is genuinely predicted by the input and the shuffle destroys that genuine prediction just as it would destroy a real one. **The shuffle is the empirical audit; the repackaging tests are the structural audit; they are different audits and both are required.** And the shuffle's own calibration is measured, not assumed: 0.108 against a nominal 0.05 for iid permutation, 0.120 for circular shift, 0.060 for block permutation [Curzi, 2026u]. Any `p` reported against the nominal threshold is therefore optimistic, and Section 12 carries that as a limitation of this paper's own headline `p = 0.0005`.

15.6.6 6.6 Reading the three rules together

```
FR1 fail  ->  the system is not a leaky accumulator. Stop. A different model is needed.
FR2 fail  ->  the model has no demonstrated predictive advantage. None may be claimed.
FR3 fail  ->  the model fits with parameters that are not this system's. Suspect the proxy.
```

The combinations are informative:

FR1	FR2	FR3	Reading
pass	pass	pass	Corroborated at this scale. Proceed to an intervention with a validated model.
pass	fail	pass	Parameters corroborated; predictive advantage not demonstrated. **Accounting frame only** — see Section 6.8.
pass	pass	fail	The classic order-proxy trap. Return to Appendix A, Form B.
pass	fail	fail	Uninformative. The series is too short, too noisy, or the proxy is wrong.
fail	any	any	Rejected. The storage law is not the right model for this system.

Note the second row, because it is the outcome the worked application produces and it is common in real institutional data. Corroborated parameters with no demonstrated predictive advantage is a real and useful state, and it licenses much less than people want it to.

15.6.7 6.7 Choosing the time scale before looking

Section 4.5 gave three constraints on the period. Here is the fourth fact, and the reason the choice must be frozen: **the time scale materially changes the result, and it changes it in a direction that can be anticipated.**

The structure is this. Audit error on a *level* does not accumulate — counting the register twice, six months apart instead of one week apart, leaves the counting error at each endpoint the same size — while the accumulated input between those endpoints has grown with the

interval. Coarsening the time scale therefore raises the signal-to-noise ratio of the `b F(U)` term, and destroys degrees of freedom linearly. There is an optimum, and it depends on quantities estimable before the holdout is examined:

```
signal per block  ~  B x eta x mean F(U)
noise per block   ~  sqrt(2) x (audit error SD)          (does not grow with B)
blocks available  =  T / B
```

The first line reads `mean F(U)`, and the distinction is not decoration. Coarsening the time scale aggregates `U` over `B` fine periods, and there are two ways to carry the input into the block: average the `U` values and take `F` once, or take `F` of each fine period and average the results. They are different numbers, and strict concavity fixes the direction:

```
mean of F(U_k)  <=  F( mean of U_k )        with equality only if U is constant within the block
```

Aggregate `F`, never aggregate `U`. Taking `F(mean U)` inflates the input term, and inflates it more the coarser the block — which means a preregistration that aggregates the wrong way will show the model improving at every increase in `B` for reasons having nothing to do with signal-to-noise, and the analyst will read a Jensen artefact as a discovery about the time scale. The gap deserves a name and a number: it is the **concavity penalty**, and in the worked office it is 0.0761 nats against an `F(mean U)` of 1.2262 — **6.2 per cent of the surplus**, lost purely to the variability of the geometry. The aggregation rule is declared alongside the aggregator itself and the penalty is reported with the fit.

`B` is chosen by writing the trade-off down and picking a value with a stated reason before the freeze. Legitimate reasons: `B` must exceed the conversion lag; `B` must give at least 8 holdout blocks; `B` must not push `delta` per block above 0.3. **Illegitimate reason: `B = 13` gave the best result.** In the worked application the answer at `B = 13` is materially better than at `B = 8` on every metric. It is also based on four holdout blocks, and it was not the preregistered choice, so it is reported as exploratory and licenses nothing. That is what the discipline costs, and paying it is the difference between a survey and an advertisement.

15.6.8 6.8 What a passing fit licenses, and what it does not

A pass licenses: using the fitted `a` and `b` as corroborated estimates of `delta` and `eta` for that system, at the fitted time scale, over the fitted regime; computing `h` from them; computing a maximum admissible increment `r <= h`; and stating a one-step prediction with an interval derived from the held-out residuals.

A pass does not license any of the following. *Multi-period forecasts* — the model was evaluated one step ahead, and a ten-step forecast of a near-unit-root series has an error that none of the discipline above has tested. *Causal claims* — the shuffle establishes that the timing of interaction carries information about subsequent order; it does not establish that intervening on interaction will produce order, which is a different claim requiring a different design. *Transfer to another system* — `delta`, `eta`, `N` and `C` are the parameters of *this* system, and the scale-free form of the law is a claim about model form rather than about parameter values [Curzi, 2026a,k]. *Transfer to another proxy* — a fit validated on live precedent rules says nothing about reviewer competence, cycle time, or public satisfaction. *Extrapolation past the ceiling* — `Q_t <= max{Q_0, eta ln N / delta}`, so a prediction above the uniform bound is a prediction the model has already forbidden.

15.6.9 6.9 Preregistration as a corruption control

A measure that becomes a target ceases to be a good measure [Goodhart, 1975], and the sociological form is sharper still: the more a quantitative indicator is used for social decision-making, the more it will distort and corrupt the processes it was meant to monitor [Campbell,

1979]. Both apply to `Y` immediately and mechanically, from the moment anyone in the organisation learns that `Y` is being counted.

The mechanism in the framework's own terms is precise. `Y` is a proxy for `Q`. Corruption is the process by which the correlation between `Y` and `Q` is destroyed by effort directed at `Y`. A review office that learns its live-rule count is the metric can raise the count without raising stored order at all: split existing rules, write rules nobody applies, restate one rule as three. The proxy rises, the order does not move, and every number downstream — `delta`, `eta`, `h` — becomes a measurement of the gaming rather than of the system. The self-fulfilling dynamic is the same one Merton [1948] described.

Five defences, in descending order of effectiveness. **Keep `Y` out of the reporting line** — the strongest by a wide margin, since a proxy not used to evaluate anyone is not worth gaming; where `Y` must be reported, report `h` and the verdict rather than `Y`. **Make the liveness correction standing practice**, because gamed units are created and never applied, so a liveness threshold removes most of them automatically and without anyone having to accuse anyone. **Preregister the proxy definition, including its corrections**, because corruption works by exploiting the *edges* of a definition and a definition frozen and dated before the incentive existed cannot be quietly widened. **Rotate the proxy** on a schedule known to the analyst and not to the surveyed — expensive, and it breaks series continuity, so reserve it for strong incentives. **Measure at least one proxy the organisation cannot influence** — in the worked office, appeal reversal counts come from an external appeals board, and a proxy the organisation does not control is a check on the ones it does.

Preregistration is therefore not only an epistemic device. It is the specific administrative countermeasure to measure corruption, because it fixes the definition of the measure at a time when nobody yet has a reason to distort it.

15.6.10 6.10 Preregistering an intervention

Everything above concerns modelling an existing system. Where the preregistration also covers an intervention, five further sections are mandatory.

The prediction, in numbers, with a direction and a magnitude. Not *improvement is expected*. The form is: `Y` will increase by at least `r` per period, measured at the preregistered time scale, over at least `k` periods, beginning no earlier than period `m` after the change. The lag `m` must be stated because a conversion lag exists and testing before it has elapsed is a test designed to fail.

The falsification criterion for the intervention, distinct from FR1–FR3. What observation would establish that the intervention did not work, stated as a number. The standard form: if the mean one-period change over periods `m` to `m + k` is below `r_min`, the intervention is judged ineffective and withdrawn. A second falsification should be preregistered alongside it because it is free: the parameter-free crossing time `t* = ln(u*/u_0)/ln(1 − lambda)` of Section 4.12, which yields a calendar date and contains no researcher degree of freedom, and which must be reported per site rather than pooled.

The stopping rules, of two kinds and both required. *Futility*: the condition under which the intervention stops because it is not working. *Harm*: the condition under which it stops immediately regardless of how well `Y` is doing. **Harm criteria must include at least one measure that is not `Y`**, because an intervention that raises the proxy while damaging the system will not stop itself.

The consent and declination clause. The framework's declination constraint is binding: no intervention that removes a person's ability to decline is in scope. The preregistration must therefore state, for each affected group, what is being changed, how they were informed, and by what mechanism an individual may decline without penalty. **Where the honest answer to the last is that they may not, the intervention is out of scope and the preregistration does not proceed.** This is not a formality appended to the science; it is a constraint on which interventions exist at all. The corpus's analysis of verification cost gives the reason such constraints have to be priced rather than assumed: verification is all-or-nothing with threshold `a*`

`= 1 − c_v*delta_0/(K − c_v)`, and at `c_v >= K` verification consumes the entire net input [Curzi, 2026s].

The reversibility statement. The exact procedure for returning the system to its prior state, who is authorised to execute it, how long it takes, and what is not recoverable. A sixth item is optional and strongly recommended: **the pre-mortem** — before the freeze, write the paragraph that would be written in a year explaining why the intervention failed. It costs twenty minutes and routinely surfaces the harm criterion nobody had thought of.

15.7 7 Specifications

Numbered, checkable requirements. A survey that does not satisfy all of Section 7.1 is not a survey and must not be used as the basis for an intervention; an analysis that does not satisfy all of Section 7.2 is not confirmatory. Nothing in either list is an empirical claim.

15.7.1 7.1 The survey

S24.1 The system boundary shall be stated in writing, including at least one named thing that is deliberately excluded and the reason for excluding it.

S24.2 All five operational choices of Section 3.2 shall be recorded before any measurement is taken, and shall be dated.

S24.3 The state encoder shall be specified to the level of "a second engineer could produce the same vectors": the probe set, the response format, the normalisation, and the administration protocol.

S24.4 The probe set shall contain at least 8 real cases drawn from the system's actual workload and shall be administered independently and in writing before discussion.

S24.5 The interaction aggregator shall be declared and badged as a modelling choice. If the mean pairwise aggregator is used, its identity with the participation-ratio effective count shall be noted so the choice is traceable to a standard diversity measure.

S24.6 Capacity `u` and realised `u` shall be reported as two separate numbers with their two separate instruments. Reporting only one is a specification violation.

S24.7 The order observable shall be tested against all five properties of §24.4, with the answers recorded.

S24.8 The four repackaging tests of §24.15 shall be run and their results recorded. Tests 1 and 2 shall be run before measurement begins.

S24.9 Test 1 shall be passed with zero shared source fields between `Y` and `U`.

S24.10 Test 2 shall be passed with a named different recorder, a named different medium, and a named different schedule.

S24.11 Where a zero-input episode exists in the record, Test 3 shall be run and its result plotted.

S24.12 Test 4 shall be run for the largest single-period increase in `Y` observed in the series. Any increase exceeding `eta ln N` shall be investigated before the survey is released.

S24.13 The time scale shall be declared with its calendar alignment and shall satisfy: period >= conversion lag; `delta` per period <= 0.3; and a stated rationale for the signal-to-noise trade-off of §24.5.

S24.14 Periods with `U_t = 0` shall be retained in the series and flagged, never dropped.

S24.15 `C` shall be denominated in `Y`-units. Every Route 2 line shall show its conversion rate and the justification for it.

S24.16 The attention tax shall appear as an explicit line in the cost tally, even if the estimate is coarse. A tally with no attention-tax line is incomplete.

S24.17 Turnover shall be assigned to `delta` or to `C` by a written rule, and shall not appear in both.

S24.18 Slack shall not be booked as cost.

S24.19 `delta` shall be estimated by Method D1 where a zero-input episode exists. Where D2 is used, the log-survival plot shall be inspected for linearity and non-linearity reported.

S24.20 `delta` shall be reported with its half-life and time constant in periods and in calendar time.

S24.21 `eta` shall be estimated by an attribution audit in which each counted `Y`-unit has a documented originating interaction. Unattributable units shall be excluded and their count reported.

S24.22 `N` shall be produced by explicit enumeration, merge, and drop steps, with each merge and drop recorded with its reason.

S24.23 Categories with pairwise `u < 0.10` shall be merged.

S24.24 `Q` shall be reported pre-correction, with the liveness correction and the applier correction shown separately, and post-correction.

S24.25 The line-item `C_hat` shall be reconciled against the cost implied by the observed series, and the residual reported. A residual exceeding the declared tolerance blocks release.

S24.26 `h`, the realised one-step change, and `Q_inf` shall all be computed and reported.

S24.27 A negative `Q_inf` shall be reported as negative, with the Theorem 3.5 failure clause quoted.

S24.28 Every number on the survey output page shall carry a provenance note naming the instrument and the date range.

S24.29 The survey shall state, in one sentence each, the three things that would most change its conclusions if measured differently.

S24.30 The survey shall not recommend an intervention. Recommendation is the function of the intervention protocol that follows in this series, and requires the preregistration of Section 6 first.

15.7.2 7.2 The preregistration

S25.1 A preregistration document shall exist, be dated, be signed, and be held in a copy by a person who is not the analyst.

S25.2 The freeze shall occur before any examination of holdout data.

S25.3 The model specification shall be exactly `Y_{t+1} = a Y_t + b F(U_t) − C_hat_t + eps_t` with `0 <= a <= 1` and `b >= 0`, unless a deviation is declared at the freeze with its reason.

S25.4 `C_hat_t` shall enter with a fixed coefficient of one. Estimating a coefficient on cost is a declared deviation and changes the identification.

S25.5 No intercept shall be added unless declared at the freeze with a stated interpretation.

S25.6 The train/holdout split shall be by calendar time, never at random, and the boundary period shall be named.

S25.7 The holdout shall contain at least 8 estimation blocks. If it cannot, the analysis shall be labelled exploratory throughout.

S25.8 The unconstrained fit shall be computed and reported before the constrained fit.

S25.9 FR1 shall be evaluated on the unconstrained optimum, not on the constrained one.

S25.10 All four baselines shall be computed: persistence, direct-input, matched autoregressive, and shuffled-input.

S25.11 The matched autoregressive baseline shall have the same number of free parameters as the storage model.

S25.12 The shuffled-input control shall refit the model under each permutation, permute the holdout independently, and use at least 1,000 permutations.

S25.13 The shuffled-input control shall not permute `C_hat`.

S25.14 Raw held-out RMSE shall be reported for the model and for all four baselines, in `Y`-units, alongside any skill scores.

S25.15 The margins for FR2 shall be declared at the freeze. The recommended defaults are 10% RMSE reduction against each of the first three baselines and `p <= 0.05` against the shuffle.

S25.16 The tolerance for FR3 shall be declared at the freeze. The recommended default is +/-25% on each of `delta` and `eta`.

S25.17 FR1, FR2 and FR3 shall each be reported as PASS or FAIL individually. They shall not be averaged, weighted, or combined into a score.

S25.18 A failure of any one of the four baselines is a failure of FR2.

S25.19 The time scale shall be chosen and justified before the freeze. Results at other time scales may be reported only as exploratory and only with that label attached in the same sentence.

S25.20 The fitted `a` shall be reported with a profile interval, and the corresponding interval on the half-life shall be stated in calendar units.

S25.21 Held-out prediction shall be one step ahead using observed `Y_t`, not free-running.

S25.22 Residual autocorrelation shall be reported.

S25.23 Periods with `U_t = 0` shall be retained, with `F(0) = 0`.

S25.24 The outlier rule shall not reference residuals.

S25.25 Known structural breaks shall be declared at the freeze, with the handling rule.

S25.26 The verdict shall be written as one sentence naming the rule that failed, if any.

S25.27 A verdict of “parameters corroborated, predictive advantage not demonstrated” shall be reported in those words and shall not be paraphrased upward.

S25.28 Where the preregistration covers an intervention, it shall state the numeric prediction, the falsification criterion, both stopping rules, the consent and declination mechanism, and the reversibility procedure.

S25.29 At least one harm criterion shall be a measure other than `Y`.

S25.30 If no mechanism exists by which an affected individual may decline without penalty, the preregistration shall not proceed and the reason shall be recorded.

15.8 8 Failure modes

Each entry gives a description, what it damages, its signature, how it is detected, and the repair. They are the named faults for which the survey and the preregistration are responsible.

15.8.1 8.1 Faults of the survey

F24.1 — THE ORDER PROXY THAT WAS REALLY THE INPUT. *Description.* `Y` is a function of `U`, so the model fits an identity. *Damages.* Everything. The survey has no empirical content. *Signature.* Fitted `b` far outside the audited `eta`; fitted `a` implying an implausible half-life; `Y` collapses to zero during a shutdown; single-period jumps exceeding `eta ln N`. *Detection.* The four tests of §24.15. Tests 1 and 2 before measurement; 3 and 4 on the series. *Fix.* Redefine `Y` into a different medium with a different recorder. There is no statistical remedy; this is a definitional error and only a definitional change repairs it.

F24.2 — THE MISSING DENOMINATOR. *Description.* `C` is measured in hours or money while `Y` is measured in rules or modules, and `h` is computed anyway by implicitly treating them as commensurate. *Damages.* `C`, and therefore `h`. *Signature.* The headroom calculation has mixed units. The number is arithmetically well-formed and physically meaningless. *Detection.* Write the units next to every term in `h = eta ln N − delta Q − C`. They must match. *Fix.* §24.6. Route 1 where possible; a declared and justified Route 2 rate otherwise.

F24.3 — THE SNAPSHOT SURVEY. *Description.* `Q` is measured once. No series, therefore no `delta`, therefore no `h`. *Damages.* `delta`, and by omission the verdict. *Signature.* The survey reports a level and a judgement about whether it is “healthy”. *Detection.* Ask for the second measurement date. If there is not one, this is the fault. *Fix.* Reconstruct a retrospective series

from the register's own history. Most durable registers carry creation and strike dates and can be replayed.

F24.4 — THE MISSING ZERO-INPUT EPISODE. *Description.* No shutdown in the record, so `delta` is estimated by testimony. *Damages.* `delta`, and through `delta Q` the whole budget. *Signature.* `delta` reported as a round number with no derivation. *Detection.* Check Form D for a named episode. *Fix.* Method D2, the cohort decay curve, which needs no episode. Failing that, run a deliberate, bounded, reversible zero-input trial on a subset, under the pilot rules of the intervention protocol.

F24.5 — ATTENDANCE ENCODED AS PARTICIPATION. *Description.* Categories present but silent are counted in `U_t`. *Damages.* `u`, upward. Inflates `F(U)` and hides the realisation deficit. *Signature.* Realised `u` equals capacity `u` exactly, which essentially never happens. *Detection.* Compare the participation rule in A12 against the actual record of who spoke. *Fix.* Require a recorded disposition. A category with no recorded position is not in that period's geometry.

F24.6 — THE PERMISSIVE ATTRIBUTION AUDIT. *Description.* `eta` is computed by dividing all new `Y`-units by all surplus, without checking which units actually came from interaction. *Damages.* `eta`, upward, often by a large factor. *Signature.* `eta` implausibly high relative to the observed trajectory; the fitted `b` of Section 6 comes out far below the audited `eta`. *Detection.* Recount with the strict rule: documented originating interaction or excluded. *Fix.* Redo Form E. Report the unattributable count; it is itself a useful diagnostic, because a large unattributable fraction means the system's order is being made somewhere the survey is not looking.

F24.7 — CATEGORY INFLATION. *Description.* `N` counted from the org chart rather than from the geometry, so relabelled duplicates are counted separately. *Damages.* `N` upward, and therefore `eta ln N` and `h` upward. *Signature.* Two categories in the pairwise table with `u < 0.10` and separate rows. *Detection.* Form C, the merge step. *Fix.* Merge, and record that the merge has *reduced* the measured headroom, which is the survey doing its job.

F24.8 — THE UNRECONCILED TALLY. *Description.* The cost line items are summed and never checked against the series. *Damages.* `C`, in either direction. *Signature.* Form F3 blank. *Detection.* Compute the cost implied by the observed trajectory given `delta`, `eta` and `F(U)`, and compare. *Fix.* Reconcile. A large residual usually means an omitted cost category, not an arithmetic error.

F24.9 — GOODHART CAPTURE OF THE PROXY. *Description.* Once `Y` is known to be measured, the organisation optimises `Y` directly. *Damages.* The validity of `Y` as a proxy for `Q`, progressively, over time. *Signature.* `Y` rises while every qualitative indicator falls. Newly created units are small, uniform, and never applied. *Detection.* The liveness audit (§24.12) is the counter-instrument: Goodharted units are created and never used. *Fix.* Section 6.7. In the survey, the immediate mitigations are to keep `Y` in a register that is not reported upward, to include the liveness correction as standing practice, and to rotate the proxy definition on a schedule known to the surveyor and not to the surveyed.

F24.10 — THE INVISIBLE MAINTENANCE REGIME. *Description.* Everything that works is invisible, so the survey under-measures both `Q` and the effort holding it (Star and Ruhleder 1996). *Damages.* `Q` downward and `C` downward — which can mask an unsustainable `h` behind two compensating errors. *Signature.* No records exist for the parts of the system nobody complains about. *Detection.* For each `Y`-unit class, ask what keeps it alive and who. Expect a person. *Fix.* Count the named people as a maintenance line in `C` and note the concentration risk. A maintenance regime resting on one un-deputised person is an orphaning event waiting for a date.

15.8.2 8.2 Faults of the preregistration and the fit

F25.1 — THE MOVED GOALPOST. *Description.* A tolerance or margin is adjusted after the held-out numbers are seen. *Damages.* The entire evidential status of the analysis. *Signature.* A reported margin that is not a round number, or that differs from the preregistration by a small amount in exactly the direction needed. *Detection.* Compare the report to the frozen document held by the independent holder. This is what the independent holder is for. *Fix.*

Relabel as exploratory, in every sentence, and rerun the confirmatory analysis on a fresh holdout in the next cycle.

F25.2 — THE OMITTED SHUFFLE. *Description.* Three baselines are reported and the shuffled-input control is not. *Damages.* The claim that interaction is doing anything. *Signature.* A results table with exactly three baseline rows. *Detection.* Trivial, and it is the first thing to look for in any report using this framework. *Fix.* Run it. It takes a loop and a minute of compute. Expect it to change the conclusion in a meaningful fraction of cases.

F25.3 — THE UNMATCHED AUTOREGRESSION. *Description.* The AR baseline is given fewer free parameters than the storage model, usually by dropping the intercept. *Damages.* FR2, in the model's favour. *Signature.* An AR baseline described as "AR(1)" with one coefficient reported. *Detection.* Count the parameters on both sides. *Fix.* Restore the intercept and rerun. Expect the model's apparent advantage to shrink substantially; on slow stocks it usually does.

F25.4 — MULTI-STEP FLATTERY. *Description.* Held-out performance is computed on free-running multi-step forecasts, where persistence and AR degrade fast and the model looks heroic. *Damages.* FR2, in the model's favour, sometimes by an order of magnitude. *Signature.* Skill scores above 0.9 against persistence on a stock with a long half-life. *Detection.* Ask which `Y_t` was used at each step: the observed one, or the model's own previous prediction. *Fix.* One-step-ahead with observed `Y_t`. If multi-step performance is genuinely of interest, preregister it separately, with its own baselines evaluated the same way.

F25.5 — TIME-SCALE SHOPPING. *Description.* Several block lengths are tried and the best is reported as the analysis. *Damages.* Everything; this is `p`-hacking with an unusually large search space, because the block length also changes the effective sample size. *Signature.* A block length with no stated justification, or a justification that could equally have supported two other values. *Detection.* Check Part 2.3 of the preregistration for a justification that does not reference results. *Fix.* Report the preregistered scale as confirmatory and all others as exploratory, in the same table, with the label in the row.

F25.6 — THE COST COEFFICIENT. *Description.* `C_hat` is entered as a regressor with a free coefficient because the fit is better. *Damages.* The identification. With a free coefficient on cost, `b` is no longer `eta` and `h` can no longer be computed from the fit. *Signature.* Three fitted coefficients reported instead of two. *Detection.* Count them. *Fix.* Fix the coefficient at one. If the fit is materially worse, that is information: the cost observable is mis-denominated, and the repair is in Section 4.6, not in the regression.

F25.7 — THE RESIDUAL-BASED OUTLIER RULE. *Description.* Periods with large residuals are excluded as "data quality issues". *Damages.* Guarantees a good fit and destroys FR2. *Signature.* An exclusion list whose members are all large residuals. *Detection.* Ask what the exclusions have in common in the *record*. If the answer is only "the model predicted them badly", this is the fault. *Fix.* Restore them. Investigate them individually against the record; genuine restatements can be excluded with a documented, record-based reason.

F25.8 — THE UNLABELLED EXPLORATORY RESULT. *Description.* An analysis run after the freeze, or after a deviation, is reported alongside confirmatory results without a label. *Damages.* The reader's ability to weight the evidence. *Signature.* A results section in which every number has equal typographic status. *Detection.* Cross-reference every reported number against the frozen document. *Fix.* Label in the sentence, not in a footnote. The convention that works: the word "exploratory" appears in the same sentence as the number.

F25.9 — THE ETHICS APPENDIX. *Description.* Consent, declination, stopping and reversibility are written after the design is settled, as a compliance step. *Damages.* The design itself, invisibly, because an intervention designed without a declination mechanism usually cannot have one retrofitted. *Signature.* Part 5.8 of the form completed last, in different handwriting. *Detection.* Ask what the design would have been if declination had been a constraint from the start. If the answer is "different", the fault is present. *Fix.* Redesign. **The declination constraint is not a review gate; it is a constraint on the space of admissible designs, and it belongs at the front of the process.**

F25.10 — SUCCESS DECLARED FROM AN ACCOUNTING FRAME. *Description.* FR2 fails, FR3 passes, and the report says the model "was validated". *Damages.* Everything downstream, be-

cause the intervention protocol's pilot rules depend on which of these happened. *Signature.* The phrase "broadly consistent with" doing load-bearing work. *Detection.* Look for the individual PASS/FAIL lines. If they are not individually reported, S25.17 has been violated. *Fix.* Report the verdict in the prescribed words: *parameters corroborated, predictive advantage not demonstrated.* Then apply the licence list of Section 6.8, which permits computing `h` and forbids claiming a forecast.

15.9 9 Results: one system surveyed, preregistered, and tested

15.9.1 9.1 The system, and what kind of object it is

Meridian County Development Review Office. A municipal development review office: 26 staff, five review disciplines, a weekly cross-discipline review board, and a standing review manual of written precedent rules that reviewers are required to apply.

Badge — this is a constructed composite, not a field study. The organisation is invented. The arithmetic is real, computed, and reproducible: the audit series is a simulation with declared generating parameters, produced so that every number in this paper can be checked by the reader. **It must not be cited as evidence about any real review office.** Its function is to show the procedure operating end to end on numbers that behave the way real numbers behave — including the places where they refuse to cooperate.

The five choices as declared:

#	Choice	As declared for MCDRO
1	State encoder	Encoder A. Probe set of `m = 12` real development applications from the previous two years, each with a forced approve/refuse disposition, recorded independently and in writing by each discipline lead before any discussion. Vector = the 12 signs, normalised.
2	Interaction observable	Mean pairwise `1 - (x_i . x_j)^2` over the disciplines that recorded a disposition in that week's board. Participation = a recorded disposition, not attendance. Badged as a declared aggregator.
3	Order observable	`Y` = count of **live precedent rules in the standing review manual**. A rule is live if it is in the register, not superseded, and has been applied at least once in the previous 156 weeks. Maintained by the code administrator, who does not attend the board.

#	Choice	As declared for MCDRO
4	Time scale	One week. Audit taken every Friday. Conversion lag measured at up to 6 weeks (drafting plus the 10-working-day publication requirement).
5	Cost observable	Route 1 for appeal strikes, orphaning, and contradiction withdrawals. Route 2 for rework and the attention tax, at a declared displacement rate.

The repackaging audit was run first, before measurement began:

Test	Result
1 Algebraic derivation	`Y` fields: rule id, adoption date, supersession date, last-applied date. `U` fields: board date, discipline, recorded disposition. **Shared fields: 0. PASS.**
2 Instrument independence	`Y` recorded by the code administrator into the rule register, audited Fridays. `U` recorded by the board clerk into the minutes, at the session. Different person, medium, schedule. **PASS.**
3 Zero-input persistence	Weeks 121-154, board suspended by a budget freeze. `Y`: 206 at week 121, 186 at week 154, 186 at week 155 when the board resumed. Smooth monotone decay through the episode, continuous across resumption. **PASS.**
4 Ceiling	Largest single-week rise observed: 2 rules. Ceiling `eta ln N = 0.5015 x 1.6094 = 0.8071` per week; over the 6-week conversion lag the admissible burst is well above 2. **PASS.**

Only then did measurement begin.

15.9.2 9.2 The survey: six numbers and one sign

Categories and geometry.

Five disciplines survive enumeration: planning (PLAN), structural and building (STRU), fire and life safety (FIRE), environmental (ENVR), transportation (TRAN). No merges: the smallest pairwise `u` is 0.3056, comfortably above the 0.10 merge threshold. No drops: all five have a route into the board.

```
N = 5       ln N = 1.6094
```

pair	opposed cases k/12	d	cos = 1 - 2d	u = 1 - cos^2
PLAN-STRU	3/12	0.2500	0.5000	0.7500
PLAN-FIRE	2/12	0.1667	0.6667	0.5556
PLAN-ENVR	5/12	0.4167	0.1667	0.9722
PLAN-TRAN	4/12	0.3333	0.3333	0.8889
STRU-FIRE	1/12	0.0833	0.8333	0.3056
STRU-ENVR	3/12	0.2500	0.5000	0.7500
STRU-TRAN	2/12	0.1667	0.6667	0.5556
FIRE-ENVR	3/12	0.2500	0.5000	0.7500
FIRE-TRAN	2/12	0.1667	0.6667	0.5556
ENVR-TRAN	4/12	0.3333	0.3333	0.8889

```
U capacity = 0.6972
N_eff capacity = 1 + 4(0.6972) = 3.7889
F capacity = ln 3.7889 = 1.3321 nats
```

Realised, from the 278 operating weeks of the audit series:

```
U realised = 0.6019      F realised = 1.1498 nats
realisation deficit = 1.3321 − 1.1498 = 0.1823 nats
```

The cause is visible in the record: **32.7% of board sessions ran with fewer than the full set of disciplines recording a disposition.** Those sessions have a mean `u` of 0.2071 against 0.7940 for full sessions. The office has five genuinely non-parallel disciplines and uses about four-fifths of them.

Note the FIRE-STRU pair at `u = 0.3056`. That is the closest thing to redundancy in the set and is exactly where a future reorganisation would be tempted to merge two roles. Merging them would drop `N` from 5 to 4 and cost `ln 5 − ln 4 = 0.2231` nats of ceiling — which, at the office's current `eta`, is 0.112 rules per week, or about 5.8 rules a year, given away permanently.

Decay.

Method D1. The budget freeze of weeks 121-154 suspended the board entirely; no dispositions, no new rules, and — because intake was also halted — no appeals, rework, or contradiction maintenance, so `C = 0` as well as `U = 0`.

```
Y at week 121 = 206
Y at week 154 = 186
n = 33 steps
ratio = 186/206 = 0.90291
delta = 1 − 0.90291^(1/33) = 0.003090 per week

half-life = ln 2 / (−ln(1 − 0.003090)) = 224.0 weeks = 4.31 years
tau = 1/delta = 323.6 weeks = 6.22 years
3 tau = 971 weeks = 18.7 years
```

The office's stored order has a four-and-a-third-year half-life, and its settling time to a new equilibrium is nearly nineteen years. Both facts matter to any proposed intervention. The first says the manual is genuinely durable. The second says nobody now working in the office will see the equilibrium of any change made today.

Conversion.

Window: the last 26 operating weeks of the series.

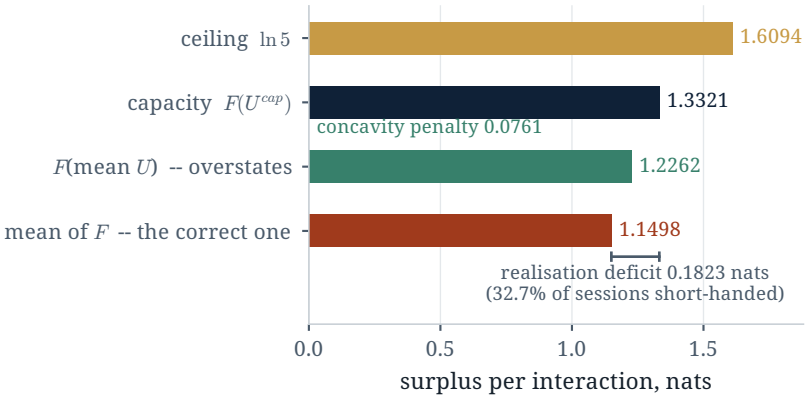

Figure 15.1: Capacity, and the two different realised numbers. The office's five disciplines are genuinely non-parallel: capacity `U = 0.6972` gives `N_eff = 3.7889` against a roster of 5 and `F = 1.3321` nats against the ceiling `ln 5 = 1.6094`. Realised surplus must be computed as the **mean of `F`** over the 278 operating weeks, 1.1498 nats, and not as `F` of the mean `U`, 1.2262 nats; the 0.0761-nat gap between them is the concavity penalty, 6.2 per cent of the surplus, lost to the variability of the geometry alone. Against capacity, the realisation deficit is 0.1823 nats, traced to 32.7 per cent of sessions running short-handed. Measured from the pairwise table and the period record above; generated by `figs/src/CCP-015_fig01.py`.

```
sum of F(U_t) over the window = 31.903 nats
Y-units created in the window = 26 (register count)
of these, attributable with a documented originating board decision = 16
unattributable, excluded = 10

eta = 16 / 31.903 = 0.5015 rules per nat
```

The 10 unattributable rules are themselves a finding: they were written by individual reviewers without a board decision behind them. They are real rules and they are in `Y`, but they were not produced by interaction, so they cannot be used to estimate the conversion of interaction into structure. **A high unattributable fraction is not a measurement nuisance. It reports that the board is not the thing making the order, which is a substantive claim about the office.**

Cost.

line	category	route	Y-units/week
1	Appeal reversals that strike a live rule	1	0.14
2	Rules orphaned by departure (no qualified applier remains)	1	0.11
3	Rework: items re-reviewed after disposition	2	0.16
4	Contradiction maintenance	1	0.09

line	category	route	Y-units/week
5	Attention tax at the declared conversion rate	2	0.13
	C_hat		**0.63**

Reconciliation: the cost implied by the observed series over the operating weeks is 0.6275 Y-units per week. Residual against the line-item tally: **0.0025**, against a declared tolerance of 0.05. The tally may be used.

Slack is not booked. Turnover is assigned by the standing rule: routine attrition sits in `delta`; the two departures that orphaned specific rules sit in line 2 of `C`.

Stock, headroom, and the verdict.

```
Y register count at survey date (week 312)  = 121
liveness correction (no application in 156 weeks) = −6
applier correction (orphaned, no qualified applier) = −2
Q = 113

eta ln N   = 0.5015 x 1.6094 = 0.8071
delta Q    = 0.003090 x 113  = 0.3492
C_hat      =                   0.6300
----------------------------------------
h          = 0.8071 − 0.3492 − 0.6300 = −0.1720
```

VERDICT: h < 0. Unsustainable in this model. No interaction geometry saves it.

This is Corollary 3.4 in its operative form. `C_hat = 0.63` exceeds `eta ln N − delta Q = 0.4579`, and therefore **no rearrangement of who sits on the board, in what order they speak, or how vigorously they disagree can prevent the manual from declining.** Even a perfectly orthogonal board running every week at `U = 1` would return `eta ln N − delta Q − C = −0.1720` rules per week.

The realised picture:

```
one-step = eta F_real − delta Q − C_hat
         = 0.5015 x 1.1498 − 0.3492 − 0.6300
         = 0.5766 − 0.9792
         = −0.4025 rules per week  =  −20.93 rules per year

realisation deficit = h − one-step = −0.1720 − (−0.4025) = 0.2305 rules/week
```

And the steady state, Theorem 3.5:

```
Q_inf = (eta F_real − C_hat) / delta = (0.5766 − 0.6300)/0.003090 = −17.3
```

`Q_inf` is negative. Reported as negative, per S24.27. Theorem 3.5 does not hide this failure mode: the equilibrium is negative, so the regime is unsustainable or the linear model must be replaced. Operationally it means the manual is being driven to the boundary of the model's validity — to zero live rules — and that the linear model says nothing useful below that boundary.

Projected trajectory at current parameters, from `Q = 113`:

horizon	Q
1 year	93.6
3 years	63.1
5 years	41.0
12.6 years	0

15.9.3 9.3 Why the decline was invisible

The office lost 177 rules over the 312 weeks of the audit series — from 290 down to 113, a decline of 61%. At the observed rate of about 21 rules a year out of a stock of roughly 150, the quarter-to-quarter change is under 2%, which is inside the noise of the register and well inside the noise of anyone's impression. **The decline was invisible at every time scale on which the office actually looks at itself, and unmistakable on the one time scale nobody was using.**

That is the argument for the survey in a single sentence. The office's staff were not negligent and were not wrong about their own experience. They were reading a slow variable at a fast cadence.

The three measurements that would most change this conclusion.

1. **The attention-tax conversion rate.** Line 5 of the cost tally, at 0.13 `Y`-units per week, is the only line resting on a declared conversion rather than a direct count. If the true rate is half what was declared, `h` rises to -0.107 — still negative, but the margin changes materially. Measuring displacement directly, by timing rule production against interrupted and uninterrupted weeks, would settle it.
2. **The unattributable fraction in the eta audit.** Ten of 26 new rules had no documented board origin. If half of those were in fact board-originated and simply undocumented, `eta` rises to about 0.658 and `h` becomes -0.0424 — close enough to zero to change the verdict from "unsustainable" to "maintenance only", which is a different regime of the intervention protocol entirely.
3. **The liveness threshold.** `Y` uses 156 weeks of non-application as the liveness cutoff. At 104 weeks the count would be lower and `delta Q` smaller; at 260 weeks, higher. The cutoff was declared in advance and must not be moved after seeing the result, but its sensitivity should be reported, and it is: moving the cutoff by one year in either direction changes `Q` by about 5 rules and `h` by about 0.015.

None of these three would reverse the sign of `h` on its own. Two of them together would. **That is the honest statement of how firm this survey's verdict is, and it belongs in the survey rather than in a footnote.**

What the survey does not say. It does not say the office is badly run. It does not say the board is useless. It does not recommend anything. It reports six numbers and one sign. Everything downstream — whether the model can be trusted at all, and what may be built if it can — depends on the fact that the sign is negative and on the fact that the survey can now state exactly what it would take to change it.

15.9.4 9.4 The preregistered design, the fit, and held-out performance

```
Y            = live precedent rules in the standing review manual
N            = 5,  ln N = 1.6094
delta        = 0.003090 per week   (Method D1, weeks 121–154 freeze)
eta          = 0.5015 rules per nat (attribution audit, 26 weeks)
C_hat        = 0.63 rules per week
Q at survey  = 113
h            = −0.1720            VERDICT: h < 0
```

```
Repackaging tests 1–4: all PASS

Series:           weeks 1 to 312
Block length:     B = 8 (two-month blocks)
Justification:    conversion lag measured at up to 6 weeks, so B must exceed 6;
                  B = 8 leaves 8 holdout blocks at the declared split, meeting S25.7;
                  delta per block = 1 - (1-0.003090)^8 = 0.0244, well under 0.3.
Split:            train = blocks beginning on or before week 240 (n = 29)
                  holdout = blocks beginning after week 240 (n = 8)
Model:            Y_{k+1} = a Y_k + b F(U_k) - C_hat_k + eps_k,  0<=a<=1, b>=0
FR2 margins:      10% RMSE against persistence, direct input and matched AR;
                  shuffle p <= 0.05
FR3 tolerance:    +/- 25% on delta and on eta; conversion-lag allowance 6 weeks
Permutations:     2000
```

Frozen and signed before the holdout was examined.

```
Unconstrained optimum:   a = 0.97439    b = 0.5859
Constrained optimum:     a = 0.97439    b = 0.5859     (interior; constraints not binding)

delta implied per block = 1 - 0.97439 = 0.02561
delta implied per week  = 1 - 0.97439^(1/8) = 0.003237
half-life implied       = 4.11 years
```

Held-out performance, one step ahead, over the 8 holdout blocks:

Model	held-out RMSE (rules)	skill vs this baseline
Storage model (frozen)	**1.852**	—
Persistence	3.102	+0.403
Direct input	79.397	+0.977
Matched AR(1) with intercept	1.906	+0.028
Shuffled input, mean of 2000	3.400	—
Shuffled input, 5th percentile	2.657	—
Shuffled input, permutations beating the fit	0 of 2000	`p = 0.0005`

15.9.5 9.5 The three rules evaluated, and the one that failed

FR1 — ADMISSIBLE BOX. The unconstrained optimum is `a = 0.97439`, `b = 0.5859`. Both lie strictly inside the box; the constraints are not binding. **PASS.** The office's manual behaves like a leaky accumulator: it retains most of what it has and gains in proportion to a non-negative multiple of the surplus input.

FR2 — BASELINE DOMINANCE.

Baseline	required margin	achieved	result
Persistence	10% RMSE reduction	40.3%	PASS
Direct input	10% RMSE reduction	97.7%	PASS
Matched AR(1)	10% RMSE reduction	**2.8%**	**FAIL**
Shuffled input	`p <= 0.05`	`p = 0.0005`	PASS

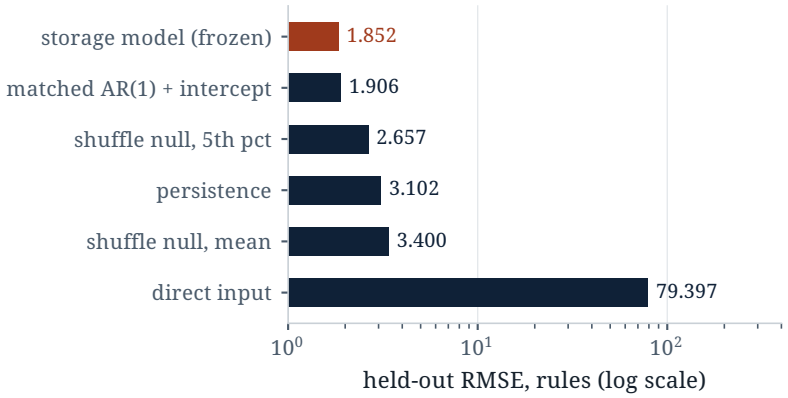

Figure 15.2: Raw held-out error, one step ahead, on a logarithmic scale because the direct-input baseline is two orders of magnitude worse than the rest. The storage model's 1.852 rules sits just below the matched AR(1)'s 1.906 — a 2.8 per cent reduction — and well below persistence at 3.102 and the shuffle null's mean of 3.400 and fifth percentile of 2.657. Measured from the held-out table above; generated by `figs/src/CCP-015_fig02.py`.

FR2 FAILS. The storage model beats a matched autoregression by 2.8% on held-out RMSE, against a preregistered requirement of 10%. Under S25.18, failure against any one of the four baselines is a failure of the rule, and the rule is not averaged.

FR3 — INDEPENDENT-PARAMETER AGREEMENT.

Parameter	survey (independent)	fit	difference	tolerance	result
`delta` per week	0.003090	0.003237	+4.8%	+/-25%	PASS
`eta` (= `b`)	0.5015	0.5859	+16.8%	+/-25%	PASS
Ceiling check	max weekly rise 2 rules vs `eta ln N = 0.8071` over a 6-week lag allowance	—	—	—	PASS

FR3 PASSES. Note the direction of the `eta` discrepancy: the fit is 16.8% *higher* than the attribution audit. That is the expected direction, and it is consistent with two things at once — the audit's deliberate strictness (unattributable units excluded, Section 9.2) and the honesty clause that the surplus functional as deployed is a lower bound. **We log the floor, not the ceiling**, so a fitted conversion slightly above the audited one is not an anomaly to be explained away.

The verdict sentence (S25.26)

The storage law is not corroborated as a predictive model of live precedent rules in the Meridian County Development Review Office at the preregistered eight-week time scale; it failed FR2 against the matched autoregressive baseline at a margin of 2.8% against a required 10%, while passing FR1 and FR3.

Row two of the table in Section 6.6: **parameters corroborated, predictive advantage not demonstrated.**

15.9.6 9.6 Exploratory results at other time scales

Reported for completeness. **Every row except `B = 8` is exploratory and licenses nothing.**

Transposed so that every figure fits the measure; no value is altered. The confirmatory

quantity	B = 1	B = 2	B = 4	**B = 8**	B = 13
RMSE, storage model	1.372	1.513	1.541	**1.852**	1.209
RMSE, persistence	1.439	1.558	1.863	**3.102**	4.637
RMSE, direct input	80.015	79.920	79.882	**79.397**	76.914
RMSE, matched AR(1)	1.387	1.386	1.450	**1.906**	1.980
skill vs persistence	+0.046	+0.029	+0.173	**+0.403**	+0.739
skill vs matched AR(1)	+0.011	-0.091	-0.063	**+0.028**	+0.389
shuffle `p`	0.0015	0.0030	0.0005	**0.0005**	0.0155

Four observations, all of which are why S25.19 exists.

1. **The shuffled-input control passes at every scale**, at `p` between 0.0005 and 0.0155. The timing of interaction carries real information about the subsequent rule count at all five scales tested. This is the strongest single positive result in the analysis.
2. The matched autoregression is beaten at only two scales, and at `B = 2` and `B = 4` it beats the storage model outright. A declining stock is an exponentially-approaching trend, and an AR(1) with an intercept represents that trend exactly. This is the hard baseline, and it is hard for a structural reason rather than an accidental one.
3. **`B = 13` would have passed everything**, at +73.9% against persistence and +38.9% against the matched autoregression. It was not the preregistered scale and it rests on four hold-out blocks. Reporting it as the result would have been the exact fault named in F25.5. It is reported here as exploratory, and the correct action it licenses is not a claim but a plan: extend the series and preregister `B = 13` for the next cycle, with the holdout requirement met.
4. **The implied `delta` is stable across scales** — 0.00289 to 0.00373 per week, against a directly measured 0.00309 — which is a genuine and reassuring consistency, and is FR3 doing its job independently of FR2's outcome.

15.9.7 9.7 Two repackaging demonstrations, one of which passed everything

The office was, at one point in the survey, offered two alternative order observables. Both were tested. Both are instructive.

Candidate PD-1 — "items dispositioned per session" (contemporaneous repackaging). Proposed because the minutes already contain it. It shares source fields with `U` and fails Test 1 of Section 5.1 immediately, so it never reached the estimation stage — but it was fitted anyway, as a demonstration.

Model	held-out RMSE
Storage model	3.079
Persistence	3.314
Direct input	**2.443**
Matched AR(1)	2.657

Model	held-out RMSE

Fitted `a = 0.7106`, `b = 13.759`; shuffle `p = 0.2278`.

The direct-input baseline beats the storage model outright — a skill of -0.261. That is baseline 2 performing its designed function: when the input alone predicts the order observable better than an accumulator driven by the input, the order observable is a function of the input. The shuffle also fails, at `p = 0.2278`. PD-1 is caught twice over and would have been caught for free by Test 1 of Section 5.1.

Candidate PD-2 — "the board disagreement index", a rolling weekly index published by the board clerk from the minutes (filtered repackaging). This one is dangerous.

Model	held-out RMSE	skill
Storage model	**0.833**	—
Persistence	7.870	+0.894
Direct input	12.940	+0.936
Matched AR(1)	7.720	+0.892
Shuffled input, mean of 2000	7.842	`p = 0.0005`

PD-2 passes all four baselines, decisively, on every margin. It beats persistence by 89.4%, the matched autoregression by 89.2%, direct input by 93.6%, and the shuffled-input control at `p = 0.0005`. Against the actual proxy's marginal 2.8% against the autoregression, PD-2 looks like the far better model of the office.

PD-2 is a rolling average of the input. It stores nothing. There is no institution behind it.

What catches it:

Test	Result
FR3, `eta`	fitted `b = 20.205` against an audited `eta = 0.5015` — a factor of **40**, far outside the +/-25% tolerance. **FAIL.**
FR3, `delta`	fitted `a = 0.7038`, implying a half-life of **1.97 weeks** against a directly measured **224 weeks** — a factor of **114**. **FAIL.**
Test 3, zero-input persistence	across the 34-week freeze, PD-2 fell 82.1 -> 57.9 -> 28.5 -> 6.7 -> 1.6 -> 0.1, and then returned to **31.6 in the single week the board resumed**. The true proxy went 206 -> 186 and continued from 186. **FAIL.**
Test 4, the ceiling	that single-week jump is 31.1 units. The largest admissible one-step increment is `eta ln N = 0.8071`. The observed jump is **38.5 times the theoretical maximum**. **FAIL.**

A stock cannot teleport. The ceiling test is arithmetic, requires no statistics, takes one line, and is the single most reliable detector of the order-proxy trap in this protocol.

And the lesson that governs the architecture of these three chapters: **the shuffled-input control is the empirical audit and it cannot see repackaging; the structural tests of Section 5 and FR3 are the definitional audit and they can. Both are required, and they are required in that order, because the structural audit is free and the empirical one is not.**

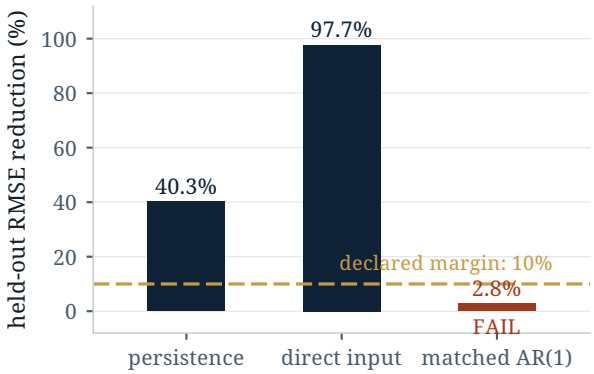

Figure 15.3: The preregistered rule was not met. The storage model's held-out RMSE reduction against each baseline is plotted against the margin declared before the holdout was examined. Persistence (40.3 per cent) and direct input (97.7 per cent) clear the 10 per cent requirement comfortably; the matched AR(1) with intercept — the baseline with the same two free parameters as the model — is beaten by **2.8 per cent**, which does not reach the line. Under the rule that failure against any one of the four baselines is a failure of the rule, FR2 fails. Measured from the held-out RMSE table of Section 9.4; generated by `figs/src/CCP-015_fig03.py`.

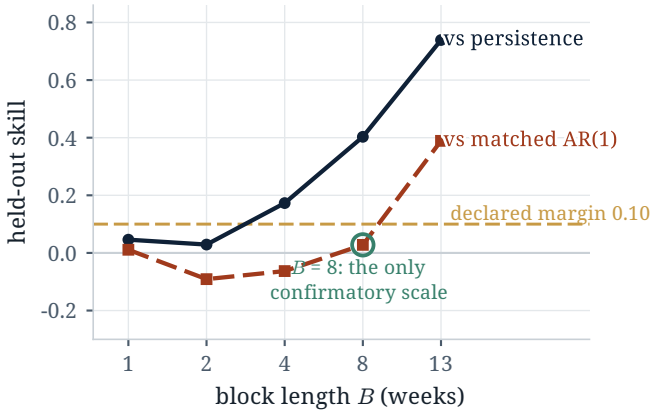

Figure 15.4: The scale that would have passed was not the scale that was declared. Held-out skill against persistence and against the matched autoregression at five block lengths; only `B = 8` is confirmatory and every other row is exploratory. `B = 13` returns +73.9 per cent and +38.9 per cent and would have cleared every margin — on four holdout blocks, against the eight the specification requires — while `B = 2` and `B = 4` are beaten outright by the autoregression. Measured from the exploratory table above; generated by `figs/src/CCP-015_fig04.py`.

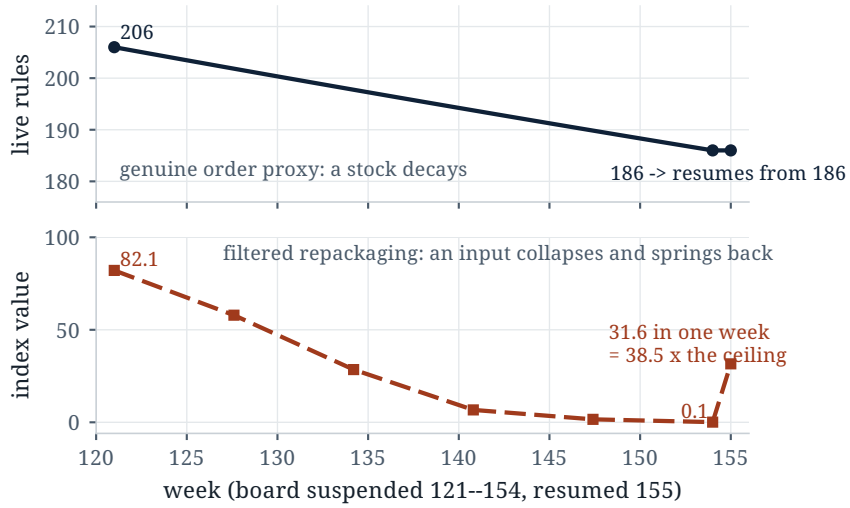

Figure 15.5: A repackaged proxy is caught by a stock's own arithmetic, not by its statistics. Across the 34-week zero-input freeze the genuine order proxy decays smoothly from 206 to 186 and resumes from 186; the filtered repackaging collapses from 82.1 to 0.1 and springs back to 31.6 in the single week the board resumes — a jump of 31.1 units against a maximum admissible one-step increment of `eta ln N = 0.8071`, which is 38.5 times the theoretical maximum. Plotted as small multiples rather than on shared axes because the two series are not commensurable. Measured from the freeze record of Section 9.7; generated by `figs/src/CCP-015_fig05.py`.

15.9.8 9.8 What the office is licensed to do

Under the licence list of Section 6.8, with FR1 and FR3 passed and FR2 failed:

Licensed. Treat `delta = 0.003090`, `eta = 0.5015`, `N = 5`, `C_hat = 0.63` and `Q = 113` as corroborated parameters of the system at the eight-week scale. Compute `h = −0.1720`. Conclude that the arrangement is unsustainable in this model. Use `h` as a budget constraint on any proposed increment.

Not licensed. Claim that the storage law forecasts the manual's rule count better than a trend line does. Claim that raising interaction will raise the rule count, on the strength of this analysis — the shuffle establishes that the timing of interaction carries information, not that intervening on it produces order. Forecast beyond one step. Extend any of it to cycle time, staff competence, or applicant satisfaction.

Required next. Any intervention proceeds on the accounting frame only: a capped, reversible pilot, preregistered under Part 5 of the form in Appendix B, whose own falsification criterion is stated in numbers before it begins — and which, if it works, supplies exactly the causal evidence this analysis is not entitled to assume.

15.10 10 Discussion

15.10.1 10.1 What the failure means, and what it does not

The preregistered confirmatory fit did not meet its own second falsification rule. The storage model beat a matched autoregression by 2.8 per cent on held-out RMSE against a margin of 10 per cent declared before the holdout was examined. Under the rule that failure against any one of the four baselines is a failure of the rule, and the rule is not averaged, FR2 fails. **The storage law is therefore not corroborated as a predictive model of live precedent rules in that office at the preregistered eight-week time scale.** That sentence is the result of this paper and

it is not softened anywhere in it.

What the failure does **not** mean is worth stating with equal precision, because both over-reading and under-reading it are available. It does not mean the storage law is false; a single system at a single time scale cannot establish that. It does not mean the parameters are wrong: FR1 passed with the unconstrained optimum strictly interior to the admissible box, and FR3 passed with implied decay within 4.8 per cent and implied conversion within 16.8 per cent of independently measured values. And it does not mean the timing of interaction is uninformative: the shuffled-input control rejected at `p = 0.0005`, and did so at every block length tested.

The honest reading is the one the framework's own table gives for this combination: parameters corroborated, predictive advantage not demonstrated. That is a real and useful state and it licenses much less than people want it to. It licenses treating the survey's parameters as corroborated estimates and computing headroom from them. It does not license the claim that the storage law forecasts the manual's rule count better than a trend line does, because on this evidence it does not.

The reason the matched autoregression is hard to beat is structural rather than accidental, and this is the most useful methodological finding in the paper. A declining institution is an exponentially-approaching trend, and an AR(1) with an intercept represents an exponentially-approaching trend exactly. Any leaky-accumulator model of a slow stock is therefore competing against a baseline that already contains most of the signal. **Beating it requires that the input term carry information about deviations from trend, not about the trend itself** — which is a much narrower claim than the framework usually makes, and one that a 34-block series has little power to detect. The corpus's own measurement of the suite bears this out from the other side: the matched autoregressive baseline evaluated *alone* false-passes 35.8 per cent of the time [Curzi, 2026u], so a suite that reads it in isolation is uninformative in both directions.

15.10.2 10.2 What the passing tests were worth

Two of the three rules passed, and the paper's own results limit what those passes establish.

FR1 passed and is cheap. The unconstrained optimum landed at `a = 0.97439`, `b = 0.5859`, strictly interior. This is a genuine finding — the office's manual behaves like a leaky accumulator rather than a compounding or oscillating quantity — and it is the finding that would have been most decisively negative had the data disagreed.

FR3 passed, and the direction of the `eta` discrepancy is informative. The fit is 16.8 per cent *higher* than the attribution audit, which is the expected direction, and it is consistent with two things at once: the audit's deliberate strictness, which excludes unattributable units, and the standing clause that the surplus functional as deployed is a lower bound. A fitted conversion slightly above the audited one is not an anomaly to be explained away.

The shuffle passed at `p = 0.0005`, and its calibration is measured and poor. Against a nominal 0.05 across 500 null trials, the same control measures a false-rejection rate of 0.108 under iid permutation and 0.120 under circular shift, with only block permutation near nominal at 0.060 [Curzi, 2026u]. **The reported `p` is therefore optimistic by an unknown but non-trivial factor**, and the correct procedure — calibrating the control by simulation on the study's own design and preregistering the calibrated threshold — was not run here. That is a limitation of this paper's own headline positive result and it is carried in Section 12.

And the shuffle is blind to the failure that matters most. Candidate PD-2, a rolling index of the board's own disagreement score, stores nothing, has no institution behind it, and **passed all four baselines decisively** — 89.4 per cent against persistence, 89.2 per cent against the matched autoregression, 93.6 per cent against direct input, and `p = 0.0005` against the shuffle. Against the genuine proxy's marginal 2.8 per cent, PD-2 looks like the far better model of the office. It was caught by a fitted half-life of 1.97 weeks against a measured 224 weeks, by a fitted `b` forty times the audited `eta`, by a collapse to 0.1 during the freeze, and by a single-week jump 38.5 times the admissible maximum. **A stock cannot teleport.** The ceiling test is arithmetic,

requires no statistics, takes one line, and is the single most reliable detector of the order-proxy trap available.

15.10.3 10.3 Relation to the surrounding literature

The protocol is an application of three established methodological positions and one identity.

Preregistration and held-out testing as corruption controls. The analytic-flexibility literature establishes that the damage is done at design time and is not repaired by subsequent computation [Simmons et al., 2011, Gelman and Loken, 2013, Nosek et al., 2018], and the replication record establishes what an uncontrolled literature looks like afterwards [Ioannidis, 2005, Open Science Collaboration, 2015]. The specific administrative claim made here — that preregistration is the countermeasure to measure corruption because it fixes the definition before anyone has a reason to distort it — is a corollary of Goodhart's and Campbell's statements rather than a new one [Goodhart, 1975, Campbell, 1979]. And the point prediction with a constant, rather than a directional prediction, is the response Meehl [1967] demands of any social science that wants its tests to cost something.

The effective count. The participation-ratio identity places the chosen aggregator inside a recognised family [Rényi, 1961], and the effective-numbers literature supplies the idiom [Hill, 1973, Jost, 2006], with independent reinvention in political science as the effective number of parties [Laakso and Taagepera, 1979] and in industrial organisation as the numbers-equivalent reading of concentration [Adelman, 1969, Herfindahl, 1950]. Two qualifications are required and both are made in Section 12: `1 + (N−1)u` is not itself a Hill number, and effective-count estimators are biased on small rosters, which is precisely the regime of a five-discipline board [Chao et al., 2014].

Measurement. The five operational choices are a specification of operations in the sense the measurement-theory literature requires before a construct is quantified [Krantz et al., 1971, Cronbach and Meehl, 1955], and the instrument-independence test is the multitrait–multimethod requirement in miniature [Campbell and Fiske, 1959]. The unanswered objection is Michell [1997]'s: psychology routinely assumes quantitative structure without testing for it, and neither conjoint measurement [Luce and Tukey, 1964] nor a Rasch demonstration [Rasch, 1960] has been run for `u` or for `Q`.

Within the corpus, the survey is the instrument that the storage law's derivations require in order to say anything about an organisation [Curzi, 2026a], the headroom gauge is what it computes [Curzi, 2026b,h], and the same five-parameter procedure applied across five systems from one desk to a 22-household block reproduced each system's observed decline — predicted −0.250474 against observed −0.250 at the desk, −0.996371 against −1.000 at the library, with residuals under 1.4 per cent of the ceiling term [Curzi, 2026k]. The ratio-invariance test that licenses a ratio scale in the perceptual setting — two fourfold physical steps returning 2.5100 and 2.5000, agreeing to 0.40 per cent and matching the fitted `4^0.6569 = 2.4859` [Curzi, 2026n] — is the kind of demonstration `u` still owes. The protocol's structural analogues elsewhere are the product-not-average scoring of the five-criterion disclosure test, where five structures averaging 0.80 score a group product of zero because two contain a zero [Curzi, 2026]; the staged-inspection result, where moving from terminal to per-stage checking at seven stages with `q = 0.10` and `d = 0.90` raises final yield from 47.83 per cent to 93.21 per cent at 0.63 reworks per unit [Curzi, 2026]; the exact invariance of summed drive under cost transfer, verified at +0.643688229683 and +1.268940530229 with residual 0.000e+00 [Curzi, 2026]; and the frequency criterion `f_min = k e^(2c/eta)` with `k = 0.483425732988414` Hz and the trichotomy `f > = < f_min` matching `Q_inf > = < 0` [Curzi, 2026], which is the same sign test this survey performs in a different unit.

15.11 11 Verification

15.11.1 11.1 Dimensional audit

The estimation model must balance before its fit is worth discussing. `[Q]` is the dimension of the order proxy — whatever unit it counts — and `[T]` is time, with the block as its unit.

Symbol	Dimension	Unit	Status
`Y_k`	`[Q]`	live precedent rules	**measured** by the declared order observable
`U_k`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2` on unit vectors
`F(U_k)`	`[1]`	nats	**derived** dimensionless: a logarithm of an effective count
`a`	`[1]`	per block	**fitted** dimensionless; `a = 1 - delta`
`b`	`[Q]` per nat per block	rules per nat per week	**fitted**; identified with `eta`, and *not* dimensionless
`C_hat_k`	`[Q]` per block	rules per week	**measured**, denominated in `Y`-units by construction
`eps_k`	`[Q]` per block	rules per week	**residual**
`h`	`[Q]` per block	rules per week	**derived**
`Q_inf`	`[Q]`	rules	**derived**: `[Q]`/block ÷ `[1]`/block returns `[Q]`
RMSE	`[Q]`	rules	**measured**
`p`	`[1]`	none	**derived**, a probability

Does it balance? `Y_{k+1} = a Y_k + b F(U_k) - C_hat_k + eps_k` balances if and only if every right-hand term carries `[Q]`. The first does because `a` is dimensionless. The third does by the denomination rule, which is exactly why that rule is a specification and not a preference: **a cost observable left in hours or currency makes the equation dimensionally malformed however tidy the arithmetic looks.** The second does only if `b` carries `[Q]` per nat per block, which is why the survey reports `eta` as *rules per nat* and not as a bare number. The fixed coefficient of one on `C_hat` is a dimensional statement as much as an identification one.

Where the framework has no operational unit, that is said here. `Q` is stored order and has no natural unit; it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. The underlying construct — comfort — has **no operational unit at all** and is treated as a dimensionless magnitude by stipulation. Section 12 records that the quantitative structure required for that stipulation has not been tested.

15.11.2 11.2 Postulates and the compounding chain

Five postulates. Each is atomic, each is checkable alone, and each carries its status. Where a postulate could be dropped and the conclusion still follow, it has been dropped.

P1 — The declared margin was 10 per cent held-out RMSE reduction against each of persistence, direct input and the matched autoregression, and `p <= 0.05` against the shuffle. *Status:* **DEFINITION** — the rule the analyst set, recorded in the frozen document before the holdout was examined, and reproduced verbatim in Section 2.2. It carries no empirical weight; it is a commitment.

P2 — Held-out RMSE, one step ahead, over the eight holdout blocks: storage model 1.852, persistence 3.102, direct input 79.397, matched AR(1) with intercept 1.906. *Status:* **ARITHMETIC** from the frozen coefficients and the observed holdout; the numbers are in the table of Section 9.4 and any reader with those four values can redo every step below.

P3 — Skill is `1 - RMSE_model / RMSE_baseline`. *Status:* **DEFINITION** — the convention declared in Section 6.3.

P4 — The matched autoregression has the same number of free parameters as the storage model: two. *Status:* **DEFINITION** — `a_0, a_1` against `a, b`, with `C_hat` fixed at coefficient one in the storage model and no intercept added. This is the postulate that makes the comparison fair, and it is the one a reviewer should check first.

P5 — Failure against any one of the four baselines is a failure of FR2; the four are not averaged. *Status:* **DEFINITION** — the aggregation rule, declared at the freeze.

15.11.3 11.3 The chain, ending in the negative result

```
P2 + P3   -> L1   skill vs persistence   = 1 - 1.852/3.102  = 0.40296...  ARITHMETIC
P2 + P3   -> L2   skill vs direct input  = 1 - 1.852/79.397 = 0.97668...  ARITHMETIC
P2 + P3   -> L3   skill vs matched AR(1) = 1 - 1.852/1.906  = 0.02833...  ARITHMETIC
L1 + P1   -> R1   40.3% >= 10%   -> persistence margin met                 ARITHMETIC
L2 + P1   -> R2   97.7% >= 10%   -> direct-input margin met                ARITHMETIC
L3 + P1   -> R3   2.8%  <  10%   -> matched-AR margin NOT met              ARITHMETIC
P1        -> R4   shuffle p = 0.0005 <= 0.05 -> shuffle margin met         ARITHMETIC
R3 + P5   -> R5   FR2 FAILS                                               ARITHMETIC
R5 + P4   -> R6   the failure is against the parameter-matched baseline,
                  so it is not explained by a parameter-count advantage   ARITHMETIC
```

Every line is checkable from its own inputs. **The three long divisions a reviewer can redo in a minute are `1.852/3.102 = 0.59704`, `1.852/79.397 = 0.02333`, and `1.852/1.906 = 0.97167`; the third subtracted from one is 0.02833, which is 2.8 per cent, which is less than 10 per cent.** That is the whole of the negative result. It follows from two definitions the author set in advance and one table of measured errors, and from nothing else.

What the chain does not establish. It does not establish that the storage law is false. It does not establish that the AR(1) is a better model of the office — a 2.8 per cent advantage in the model's favour is not evidence for the baseline either. What it establishes is that **the predictive advantage the preregistration required was not demonstrated**, which is a statement about the evidence and not about the world.

15.11.4 11.4 The participation-ratio identity, checked on the smallest case

The identity `N_eff = 1 + (N−1)U = N + 1 − N/PR` is a derivation, and the smallest case that exercises it is `K = 2`. Take two unit vectors with inner product `c`. Then `||G||_F^2 = 2 + 2c^2`, so `PR = 4/(2 + 2c^2) = 2/(1 + c^2)`, and

```
N + 1 − N/PR = 3 − 2(1 + c^2)/2 = 3 − (1 + c^2) = 2 − c^2
```

while `U = 1 − c^2` for the single pair, so `1 + (N−1)U = 1 + (1 − c^2) = 2 − c^2`. **The two agree identically, for every `c`.** *Status:* **ARITHMETIC.** The `K = 3, 5, 8, 12` checks reported in Section 4.3 are checks on the implementation rather than on the mathematics, and the 1e-12

agreement should be read as a floating-point tolerance and not as an empirical result. The independent re-verification over six random correlation matrices, returning 6.486606017883 by both routes at `N = 8` and `u_bar = 0.783801`, is the same kind of check [Curzi, 2026].

15.11.5 11.5 Model comparison, audited against what proper model comparison requires

RMSE against a baseline is not model comparison. Measured against the full requirement, this paper's fit stands as follows, and two of the five items are **not met**.

Requirement	Status in this paper
Out-of-sample rather than in-sample performance	**Met.** One-step-ahead on a calendar holdout of 8 blocks, examined once.
A matched null with the same free-parameter count	**Met.** AR(1) with intercept: 2 parameters against the storage model's 2.
The number of free parameters stated explicitly	**Met.** Storage model 2 (`a`, `b`), with `C_hat` at fixed coefficient 1 and no intercept; persistence 0; direct input 2; matched AR(1) 2.
An information criterion, so the parameter count is paid for	**NOT MET.** No AIC or BIC was computed, at any block length, for any model.
Effect sizes with intervals, not only p-values	**PARTIALLY MET.** A profile interval on `a` is specified by the procedure and the fitted `a` is reported; no interval accompanies the RMSE differences, and no effect size accompanies the shuffle `p`.

The two unmet items are stated plainly because they change how the headline number should be read. The parameter count was not paid for: with a matched two-parameter baseline the information criterion would differ from the RMSE comparison only through the likelihood scaling, so the omission is less damaging here than it would be against an unmatched baseline — but it was not computed, and the claim that a 2.8 per cent RMSE advantage is *any* advantage is therefore untested against a criterion that penalises complexity. And a `p` without an effect size is an incomplete statistical claim: the shuffle's `p = 0.0005` says the real fit sits outside the null, and the corresponding **effect size, which can be read off the table in Section 9.4, is that the real fit's RMSE of 1.852 lies 45.5 per cent below the null mean of 3.400 and 30.3 per cent below the null fifth percentile of 2.657.** Those two figures should have been reported beside the `p` and were not; they are reported here.

15.12 12 Limitations

The worked system is a constructed composite, not a field study. The organisation is invented and the audit series is a simulation with declared generating parameters, produced so that every number in the paper can be checked by the reader. **It must not be cited as evidence about any real review office.** Its function is to show the procedure operating end to end on numbers that behave the way real numbers behave — including where they refuse to cooperate. Every statement in Section 9 is therefore a statement about the protocol's behaviour and not about municipal government.

The preregistered confirmatory fit failed FR2. It is recorded here as well as in Sections 9.5 and 10.1 because a limitations section that omitted it would be dishonest. The storage law is not corroborated as a predictive model of that system at that time scale.

The reflection problem: the specification is not identified from observational data. Where a group's members both influence and constitute the aggregate — which is the case for a review board — the endogenous social effect cannot be separated from contextual effects or from correlated unobservables, however much data is collected [Manski, 1993], and influence and selection are generically confounded in observational network data [Shalizi and Thomas, 2011]. **This is a deeper limitation than the failed rule.** It means that even a fit passing all three falsification rules would not have identified `eta` as the conversion of interaction into structure, because a contextual effect or a common driver would produce the same fit. No remedy is adopted in this paper — not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001], which is the most realistic route and is the one the fixed category set and declared participation rule of Sections 4.2 and 4.3 point toward without yet taking. **Until one of them is executed, the fitted `b` is a coefficient in a declared specification, not an identified social effect**, and Section 9.8's licence list should be read as narrower still than it is written.

The shuffled-input control is anti-conservative and was not calibrated here. Its measured false-rejection rate is 0.108 for iid permutation and 0.120 for circular shift against a nominal 0.05, with only block permutation near nominal at 0.060 [Curzi, 2026u]. **The `p = 0.0005` reported in Section 9.4 is therefore optimistic by an unknown factor**, and the required repair — calibrating the control by simulation on this study's own design and preregistering the calibrated threshold — was not performed. The positive result on H2 is correspondingly weaker than its nominal `p` suggests.

No information criterion was computed. Section 11.5 gives the audit. A model with more parameters that fits better has not been shown to be better, and although the baseline here is parameter-matched, the omission means the comparison rests on RMSE alone.

The functional form of the surplus term is underdetermined by the evidence. At least two published alternatives fit the same qualitative facts: social impact rising as a sub-linear power of the number of sources [Latané, 1981], and value growing as `n log n` [Briscoe et al., 2006]. Nothing in this paper discriminates between them and `ln(1 + (N−1)u)`. **The logarithmic form is chosen for its axiomatic characterisation, not established by measurement**, and the model-comparison exercise that would settle it — fitting the alternatives on the same holdout and paying for their parameters — has not been run.

`N_eff = 1 + (N−1)u` is not a Hill number. `1/HHI` and `exp(H)` are Hill numbers of order two and one and are fully grounded [Hill, 1973, Jost, 2006]; `1 + (N−1)u` is a linear interpolation between 1 and `N`, is this framework's own construction, and has no counterpart in the ecological, economic or information-theoretic literature. The participation-ratio identity of Section 4.3 establishes that the chosen aggregator coincides with the Rényi-2 effective count *for this encoding* [Rényi, 1961], which is a narrower claim and the only one made.

Effective-count estimators are biased on small rosters, and five disciplines is a small roster. Estimation bias in diversity measures from finite samples is well documented [Chao et al., 2014], and no bias correction was applied to `U` or to `N_eff` here. With a 12-case probe set and five categories the pairwise estimates rest on ten pairs of twelve binary judgements; the reported `U = 0.6972` carries no interval and should not be treated as though it did.

Scale type is stipulated, not demonstrated. `u` and `Y` are treated as ratio-scale quantities throughout — differences, ratios, logarithms and means are all taken — and the conjoint-measurement conditions that would license that treatment have not been tested [Luce and Tukey, 1964, Krantz et al., 1971]. Michell [1997]'s objection, that psychology assumes quantitative structure without testing for it, applies directly and is not answered here. The ratio-invariance demonstration that the corpus runs for the perceptual scale [Curzi, 2026n] is the kind of test `u` still owes.

The parameters were chosen rather than measured in one important place. `delta` comes from a single 33-week episode, so it rests on two endpoint counts and an exponential assumption; the liveness threshold of 156 weeks was declared in advance but is a choice, and moving it by a year in either direction changes `Q` by about 5 rules and `h` by about 0.015; and the attention-tax line of the cost tally, at 0.13 `Y`-units per week, is the only line resting on a declared

conversion rather than a direct count. Section 9.3 reports that none of the three named sensitivities reverses the sign of `h` alone and that two of them together would.

Two claims the paper does not make. It makes **no scaling or heavy-tail claim**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply. And it makes **no causal claim**: the shuffle establishes that the timing of interaction carries information about subsequent order, not that intervening on interaction produces order.

The Lucas critique applies to this framework's own parameters. Section 6.9 asserts that a measure changes the system measured by it, and the model then treats `delta`, `eta` and `N` as constant over the estimation window. The position taken here is the narrow one: constancy is assumed **only over a declared window and only while `Y` is not itself reported upward**, which is why the first and strongest corruption defence is to keep the order proxy out of the reporting line. Where `Y` is reported upward, the framework's own reflexivity applies to it and the constancy postulate fails. That is a restriction on where the protocol may be used, and it is stated as one.

What would falsify the protocol itself, as opposed to the model it tests. If a system that passed all three rules subsequently failed a randomised intervention predicted from its fitted parameters, the protocol would have licensed a claim it should not have. If the four repackaging tests passed on a proxy later shown to be a filtered input, the structural audit would be insufficient. And if the calibrated shuffle threshold, once computed, moved the reported `p` above 0.05, H2 would be undecided rather than supported.

15.13 13 Conclusion

This paper specifies an end-to-end measurement protocol for the storage law — five operational choices, an estimator for each of six parameters, a one-page output format, and four structural tests against the order-proxy trap — and adds a participation-ratio identity, `N_eff = N + 1 − N/PR`, equivalent to `K/PR = 1 + (K−1)(1−U)`, that makes a redundancy audit computable from a Gram matrix and agrees with direct computation at `K = 3, 5, 8, 12` to better than 1e-12. Applied to a constructed county development-review office, the survey returned `N = 5`, capacity `U = 0.6972` against a realised `U = 0.6019` — a realisation deficit of 0.1823 nats caused by 32.7 per cent of sessions running short-handed — `delta = 0.003090` per week from a 33-week zero-input episode with a half-life of 224 weeks, `eta = 0.5015` rules per nat, `Q = 113` after liveness and applier corrections, headroom `h = −0.1720`, and a steady state `Q_inf = −17.3`, reported as negative.

The preregistered confirmatory fit at the declared eight-week block scale returned `a = 0.97439` and `b = 0.5859`, both strictly interior to the admissible box, with implied decay within 4.8 per cent and implied conversion within 16.8 per cent of independently audited values. It beat a matched autoregression by 2.8 per cent on held-out error against a declared requirement of 10 per cent. FR2 therefore fails, and the verdict is: parameters corroborated, predictive advantage not demonstrated. An alternative block scale that would have passed everything was reported as exploratory and licenses nothing. A repackaged order proxy that stores nothing passed all four baselines decisively and was caught only by structural tests — a fitted half-life of 1.97 weeks against a measured 224, and a single-week jump 38.5 times the maximum admissible increment `eta ln N = 0.8071`.

Two results limit the weight of everything that passed, and both are reported here rather than left for a reviewer. The shuffled-input control on which the empirical audit depends is anti-conservative, measuring 0.108 against a nominal 0.05, so the reported `p = 0.0005` is optimistic. And the specification is reflexive, so the endogenous social effect is not identified from observational data at all; no fit, however honestly held out, recovers it. **A framework that cannot fail cannot be trusted. This one named exactly how it fails, ran the test, and failed it.**

15.13.1 Declarations

Data and code availability

No external dataset was collected for this paper. The worked system is a constructed composite: the organisation is invented and its audit series is a simulation with declared generating parameters, produced so that every reported number can be re-derived by the reader from the parameters and equations printed in the text. **It must not be cited as evidence about any real organisation.** The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi designed the protocol, specified the falsification rules, performed the analysis, produced the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The surveyed organisation is constructed. The declination requirement discussed in Section 6.10 — that no intervention removing a person's ability to decline is within scope — is a constraint on prospective work and is not a report of any study performed.

Preregistration

The falsification rules FR1, FR2 and FR3 and their numerical tolerances were declared in the frozen preregistration document reproduced as Appendix B, before the holdout data were examined: a 10 per cent held-out RMSE reduction against each of persistence, direct input and a matched autoregression, `p <= 0.05` against the shuffled-input control, and ±25 per cent agreement between fitted and independently measured `delta` and `eta`. Those rules are restated in Section 2.2 of this paper in advance of any result.

The result did not meet them. FR1 passed and FR3 passed; FR2 failed, against the matched autoregressive baseline, at a margin of 2.8 per cent against the required 10 per cent. No tolerance was moved after the holdout was examined. An alternative block scale, `B = 13`, would have passed every rule; it was not the preregistered scale, it rests on four holdout blocks rather than the eight the specification requires, and it is reported as exploratory and licenses nothing. The verdict recorded in the frozen form's own prescribed words is *parameters corroborated, predictive advantage not demonstrated.*

Chapter 16

A Gated Intervention Procedure and a Thirty-Two-Entry Failure Catalog for the Storage Law

Abstract. This paper converts the headroom gauge $h_t = \eta \ln N - \delta Q_t - C_t$ into a decision procedure and pairs it with a closed catalog of failure modes. Seven gates run from evidence admissibility through regime, feasibility, lever ranking, sequencing, reversibility, consent, and a capped preregistered pilot. The binding rules are that a requested increment must satisfy $r_t \le h_t$ with a recommended reserve $r_t \le 0.7\,h_t$, since the maximum increment $r_{\max} = h_t$ is attained only at $U_t = 1$, and that the $h_t < 0$ branch forbids building at any interaction geometry. In the worked case a request for $r = 0.55$ rules per week was refused at $h = -0.1720$; raising conversion from 0.5015 to 1.05 supplied $+0.8828$, or 80.8 per cent of the recovery, and cutting cost from 0.63 to 0.42 the remaining $+0.2100$, bringing headroom to $+0.9207$, after which the request fitted inside the budget at a reserve ratio of 0.597. The shedding lever was computed and declined: at a weekly decay of $\delta = 0.003090$ a fourteen-unit shed returns $\delta q = 0.0433$, sixteen times less than the same shed at $\delta = 0.05$. Feasibility is tested on the mean of F and never on F of the mean U: cutting the low-participation share from 32.7 to 12 per cent raises the mean of F from 1.1498 to 1.3241 nats and the realised step from $+0.4381$ to $+0.6211$, while the concavity penalty falls from 0.0761 to 0.0354 nats. The catalog's thirty-two entries each name the damaged parameter, its measurement and its price. A ward-handover case carries the central diagnostic distinction: headroom was $+1.686$ per week while the ward lost 0.755 per week, because three of five declared categories did not attend — and that intervention's own predicted fixed point of 71.46 exceeds a 34-bed census and is declared outside the model's range rather than reported as a forecast.

Keywords: headroom gauge; lever ranking; reversibility; capped pilot; failure catalog; frozen denominator; realisation deficit; sequencing

Series: B. Engineering the Surplus **Paper:** CCP-016

16.1 1 Introduction

A measurement framework earns nothing until it can refuse. The preceding papers in this series establish a storage law for institutional capability, a gauge computed from its parameters, and a preregistered protocol for putting the law at risk against data. What none of them

supplies is the step an analyst is actually asked for: given the six numbers, what may be built, how much of it, in what order, and under what conditions must the answer be *nothing*.

This paper supplies that step in two parts. The first is a **gated decision procedure** — seven gates running from the admissibility of the evidence, through the regime of the gauge, feasibility, lever ranking, sequencing, reversibility, consent, and a capped preregistered pilot. The procedure is binding in a specific arithmetic sense: it converts the headroom gauge from a diagnostic number into a constraint on what may be promised, and its central rule is a single inequality that a sponsor can check in one subtraction. The second is a **closed catalog of thirty-two named failure modes**, each priced. The catalog is closed because the law it serves has six degrees of freedom, so every failure of a system the law describes is a claim about one of six quantities; the thirty-two names are recurring routes into six parameter faults, distinguished because the routes have different signatures, instruments and fixes.

The gauge is inherited. The storage law `Q_{t+1} = (1−delta) Q_t + eta S_t − C_t` with `S_t = F(U_t) = ln(1 + (N−1)U_t)` is established as a first-order discrete filter, with its steady state, its pole and its time constant, in Curzi [2026a], whose principal result is that the map is Lipschitz with modulus `1 − delta`, so any positive loss makes it a contraction with steady state `Q* = (eta S − C)/delta`, and `delta = 0` is a pathology rather than an ideal. The headroom gauge itself — `h_t = eta ln N − delta Q_t − C_t`, its three regimes, its maximum increment `r_max = h_t`, and the separate admissibility and sustainability constraints — is established in Curzi [2026b]. The surplus functional, its axiomatic characterisation, and the affine effective count `N_eff = 1 + (N−1)u` are established in Curzi [2026]. The survey that produces the six numbers and the preregistration that puts them at risk are established in Curzi [2026i], whose confirmatory application **failed its own second falsification rule**: a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared 10 per cent margin, despite +40.3 per cent over persistence, +97.7 per cent over direct input, and `p = 0.0005` against the shuffled-input control. That failure is not a footnote to this paper; it is the evidential status of every applied statement in it, and it determines what the worked cases below are permitted to claim.

Four things are contributed here that the surrounding literature does not supply and the preceding papers do not state.

First, the increment rule with a reserve. `r_t <= h_t` follows from the gauge, but `r_max = h_t` is attained only at `U_t = 1` — perfect mutual orthogonality of every category — so taking `r = h` is promising the extremal case as the plan. The procedure therefore carries a recommended reserve `r <= 0.7 h`, stated as a reserve rather than absorbed, and it carries the `h < 0` branch in which **no interaction geometry can prevent order from decreasing**, so that the refusal is a computed result rather than a judgement.

Second, a priced separation between creating headroom and realising it. `h` is defined on the ceiling `ln N`; the realised one-step change is defined on `F(U)`. Raising the non-parallelism `u` therefore does not raise `h` at all — it closes the gap. The difference, `h − step = eta (ln N − F(U))`, is named here as the *realisation deficit*, and it is typically the cheapest quantity in the building.

Third, the concavity correction at the feasibility gate. What accumulates over many periods is the sum of `eta F(U_t)`, so the operative quantity is the **mean of `F`** and not `F` of the mean `U`. Because `F` is strictly concave, Jensen's inequality makes the second strictly larger whenever the geometry varies. In the worked office the gap is 0.0761 nats — 6.2 per cent of the surplus, lost to variability alone — and the practical consequence is that regularising a variable geometry pays twice, once by raising the mean and once by shrinking the penalty the variability was charging. The distinction is not pedantic: a feasibility test run against `F` of the mean passes systems that will not deliver.

Fourth, the counter-result, which is the most useful thing in the paper. Positive headroom is not health. The gauge uses the ceiling; the one-step condition uses what actually happened. A system can have large positive headroom and shrink every period because it operates far below its own ceiling. The hospital ward worked in Section 8.2 has `h = +1.69` carried-patients per week and is losing 0.76 per week, and a diagnosis that stopped at "headroom is positive, we are fine" would have been exactly wrong. The catalog names the misdiagnosis, and the same

worked case carries a second disclosure of the same kind: the intervention's own predicted fixed point of 71.46 exceeds the ward's 34-bed census, so the linear law is outside its range there and is reported as a saturation date rather than as an equilibrium.

Two things this paper does not do, stated at the outset because they bound everything that follows. **No dataset was collected.** Both worked systems are constructed — one a declared composite with simulated audit series, one a constructed clinical case — and their arithmetic is real and reproducible while their organisations are not. And **the reflexive specification underlying the law is not identified from observational data** [Manski, 1993]. Section 3.4 states that where it bites hardest, which is Gate 0, since Gate 0 is exactly where an identification claim would have to be made and is not.

Section 2 states the hypotheses and what would falsify each. Section 3 gives the framework, the inherited results, the identification problem, the scale-type audit, and the badged postulates. Section 4 develops the seven gates. Section 5 gives the twelve faults of the procedure itself. Sections 6 and 7 give the catalog's warrant and its thirty-two entries, followed by the seven faults of diagnosis. Section 8 works two systems end to end. Sections 9 to 12 discuss what follows, verify the chain, state the limitations, and conclude. Appendices A to C carry the specification schedules and the two working forms.

16.2 2 Hypotheses

The procedure of Section 4 is a **decision rule**, and a decision rule is not falsifiable by observation: it can be shown to be badly designed, expensive, or inconsistent with its own premises, but it makes no claim about the world. The same is true of the consent gate (Section 4.12), which is a **constraint on the space of admissible designs** and not a prediction. The arithmetic results of Section 3.2 are derivations from an equation and are labelled as such where they appear.

What *is* falsifiable is the claim that the gauge and the catalog describe real accumulating systems. The hypotheses below separate the two. **None of them was tested against collected data in this paper**; both worked systems in Section 8 are constructed, and Section 11 records that as the paper's principal limitation. Each hypothesis names the observation that would defeat it.

> **H1 — The headroom bound binds.** A requested per-period increment exceeding the measured headroom cannot be delivered by any arrangement of the interaction, because `r_max = h_t` is the extremal value over all admissible geometries. **Predicted:** a system committing to `r > h` under-delivers by at least `r − h` per period once the conversion lag has elapsed, and its shortfall is insensitive to facilitation, seating, ordering or effort. **Falsified by:** a system delivering a sustained per-period increment above its measured `h` over several time constants with `eta`, `delta`, `N` and `C` stable and independently re-measured.
>
> **H2 — Positive headroom does not imply growth.** The gauge is computed on the ceiling `ln N` while the realised step is computed on `F(U)`, so the sign of `h` and the sign of the one-step change are independent quantities. **Predicted:** systems with `h > 0` and a low realised fraction `S / ln N` decline, at a rate `eta(ln N − F(U))` below the headroom; the worked ward has `h = +1.686` and a step of `−0.756` per week at `S / ln N = 46.04` per cent. **Falsified by:** systems with positive headroom reliably growing irrespective of their realised fraction, or a measured realised fraction that fails to predict the sign of the one-step change when the other parameters are held.
>
> **H3 — The shedding lever is worth `delta x q` and nothing more.** Removing `q` units of stored order returns exactly `delta x q` of headroom per period, so shedding is decisive in fast-decaying systems and nearly worthless in durable ones. **Predicted:** at `delta = 0.003090` per week a fourteen-unit shed returns 0.0433 per week; the

same shed at `delta = 0.05` returns 0.70, a factor of sixteen. **Falsified by:** a measured headroom gain from a shed that materially exceeds `delta x q` in the absence of a simultaneous change in `C` — which would show that the retained units were charging more than the decay term accounts for, and that the cost ledger is misspecified.

H4 — Conversion outranks category count, per unit of committed resource. At parameter values typical of surveyed systems, raising `eta` returns more headroom per unit of resource than raising `N`, because `eta` multiplies the ceiling while `N` enters it logarithmically against a coordination cost that grows with the number of pairs [Brooks, 1975, Conway, 1968]. **Predicted:** in the worked office, `eta` returns 2.207 rules per week per full-time equivalent against the sixth discipline's 0.158 on the source's own comparison — a factor the source states as fourteen and this paper reports as basis-dependent, between ten and eighteen, in Section 8.1. **Falsified by:** a system in which the measured cost per unit of `eta` gain exceeds the cost per unit of `N` gain. **The ranking is a default and is expected to invert** in systems whose capture discipline is already near its medium's absorption limit; the procedure requires the analyst to compute their own costs and to report an inversion when it occurs.

H5 — Regularising a variable geometry pays twice. Because `F` is strictly concave, a system whose geometry varies delivers strictly less than a system sitting at its own average every period; reducing the variability raises the mean *and* shrinks the concavity penalty. **Predicted:** cutting the low-participation share from 32.7 to 12 per cent raises the mean of `F` from 1.1498 to 1.3241 nats and the realised step from +0.4381 to +0.6211 rules per week, of which 0.0427 comes from the penalty falling from 0.0761 to 0.0354 nats. **Falsified by:** an observed step gain that tracks the change in `F` of the mean `U` (1.2262 to 1.3595) rather than the change in the mean of `F`. Note that `mean F <= F(mean U)` itself is a **derivation** from concavity, not a hypothesis; what is at risk here is the claim that the accumulating system is driven by the mean of `F`.

H6 — The frozen denominator is the dominant category fault. Declared category counts systematically exceed epistemically active counts, so systems plan against ceilings they do not own. **Predicted:** a ward declaring five handover categories with two attending plans against `ln 5 = 1.6094` rather than `ln 2 = 0.6931` — a ceiling 132 per cent higher than the one it owns; the general prediction is that a capability-partition audit reduces `N` in a majority of surveyed systems. **Falsified by:** surveys in which declared and capability-audited category counts agree within measurement error across a range of systems.

One further claim is stated and is explicitly not a hypothesis. That the catalog is *closed* — that there are exactly six kinds of failure — is **true by construction** given the model, since the law has six free quantities. It is a **definition**, it carries no empirical weight, and it would be defeated not by an observation but by the adoption of a different model. Section 6.1 says so at the point where the closure claim is made.

16.3 3 Framework

16.3.1 3.1 The gauge, and what it is a budget for

The gauge is

```
h_t := eta ln N − delta Q_t − C_t
```

and it is read as a budget in the following sense, which is a **shared arithmetic form and not an economic derivation**: `eta ln N` is the largest per-period income the interaction can deliver, attained only at the geometric ceiling; `delta Q_t` is the standing charge on what is already stored; `C_t` is dissipation. What remains is what may be committed.

```
h_t <  0    unsustainable in this model; no interaction geometry rescues it
h_t =  0    maintenance only
h_t >  0    growth available, and any requested increment must satisfy r_t <= h_t
```

`h` is not a score. It is a sign with a magnitude, and the sign changes what the procedure permits. The three regimes and the increment ceiling are established in Curzi [2026b]; what this paper adds is the procedure that consumes them and the reserve that keeps a plan off the extremal value.

`h` shrinks as `Q` grows. That is the structural reason institutions ossify: success accumulates stored order, `delta Q` grows in proportion, and the budget for anything new closes. It has an operational consequence at once — **the headroom measured last year is not the headroom now, and it is re-measured before every commitment.**

16.3.2 3.2 The six inherited results

Six results from the corpus's foundational and dynamical papers do the load-bearing work in Sections 4 to 8. They are relabelled **CC-T1** to **CC-T6** here so that the paper's own contributed results (R1 to R6 and CR, stated in Section 12) cannot be confused with them. Their original numbering in the source volumes is given for traceability; none of them is proved here.

Label	Statement	Source	Original
CC-T1	Maximum one-step increment. `r_max = eta ln N − delta Q_t − C_t = h_t`, and no policy based on interaction geometry alone can guarantee more. `r_max` is attained only at `U_t = 1`.	Curzi [2026b]	Corollary 4.2
CC-T2	Target increment feasibility. `Q_{t+1} − Q_t >= r_t` if and only if `S_t >= (delta Q_t + C_t + r_t)/eta`, which is attainable only if `delta Q_t + C_t + r_t <= eta ln N` — that is, only if `r_t <= h_t`.	Curzi [2026b]	Proposition 4.1

Label	Statement	Source	Original
CC-T3	Sustainability ceiling. A nondecreasing step requires `C_t <= eta ln N − delta Q_t`. If `C_t` exceeds it, **no choice of interaction geometry prevents order from decreasing.**	Curzi [2026b]	Corollary 3.4
CC-T4	Steady state. With constant `U = u∗`, `C = c∗` and `delta > 0`, `Q_inf = (eta F(u∗) − c∗)/delta`. If `eta F(u∗) < c∗` the equilibrium is negative, and the regime is unsustainable or the linear model must be replaced.	Curzi [2026a]	Theorem 3.5
CC-T5	Uniform bound and arrival. `Q_t <= max{Q_0, eta ln N / delta}`; and because `delta > 0` makes the update map a contraction, a unique fixed point exists and iteration reaches it from any start, at a rate set by `1/delta`.	Curzi [2026a], Curzi [2026]	Theorem 3.3; Banach
CC-T6	Range and concavity of the surplus functional. `0 <= F(u) <= ln N` on `u` in `[0,1]`, with `F(u) = ln(1 + (N−1)u)` strictly concave in `u`, and `N_eff = 1 + (N−1)u`.	Curzi [2026]	Derived results 3.2, 3.3

CC-T5's arrival clause is what makes an intervention arrive at all, and it is also why interventions arrive slowly. The a posteriori form of the same contraction argument — `d(x_n, x∗) <= (k^n/(1−k)) d(x_0, x_1)`, read operationally as *distance to arrival is the last correction scaled by* `q/(1−q)` — is established in Curzi [2026] and is the reason the monitoring rule of Section 4.16 can read the size of the most recent revision as a gauge of remaining distance.

On the effective count, one correction is mandatory and is made here rather than in a footnote. `N_eff = 1 + (N−1)u` is **this framework's own construction**, adopted by design axiom, and it is **not a Hill number**. `1/HHI` is the Hill number of order two and `exp(H)` is the Hill number of order one; both are grounded in the diversity literature [Hill, 1973, Jost, 2006], and neither is the quantity used here. A reviewer reaching for that literature as support for the affine effective count will find it does not apply. Every occurrence of an effective count in this paper is the affine one, and it is named as such.

16.3.3 3.3 Two kinds of lever, and the two master numbers

The distinction is easy to miss from the equations and it governs half of the procedure.

```
h    = eta ln N − delta Q − C        uses the CEILING, ln N
step = eta F(U) − delta Q − C        uses what ACTUALLY HAPPENED, F(U)
```

Raising `u` does not raise `h`. It closes the gap between `step` and `h`. The gauge already assumes the best possible geometry, so working on `u` collects headroom that already exists and is being left on the table, while working on `eta`, `C`, `Q` or `N` changes how much headroom exists at all. Define the

```
realisation deficit  =  h − step  =  eta ( ln N − F(U) )
```

which is the amount of headroom a system has and is not collecting. **The two master numbers of any diagnosis are therefore `h` and the realised fraction `S / ln N`, and a diagnosis reporting one without the other is half a diagnosis** — it will send the analyst to the wrong lever. This is the analytical content of the paper's counter-result, and Section 8.2 is the case that exhibits it.

The realisation lever has two sub-levers with very different costs. **Capacity `u`** — how non-parallel the categories are when all of them speak — is slow, changed by recruitment, rotation and the deliberate outsider. **Realised `u`** — how much of that capacity appears in the period record — is changed by attendance rules, by requiring a recorded disposition from every category, by protocols that elicit positions in writing before discussion, and by room geometry. The realised sub-lever is nearly always the cheaper and nearly always available, because most organisations run sessions below their own measured capacity.

16.3.4 3.4 Identification: the objection Gate 0 cannot answer

This belongs in the framework rather than in a caveat, because it bounds what the procedure can deliver before any survey is run, and because Gate 0 is precisely where an identification claim would have to be made.

The specification underlying the gauge is reflexive. The interaction observable `U` is a property of a group; the group's stored order shapes what its members do next; and the members are what the group is made of. That is a linear-in-means reflexive structure, and Manski [1993] proves that in such a structure **the endogenous social effect is not identified from observational data** — it cannot be separated from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] establish the same confounding for network data, where influence and selection cannot generically be told apart from observation.

The consequence for this paper is exact. Gate 0 admits evidence on three grounds: a complete survey, passed repackaging tests, and an evaluated preregistration [Curzi, 2026i]. **None of the three identifies `eta`.** A survey that passes every gate has established that the order proxy is not a repackaging of the interaction observable and that the fitted model predicts out of sample; it has not established that `eta` measures the conversion of interaction into structure rather than a contextual effect, a common driver, or selection into the group. **A fit that passed all three falsification rules would still not have identified that parameter**, and the corpus's one confirmatory application did not pass all three [Curzi, 2026i].

This paper adopts no remedy, so the honest label is a modelling position rather than an identified empirical result. The four known routes are randomisation, an instrument, partial-population variation, and stipulating the reference group and defending the stipulation; Brock and Durlauf [2001] is the template for the last and the most realistic here. The survey's fixed category set, declared merge and drop rules and explicit participation rule are the machinery a defended stipulation would need — but stipulating a reference group and

defending it are two acts, and only the first has been performed. **Every `eta` in every worked case below is a coefficient in a declared specification.**

One consequence deserves separate statement because it is where the procedure is strongest. The **capped, preregistered, reversible pilot of Gate 7 is the only element of the procedure that can supply causal evidence**, precisely because it introduces exogenous variation the estimation did not have. That is the reason it is a gate rather than an option, and it is why the accounting-frame restriction of Section 4.2 permits a pilot while forbidding the claim that the model predicts its outcome. Where the corpus needs an existence proof that reflexive loops occur and can be caught in the field, MacKenzie and Millo [2003] supplies one with dates and price data; it is not a substitute for identification here.

The Lucas critique applies to this framework's own parameters. The procedure asserts that a measure changes the behaviour of the system measured by it, and prescribes raising a captured metric's decay rate in response (Section 7.6, FM-28), while treating `delta`, `eta` and `N` as constants over an estimation window. **Both cannot be true without qualification** [Lucas, 1976]. The position taken here is the narrow one: the parameters are treated as stable *only over a declared window and only while the order proxy is not itself a reported target*, which is exactly why Section 4.16's first prescription is to keep the proxy out of the reporting line. Where the proxy is reported upward, the constancy assumption fails and the model is outside its domain.

16.3.5 3.5 Scale type, and what licenses the arithmetic

The scale type of every measured construct is stated here, with what licenses it, because the procedure computes differences and ratios and neither is licensed on an ordinal scale.

Construct	Instrument	Scale type claimed	What licenses it	Verdict
`Q` — stored order	a count of declared proxy units (live rules; patients with stated concerns)	**ratio**	counting, with a fixed zero and a defined unit	licensed *for the proxy*; the identification of the proxy with stored order is a postulate
`C` — dissipation	a residual in the same proxy units per period	**ratio**	derived from two counts on a common denominator	licensed, conditional on the residual being complete (FM-23)
`delta` — retention loss	decay under a zero-input window	**ratio** (a dimensionless fraction)	a ratio of two counts of the same proxy	licensed
`eta` — conversion	attributable change in `Q` per nat of surplus	**ratio**	a ratio of a count to a derived dimensionless quantity	licensed as arithmetic; **not identified** (Section 3.4)
`N` — category count	capability partition	**absolute count**	counting, after a declared merge rule	licensed; the merge threshold is a stipulation
`u` — non-parallelism	`u = 1 - rho^2` from independently elicited estimates	**stipulated ratio**	**nothing external**; the quantitative structure has not been tested	**NOT licensed by measurement.** See below.

Construct	Instrument	Scale type claimed	What licenses it	Verdict
`h`, `step`, `r`	arithmetic on the above	**ratio, per period**	inherited from the terms, all in proxy units per period	licensed where `u` is
`r/h` — reserve ratio	a quotient of two headroom quantities	**ratio**	same unit, common zero	licensed **only on the `h > 0` branch**; at `h <= 0` the quotient is meaningless and the procedure does not form it

`u` is where the framework is most exposed, and the exposure is conceded rather than argued away. Michell [1997] argues that psychology routinely fails to test whether its attributes are quantitative at all before measuring them, and that this is the discipline's characteristic methodological error. **This is the strongest single objection to the framework, and this paper does not answer it.** The formal remedy is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971], which tests directly whether an attribute has additive quantitative structure, or a Rasch demonstration [Rasch, 1960]. **Neither has been run for `u`, here or anywhere in this corpus.** Until one is, the treatment of `u` as a ratio-scale quantity — which is what taking `1 - rho^2`, its mean, and a logarithm of an affine function of it all require — is a **stipulation**, and every quantity downstream of it inherits that status. Stevens [1946] supplies the taxonomy the table above uses; it does not license the entry it is used to classify.

Two operations in this paper are worth naming because they are exactly the ones an ordinal scale would forbid. The **headroom difference** `h - step` and the **reserve ratio** `r/h` are both computed. Both are licensed if and only if `u`, and through it `F(U)`, is genuinely a ratio-scale magnitude. **If `u` is merely ordinal — if all that is defensible is that one board was more nonparallel than another — then the realisation deficit is not a quantity, the reserve ratio is not a proportion, and the correct downgrade is to report the *sign* of `h - step` and the *ordering* of levers while withdrawing every decimal place.** That downgrade is stated here so a reviewer does not have to propose it.

16.3.6 3.6 Badged postulates

P-A — Parameter separability (POSTULATE). The procedure treats `eta`, `C`, `u` and `N` as levers that can be moved one at a time. In real systems they interact: adding a category raises `C`; raising `eta` by adding a scribe consumes capacity that was producing something else; cutting `C` by removing rework may cut `u` if the rework was where disagreement surfaced. The procedure handles this by requiring each lever's second-order cost to be entered explicitly in the specification (Appendix B), but **the separability is an approximation and it has no external support.**

P-B — Hyperrecursive symmetry (POSTULATE). The storage law is scale-free in *form*: only `(delta, eta, N, C)` change between a desk, a room, a team, a building, an institution and a city. **This is a claim about model form, not about physics and not about parameter values.** It licenses running the same procedure at a different scale; it does not license carrying a number across scales. The claim has been exercised across five systems from a single desk to a 22-household block, reproducing each system's observed decline — predicted `−0.250474` against observed `−0.250` at the desk and `−0.996371` against `−1.000` at the library, with residuals under 1.4 per cent of the ceiling term [Curzi, 2026k]. **That is five systems, one corpus, one author, and no independent replication**; the invariance has been exercised, not established.

P-C — A single scalar `Q` describes an institution (POSTULATE). That the law describes a real institution at all is a choice of model, not a theorem. The foundational papers prove things *about* the law; they prove nothing about any organisation. Where a fault sits outside the model — a legal shutdown, a fire, a death — the catalog will not name it, and the correct response is to say so rather than force a parameter.

P-D — Cost accrues each period whether or not surplus was delivered (POSTULATE). This is an assumption about how organisations charge overhead. It has no external support and it is consumed at exactly one place, the sustainability ceiling CC-T3.

P-E — Consent (DESIGN CONSTRAINT, not a claim). No intervention that removes a person's ability to decline is within the scope of this procedure. This is stated in the framework rather than in an ethics section because it is a constraint on the *space of admissible designs* and therefore on the arithmetic: a design requiring compliance is not a cheaper version of a design inviting participation; it is a design the procedure does not produce. The constructive alternative is to build the more comfortable position next door and let people arrive at it — a method that works by removing resistance has no coercive failure mode, and its worst outcome is that someone declines to move. **This is a normative commitment. It is not derived from the arithmetic and it is not falsifiable**, and it is badged accordingly. Hacking [1995] is the relevant caution about classification acting on the classified; it supports the concern, not the rule.

16.3.7 3.7 Standing honesty clauses

These constrain every number in the paper and are repeated here because the catalog is the part of the material most likely to be quoted out of context.

- As deployed, the surplus functional is a **lower bound** on the ensemble's information, not the information itself. Every price quoted in Section 7 is a floor. A computed `h` is conservative in that one respect, and **that is not a licence to exceed it.**
- The foundational surplus paper is pure mathematics and makes **no empirical or metaphysical claim** [Curzi, 2026]. Nothing in this paper's arithmetic is validated by a theorem; it is validated, if at all, by the survey and preregistration that precede it.
- **No thermodynamic negentropy law is proved anywhere in this corpus**, and higher static surplus does not imply higher canonical concentration. Any entropy invoked near `ln N` is **Shannon entropy**, a dimensionless information measure in nats, not thermodynamic entropy, which carries `[energy][temperature]^-1`.
- Subadditivity holds on `u` only. **The triangle inequality fails for geometric triples** [Curzi, 2026], so interventions may not be composed across three groups by adding their surpluses. The empirical counterpart is that psychological similarity is asymmetric and violates the triangle inequality [Tversky, 1977].
- **Where an entry in the catalog cites an external result, the result is real and the *transfer* to a given system is a modelling assumption**, badged at each occurrence. The three-drawer honesty classification that governs this practice — established mathematics, established psychology, and declared postulates, with every protocol stated to run on the first two and steer by the third — is set out in Curzi [2026].
- `0 <= F(u) <= ln N`. **`ln N` is the hard ceiling on surplus per interaction**, which is why `h` is defined with `ln N` and not with `F(U_t)`.

16.3.8 3.8 Analogy discipline

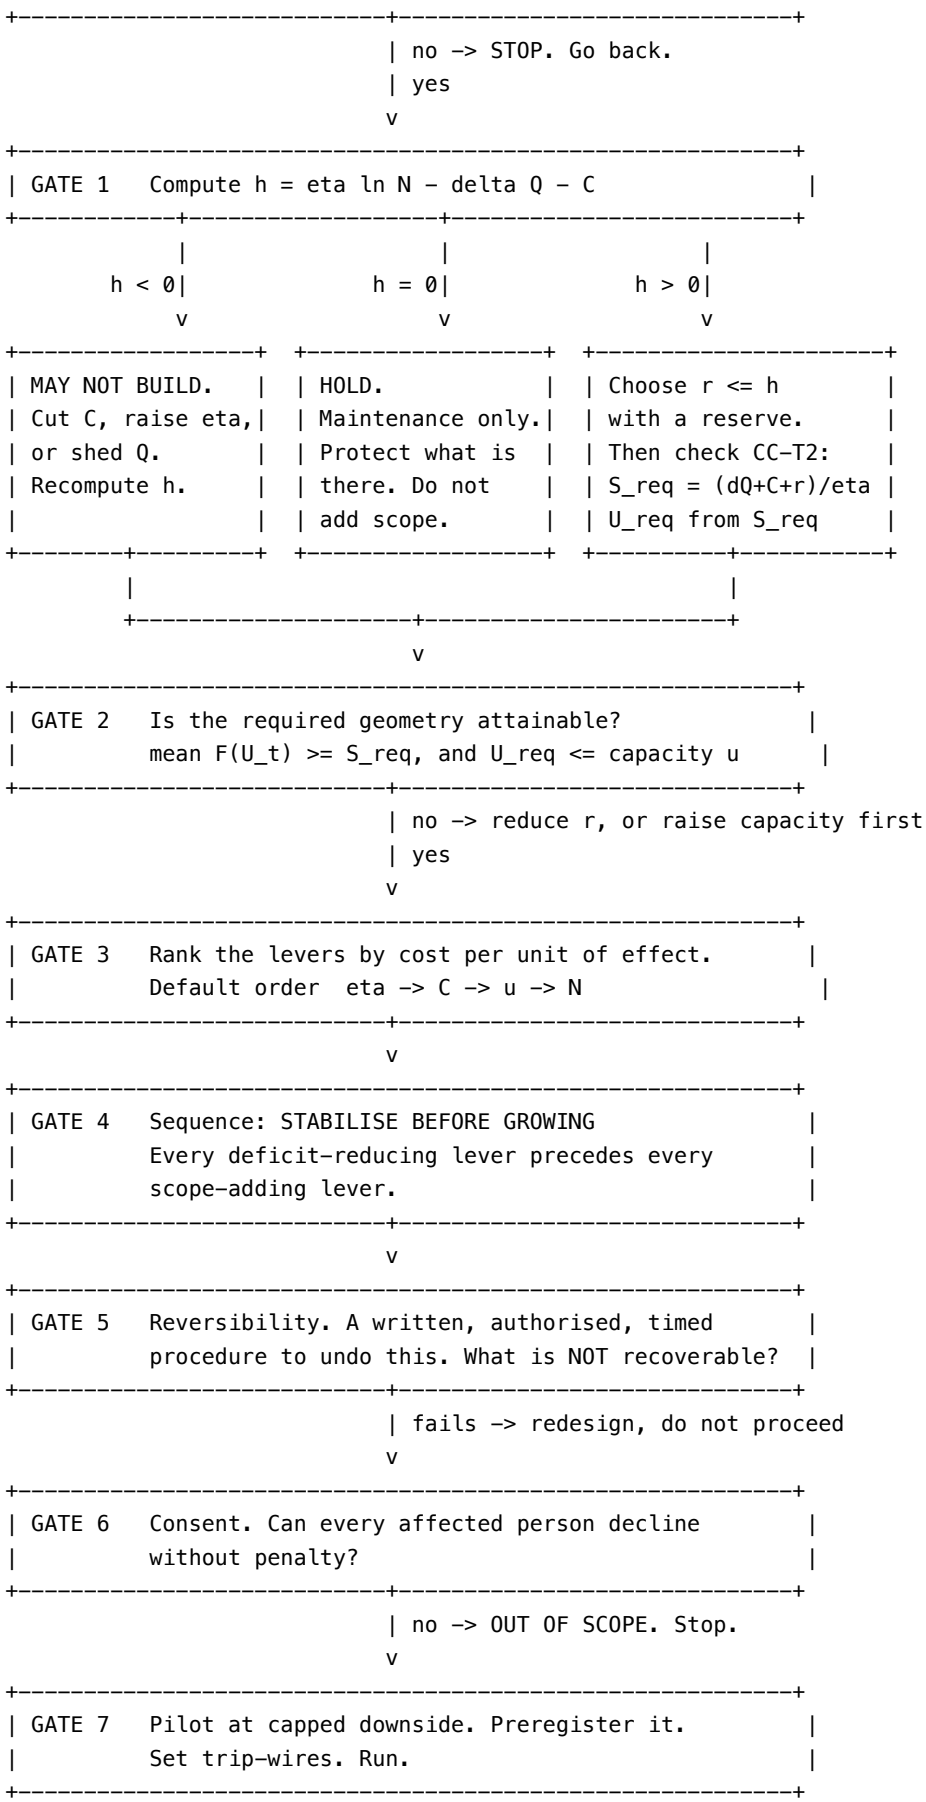
Four borrowings run through this paper and each is labelled at first use, following the three-way rule that a physical result may be used as a **derivation** (the premises are genuinely satisfied), as a **shared mathematical form** (the same equation governs both, with no claim that the physics applies), or as an **analogy** (suggestive, never evidence).

The storage law as a leaky integrator is a shared mathematical form. The law and the first-order discrete section obey the same difference equation, so every theorem about first-order systems applies [Oppenheim et al., 1996, Elaydi, 2005]. Nothing about charge or current is claimed of an institution.

Queueing is a shared mathematical form. The utilisation cliff (Section 7.5, FM-22) uses the standard result that expected wait scales as `1/(1−rho)` [Kingman, 1962, Hopp and Spearman, 2011] and Little's Law `L = lambda W` [Little, 1961]. The premises — a service system with arrivals and a queue — are plausibly satisfied for a review board, and the transfer is nonetheless badged as a modelling assumption because the arrival and service distributions are never measured in the worked cases.

Room acoustics is a derivation, and the only one in the paper. Sabine's relation `RT60 = 0.161 V / A` is a physical result about a real room, and a meeting room is a room [Sabine, 1922, Schroeder, 1965]. **What is *not* a derivation is the step from reverberation time to non-parallelism `u`**: that a longer tail excludes the quiet participant, and that the exclusion registers as a fall in `u`, is a modelling assumption. The tail arithmetic that connects them — the gap for a previous talker to fall 15 dB is `t_15 = RT60/4`, giving 488 ms before treatment and 98 ms after — is established in Curzi [2026e] and is itself acoustics; its consequence for participation is not.

"Budget", "mortgage", "income" and "overdrawn" are analogy only. They are used because they make the gauge legible to a sponsor and for no other reason. No result in this paper depends on any of them, and none of them transfers the authority of accounting to a psychological claim.



One borrowing is refused. The logarithm in `F(u)` is not justified here by Fechner's law [Fechner, 1860]; the perceptual story is not needed and Stevens [1957] disputes it. Where the logarithm needs a warrant, the stronger one is Peters and Gell-Mann [2016], which derives a logarithmic form from multiplicative dynamics with no psychological assumption at all. **That warrant is still not a discrimination**: Latané [1981]'s sub-linear power law and Briscoe et al. [2006]'s `n log n` fit the qualitative facts as well as `ln(1+(N−1)u)` does, and **nothing assembled in this paper discriminates among the three.** The logarithm is adopted for its axiomatic characterisation [Curzi, 2026] and not because it has been shown to be the right shape.

No scaling, power-law or heavy-tail claim is made or estimated in this paper. Where the catalog invokes preferential attachment and scale-free structure (Section 7.2, FM-10), the exponent is a property of the *cited model* [Barabási and Albert, 1999], not a quantity fitted here; no distribution was fitted, so the estimation procedure that any such claim would require [Clauset et al., 2009] does not apply, and the reader should note that the empirical generality of scale-free structure is itself contested [Broido and Clauset, 2019]. The entry is used for its *mechanism* — a hub redistributes rather than generates — and not for a tail exponent. # 4 The gated procedure

16.3.9 4.1 The gate sequence, and a correction to the source ordering

The procedure runs seven gates in the order below. **The source material this paper converts develops Gate 7 before Gate 5 in its expository body while running them in numerical order in its worked case. That is an inconsistency in the source, it is recorded here rather than silently repaired, and this paper adopts the numerical order 0 through 7 throughout** — so reversibility (Gate 5) is developed in Section 4.11, consent (Gate 6) in Section 4.12, and the pilot (Gate 7) in Section 4.13. The ordering matters: reversibility and consent are admissibility conditions on a design, and a pilot is a design, so a pilot cannot be specified before the conditions its design must satisfy.

```
+-------------------------------------------------------+
| GATE 0   Is the evidence admissible?                  |
|          Survey complete?  Repackaging tests all PASS?|
|          Preregistration frozen and evaluated?        |
```

| no -> STOP. Go back.
| yes
GATE 1 Compute h = eta ln N - delta Q - C
h < 0|
h = 0|
h > 0|
MAY NOT BUILD. Cut C, raise eta, or shed Q. Recompute h.
HOLD. Maintenance only. Protect what is there. Do not add scope.
Choose r <= h with a reserve. Then check CC-T2: S_req = (dQ+C+r)/eta U_req from S_req
GATE 2 Is the required geometry attainable? mean F(U_t) >= S_req, and U_req <= capacity u
| no -> reduce r, or raise capacity first
| yes
GATE 3 Rank the levers by cost per unit of effect. Default order eta -> C -> u -> N
GATE 4 Sequence: STABILISE BEFORE GROWING Every deficit-reducing lever precedes every scope-adding lever.
GATE 5 Reversibility. A written, authorised, timed procedure to undo this. What is NOT recoverable?
| fails -> redesign, do not proceed
GATE 6 Consent. Can every affected person decline without penalty?
| no -> OUT OF SCOPE. Stop.
GATE 7 Pilot at capped downside. Preregister it. Set trip-wires. Run.

16.3.10 4.2 Gate 0 — the admissibility of the evidence

The procedure may not be run on estimates. Three conditions are required.

- **A survey with a failed repackaging test produces no admissible `h`.** If the order observable is a function of the interaction observable, then `Q`, `delta` and `eta` are all measurements of the same artefact and `h` is a number about the instrument [Curzi, 2026i].
- **A failed first falsification rule means the storage law is the wrong model**, and the procedure does not apply. A system that compounds rather than accumulates, or that oscillates, is a real system with a different manual.
- A failed second rule with a passed third — the **accounting frame** — permits the procedure with one restriction developed in Section 4.13: `h` may be used as a budget constraint and a preregistered pilot may be run, and **no claim may be made that the model predicts the pilot's outcome.**

A passed shuffled-input control is not evidence of admissibility, and Gate 0 must not be read as though it were. The four-baseline suite ends with the shuffle, and the shuffle is the test a sponsor will quote back. Measured by simulation elsewhere in this corpus, it has three failure modes.

1. **It is anti-conservative as ordinarily run.** Against a nominal `alpha = 0.05`, measured false-rejection rates were **0.108 for iid permutation (2.2 times nominal), 0.120 for circular shift (2.4 times nominal), and 0.060 for block permutation.** A shuffle passed at the nominal threshold has roughly twice the advertised false-positive rate unless it was calibrated by simulation on the study's own design, which Gate 0 therefore requires.
2. **It cannot see repackaging.** A filtered repackaging passed all four baselines including the shuffle at `p = 0.0005` and was caught only by the structural ceiling test CC-T1, its single-step jump being **38.5 times** the theoretical maximum [Curzi, 2026i].
3. **It cannot see confounding by a shared slow driver.** In a 4,000-trial simulation the control **passed 98.35 per cent of the time** against a third variable driving both the interaction and the order observables, while behaving honestly in the clean case at 48.17 per cent detection.

The remedy is design controls, not more surrogates: blinding, channel separation, prospective sampling, and a yoked control. The second of the four is a structural property rather than a matter of care, and the corpus states it in another domain as the channel-separation principle: in-band architectures admit an impersonation class that no care *within* the shared channel can close, while out-of-band separation closes it structurally — measured at 0.383 per cent in-band ambiguity against 0.000 per cent out-of-band over 100,000 values [Curzi, 2026]. **A survey whose order observable and interaction observable are gathered through the same instrument is the in-band case**, and no amount of statistical care inside that instrument closes it. All four are properties of how the evidence was gathered, so Gate 0 is the last moment at which they can be checked and the first at which it is too late to add them. **A survey reporting a passed shuffle and none of the four design controls has not cleared Gate 0; it has cleared the weakest test available.** The wider point is the one the integrity literature makes about analytic flexibility and undeclared choices [Simmons et al., 2011, Gelman and Loken, 2013]: a control chosen after the data are seen is not a control. And Section 3.4 states the limit no control reaches — **none of these conditions identifies `eta`**, so Gate 0 governs admissibility of *evidence about the proxy* and never admissibility of a causal claim.

16.3.11 4.3 Gate 1 — the three regimes

Regime	Meaning	Permitted	Forbidden
`h < 0`	maintenance draw plus dissipation exceeds best-case income	cut `C`; raise `eta`; shed `Q`; raise `N`; recompute	any commitment to increase `Q`; any new scope; any promise with a date
`h = 0`	income exactly covers upkeep	maintenance; substitution at constant scope; measurement	growth of any kind, including growth described as a small addition
`h > 0`	budget remains	an increment `r <= h`, subject to Gates 2 to 7	`r > h`, under any argument

16.3.12 4.4 The `h < 0` branch: the procedure forbids building

This is the branch most analysts arrive in and the branch most briefs are written to avoid.

When `h < 0`, the procedure forbids building — not slowly, not partially, not as a pilot whose objective is growth, and not alongside other work. CC-T3 states that when `C > eta ln N − delta Q`, no arrangement of the interaction prevents decline. There is no seating chart, no facilitation technique, and no leadership change that alters an inequality between three measured quantities.

Three remedies are available before `N`.

Remedy 1 — cut `C`. Immediate, usually cheap, and acting on the term measured most carefully. The recommended order is rework loops first — they are pure dissipation and are hard to defend once counted — then contradiction maintenance, then the attention tax, then coordination overhead. Appeal and orphaning costs are usually structural and are cut by repairing the process that produces them.

Remedy 2 — raise `eta`. The most reliably cheap lever [Curzi, 2026b]. Interaction that happens and interaction that sticks are different quantities and only one is in the equation. Capture mechanisms are administrative: a designated scribe, a template, a decision log, a publication deadline, a named owner for each new unit of order, an apprenticeship. **Because `eta` multiplies `ln N`, it is the only lever that raises the ceiling itself rather than moving the system toward it.**

Remedy 3 — shed `Q`. The remedy nobody proposes. Shedding stored order to regain headroom is legitimate and underused: sunset clauses, term limits, planned demolition, retiring a product line, forgetting by design. **The arithmetic is exact — shedding `q` units returns `delta x q` of headroom per period — so shedding buys headroom in strict proportion to `delta`.** In a fast-decaying system it is decisive; in a durable one it is nearly worthless. In the worked office of Section 8.1, shedding 14 rules from a stock with a 4.31-year half-life returns 0.0433 rules per week, where the same shed at `delta = 0.05` would return 0.70 — a factor of sixteen. **The multiplication is computed before the shed is proposed; if the product is small, the proposal destroys something for nothing.**

One distinction is carried from the survey protocol and is easy to lose. **Striking units that were already inert is not shedding `Q`; it is correcting the order observable** [Curzi, 2026i]. Correcting the measurement changes the number and not the world. Shedding has real effects, including effects on the people whose work the shed units were.

16.3.13 4.5 The `h = 0` branch: hold

`h = 0` is maintenance only. What is permitted is protecting what is there and funding the maintenance regime **explicitly**, because working infrastructure produces no observable signal and is therefore chronically underfunded — infrastructure becomes visible only on breakdown

[Star and Ruhleder, 1996]. Substitution is permitted: retiring one unit of scope to make room for another is admissible at `h = 0` and adding one is not.

What is not permitted is describing `h = 0` as stability and treating it as safe. `delta Q` grows whenever `Q` grows and `C` grows whenever the organisation grows, so **`h = 0` is an unstable point that drifts negative on its own.** A system at `h = 0` is one hiring round, one new reporting requirement, or one departure away from `h < 0`, with no margin to absorb any of them. Organisational slack is the classical name for the margin that is missing here [Cyert and March, 1963].

16.3.14 4.6 The `h > 0` branch: choosing `r <= h`

The rule is absolute. **`r <= h`**: CC-T1 states that nothing based on interaction geometry guarantees more, and `r_max = h` is attained only at `U = 1`.

1. **The procedure forbids taking `r = h`.** That is the extremal value, attainable only at perfect orthogonality of every category from every other. Taking it means promising the best case as the plan.
2. **Reserve for parameter drift.** Non-parallelism decays, `C` grows, staff leave. The working convention is **`r <= 0.7 h`**, with the reserve stated explicitly as a reserve rather than quietly absorbed. The 0.7 is **a stipulated convention, not a derived quantity**, and it is badged as such wherever it appears.
3. **Check it against what the system has been doing.** If the realised one-step change is negative, a positive `r` requires the levers of Section 4.9 to have landed first. `r` is a promise about the future state of the parameters, not the current one.

16.3.15 4.7 Gate 2 — feasibility, the two failures, and the concavity correction

CC-T2 gives the required surplus and its geometric inverse:

```
S_req = (delta Q + C + r) / eta          feasible only if S_req <= ln N

U_req = (exp(S_req) − 1) / (N − 1)
```

There are two distinct failure modes with different fixes.

Failure A — the budget fails. `S_req > ln N`, equivalently `r > h`. The increment lies outside the ceiling and no geometry delivers it. Fix: reduce `r`, or raise `h` with the headroom levers of Section 4.9.

Failure B — the geometry fails. `S_req <= ln N`, so the increment is inside the budget, but `U_req` exceeds the measured capacity. The budget permits it; the categories cannot deliver it, because they are not that different from one another. Fix: raise capacity — recruitment across training lineages, rotation, adversarial roles, the deliberate outsider — or raise realised non-parallelism toward capacity, or reduce `r`.

Confusing the two is the most common design error at this gate, because both present as an inability to hit the target. Failure A is an accounting problem; Failure B is a personnel and protocol problem. They cost different amounts and take different lengths of time, and they are routed to different parts of an organisation.

The concavity correction, which is applied before either check. `U_req` is the geometry required *if `U` were constant every period.* It never is. What accumulates is the sum of `eta F(U_t)`, so the operative quantity is the **mean of `F`**, not `F` of the mean; and because `F` is strictly concave (CC-T6), Jensen's inequality gives

```
mean of F(U_t)  <=  F( mean of U_t )        with equality only if U is constant
```

A system whose geometry varies delivers strictly less surplus than a system sitting at its own average every period. The requirement is therefore stated as `mean F(U_t) >= S_req` and compared against the measured **mean of `F`**, never against `F` of the measured mean. `U_req` may be reported for legibility; it may not be tested against. The gap is the **concavity penalty**, it is often several per cent of the surplus, and regularising a variable geometry recovers it at no cost. Section 8.1 measures the penalty at 0.0761 nats in a case whose mean `F` is 1.1498 and whose `F` of the mean `U` is 1.2262 — a distinction that the notation `F(U)` invites an analyst to lose, and which Section 9.4 records as a defect in the source's own notation.

16.3.16 4.8 Creating headroom against realising it

Section 3.3 defines the realisation deficit `h - step = eta(ln N - F(U))`. Its operational content at this point in the procedure is a routing rule.

Lever	Acts on	Raises `h`?	Raises `step`?
`eta`	the ceiling coefficient	**yes**	yes
`C`	dissipation	**yes**	yes
shed `Q`	the maintenance charge	**yes**, by `delta x q`	yes
`N`	the ceiling, logarithmically	**yes**, net of path cost	yes
capacity `u`	attainable geometry	**no**	yes
realised `u`	geometry actually recorded	**no**	yes

The realisation sub-levers cannot take a system past `h`. A second opinion from someone whose training and incentives replicate the first is worth `ln(1) = 0`; and conversely the largest single gain available anywhere in the framework is the second genuinely different member. **Neither fact raises the ceiling.** The evidence that difference produces value is real and is bounded: Hong and Page [2004] give the formal result, and Thompson [2014] shows that the result's popular reading outruns what was proved — the pair is cited together here and never one without the other, as are the subsequent repairs [Singer, 2019]. **The relationship is not monotone in the field:** Uzzi and Spiro [2005] find an inverted U, creative success rising and then falling with cohesion, and Putnam [2007] finds that diversity in the short run reduces trust and civic participation, with Abascal and Baldassarri [2015] as the rebuttal. **The framework's surplus is monotone increasing in `u`; that is a property of the model, and the field evidence says the real curve turns over.** Contact across difference produces value only under conditions [Allport, 1954, Pettigrew and Tropp, 2006], and `u` needs the same qualification.

16.3.17 4.9 Gate 3 — the lever cost ranking

The default ranking, in ascending order of cost per unit of effect: `eta`, then `C`, then `u`, then `N`. Shedding `Q` is a conditional lever whose value is `delta x q` and which therefore belongs wherever `delta` puts it. **The ranking is a default and not a law**; the procedure requires an analyst to compute their own system's costs and to report an inversion when one occurs (Appendix A, IS-13). **A lever can also be exhausted rather than merely expensive**, and the corpus computes an instance of that in its frequency register: on a carried dyad the reserves available from non-parallelism and from cost, 5.545206 and 5.963140 octaves, each close a deficit of 4.338420, while the conversion reserve at its own ceiling supplies only 4.174198 and cannot close it at all [Curzi, 2026]. **A ranking by cost answers which lever to pull first; it does not answer whether a lever has enough left in it to finish**, and both questions are computed separately.

1. **`eta` — usually cheapest, and the first move in almost every real system.** Most organisations sit near the floor without knowing it, because capture is nobody's job. The fixes are administrative rather than structural — a scribe, a template, a named owner, a publication deadline — and require no hiring, no reorganisation and no consequential budget line. `eta`

multiplies `ln N`, so it raises the ceiling itself, and it is the only lever with that property that does not require adding people. It is neglected because "we had a great conversation" is a report of `eta = 0` and feels like a success. **Its limit is real: `eta` cannot exceed the rate at which the durable medium absorbs structure**, and a scribe writing faster than the register can be reviewed produces a backlog rather than order.

2. **`C` — next cheapest and usually fastest to act.** Rework loops and contradiction maintenance are pure dissipation; once counted in proxy units they are hard to defend, and cutting them requires a decision rather than a resource. It ranks below `eta` because `C` has a floor — some coordination *is* the work — where `eta` has no comparable floor in the ranges real organisations occupy.

> *Caution.* **Slack is not cost.** Waiting time explodes as utilisation approaches one [Kingman, 1962, Hopp and Spearman, 2011], so unused capacity is a cost-control device. An enthusiastic cost-cutting programme that removes slack raises `C` in the following periods through queueing, and the analyst will not connect the two.
>
> *Second caution.* Cut rework, not the places where disagreement surfaces. If the appeal process is where non-parallelism is realised, cutting it cuts `C` and cuts `F(U)` at once.

3. **`u` — cheap in money, expensive in time and political capital, and it realises rather than creates.** The realised sub-lever is often nearly free: an attendance rule, a recorded disposition requirement, a change of table. The capacity sub-lever is not: it means recruitment, rotation, and the deliberate importation of people whose training and incentives do not replicate the incumbents'. That is slow, and it is the change organisations resist most, because hiring for cultural fit, promotion by similarity and shared training are precisely the mechanisms that drive `u` toward zero and every one of them is popular. **`u` is not a property acquired once; it is a quantity that decays and must be maintained**, and cascades collapse it even in a group that began diverse [Bikhchandani et al., 1992]. Budget for its maintenance as a recurring cost, not as a project.

4. **`N` — most expensive and least rewarding, because the return is logarithmic.** Going from `N` to `N+1` adds `ln((N+1)/N)` nats to the ceiling, multiplied by `eta`. **Doubling the number of categories adds `ln 2 = 0.693` nats wherever one starts** — the same absolute gain from 2 to 4 as from 50 to 100.

N	ln N	gain over N-1	paths n(n-1)/2	paths added
2	0.6931	0.6931	1	1
3	1.0986	0.4055	3	2
4	1.3863	0.2877	6	3
5	1.6094	0.2231	10	4
6	1.7918	0.1823	15	5
8	2.0794	0.1335	28	7
10	2.3026	0.1054	45	9
12	2.4849	0.0870	66	11
16	2.7726	0.0645	120	15
20	2.9957	0.0513	190	19
30	3.4012	0.0339	435	29
50	3.9120	0.0202	1225	49
100	4.6052	0.0101	4950	99

Surplus grows logarithmically while coordination cost grows with the number of pairs [Brooks, 1975, Conway, 1968]. The gain column falls and the paths-added column rises, and they cross; where they cross is the maximum useful team size and it is computable from a system's own `eta` and per-path cost. **The consequence to be said out loud to every sponsor**

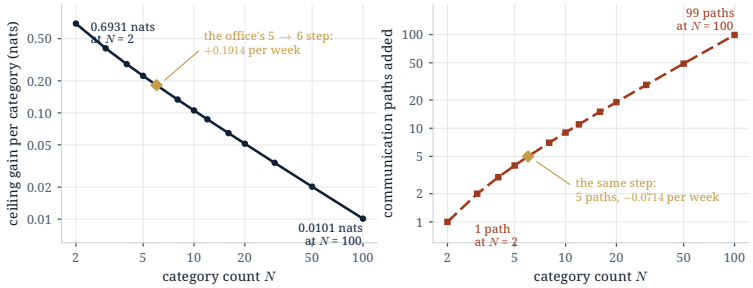


Figure 16.1: **Logarithmic gain against quadratic cost, on the source's own table.** The marginal ceiling gain `ln N − ln(N−1)` falls from 0.6931 nats at `N = 2` to 0.0101 at `N = 100` while the number of communication paths added by the same step rises from 1 to 99. The two curves are plotted against a common index because they are not commensurable in value — the crossing point is set by a system's own `eta` and per-path cost and is not a universal constant. Read from the `N`-lever table of Section 4.9; generated by `figs/src/CCP-016_fig03.py`.

is that a headroom problem cannot be escaped by adding domains. The same arithmetic is computed in another domain with the sign made explicit: at a 15 per cent annual hard-currency drag, a local-currency allocation of 25.17 per cent of protected capital sets headroom to exactly `-0.500000` and **cancels the whole `eta ln N = 0.377583` diversification gain**, while a 10 per cent allocation costs 0.150000, or 39.73 per cent of that gain [Curzi, 2026]. **A cost term attached to the same move that raises `N` can consume the entire ceiling gain and more**, which is why IS-17 requires the net effect and not the gross. The most common response to `h < 0` is to propose a new function, working group or discipline; the ceiling gain is small and logarithmic and is paid for with a cost that grows quadratically.

The one condition under which `N` is worth it is that the new category be **genuinely distinct** rather than relabelled. A sixth discipline duplicating an existing one raises `N` on the organisation chart and raises `C` for real while raising `u` not at all. The merge rule — categories with pairwise `u` below 0.10 are one category — is the test, and it is applied to the *candidate* before hiring, using the probe set [Curzi, 2026i]. Section 8.1 prices the difference at a 34 per cent haircut on the headline benefit.

5. Shed `Q` — conditional, valued at `delta x q`. Rank it by computing the product and inserting it into the list. In a durable institution it is last; in a fast-decaying one — a codebase with a two-month half-life, a training regime, a stock of active campaigns — it can outrank everything.

16.3.18 4.10 Gate 4 — sequencing: stabilise before growing

Every lever that reduces the deficit precedes every lever that adds scope. This is arithmetic rather than temperament: adding scope raises `Q`, and `delta Q` is subtracted from the same budget the intervention was repairing. **Growth taken before stabilisation consumes the headroom it was meant to produce.**

```
Phase 0   MEASURE          The survey. Not skipped, not shortened.
Phase 1   STOP THE LEAK    Cut C. Raise eta. Both act immediately and
                           neither adds scope. Recompute h.
Phase 2   CORRECT Y        Liveness and applier audits. Changes the number,
                           not the world, and precedes any shed.
Phase 3   SHED, IF delta x q IS WORTH IT
Phase 4   REALISE          Close the realisation deficit: attendance rules,
                           recorded dispositions, table geometry, written
                           positions before discussion. Cheap, fast, reversible.
```

```
Phase 5   RE-MEASURE h     Everything above changed it.
Phase 6   COMMIT r <= h    With a reserve. Preregister. Pilot.
Phase 7   RAISE CAPACITY u Slow. Recruitment, rotation, the outsider.
Phase 8   RAISE N          Last, and only against the merge test.
```

Phase 5 is the phase that gets dropped and the phase that matters most. Phases 1 to 4 change `eta`, `C`, `Q` and `F(U)` — every term in the gauge. Committing to an increment computed from the pre-intervention headroom is committing to the wrong number, and it is wrong in both directions: under-committing wastes headroom that now exists, over-committing breaks a promise.

The sharpest instance of the sequencing rule concerns trust, and it inverts naive practice. Trust is the intervention most often reached for in a system going badly. In a worked consortium reported elsewhere in this corpus, **trust alone moved the steady state from `-0.0836` to `-0.2114` — worse, by a factor of two and a half.** Reciprocity alone moved it to `+0.7394`; the two together to `+1.8701`. The mechanism follows from CC-T4: `Q_inf = (eta F(u*) - c*)/delta`. **Trust acts on the denominator — it reduces `delta`, the rate at which stored order leaks away — and when the numerator is negative, dividing by a smaller positive denominator makes the result more negative.** Trust does not add order; **it amplifies whatever sign the system already has**, and a system with `eta F(u*) < c*` already has a negative one. A high-trust failing institution fails harder and holds its failure longer, because trust is exactly the property that stops things from being forgotten.

Design rule: fix the numerator first. Raise `eta` or cut `C` until `eta F(u*) > c*` — Phases 1 and 2, in that order — and only then invest in trust, which belongs in Phase 6 or later for arithmetic rather than temperamental reasons. **An intervention beginning with a trust-building programme in a system whose numerator is negative is not a slow start; it is a lever pulled in the wrong direction, and it will be defended by everyone who felt the relationships improve.** The reciprocity half of the same result is where the external literature is strongest [Axelrod, 1984, Ostrom, 1990]; the trust half is a claim about a denominator and is derived from CC-T4, not from that literature.

16.3.19 4.11 Gate 5 — reversibility as a hard design requirement

A design that cannot be undone is not admissible under this procedure, regardless of its expected value. The requirement has three justifications, in ascending order of weight.

Epistemic. The model failed at least one falsification rule, or passed with a finite holdout and stated tolerances [Curzi, 2026i]. The analyst is acting under quantified uncertainty, and a design that cannot be undone converts an estimate into a commitment.

Structural. Interventions change `Q`, and `Q` is subtracted from the gauge through `delta Q` forever. An irreversible addition is a permanent charge against all future headroom. **Every irreversible intervention is a decision made on behalf of every future decision-maker in the system.**

Ethical. Reversibility is what makes declination meaningful. If a person may decline but the change cannot be undone, the declination is a gesture.

The reversibility statement answers five questions in writing. **These are labelled RV1 to RV5 here; the source labels them R1 to R5, which collides with this paper's own contributed results, and the collision is resolved by renaming the source's.**

```
RV1  What exactly returns to the prior state?
RV2  What does NOT return, ever?  (be specific: trust, a person who left,
     demolished fabric, a public commitment, a dissolved team, elapsed time)
RV3  Who is authorised to execute the reversal, without asking anyone?
RV4  How long does the reversal take, in periods?
RV5  What does the reversal itself cost, in proxy units?
```

RV2 is the load-bearing question. Most designs have a substantial irreversible component nobody has named, and naming it usually changes the design. RV3 matters nearly as much: a reversal requiring the approval of the person who authorised the intervention will not happen. The design and safety literature reaches the same conclusion from a different direction — interactive complexity plus tight coupling makes some failures a property of the system rather than of its operators [Perrow, 1984], and redundancy added without a reversal path can reduce safety rather than raise it [Sagan, 1993].

Class	Definition	Rule
Fully reversible	prior state restorable within a few periods at low cost	proceed under the normal gates
Costly-reversible	restorable, but the reversal costs a stated number of proxy units	proceed only if the reversal cost is inside `h`
Partially irreversible	some named component does not return	proceed only if that component is separately justified and separately consented
Irreversible	prior state unrecoverable	**not admissible**

16.3.20 4.12 Gate 6 — consent

Every affected person has a stated mechanism to decline without penalty. If none exists, the intervention is out of scope and does not proceed. This is postulate P-E of Section 3.6, and it is a boundary rather than a trade-off: it is not priced, because it is not for sale.

The gate has an engineering content as well as a normative one, and the engineering content is what makes it operative here. **Coerced non-parallelism is not non-parallelism.** A person compelled to voice a difference voices the difference the compeller expects, which returns the system to a parallel wall by a longer road. The declination mechanism is therefore not a concession attached to a design; it is part of the measurement.

A design whose parameters have no defined value under declination has not actually offered one. The test is a single written question for every protocol in the design: *what happens to a person who declines?* If the answer includes any adverse consequence, the protocol is out of scope. Section 8.1 exhibits the honest form: a discipline lead may abstain and the item proceeds with the remaining disciplines at a correspondingly lower `U_t`; an analyst offered the scribe role may decline, in which case the `eta` lever is unavailable and `h` is recomputed without it. **The declination is not free — it changes the arithmetic, and the arithmetic is published — but it carries no penalty to the person, and the design has a defined behaviour when it is exercised.**

16.3.21 4.13 Gate 7 — the pilot at capped downside

A pilot is not a small version of the intervention. A pilot is an experiment whose worst outcome has been computed and can be afforded.

1. **Cap the downside in proxy units, not in money.** State the maximum stored order that can be lost if the pilot fails completely, and confirm the system absorbs it. The admissibility condition `C_t <= (1-delta)Q_t + eta S_t` guarantees `Q_{t+1} >= 0` [Curzi, 2026b]; a pilot that could violate it is not capped.
2. **Bound it in scope and in time.** One team, one room, one product line, one quarter. The bound is what makes the downside computable.

3. **Preregister it**: the numeric prediction, the falsification criterion, both stopping rules, the consent mechanism, the reversibility procedure. Preregistration is the appropriate evidentiary form here for the reasons the reform literature gives — it separates the confirmatory from the exploratory and removes the analytic flexibility that otherwise makes a favourable result uninformative [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013] — and it is what converts a prediction into a risk [Platt, 1964]. **The corpus's own defence against the standard objection that directional predictions in the social sciences are nearly costless [Meehl, 1967] is that it makes point predictions with constants**; that defence is only good where the point prediction is actually declared in advance, which is what this gate requires.
4. **Respect the conversion lag.** The prediction must not begin before `m` periods have elapsed, where `m` is the measured lag from interaction to durable artefact. Testing earlier is designing a failure.
5. **Keep a matched comparison where one exists honestly.** A second team, a second room, a preceding period of the same length. Where no honest comparison exists, say so: **a pilot with no comparison is a demonstration, and demonstrations are evidence about feasibility, not about effect.**
6. **Under the accounting frame** — second rule failed, third passed — the pilot carries an extra restriction: it is not a confirmation of the model, and its preregistered prediction is stated as a prediction about the *intervention*, not as a test of the storage law. It may nonetheless supply the causal evidence the estimation could not, which is precisely why it is worth running (Section 3.4).

One caution on the pilot's own measurement. A survey period that shows improvement may have told the analyst about the survey. The Hawthorne pattern is invoked far more casually than the evidence supports [McCambridge et al., 2014], which cuts both ways: it is not a sufficient explanation of a favourable result, and it is not a sufficient dismissal of one either. The remedy is the matched comparison of rule 5 and the mediation check of Section 8.2, not an appeal to the pattern's name.

16.3.22 4.14 The three-posture table

Every intervention encounters behaviour it did not plan: an informal practice, a dissenting group, a workaround, a shadow process, a person who does it differently. Three postures are available and each has a determinate effect on the parameters. **The default is *ignore*, and ignore is a choice with consequences.**

Posture	What is done	`u`	`eta`	`C`	`Q`
ENGAGE	bring it into the record: a category, a seat, a recorded disposition	rises toward capacity	rises: the practice becomes capturable	rises modestly: one more path, one more voice	rises if it converts
IGNORE	leave it outside the record	decays: the practice drifts and stops informing the centre	zero for that practice: it produces nothing durable	low now, unbounded later: a shadow process accrues its own maintenance	flat; the order it makes is not the system's

Posture	What is done	u	eta	C	Q
SUPPRESS	forbid it	falls, often sharply: suppression teaches every category not to differ	falls: the suppressed practice was producing, and adjacent practices go quiet	rises: enforcement, monitoring, appeals, and the attention tax of everyone watching	falls: the order the practice held is destroyed

The risk profile of each is different in kind and not only in size. **Engaging has a bounded and visible cost**; its failure mode is that the practice is genuinely redundant, so C has been bought for no gain in u, and the remedy is to test the candidate against the probe set before engaging. **Ignoring is the default and it is a slow loss**; its failure mode is that the shadow process becomes load-bearing while remaining unmeasured, so Q and C are both wrong and the survey that reports them is inadmissible. **Suppressing is worst on every parameter at once**, and the consent gate is decisive against it independently of the arithmetic: suppression that removes a person's ability to decline is out of scope (Section 4.12).

Suppression is the only posture that damages all five parameters simultaneously, and it is the posture organisations reach for first, because it is the only one that feels like action. Neither the arithmetic nor the constraint of Section 4.12 permits it. The constructive alternative is to make the alternative position the more comfortable place to stand and let people arrive there; its worst outcome is that someone declines, which is a permitted outcome.

16.3.23 4.15 Time constants, and what may be promised

The contraction guarantees arrival (CC-T5). It says nothing about arriving this quarter.

```
time constant  tau = 1/delta        periods
95 per cent of the way to a new equilibrium:  about 3 tau
99 per cent:                                  about 5 tau
```

The rule that follows is short: promise increments, never equilibria. r is a per-period increment observable within a few periods of the conversion lag; Q_inf is where the system ends up after roughly three time constants [Oppenheim et al., 1996], which in a durable institution is a span of years or decades. A sponsor told the equilibrium hears a promise; a sponsor told the increment can check it. **The evidence that people systematically misjudge stocks with delays is direct and experimental** [Sterman, 1989], which is why the four numbers below are said out loud at the commitment meeting and entered in the specification:

1. the conversion lag m — nothing is observable before it;
2. the increment r per period, and the horizon over which it is judged;
3. the time constant tau, in calendar units;
4. 3 tau, in calendar units, labelled the settling time and explicitly **not** a delivery date.

A low delta is what makes an institution durable and it is the same number that makes it slow. Durability and speed cannot be bought from the same parameter, and any promise implying they can is a promise the arithmetic will break.

Cadence against intensity — a correction, because the usual argument for cadence is false. Given a fixed total input, an intervention may deliver it as one large occasion or spread it periodically, and practitioners hold that cadence delivers more. **It does not, and this is computed rather than asserted: the integrated effect of one impulse and of the same total spread over any schedule is identical to every digit.** Summing the exact solution of the storage law

gives `sum_t Q_t = (total input)/delta` regardless of how the input is distributed in time; the corpus reports 433.3333 in all three regimes it tested. **That is linear time-invariance** [Oppenheim et al., 1996], and a procedure claiming otherwise would be claiming its own governing equation is not linear.

What cadence actually buys is three things, each of them real.

1. **The steady state differs absolutely.** An impulse decays to zero; sustained periodic forcing at mean rate `m` holds `m/delta`. The integrated effect is the same; the level that can be stood on is not, and for an intervention that must leave a platform behind, the level is the deliverable.
2. **The ceiling clips the impulse.** `S_t <= ln N` (CC-T6), so a one-off input larger than the ceiling is truncated and the excess is simply not received. In a worked annual rite reported elsewhere in this corpus the clipping destroys **97.2 per cent of the nominal budget** — the money is spent and the surplus is not admitted, because no geometry pushes a single period above `ln N`.
3. **Concavity favours splitting, independently of the ceiling.** Strict concavity of `F` (CC-T6) alone makes an input split across occasions strictly dominate the same input delivered at once. **This is the same Jensen arithmetic as Section 4.7 read forwards: variability is charged against the system when the geometry varies, and paid to it when the input is spread.**

So cadence beats intensity because of the ceiling and because of concavity, not because it delivers more. It delivers exactly the same amount. The honest counter-case is kept in print: above a threshold no realistic cadence reaches, the impulse wins. **The true reason is stated when a cadence is specified, because the false reason will not survive the first sponsor who checks it.**

16.3.24 4.16 Monitoring, trip-wires, and the standing gauge

An intervention without instrumentation is an assertion. Three things are installed before it starts.

The standing gauge. Recompute `h` every period from the same instruments with the same definitions, and post it — not the order proxy, and not a dashboard, but `h` and its three components, so a reader can see which term is moving. **Keeping the order proxy itself out of the reporting line is the primary defence against the measure becoming a target** [Goodhart, 1975, Campbell, 1979].

Trip-wires. Pre-declared thresholds that trigger a specific action without further discussion, because discussion at the moment of a threshold is how thresholds get moved.

Trip-wire	Threshold	Action
realised geometry falls	mean `F(U_t)` below `S_req` over a declared block	the promised `r` is no longer feasible; notify the sponsor in the same period
`C` rises	above the level at which `h < r`	suspend the growth commitment; resume the cost work
`h` crosses zero	`h <= 0`	stop building immediately; revert to Section 4.5
any single-period rise in the proxy	exceeds `eta ln N` plus lag allowance	investigate the proxy before believing the number
a harm criterion fires	as preregistered	stop, regardless of the proxy

The geometry trip-wire fires most often and is watched least. Non-parallelism decays; the promise was computed at a level of realised surplus the system must actively maintain; and the decay is invisible because it looks like agreement.

The review cadence. At least every `tau/4` periods, and at least once per conversion lag. In a system with a six-year time constant, quarterly is ample and monthly is theatre. The contraction's a posteriori bound gives the reading a second use: the size of the most recent correction, scaled by `q/(1−q)`, bounds the remaining distance to arrival [Curzi, 2026]. A control-theoretic caution belongs here as well: a correction gain applied outside the stability band of a first-order loop does not merely act slowly, it diverges [Åström and Murray, 2008], so a monitoring regime that responds to every deviation with a larger correction is a design fault and not diligence.

16.3.25 4.17 When the procedure directs no intervention

The default is not to intervene. Interventions cost `C` while they run, raise `Q` if they succeed — which permanently charges `delta Q` against all future headroom — and consume an organisation's finite tolerance for being changed. **The burden of proof is on action.** Eleven conditions follow, each a hard stop except where noted.

1. The system has not been measured. No survey, or a survey with a failed repackaging test. No argument survives this, including urgency. **An intervention designed on an unmeasured system is a guess with a budget, and its most likely effect is to move a parameter that was not the binding one.**

2. `h < 0` and the proposal is to build. CC-T3. The remedies of Section 4.4 are repairs and are permitted; building is not.

3. `r > h`. No argument, no exception, no phasing. **A request exceeding the budget is refused and the refusal is the deliverable. The number is said.**

4. `U_req` exceeds capacity. Failure B of Section 4.7. Building anyway produces a shortfall that will be attributed to effort rather than to geometry, and the organisation will conclude that people did not try hard enough. **That conclusion is worse than not having acted.**

5. The design is irreversible. Section 4.11. Not admissible, regardless of expected value.

6. Any affected person cannot decline without penalty. Section 4.12. Out of scope. This is not a severity judgement about the intervention; it is a statement about what this procedure produces.

7. The system is already at its uniform bound. `Q_t` at or near `max{Q_0, eta ln N/delta}` (CC-T5). Nothing designed exceeds it. An intervention aimed above the bound is aimed at a number the model has already forbidden, and the effort will appear entirely as `C`.

8. The binding constraint is outside the model. The survey produces six numbers about interaction, conversion, decay and cost. If the actual constraint is a legal prohibition, a funding cliff, a safety failure, a physical limit, or a person in acute distress, then the framework is measuring a room in a building that is on fire. **Say so plainly and stop; the strongest thing an analyst can do with a model is state where it does not apply.**

9. The measurement is the intervention. Where the survey itself has changed behaviour enough that the parameters are already moving, wait a full `tau/4` and re-measure before adding anything. Acting on top of an unresolved measurement effect makes both uninterpretable.

10. The system is in an identifiable transient. `(1−delta)^t Q_0` decaying while the driven term builds looks exactly like decline. Before intervening on a declining proxy, check whether it is a transient from a known change within the last `3 tau`. Intervening in a transient adds a second transient and neither can be attributed.

11. A cheaper lever has not been tried. Not a hard stop but a discipline: if `eta` has never been examined and the proposal is to hire, the proposal is premature. Section 4.9's ranking exists to be checked, in order, before a design is accepted.

Two closing dispositions.

Not intervening is a decision and is recorded as one. A survey ending in *no intervention is warranted* is a completed piece of work with a deliverable: the six numbers, the sign of `h`, the reason, and the trip-wire that would change the answer. **File it, date it, and name the observation that would reopen it. Undocumented restraint is indistinguishable from neglect and will be read as neglect.**

The request for an intervention is not evidence that one is needed. The analyst was called because something is uncomfortable. Discomfort is a gradient, and a gradient indicates which way is downhill; it does not establish that the system has a budget for the journey. **The service being paid for is the number, and sometimes the number is `-0.17`.**

That said, the gradient is a real measurement and is treated as one. Since `h = eta ln N - delta Q - C` and only `C` varies with a local design choice, `grad h = -grad C`: the direction of steepest increase in headroom is exactly the direction of steepest decrease in cost. Discomfort, at the point where it is felt, is `C`. **Therefore a cheap desire-line survey — where do people work around this system — is a headroom measurement**, and the full instrument programme is not always required to locate the direction of steepest improvement. Direct observation of where people actually go, against where the design intended them to go, is the classical instrument [Whyte, 1980, Jacobs, 1961, Alexander et al., 1977]. **The division of labour is exact and is worth stating as a rule: the cheap survey gives the direction; only the full survey gives the sign and the size of `h`, which is what decides whether the analyst may move at all.** Run the cheap one first, every time, and do not let it authorise a commitment.

A correction to the received advice about deliberate discomfort. *Leave the comfort zone* is usually stated as a general principle, and stated that way the arithmetic rejects it — but the rejection is narrower and more interesting than a flat denunciation, and both branches have been measured in this corpus. **Raising cost globally is strictly harmful**: in a worked landscape the time to reach a better configuration runs 32, 35, 42, 89, 297 weeks and then never, as global cost rises. **Raising cost only at the origin genuinely shortens the wait — 32.0 weeks down to 9.9 — and charges for it: the permanent fund that results is 37 per cent smaller.**

The operative question is therefore not whether to add discomfort but whether it is a cost that can be left behind or a cost that is carried. Making the current position expensive is a departure lever; it works, at a permanent price. Making the whole landscape expensive destroys the platform the system was trying to leave *for*. An intervention raising `C` everywhere in the name of urgency has raised `delta Q + C` against `eta ln N` in every future period, which is the `h < 0` branch arrived at deliberately. **Price the discomfort, name which kind it is, and put the 37 per cent in the specification next to the 9.9 weeks.** The related result on momentum — that momentum at `beta = 0, 0.5, 0.8, 0.9, 0.95` all terminates at the same `x = 1.9972` in the same basin, so momentum defeats narrow barriers and is useless against wide shallow ones, and is refused entry to the formulary — is established in Curzi [2026p] and bounds what a departure lever can be expected to do.

16.4 5 Faults of the procedure itself

Twelve faults attach to the procedure rather than to the system it is run on. **They are labelled PF-1 to PF-12 here; the source labels them F26.1 to F26.12 against a chapter number that no longer exists.**

PF-1 — Building at negative headroom. *Description.* `h < 0` and the intervention adds scope anyway, usually described as investing a way out. *Damages.* `Q`, then `C`, then morale. *Signature.* A growth plan whose first phase does not reduce `C` or raise `eta`. *Detection.* Gate 1; it is one subtraction. *Fix.* Refuse, and return to Section 4.4. **The refusal is the deliverable and the number is the argument.**

PF-2 — The promised equilibrium. *Description.* `Q_inf` is quoted as the outcome without `3 tau`. *Damages.* Credibility, and eventually the intervention itself when a sponsor stops it early for under-delivery. *Signature.* A target level with no per-period increment attached. *Detection.* Ask what is expected next quarter; if the answer is a fraction of `Q_inf` computed by

straight-line interpolation, the fault is present, because approach to a fixed point is exponential and not linear. *Fix.* Section 4.15: promise `r`, report `Q_inf`, state `3 tau` and label it settling time.

PF-3 — Confusing Failure A with Failure B. *Description.* An infeasible target is treated as a budget problem when it is a geometry problem, or the reverse. *Damages.* Wasted lever effort; the wrong department is asked for the fix. *Signature.* More money offered for a problem where `S_req <= ln N` but `U_req` exceeds capacity. *Detection.* Compute both checks of CC-T2 and report them separately. *Fix.* Route Failure A to `eta`, `C` and `Q`; route Failure B to recruitment, rotation and realisation protocols.

PF-4 — The hiring reflex. *Description.* `h < 0`, so a new function, working group or discipline is added. *Damages.* `C`, with the number of pairs; `h`, immediately; and `u`, if the addition is a relabelling. *Signature.* A headcount proposal with no `ln((N+1)/N)` calculation and no path-count calculation. *Detection.* Compute the ceiling gain, compute the added paths, subtract. *Fix.* Run the merge test on the candidate first, then compare against the `eta` lever's cost per unit of effect — which in Section 8.1 is an order of magnitude better on every basis examined.

PF-5 — The shed that bought nothing. *Description.* Stored order is destroyed to create room in a system with small `delta`. *Damages.* `Q`, permanently; trust, permanently; `h`, by `delta x q`, which is negligible. *Signature.* A sunset or cull proposed without `delta x q` computed. *Detection.* One multiplication. *Fix.* Compute it. In Section 8.1 the shed returns 0.0433 rules per week against an `eta` lever returning 0.8828 — **a factor of twenty on that comparison**, which is a different comparison from the factor of sixteen between the same shed at two different decay rates, and the two are not to be conflated.

PF-6 — Slack cut as cost. *Description.* A cost-reduction programme removes unused capacity. *Damages.* `C`, upward, in following periods, through queueing. *Signature.* Utilisation rises toward one and waiting times begin to grow non-linearly. *Detection.* Track utilisation alongside `C`; the signature is unmistakable once both are plotted. *Fix.* Restore slack. **Slack is a cost-control device, not a dissipation** [Kingman, 1962, Cyert and March, 1963], and this is one of the few places where the intuitive reading of the equation is exactly backwards.

PF-7 — The unwatched geometry. *Description.* `r` was computed at a level of realised surplus the system stops maintaining. *Damages.* The feasibility of the promise, silently. *Signature.* Increasing agreement, decreasing meeting length, fewer recorded dissents — all of which read as improvement. *Detection.* The realised-geometry trip-wire on `mean F(U_t)`, plus an annual probe set. *Fix.* Reinstate the realisation protocols. If capacity itself has fallen, the problem is slow.

PF-8 — The irreversible pilot. *Description.* A pilot that dissolves a team, demolishes a wall, or announces publicly. *Damages.* Everything, because the option value that made it a pilot is gone. *Signature.* RV2 on the reversibility statement is blank or reads "none". *Detection.* RV2 is never honestly "none"; if it is blank, it has not been attempted. *Fix.* Redesign to a reversible form, or classify it as an intervention and put it through the full gates.

PF-9 — The default suppression. *Description.* An unplanned practice is forbidden without a posture decision being made explicitly. *Damages.* `u` down, `eta` down, `C` up, `Q` down — all four at once. *Signature.* A prohibition with no recorded alternative and no recorded reason. *Detection.* The posture table has a row for every unplanned practice or it does not. *Fix.* Reverse the prohibition and choose engage or ignore deliberately. Where a practice genuinely must end, make the alternative the more comfortable place to stand.

PF-10 — Re-measurement skipped. *Description.* `r` is committed from the pre-intervention `h` after Phases 1 to 4 have changed every term in it. *Damages.* The commitment, in either direction. *Signature.* One `h` value in the document, at the top. *Detection.* Count the `h` values in the specification; Appendix B has a slot for each phase because each phase has one. *Fix.* Phase 5. It costs an afternoon.

PF-11 — The intervention that was the measurement. *Description.* Acting on a survey whose administration already changed the behaviour it measured. *Damages.* Attribution, permanently. *Signature.* The proxy or realised geometry moves during the survey window itself. *Detection.* Plot the series against the survey's own dates. *Fix.* Condition 9 of Section

4.17: wait `tau/4`, re-measure, then design.

PF-12 — The unrecorded restraint. *Description.* The correct decision — do not intervene — is taken and not documented. *Damages.* Nothing now; everything in eighteen months, when the same question returns with no record of the six numbers or the reason. *Signature.* A survey with no closing decision page. *Detection.* Appendix A, IS-32. *Fix.* File the decision, the numbers, the sign, and the observation that would reopen it. # 6 The failure catalog: warrant, identities, and entry format

16.4.1 6.1 Why a finite catalog is possible

The storage law has exactly six degrees of freedom.

```
Q_{t+1} = (1 − delta)Q_t + eta S_t − C_t        S_t = F(U_t) = ln(1 + (N−1)U_t)

    delta   retention loss              in [0,1]
    eta     conversion efficiency       >= 0
    N       category count              integer >= 1
    u       non-parallelism             in [0,1]
    C       dissipation                 >= 0
    Q       stored order                >= 0
```

Every failure of a system modelled by this law is a claim about one of those six quantities, so there are exactly six kinds of failure however many names they wear. That is the whole warrant for a closed catalog, and it is worth being precise about its status: **the closure is a DEFINITION, true by construction given the model, and it carries no empirical weight.** It would be defeated not by an observation but by the adoption of a different model. The thirty-two names below are not independent phenomena; they are recurring *routes* into six parameter faults, distinguished because the routes have different signatures, instruments and fixes.

That the law describes a real institution at all is **badged as a postulate** (P-C of Section 3.6): a single scalar `Q` for a team is a choice of model, not a theorem. Where a fault sits outside the model — a legal shutdown, a fire, a death — the catalog will not name it, and the correct response is to say so rather than force a parameter.

16.4.2 6.2 The three diagnostic identities

Every entry is priced against one of three identities, and they are the only arithmetic the catalog needs.

Identity 1 — the effective count. `N_eff = 1 + (N−1)u`, and `S = ln N_eff`. Difference is counted before headcount is credited, so any fault lowering `u` lowers `S` non-linearly and invisibly, because headcount does not change. **This effective count is the affine one adopted by design axiom in Curzi [2026]. It is not a Hill number** (Section 3.2), and the diversity literature is not support for it.

Identity 2 — the one-step condition. `Q_{t+1} > Q_t` if and only if `eta S_t > delta Q_t + C_t` [Curzi, 2026b]. **Growth is a comparison, not a quantity.**

Identity 3 — headroom. `h_t = eta ln N − delta Q_t − C_t`. `h_t < 0` is unsustainable **in this model** and no interaction geometry rescues it (CC-T3); `h_t = 0` is maintenance; `h_t > 0` is the maximum available increment, `r_max = h_t` (CC-T1).

16.4.3 6.3 The distinction on which half of all misdiagnosis turns

`h_t` uses `ln N`. The one-step condition uses `S_t = ln N_eff`. **Headroom is the ceiling; non-parallelism decides how much of the ceiling is actually collected.** A system can have large positive headroom and shrink every period, because it operates far below its own ceiling.

The practical consequence is a rule: **compute both numbers, always.** A diagnosis reporting `h` without the realised fraction `S / ln N` is half a diagnosis and will send the analyst to the wrong lever. Section 8.2 is the case that exhibits it, and Section 12's counter-result is its statement.

16.4.4 6.4 Entry format, and the honesty clauses that constrain every entry

Every entry carries the same eight fields in the same order, so the catalog can be scanned in a column.

Field	What it holds
Damages	which of `delta`, `eta`, `N`, `u`, `C`, `Q` the fault attacks, and in what direction
Clinical	what the fault is, stated without metaphor
Signature	what is observable from outside, before anything is measured
Measurement	the specific instrument that confirms or excludes it
Price	the arithmetic cost, computed
Fix	the intervention, and which lever it pulls
Confusable with	the entries most often mistaken for this one
Elsewhere	where the mechanism is developed

The standing honesty clauses of Section 3.7 constrain every entry and are recalled here because the catalog is the part of the material most likely to be quoted without context. **Every price below is a floor**, since the surplus functional as deployed is a lower bound on the ensemble's information. **Where an entry cites an external result, the result is real and the transfer to any particular system is a modelling assumption**, badged at that point. **No thermodynamic law is invoked anywhere**, and every logarithm is a dimensionless count in nats.

16.5 7 The catalog

16.5.1 7.1 Class I — Geometry faults (`u` and `N`)

The largest class: non-parallelism decays silently, and `N` is the parameter people believe they have when they do not.

FM-01 · The Parallel Wall

Damages: `u -> 0`. Through Identity 1, the effective count collapses with it. **Clinical:** Every member of the ensemble occupies the same direction in state space. Their outputs are copies. The group behaves as a single instrument with a redundant power supply. **Signature:** Unanimity arriving fast and without argument. A second opinion that is procedurally distinct and substantively identical. Nobody can name the last time the group changed its mind because of an internal objection. **Measurement:** Independent estimation before discussion on 15 to 25 live questions; compute the mean pairwise correlation of signed error, `rho`; then `u = 1 - rho^2`. Confirm with an error-decorrelation audit on past decisions: if the group's mistakes were the *same* mistakes, `u` is low regardless of how the roster looks. **Price:** At `N = 12` the wall is total when `u = 0`: `N_eff = 1`, `S = ln 1 = 0` — twelve people purchase zero surplus. Partial walls are priced the same way. `u = 0.02` gives `N_eff = 1.22` and `S = 0.1989`, which is **8.00 per cent** of the

ceiling `ln 12 = 2.4849`; `u = 0.05` gives `S = 0.4383`, or **17.64 per cent**; `u = 0.30` gives `S = 1.4586`, **58.70 per cent**. **Fix:** Raise `u`: recruit across training lineages, import a practitioner from an unrelated trade, install adversarial roles, rotate. Raising `N` first is wasted money — see FM-07. **Confusable with:** FM-02, which is a partial wall with a demographic alibi; FM-05. **Elsewhere:** capacity recruitment, and the decay of non-parallelism over time.

FM-02 · Pseudo-Diversity

Damages: `u`, specifically the within-category component `u_div -> 0` while the cross-category component `u_cross` looks healthy. **Clinical:** The roster spans categories; the *opinions* do not. Difference is present at the level of biography and absent at the level of method, incentive and permitted conclusion. The group is genuinely heterogeneous in every dimension that does not enter the decision. **Signature:** A visibly varied group whose internal disagreements are all about emphasis. Dissent expressed as a question rather than as a claim. Recruitment filtering late on cultural fit. **Measurement:** Decompose. `u = u_cross + u_div`. Estimate `u_cross` from the between-category share of consequential interaction; estimate `u_div` from within-category disagreement on a live question. Report the two numbers separately. Pseudo-diversity is the profile *`u_cross` moderate, `u_div` near zero*. **Price:** With `N = 8`, `u_cross = 0.30` alone buys `f(u_cross) = 1.1314` nats. Adding `u_div = 0.25` takes the pair to `f(0.55) = 1.5790` — a **39.6 per cent** gain that the roster alone will never show, because nobody was hired to obtain it. **Fix:** Buy `u_div` directly: dissent protection, anonymous-first elicitation, a standing minority-report requirement, adversarial review inside each category. **Confusable with:** FM-01 (total rather than partial); FM-08, which is the *measurement* version of this fault. **Elsewhere:** the decomposition of non-parallelism into crossing and divergence.

FM-03 · The Cascade Collapse

Damages: `u`, dynamically — a group that began diverse converges over time. **Clinical:** Once enough public signals accumulate, rational actors copy rather than report, and the copies carry no new information [Bikhchandani et al., 1992]. Aggregation stops while the appearance of aggregation intensifies. **Non-parallelism is not a property acquired once; it is a quantity that decays**, which makes this a retention problem wearing a geometry costume. *The transfer of the cascade result to a standing committee is a modelling assumption; the result itself is about sequential public choice.* **Signature:** Later speakers agree more than early speakers. The order of speaking predicts the content of speaking. Confidence rises while accuracy does not. **Measurement:** An order-effect test. Elicit estimates in writing, sealed, before any discussion, then again after. If post-discussion variance falls by more than about a third while accuracy is flat or worse, the group has a cascade and not a convergence. Log speaking order against position taken over ten meetings and test for rank correlation. **Price:** A `u` decaying 8 per cent per period from 0.60 at `N = 12` gives `S` = 2.0281 at `t = 0`, 1.7454 at `t = 4` (86.1 per cent), 1.4787 at `t = 8` (72.9 per cent), 1.2316 at `t = 12` (60.7 per cent). Nothing visible changes. The roster is identical throughout. **Fix:** Written positions before any discussion of any consequential question — the cheapest instrument available, and it breaks cascades before they start. Add round-robin ordering and the inversion that has the most junior speak first. **Confusable with:** FM-04 — the same trajectory with a different driver: cohesion is social, a cascade is informational. **Elsewhere:** independence protocols, and the geometry of the table.

FM-04 · The Cohesion Death Spiral

Damages: `u`, dynamically; secondarily raises the perceived cost of dissent. **Clinical:** The group optimises for getting along. Getting along selects for agreement. Agreement selects membership and shapes expression. The loop is positive-feedback and it feels like health the

entire way down. **Cohesion is frequently the enemy of collective intelligence, because cohesion drives u toward zero** — and the field evidence puts a shape on that claim: creative success rises and then falls with cohesion, an inverted U rather than a monotone decline [Uzzi and Spiro, 2005]. Organisational learning shows the same structure from a different direction: members who learn too fast homogenise the organisation and destroy the variance that produced its advantage [March, 1991]. **Signature:** High reported satisfaction with low external accuracy. Long tenure with no recruitment from outside the lineage. A named "difficult" person who is in fact the group's last remaining source of `u` — and celebration when that person leaves. **Measurement:** Track `u` quarterly, not once, and plot it. A cohesion spiral is a monotone decline in measured `u` against flat or rising self-reported team health; **the two series diverging is the diagnostic, not either one alone.** Cross-check with turn-taking equality — the Gini coefficient of speaking time — which is one of the measured drivers of collective intelligence [Woolley et al., 2010]. **Price:** The same arithmetic as FM-03. What differs is the fix, which is why the distinction is worth making. **Fix:** Institutionalise the outsider so that dissent does not depend on one person's nerve: rotating red-team duty, a standing external reviewer, term limits on membership. **None of these may remove anyone's ability to decline participation** (Section 4.12). **Confusable with:** FM-03; FM-09, which is a cohesion spiral with a disciplinary boundary around it. **Elsewhere:** collective intelligence and turn-taking; independence protocols.

FM-05 · The Missing Denominator

Damages: `N` — specifically, the substitution of headcount for the effective count. **Clinical:** The system counts people, seats, sources or sensors and treats that count as `N`. The law counts *categories after a redundancy audit*. The gap between the two is the fault. **Signature:** Capacity claims quoted as headcount — "we have forty reviewers" — with nobody having been asked how many of the forty are distinguishable. **Measurement:** A roster audit. For each pair, ask whether their outputs on a live question were distinguishable; collapse indistinguishable pairs. Report the effective count alongside `N` in every capacity statement thereafter. **Price:** A roster of 40 whose members are 92 per cent aligned (`u = 0.08`) has `N_eff = 4.12` and `S = 1.4159` against a ceiling `ln 40 = 3.6889` — a shortfall of **61.62 per cent**. At `u = 0.05` the shortfall is **70.67 per cent**. The organisation believes it owns 3.69 nats of ceiling and owns 1.08. **Fix:** There is no fix at the `N` lever; this is a `u` fault discovered by an `N` error. Audit, restate capacity honestly, then treat as FM-01. **Confusable with:** FM-06, which is about the *definition* of the categories rather than the count; FM-01. **Elsewhere:** the effective count and the logarithmic ceiling.

FM-06 · The Frozen Denominator

Damages: `N` — the declared categories are administrative rather than epistemic. **Clinical:** `N` is read off an organisation chart, a funding structure or a historical department list. Those boundaries were drawn for reporting, budget or accident; the categories that actually carry distinct information are a different partition. A frozen denominator also hides *vacancies*: categories declared, staffed on paper, and epistemically empty. **Making a system legible to its centre is precisely the operation that destroys the local variety that made it work** [Scott, 1998], which is why the administrative partition is the wrong one so reliably. **Signature:** A category with a name and no active member. Two "different" departments whose outputs are never in tension. Reorganisations that change the chart and change no forecast. **Measurement:** Define categories by capability, not by title: *what can this category independently detect, fix or veto that no other can?* Any category failing the question is not a category. Count only staffed categories in `N`. **Price:** In an open-source case worked elsewhere in this corpus, seven categories are declared and four are staffed: `ln 7 = 1.9459` against `ln 4 = 1.3863`, so the project plans against a ceiling **40.4 per cent higher** than the one it owns [Curzi, 2026k]. Section 8.2 prices the same fault at **132 per cent** in a hospital ward declaring five handover categories

with two attending. **Fix:** Re-partition by capability; then either staff the empty categories — a real `N` gain, priced in FM-07 before it is assumed to be worth it — or delete them from every capacity calculation. **Confusable with:** FM-05. The test: FM-05 is counting too many *people* per category; FM-06 is counting too many *categories*. **Elsewhere:** the roster audit and the merge rule [Curzi, 2026i].

FM-07 · The Ceiling Chase

Damages: `C` rises, `N` rises marginally, `h` falls. A self-inflicted fault. **Clinical:** The system has a headroom deficit and attempts to escape it by adding domains, disciplines, partners or product lines. Because the ceiling term is `eta ln N`, additional categories deliver logarithmically while their coordination cost grows with the number of pairs [Brooks, 1975, Conway, 1968]. **A headroom problem cannot be escaped by adding domains. Signature:** A growth strategy announced in response to a shortfall. New partnerships as the answer to overload. Category count rising while the realised fraction `S / ln N` falls. **Measurement:** Before adding a category, compute two numbers — the ceiling gain `eta(ln N_new − ln N_old)`, and the projected coordination increment. Compare. Refuse if the second exceeds the first. **Price:** Going from `N = 4` to `N = 5` adds `ln 5 − ln 4 = 0.2231` nats, a **16.1 per cent** ceiling gain for a 25 per cent increase in categories. From 5 to 6: **0.1823** nats, **11.3 per cent**. Doubling from 50 to 100 adds `ln 2 = 0.6931` nats, a **17.7 per cent** gain, for double the coordination surface — meanwhile channels rise from 1,225 to 4,950. **Fix:** Compute `h` first. If `h < 0`, the permitted moves are cutting `C`, raising `eta`, or shedding `Q`. Adding `N` is the most expensive lever available and the least rewarding. **Confusable with:** FM-21, which the Ceiling Chase usually *causes*. **Elsewhere:** Section 4.9; the crossover between logarithmic gain and quadratic cost [Curzi, 2026b].

FM-08 · Two-Source Blindness

Damages: the *measurement* of `u`, and consequently the direction of every downstream lever. **Clinical:** The survey measures one of the two sources of difference and reports it as `u`. Since `u = u_cross + u_div`, an organisation rich in cross-category difference and starved of within-category dissent measures as diverse on a cross-category instrument; a room of ferociously argumentative specialists in one discipline measures as diverse on a disagreement instrument. **Both readings are half-true and both send the analyst to the wrong lever. Signature:** A diversity report with one number in it. A team scoring well on whichever instrument its leadership commissioned. **Measurement:** Always two instruments. `u_cross`: the between-category share of consequential interaction. `u_div`: within-category disagreement on a live question, elicited independently. Report both, and report the bound `max(f(u_cross), f(u_div)) <= f(u) <= f(u_cross) + f(u_div)`. **Price:** At `N = 8` with `u_cross = 0.30` and `u_div = 0.25`: `f(u_cross) = 1.1314`, `f(u_div) = 1.0116`, `f(u) = 1.5790`, and the sum is 2.1430. The bound is satisfied and it is wide: **a single-instrument report could plausibly claim anything from 1.01 to 2.14 nats. Fix:** Two instruments, two numbers, every survey, both fields required [Curzi, 2026i]. **Confusable with:** FM-02, which is the *condition*; FM-08 is the failure to see it. **Elsewhere:** the crossing-versus-divergence decomposition.

FM-09 · The Silo Local Minimum

Damages: `u`, destroyed at the boundary, **and** `C`, multiplied at the boundary, simultaneously. **Clinical:** A subgroup sits at a local minimum of its own comfort landscape. The minimum is deep because training and reward carved it, and narrow because it admits one vocabulary. Every direction out is uphill, which is why exhortation fails: it asks people to be uncomfortable on purpose, indefinitely, on someone else's account. **Signature:** Translation costs at every boundary crossing. Duplicate work discovered late. The product's seams sitting exactly

where the organisation chart's seams sit [Conway, 1968]. Cross-group meetings that require a preparatory meeting. **Measurement:** A boundary-crossing cost audit — elapsed time and person-hours for a decision requiring two groups against one. The ratio is the silo tax. Separately, measure `u_cross` (low) and per-boundary `C` (high); **the co-occurrence is the diagnostic.** The structural literature supplies the mechanism: bridging ties across a structural hole carry the information that within-cluster ties do not [Granovetter, 1973, Burt, 1992]. **Price:** Both terms move the wrong way at once, so the effect on the one-step condition `eta S > delta Q + C` compounds. **Fix: Do not push; build the more comfortable position next door.** Shared instrumentation, co-located cross-function work, rotation, boundary objects, the translator role. This is a safety property: a method working by removing resistance has no coercive failure mode, and its worst outcome is that someone declines to move. **Confusable with:** FM-04, FM-21. **Elsewhere:** the desire line and the launch budget [Curzi, 2026p].

FM-10 · The Amplifier Mistaken for a Source

Damages: `u`, overestimated; `N`, overestimated. **Clinical:** A hub with high throughput is read as a source of variety. It is redistributing, not generating. Preferential attachment reliably produces such hubs [Barabási and Albert, 1999], and the volume they carry is drawn from the same upstream sources the rest of the network already sees. The network double-counts. *No tail exponent is estimated here and none is claimed; the entry uses the mechanism and not the distribution, and the empirical generality of scale-free structure is contested* [Clauset et al., 2009, Broido and Clauset, 2019]. **Signature:** One node, feed, aggregator or senior figure appears in the provenance of most "independent" inputs. Removing that node removes most of the apparent variety. **Measurement:** A provenance audit. For each input the group treats as independent, trace to origin; compute the fraction whose paths share a common upstream node; recompute `u` with the duplicated inputs collapsed. **Price:** Whatever fraction of the roster reduces to a single upstream source collapses into one category by Identity 1. If eight of twelve inputs share an origin, the effective count falls from 12 to 5 before `u` is considered at all, and the ceiling falls from `ln 12 = 2.4849` to `ln 5 = 1.6094` — a **35.2 per cent** loss. **Fix:** Cut the hub out of the sampling path for at least one input stream. Note the structural corollary: networks of this kind are robust to random failure and **fragile to targeted attack on a hub** [Albert et al., 2000], so the amplifier is simultaneously the variety illusion and the single point of failure. **Confusable with:** FM-05, FM-15. **Elsewhere:** network resilience and the concentration instrument.

16.5.2 7.2 Class II — Conversion faults (`eta`)

The cheapest class to fix and the most often ignored, which is why conversion is the first move in almost every real system [Curzi, 2026b].

FM-11 · The Leaky Vessel

Damages: `eta -> 0`. Surplus is generated and none of it is stored. **Clinical:** Interaction happens at full strength and produces no durable structure. The conversation was real, the insight was real, and nothing outside the participants' memory changed. Because `S` is unaffected, every proxy for *activity* looks healthy while `Q` declines. **Signature:** "We had a great conversation" as a status report. Meetings with no artefact. A decision three attendees remember differently a month later. High engagement metrics against falling capability. The same problem re-solved annually by different people. **Measurement:** `eta = (attributable change in Q) / (input surplus)`. Concretely: over `k` periods, count the durable artefacts that (a) outlived the meeting, (b) are usable by a non-participant, and (c) trace to a specific interaction. Divide

by cumulative `S`. **Price:** With `S = 2.0`, `eta = 0.02` delivers `eta S = 0.040` per period; `eta = 0.35` delivers **0.700** — a factor of **17.5** with no change to headcount, geometry or effort. **Fix:** Install capture. In descending order of durability: the changed default; the built object; the trained person; the altered floor plan; the decision log; the written record. Ostrom's design principles for enduring common-pool institutions read, as engineering, as a list of conversion-raising devices [Ostrom, 1990, 2010]; *that reading is a transfer and is badged as one*, and the principles have since been audited meta-analytically [Cox et al., 2010]. **Confusable with:** FM-12, a Leaky Vessel that used to work; FM-19. **Elsewhere:** conversion as the first lever [Curzi, 2026b].

FM-12 · The Ritual That Became a Meeting

Damages: `eta`, by decay, under a preserved cadence. `C` unchanged or rising. **Clinical:** A recurring event was designed with a capture mechanism. The cadence survived; the capture did not. What remains is a periodic forcing function driving a filter with a broken input stage — full cost, no conversion. **This is the most common failure of *successful* practices**, because the cadence is what everyone can see and the capture is what nobody was assigned. **Signature:** A meeting nobody can cancel and nobody can justify. The original artefact — log, board, checklist — exists, is out of date, and is not referenced. **Measurement:** Pull the artefact. Check its last-modified date against the event's cadence. If the gap exceeds about three cadence-periods, conversion for that ritual is near zero. Confirm by asking three attendees to name the last decision the ritual produced. **Price:** The event's full `C` continues to be charged against `h` while its contribution to `eta S` approaches zero. In the ward diagnosis of Section 8.2, a handover with intact cadence and degraded capture runs at **46.04 per cent** of its own ceiling. **Fix:** Restore the capture step, or cancel the cadence. Do not keep the cadence for morale. **A ritual whose artefact is dead is a cost term with a good reputation. Confusable with:** FM-11, which never had capture; FM-19. **Elsewhere:** conversion mechanisms and the artefact ladder.

FM-13 · The Import With No Socket

Damages: `eta` for the imported category specifically; `u` raised nominally and never realised. **Clinical:** The organisation correctly diagnoses low `u`, correctly hires the outsider, and then provides no channel through which the outsider's difference can reach a decision. The new category exists on the roster and not in the causal path. **The gain is real in the survey and zero in the output. Signature:** A deliberate, well-justified hire from an unrelated lineage who has not changed any decision in two quarters. The outsider asked for input after the option set is closed. **Measurement:** A decision-provenance audit for the imported category: in the last ten consequential decisions, count those where the imported member's input entered *before* the option set closed. Zero or one is diagnostic. **Price:** The ceiling gain from `N = 4` to `N = 5` is **0.2231** nats. If the fifth category has no socket, the realised gain is 0.0000 nats and the salary is pure `C`. **Fix:** Build the socket before the import: a named decision gate the new category owns, a veto scoped narrowly enough to be usable, a standing agenda slot preceding option closure. **The sequencing rule of Section 4.10 applies — the socket is stabilisation and precedes growth. Confusable with:** FM-02, which is an import with no *difference*; this is a real difference with no *channel*. **Elsewhere:** capacity recruitment; Section 4.10.

FM-14 · The Sprayed Seed

Damages: `eta` for a diffusion intervention specifically. **Clinical:** A new practice is introduced by broad thin exposure — everyone hears once. Complex contagion requires *multiple reinforcing contacts* before adoption [Centola and Macy, 2007, Centola, 2010], so thin broadcast reaches everyone and converts nobody. **Clustered topology beats random long ties**, which

is the opposite of the reach intuition that produced the spraying. **Signature:** A launch with excellent awareness metrics and no adoption. Pilot sites chosen for geographic spread. "Everyone has been informed" as the implementation report. **Measurement:** Count *reinforcing* contacts, not contacts. For each non-adopter, how many of their frequent contacts have adopted? If the modal answer is one, the topology is wrong regardless of total exposure. **Price:** Adoption is threshold-driven and therefore discontinuous [Granovetter, 1978]; below threshold the return on exposure is near zero, which is why sprayed campaigns produce a flat curve rather than a slow one. **Fix:** Cluster first, do not spray. Saturate one dense neighbourhood well above local threshold and let the boundary do the work. Size the committed minority against the measured result: roughly **25 per cent** flipped an established convention in controlled online experiments [Centola et al., 2018] — for a 22-household block that is 6 households, for a 12-person group it is 3 people. **Badged: the 25 per cent figure is from controlled online experiments and field transfer is a modelling assumption**, and the general caution about transferring a single experimental result applies [Open Science Collaboration, 2015]. **Confusable with:** FM-11. **Elsewhere:** contagion, thresholds, and the critical boundary-cost multiplier.

FM-15 · The Founder Battery

Damages: `Q` stored in a person rather than in the system; `delta` becomes a step function. **Clinical:** One individual is the conversion mechanism, the archive and the maintenance regime. Measured `eta` is high and measured `delta` is low, and **both readings are attributes of a person, not of an institution. The parameters are correct right up until the day they are catastrophically wrong. Signature:** A named person in every consequential thread. Onboarding that consists of asking them. Nobody can state the escalation path without saying their name. **Measurement:** The absence test, run deliberately and at low stakes: the person takes two consecutive periods fully off-channel; measure `Q` before and after. The decline is the person-attributable share of `Q`. **This is the single most informative measurement a healthy organisation can afford to run** [Curzi, 2026i]. **Price:** A commons block that lost its founding steward saw commons-units fall from 47 to 38 over nine months of near-zero input: `delta = 0.0233` per month, half-life **29.35 months** [Curzi, 2026k]. The decay was gentle only because that block's stored order was physical; where `Q` is procedural, the same test typically returns a far larger number. **Fix:** Externalise before replacing. Stewards of record for every asset; **put the state in the medium, not in a coordinator. Confusable with:** FM-10, FM-19. **Elsewhere:** order without a centre; stigmergic media. ## 7.3 Class III — Retention faults (`delta` and `Q`)

FM-16 · The Sealed Vault

Damages: `delta -> 0` with `S = 0`. `Q` is perfectly preserved and never updated. **Clinical:** The system has excellent retention and no input. With `S = 0` and `C = 0` the trajectory is `Q_t = (1-delta)^t Q_0` — a decay so slow it reads as permanence. The vault is not failing; it is succeeding at the wrong thing. **A system with no forgetting cannot revise**, and the boundary case is worse than slow: at `delta = 0` exactly, the update map ceases to contract, no fixed point exists, and no mistake ever decays out of the stock [Curzi, 2026a]. **Signature:** Procedures whose rationale nobody can reconstruct. Reverence for the archive combined with no additions to it. Change proposals answered with precedent rather than argument. **Measurement:** Two readings. First, an input audit: over the last twelve periods, how many elements of `Q` were *added or amended*? Second, decay under zero input: if `delta` is low and additions are zero, the vault is sealed. **Price:** `delta = 0.01` gives a half-life of **68.97** periods and a time constant of 100; `delta = 0.005` gives a half-life of **138.28** periods. At those rates an obsolete rule outlives every person who might have questioned it. The half-life is `t_half = ln 2 / -ln(1-delta)`, and it is not `1/delta`: the naive rule of thumb is out by 72 per cent at `delta = 0.30` [Curzi, 2026]. **Fix:** Raise `delta` deliberately in the compartments where learning is wanted: sunset clauses, mandatory re-justification cycles, term limits, planned demolition. Keep `delta` low where durability is

wanted. **`delta` is not a single number for a whole institution; it is a field over its compartments, and treating it as one number is itself the fault.** **Confusable with:** FM-18, which is a refusal to shed *at cost*; the vault costs nothing and simply ossifies. **Elsewhere:** Curzi [2026a]; the half-life result [Curzi, 2026].

FM-17 · The Maintenance Trap

Damages: `h`, through the `delta Q` term. No parameter is individually abnormal. **Clinical:** `Q` has grown to the point where `delta Q` alone consumes the ceiling. From Identity 3, `h` is *decreasing in* `Q`. **Success consumes its own headroom.** This is the structural reason institutions ossify, and it is arithmetic rather than moral. **Signature:** An organisation that was building five years ago and is now entirely maintaining, with no decision anyone can point to that caused the change. Every new initiative crowded out by obligations to existing ones. **Measurement:** Compute the stall point `Q_stall = eta ln N / delta` at `C = 0` and compare to current `Q`. Within about 30 per cent of the stall point, the trap is already closing. **Price:** With `eta = 0.40` units per nat and `N = 12`, so `eta ln N = 0.9940`: at `delta = 0.02` the stall point is `Q = 49.70`; at `delta = 0.05` it is **19.88**; at `delta = 0.08`, **12.43**; at `delta = 0.12`, **8.28**. **A system with `delta = 0.12` cannot hold more than about eight units of order however well it interacts.** **Fix:** Four levers and only four: raise `eta`, raise `N`, cut `C`, or **accept lower `Q`**. The last is the one nobody considers, and shedding stored order to regain headroom is legitimate and underused — see FM-18 for the failure to make the move. **Confusable with:** FM-18, FM-20. **Elsewhere:** headroom and the four levers [Curzi, 2026b].

FM-18 · The Unshed `Q`

Damages: `Q` too high for the system's own `delta`; `h` negative as a consequence. **Clinical:** The organisation retains stored order it no longer uses, cannot maintain and will not retire. Every retained unit charges `delta` against headroom every period, forever. Unlike the Sealed Vault, the Unshed `Q` is *expensive*: the retained order actively consumes maintenance. **Signature:** An asset register nobody has pruned. Modules, documents, programmes or committees unused for a year that nobody will delete. The phrase "someone might still need it". **Measurement:** A usage audit with a hard window. For every element of `Q`, when was it last used by someone other than its owner? Sum `delta x Q_unused`. **That number is the annual rent on sentimentality, in the same units as the growth budget.** **Price:** In a research group worked elsewhere in this corpus, retiring 12 of 46 assets moved `delta Q` from `0.1120 x 46 = 5.154` to `0.075 x 34 = 2.550` assets per quarter — a **50.5 per cent** reduction in the maintenance charge, obtained by *removing* things. Shedding alone moved the one-step balance from **-3.387** to **-2.043** assets per quarter before any other lever was touched [Curzi, 2026k]. **Fix:** Sunset by default. Every element of `Q` carries an expiry and must be re-justified to survive it. Archive tiers marked explicitly unmaintained are honest and cheap; pretending to maintain is neither. **Confusable with:** FM-17 — the trap is the arithmetic, the Unshed `Q` is the refusal to act on it. **Elsewhere:** Section 4.4, Remedy 3.

FM-19 · The Invisible Infrastructure

Damages: `delta`, rising unobserved; then `Q`, discontinuously. **Clinical:** Infrastructure becomes visible only on breakdown [Star and Ruhleder, 1996]. The consequence for this law is structural: **maintenance is chronically underfunded because working infrastructure produces no observable signal**, so `delta` rises for years with no reading on any instrument, and the first reading is a failure. **Signature:** No maintenance line in the budget. No named owner for a system everyone depends on. A backup nobody has restored from. The question "who

maintains this?" producing a pause. **Measurement:** Invisible infrastructure cannot be measured by watching it; it must be *interrupted*. Scheduled, announced, low-stakes interruption: take the dependency off-line for one period and measure the drop in `Q`. **That number is the infrastructure's contribution and is the only honest basis for its budget. Price:** Undetected drift in `delta` is the most expensive error in the catalog because it compounds. A `delta` drifting from 0.05 to 0.15 moves the half-life of stored order from **13.51** periods to **4.27** — a threefold acceleration producing no symptom until the stock is already gone. **Fix:** Make the invisible visible on a schedule: interruption drills, maintenance dashboards that display *what did not break*, named stewards. Budget maintenance as a fixed fraction, not as a residual. The resilience-engineering literature makes the same argument about work-as-done against work-as-imagined [Hollnagel et al., 2006]. **Confusable with:** FM-15, FM-12. **Elsewhere:** decay measurement under a zero-input window [Curzi, 2026i].

FM-20 · The Negative Fixed Point

Damages: the model itself — `eta F(u*) < c*`, so `Q_inf = (eta F(u*) − c*)/delta < 0`. **Clinical:** CC-T4 gives the steady state. When conversion times realised surplus is below cost, the equilibrium is negative. **A negative fixed point means the regime is unsustainable or the linear model must be replaced — those are the only two readings, and the organisation is usually reporting a third: "transitional".** The theorem does not conceal this failure mode and neither may a diagnosis. **Signature:** A multi-year transition with no defined end state. Reserves drawn down on a schedule described as temporary. **Measurement:** Compute `Q_inf` explicitly at every survey. It is one division. If it is negative, or below current `Q` by a wide margin, the trajectory is heading there and the arrival date is computable from `tau = 1/delta`. **Price:** In an open-source case worked elsewhere in this corpus the measured pre-intervention fixed point was `Q_inf = 20.39` modules against a current `Q` of 63 — **the project was not stable, it was 43 modules above its own equilibrium and descending at -2.47 modules per month, with a computed zero-crossing at 25.5 months** [Curzi, 2026k]. **Fix:** Change a parameter or change the model. Both are legitimate; continuing to report the current regime as steady is not. If cost cannot fall below `eta F(u*)`, the system must shrink to a scale where it can, and shrinking on purpose is cheaper than shrinking by collapse. The deficit identity `D = 2.885390(c/eta − F) = −2.885390(delta/eta)Q_inf`, cross-checked to a residual of `8.88e−16` on its carried case, states the same shortfall in the corpus's frequency register [Curzi, 2026]. **Confusable with:** FM-17, FM-23. **Elsewhere:** the steady state and its breakdown [Curzi, 2026a].

16.5.3 7.4 Class IV — Dissipation faults (C)

FM-21 · The Quadratic Committee

Damages: `C`, with the number of pairs, against a logarithmically growing ceiling. **Clinical:** Communication paths grow as `n(n−1)/2` [Brooks, 1975] while the surplus ceiling grows as `ln N`. **Cost grows quadratically while surplus grows logarithmically**, so for any fixed per-channel cost there is a group size beyond which the group is strictly worse than a smaller one. Adding people to a late project makes it later. **Signature:** Meetings requiring pre-meetings. Decisions requiring more sign-offs than arguments. A group that has grown and whose output has not. **Measurement:** Tally `C` directly in hours or in proxy units per period, then compute the crossover: for per-channel cost `c0`, find the `n` at which `c0 x n(n−1)/2` exceeds `eta ln n`. **Price:** Channels per nat of ceiling: `n = 5` gives 10 channels, **6.21** per nat; `n = 12` gives 66, **26.56**; `n = 20` gives 190, **63.42**; `n = 30` gives 435, **127.90**; `n = 150` gives 11,175, **2,230.26**. With `eta = 1.0` and a per-channel cost of 0.01, headroom peaks near `n = 10` at `h = +1.853`, is still positive at `n = 20` at

`h = +1.096`, and **crosses zero at `n = 27`. Fix:** Nest, do not enlarge. A semilattice of overlapping clusters beats both the flat group and the strict tree, because overlap preserves cross-contact while cutting channels [Alexander, 1965]. A commons case worked elsewhere in this corpus cuts 231 channels to **55.5** — **24.03 per cent** — with four overlapping clusters of 5.5 households plus a delegate layer [Curzi, 2026k]. The same structural argument appears in governance as polycentricity [Ostrom, 2010]. **Confusable with:** FM-22, which is about *load* rather than *size*; FM-07. **Elsewhere:** the crossover and the optimum group size [Curzi, 2026b].

FM-22 · The Utilisation Cliff

Damages: `C`, non-linearly, as utilisation approaches one. **Clinical:** For a single-server queue with exponential arrivals and service, expected wait scales as `1/(1−rho_u)` [Kingman, 1962, Hopp and Spearman, 2011]. Near full utilisation the derivative explodes, so the last few per cent of capacity are bought at enormous and accelerating cost in delay. **Slack is not waste; it is a cost-control device**, and removing it is the most common way an efficiency programme destroys an institution [Cyert and March, 1963]. *The queueing premises are not measured in the worked cases; the transfer is badged as a modelling assumption.* **Signature:** Everything is scheduled and everything is late. Efficiency metrics at record highs alongside collapsing responsiveness. Nobody has unallocated time and nothing gets done. **Measurement:** Compute the utilisation `rho_u` for the binding resource — written `rho_u` here because the catalog already uses `rho` for the alignment correlation of FM-01, a collision in the source material: arrival rate over service rate. For people, `rho_u` is the fraction of available hours already committed; anything above about 0.85 sustained is in cliff territory. Little's Law, `L = lambda W`, closes the loop and lets a queue length reading be checked against a wait reading [Little, 1961]. **Price:** Wait as a multiple of service time: `rho_u = 0.50` gives **2.0x**; 0.80 gives **5.0x**; 0.90, **10.0x**; 0.95, **20.0x**; 0.98, **50.0x**. Moving a team from 80 to 95 per cent booked multiplies waiting by **4.0x**, and from 80 to 98 per cent by **10.0x**. Queue length rises from 4.0 to 19.0 to 49.0 over the same range. **Fix:** Design to a target `rho_u`, typically 0.70 to 0.85 for work with variable service times. Protect slack explicitly and name it, so it cannot be reallocated by an efficiency review. **Reduce variability before raising utilisation — variability, not utilisation, is what makes the cliff steep. Confusable with:** FM-21. **Elsewhere:** stock, flow and the cost of waiting.

FM-23 · The Unbooked Cost

Damages: `C`, underestimated; `h`, overestimated; every downstream decision, poisoned. **Clinical:** The cost ledger records the costs that have invoices. Commute, emotional labour, context-switching, compliance, waiting, and the repair of relationships damaged by the last decision all dissipate stored order and appear on no line. **A survey omitting them computes a headroom that does not exist and then spends it. Signature:** Repeated overruns with no identifiable cause. People visibly exhausted by a workload the ledger describes as moderate. **Measurement:** Time-and-motion on the *whole* period, not on the tasks: everything not converting surplus into stored order is `C`. **The cost observable is defined as a residual for exactly this reason** — measure total capacity, measure productive capacity, take the difference, rather than enumerating cost items and hoping the list is complete [Curzi, 2026i]. **Price:** In a research group worked elsewhere in this corpus, coordination ran at **17.4 per cent** of 6,240 person-hours per quarter — 1,087 hours — which at the measured yield rate of 0.00147936 assets per person-hour priced `C` at **1.608** assets per quarter against a ceiling `eta ln N = 8.105`. **Omitting it would have overstated `h` by 120 per cent of its true value of 1.343** [Curzi, 2026k]. **Fix:** Book `C` as a residual, not as a list. Then validate: the survey's predicted one-step change must reproduce the observed one. Four cases reproduce observed decline to within 0.12 units [Curzi, 2026k], and that agreement is what indicates the cost ledger is complete. **Confusable with:** FM-29 — both are survey faults; this one under-reports `C`, that one mis-specifies `Q`. **Elsewhere:** the cost observable and the denomination rule [Curzi, 2026i].

FM-24 · The Abrupt Threshold

Damages: C, at every zone boundary; secondarily u, by suppressing crossing. **Clinical:** Two zones of different character meet with no transition, so every crossing costs a full reorientation — acoustic, social, visual, procedural. The threshold is a device in its own right, an impedance match between zones [Alexander et al., 1977], and its absence is a tax collected on every crossing, forever. **Signature:** A door people hesitate at. An open-plan floor where nobody uses the collaboration zone because entering it is a public act. **Measurement:** Count crossings per hour against the crossings the function requires, by direct observation [Whyte, 1980]. **Desire lines are the measured gradient; where the desire line does not match the designed line, the threshold is wrong** [Jacobs, 1961]. Personal distance and its zones are the underlying regularity [Hall, 1966]. **Price:** Context-switching is a cost term and it compounds with FM-22: at `rho_u = 0.90` each additional interruption costs **10x** its own service time in downstream delay. **Fix:** Build the transition — porch, vestibule, airlock, buffer zone, staged announcement. In organisations the equivalent is the staged decision: a proposal with a public-but-uncommitted phase. Depth, a sightline into the next zone, and a place to pause are the three specifications. **Confusable with:** FM-26 — both make crossing costly; one is geometric, one is acoustic. **Elsewhere:** thresholds and transitions in the built environment.

16.5.4 7.5 Class V — Room and instrument faults

Separated because their fixes are capital purchases with known lead times, and because they are among the cheapest interventions available per unit of effect.

FM-25 · The Head of Table

Damages: u, structurally and continuously. **Clinical:** A table with a head assigns a direction to the group. Everyone below it has a function, and that function is agreement. **Agreement between aligned instruments is echo, not evidence.** The geometry does this without anyone enforcing it, which is precisely why it is durable: **furniture governs continuously and costs nothing to administer. Signature:** Speaking order tracks seating order. Turn-taking Gini high. Contributions addressed to one seat rather than to the room. Sightlines that do not close. **Measurement:** Two instruments. (1) Turn-taking equality: record speaking time per participant for three meetings and compute the Gini coefficient — collective intelligence correlates with *equality* of conversational turn-taking [Woolley et al., 2010]. (2) Sightline reciprocity: for all pairs, can each see the other's face without moving? Report the failing fraction. **Price:** FM-01 prices the result. At `N = 12`, driving u from 0.30 to 0.05 by geometry alone moves S from **1.4586** to **0.4383** — a **70.0 per cent** loss of realised surplus, purchased with a table shape. **Fix:** Round or polygonal geometry with full sightline reciprocity. Size the table by channel count [Brooks, 1975] and by acoustics jointly. Add protocol: written positions first, round-robin, and the most junior speaking first on matters of rank. **Confusable with:** FM-01, FM-26. **The test: if the fault persists when the group meets elsewhere, it is not the table. Elsewhere:** table geometry and turn-taking equality.

FM-26 · The Reverberant Room

Damages: u, by suppressing the quiet voice; C, through the raised vocal effort a rising noise floor compels. **Clinical:** In a room with long reverberation, speech from previous syllables masks the current one. Signal-to-noise for the quiet speaker falls below intelligibility

while the loud speaker remains intelligible. **The loudest speaker wins a reverberant room by physics, not by dominance** — and the compensating rise in everyone's level raises the noise floor, which raises everyone's level again. *The acoustics is a derivation; the step from reverberation time to non-parallelism is a modelling assumption* (Section 3.8). **Signature:** People leaning in. Repetition requests. Quiet participants who are articulate elsewhere. Meetings that exhaust people disproportionately to their content. **Measurement:** Sabine's relation, `RT60 = 0.161 V / A` in metric units, where `V` is volume in cubic metres and `A` is total absorption in square-metre sabins, `A = sum(S_i x alpha_i)` plus occupants at roughly 0.45 each at 500 Hz [Sabine, 1922, Schroeder, 1965]. Measure or compute both, occupied and empty, and add a background noise reading. **Price:** A 16.0 by 9.5 by 4.2 metre reading room, `V = 638.40` cubic metres, with hard finishes has `A = 40.750` and `RT60 = 2.5223` seconds occupied, **3.1480 seconds** empty. Treated — 90 square metres of ceiling absorber at `alpha = 0.90`, 40 of wall panel at 0.85, 100 of heavy carpet at 0.25 — `A` rises to **173.150** and `RT60` falls to **0.5936 seconds**, a **4.25x** reduction. Ceiling treatment alone gives 0.8699 seconds; ceiling plus walls gives 0.6845. **Fix:** Absorption, in order of cost-effectiveness: ceiling first, as the largest uninterrupted surface and the first reflection path; then the wall opposite the primary talker; then the floor. The turn-taking consequence is arithmetic in the tail: the gap for a previous talker to fall 15 dB is `t_15 = RT60/4`, giving 488 ms before treatment and 98 ms after [Curzi, 2026e]. **Acoustic treatment is the cheapest room-scale intervention available. Confusable with:** FM-25, FM-01. **Acoustic faults vanish when the same group meets in a different room; that is the discriminating test. Elsewhere:** passive geometry and the reverberant tail [Curzi, 2026e].

FM-27 · The Single Setpoint

Damages: `u`, by narrowing who can occupy the space; `C`, through avoidance. **Clinical:** The environment is optimised to one value — one temperature, one illuminance, one noise floor, one furniture height — chosen as the population mean. Individual tolerance varies widely across the six thermal variables and across light sensitivity, so **an optimised setpoint is correct for the mean occupant and wrong for most actual occupants. Adjustability outperforms optimisation because it raises the range of people who can be present at all**, and presence is prior to every other parameter. **Signature:** Personal heaters and fans in a climate-controlled building. Blinds permanently down. Complaints in both directions about the same setting. **Measurement:** Occupancy mapping by seat over two weeks, applying the direct-observation method indoors [Whyte, 1980]. Persistently unoccupied positions in an otherwise-used room are an environmental reading, not a furniture preference. Cross-check with a two-sided complaint tally. **Price:** Any occupant excluded is a category removed from `N`, or a member removed from a category, priced by Identity 1. Excluding one of five staffed categories moves the ceiling from `ln 5 = 1.6094` to `ln 4 = 1.3863`, a **13.9 per cent** loss — for a thermostat. **Fix:** Provide gradient and control rather than a single value: a range of thermal zones, task lighting alongside ambient, seating variety, sun and shade both available. **A well-known 1984 study reporting faster post-surgical recovery with a window view of trees is often cited here; this corpus's bibliography contains no entry for it, so it is named without a citation and is not relied on.** The argument it is usually used to make — provide the good condition rather than average it away — stands on the arithmetic above without it. **Confusable with:** FM-24. **Elsewhere:** environmental range against environmental optimisation.

16.5.5 7.6 Class VI — Method faults (the analyst's own)

These damage nothing in the system and everything in the knowledge of it. **Listed last; checked first, because a method fault invalidates every other reading.**

FM-28 · Goodhart Capture

Damages: the measurement, and then `Q`, once the measurement drives behaviour. **Clinical:** A measure that becomes a target ceases to be a measure [Goodhart, 1975, Campbell, 1979]. Once the proxy for stored order is rewarded, effort flows to the proxy rather than to `Q`, and the correlation that justified the proxy is destroyed by the act of using it. **The same reflexivity the framework asserts about the systems it models applies to its own instrument** [Lucas, 1976]. **Signature:** A metric improving faster than any plausible underlying change. Improvement concentrated exactly at the measurement boundary. Practitioners who can explain how the number is produced but not what it means. **Measurement:** Hold out a second, unrewarded proxy for the same `Q` and track both. Divergence between rewarded and unrewarded proxies is the capture signal. Rotate the unrewarded proxy periodically so it does not become rewarded by attention. **Price: Not directly computable in nats.** The damage is that the `h` estimate is now fiction, so every subsequent number in this catalog is fiction. **Fix:** Never reward the proxy used for measurement. Keep an audit proxy that is unpublished, unincentivised and rotated. Prefer proxies expensive to fake and cheap to verify: physical state, third-party usability, independent re-execution. **Confusable with:** FM-29. **Elsewhere:** Section 4.16; the reporting-line defence [Curzi, 2026i].

FM-29 · The Order Proxy That Was Really the Input

Damages: the entire estimation. The fitted model is a tautology. **Clinical: This is the most common measurement error in the framework** [Curzi, 2026i]. If the chosen order observable is a repackaging of the interaction observable, then `Y_{t+1} = a Y_t + b F(U_t) − C + e` fits beautifully and says nothing: interaction has been measured twice and the correlation called a law. **Signature:** A proxy defined in terms of meetings, messages, commits, attendance or engagement. Extremely good fit on the first attempt. The proxy falling to zero the instant interaction pauses. **Measurement:** The lag test. **Genuine stored order *persists* when input stops — that is what "stored" means, and it is why `delta` is measurable at all.** Pause input for one to three periods and watch the proxy. If it tracks the pause with no lag, it is the interaction observable. If it decays with a measurable time constant, it is stored order, and `delta` has been measured as a bonus. **Price:** Every parameter downstream is unidentified. **There is no partial credit. Fix:** Choose the proxy as a *state of the world outside the interaction*: modules passing tests on the current toolchain; assets a non-author can independently re-run; patrons who return without being invited; shared capabilities usable without asking anyone. The test is applied explicitly to four cases elsewhere in this corpus and rejects the naive proxy in each [Curzi, 2026k]. **Confusable with:** FM-28. **Elsewhere:** the four repackaging tests [Curzi, 2026i].

FM-30 · The Unbadged Postulate

Damages: the warrant. Nothing in the system; everything in the standing of the claims. **Clinical:** A modelling choice, an analogy, or a transfer from a laboratory result is presented with the same confidence as a theorem. **An unbadged postulate is not a lie; it is an unpriced liability, and it comes due when someone competent checks.** The programme-level description of what a badged postulate is doing — a protective belt around a hard core, adjusted deliberately and in the open — is Lakatos [1970]. **Signature:** No distinction in the prose between "the theorem gives" and "we assume". A controlled online experiment cited as a field constant. A design axiom invoked as though derived. **Measurement:** Read the document with two highlighter colours: proven, and assumed. **If the assumed colour does not appear, the reader has not found it; they have failed to look. Price:** Nothing quantitative. **A single discovered unbadged claim discredits the badged ones, which is a very poor trade for the confidence gained. Fix:** Badge in the same sentence. "The affine effective count is a design axiom — chosen, not derived." "The 25 per cent figure is from controlled online experiments; field transfer is a modelling assumption." "That this institution is described by a single scalar `Q` is a postulate."

The three-drawer classification — established mathematics, established psychology, declared postulates, with every protocol stated to run on the first two and steer by the third — is the standing instrument [Curzi, 2026]. **Confusable with:** FM-31. **Elsewhere:** Section 3.6; Curzi [2026].

FM-31 · The Borrowed Ceiling

Damages: the plan. It requests `r_t > h_t`, which CC-T1 forbids. **Clinical:** The design assumes synergy beyond additivity — that combining two sources of difference yields more than their sum, or that a good enough team escapes its own headroom. The decomposition gives an upper bound of exactly the sum: `f(u) <= f(u_cross) + f(u_div)`. **No synergy beyond additivity is promised, and honest design does not assume one.** Separately, the triangle inequality fails for geometric triples [Curzi, 2026], so three-party reasoning cannot be chained metrically at all. **Signature:** A target exceeding `r_max`. A plan justified by two things multiplying. Growth projections with no headroom calculation anywhere in the document. **Measurement:** Compute `h_t` and compare to the requested `r_t`. CC-T2: the increment is feasible only if `delta Q_t + C_t + r_t <= eta ln N`. **This is one line of arithmetic and it is not optional. Price:** At `N = 8` with `u_cross = 0.30` and `u_div = 0.25`, the honest bound is `1.1314 <= 1.5790 <= 2.1430`. A plan assuming multiplication rather than the bound over-promises by up to **36 per cent** relative to the true value even inside the permitted range. **Fix:** Plan to the bound. State `r_t <= h_t` as a hard constraint in the proposal document and put the computed `h` next to the requested `r` on the same page. **Confusable with:** FM-07, FM-30. **Elsewhere:** Sections 4.6 and 4.7.

FM-32 · The Consent Bypass

Damages: nothing in the law. **It is a refusal, not a parameter. Clinical:** An intervention raises a parameter by removing someone's ability to decline — mandatory disclosure of dissent, forced rotation, attendance that cannot be refused, "voluntary" participation with recorded non-participation. **This is outside the procedure entirely** (P-E, Section 3.6), and the reason is engineering as much as ethical: **coerced non-parallelism is not non-parallelism.** A person compelled to voice a difference voices the difference the compeller expects, which returns the system to FM-01 by a longer road. The classification of people by a measure that then acts on them is a documented mechanism, not a speculation [Hacking, 1995]. **Signature:** A protocol with no opt-out. Non-participation that is visible and therefore costly. Consent obtained from a group rather than from each person. A benefit argued at the level of the collective whose cost falls on identifiable individuals. **Measurement:** For every protocol in the intervention design, one written question: *what happens to a person who declines?* If the answer includes any adverse consequence, the protocol is out of scope. **Price: Not applicable. This is a boundary, not a trade-off, and it is not priced because it is not for sale. Fix:** Redesign so the intervention works by removing resistance rather than by applying force — build the more comfortable position next door, and the worst case is that someone declines to move. **Confusable with:** nothing. **If it is unclear whether an intervention is a Consent Bypass, it is. Elsewhere:** Section 4.12.

16.5.6 7.7 Faults of diagnosis itself

Seven faults attach to the diagnostic act rather than to the system. **They are labelled DF-1 to DF-7 here; the source labels them D-1 to D-7.**

DF-1 · Naming before measuring. The catalog's names are vivid, and vividness produces premature confidence. A named fault with no measurement behind it is a story. *Signature:*

the diagnosis arrived within ten minutes of arriving on site. *Fix:* the survey is an entry condition, not an alternative (Appendix C, CS-3).

DF-2 · The single-fault reflex. Looking for *the* problem. Systems fail in clusters, and fixing one member of a cluster while leaving the others returns the system to its previous state within a few time constants. *Fix:* require at least three named faults, or an explicit written statement of why fewer suffice.

DF-3 · Fixing the loudest fault. The most visible fault is rarely the binding one. In a library case worked elsewhere in this corpus the loud fault was conflict between patrons; the binding constraint was non-parallelism, and the instrument was ceiling absorption [Curzi, 2026k]. *Fix:* rank by computed effect on the one-step condition, not by salience.

DF-4 · The one-instance check. Verifying a fix at one site, one meeting, one week, and generalising. **A single successful instance is consistent with almost every hypothesis.** *Fix:* prespecify the number of instances and the checkpoints before running the pilot [Nosek et al., 2018].

DF-5 · Treating `delta` as a scalar for the whole system. Decay is a field over compartments. Documentation, relationships, physical plant, skills and norms decay at wildly different rates, and an average is a number describing none of them. *Fix:* estimate `delta` per compartment and report the vector.

DF-6 · Diagnosing outside the model's range. The linear storage law has no saturation term. When a predicted `Q_inf` exceeds a hard physical or organisational cap, the model is being used outside its range and must be replaced there. *Fix:* **always state the cap alongside the fixed point, and say which one binds.** Section 8.2 does exactly this, with a predicted fixed point of 71.46 against a 34-bed census.

DF-7 · Mistaking the survey for the intervention. Measurement changes behaviour, usually temporarily and favourably; a survey period showing improvement has told the analyst about the survey. *Fix:* the shuffled-input control and a matched comparison — noting that the Hawthorne pattern is invoked far more casually than the evidence supports [McCambridge et al., 2014], so its name is not an explanation. # 8 Results: two systems worked end to end

Both systems are constructed. The first is a declared composite whose audit series is a simulation with declared generating parameters; the second is a constructed clinical case. **The arithmetic in both is real, computed and reproducible; the organisations are not.** Neither may be cited as evidence about any real review office or any real hospital ward. What the two cases demonstrate is that the procedure runs, that it reports its own refusals, and that it reports its own departures from the model's valid range.

16.5.7 8.1 A development review office: a refusal, and the repair that made the request fundable

The system is a county development review office carried forward from the survey and preregistration protocol [Curzi, 2026i]. Five review disciplines, a standing rules manual as the order proxy, a weekly period.

8.1.1 Gate 0 — admissibility

Check	Result
Survey complete	Yes
Repackaging tests, all four	All PASS
Preregistration frozen and evaluated	Yes
FR1, admissible parameter box	PASS
FR2, baseline dominance	**FAIL** — matched AR(1) beaten by 2.8 per cent against a required 10 per cent

Check	Result
FR3, independent-parameter agreement	PASS

Evidence status: accounting frame only. `h` may be used as a budget constraint and a preregistered, capped, reversible pilot is permitted. **No claim may be made that the model predicts the pilot's outcome** (Sections 4.2 and 4.13). This is the status established in Curzi [2026i], whose confirmatory fit failed its own second falsification rule, and it governs every statement in this subsection.

8.1.2 Gate 1 — the gauge as surveyed

```
eta   = 0.5015       ln N = 1.6094       eta ln N = 0.8071
delta = 0.003090     Q    = 113          delta Q  = 0.3492
                                         C        = 0.6300
------------------------------------------------------------------
h = 0.8071 - 0.3492 - 0.6300 = -0.1720            REGIME: h < 0

mean of F over the period record = 1.1498 nats
step = 0.5015 x 1.1498 - 0.3492 - 0.6300 = -0.4025 rules/week
realisation deficit = h - step = 0.2305 rules/week
capacity u = 0.6972          mean realised U = 0.6019
```

A notational warning, stated here because the source material does not. The surplus figure used in the step is **the mean of `F` over the period record**, 1.1498 nats. It is **not** `F` evaluated at the mean realised `U`, which is `F(0.6019) = ln(1 + 4 x 0.6019) = 1.2260` nats. The two differ by 0.0762 nats and **only the first is the quantity that accumulates.** The source writes the first as "realised `F(U)`", a notation that reads as the second; Section 9.4 records that as a defect. Every occurrence of 1.1498 in this paper is a mean of `F`; every occurrence of 1.2260 or 1.2262 is an `F` of a mean, and the two are never interchanged.

8.1.3 The brief, and the refusal

The office director's brief was to rebuild the standing review manual at roughly thirty rules a year — that is, `r = 0.55` rules per week.

```
r = 0.55     h = -0.1720     r <= h ?   NO
```

Refused, in writing, with the number. The written refusal is reproduced because its form matters as much as its content:

> At present parameters the office has headroom of `-0.17` rules per week. This is the best case: it assumes a perfectly non-parallel board every week. It means that dissipation, at 0.63 rules per week, exceeds what conversion can deliver at the ceiling net of maintenance, which is 0.46. No arrangement of who sits on the board, in what order they speak, or how vigorously they disagree can prevent the manual from declining. The requested increment of 0.55 is not merely unfunded; the account is overdrawn by 0.17 before any increment is requested. The manual is losing 0.40 rules per week — about 21 a year — and the fitted steady state is negative, which the model reports as an unsustainable regime rather than as a small number. What follows is what it would take to make the request fundable.

That paragraph is the deliverable. Not the intervention — the refusal, with the arithmetic that makes it a fact rather than an opinion.

8.1.4 Phase 1 — stop the leak

Raise `eta`: 0.5015 to 1.05 rules per nat. The office has no capture discipline: rules reach the manual when a reviewer remembers to draft one, at a median of five weeks, and the attribution audit found 10 of 26 new rules with no documented board origin. The intervention is three administrative changes — a designated scribe at every board session, a one-page rule template completed in the session, and a ten-working-day publication requirement with a named owner per rule. **`eta` starts near the floor, which is exactly the condition under which a large multiple is available**, and it is why this lever ranks first. The office's own natural experiment supports the magnitude: in the two years before the previous code administrator retired, when a scribe role informally existed, attributable conversion ran at roughly twice the current rate.

```
headroom gain = (1.05 − 0.5015) x 1.6094 = +0.8828 rules/week
cost = 0.4 FTE, redeployed from an existing analyst post
```

Cut `c`: 0.63 to 0.42 rules per week.

line	before	after	how
Appeal reversals striking a live rule	0.14	0.14	unchanged; structural
Rules orphaned by departure	0.11	0.07	deputise a second qualified applier per rule at adoption
Rework: items re-reviewed after disposition	0.16	0.05	close the re-review loop; disposition final absent new information
Contradiction maintenance	0.09	0.09	unchanged
Attention tax	0.13	0.07	publish the decision summary once, to one place, instead of five partial circulations
total	**0.63**	**0.42**	

```
headroom gain = 0.63 − 0.42 = +0.2100 rules/week
cost = one policy decision and three weeks of process work; no recurring cost
```

The rework line is cut and the appeal line is not. The appeal process is where the environmental discipline's objections are realised; cutting it would cut `C` and cut `F(U)` at once. That is the second caution of Section 4.9, and it is explicitly declined here.

8.1.5 Phase 2 — correct the order observable

Six rules removed by the liveness audit and two by the applier audit, bringing the register count of 121 to `Q = 113`. **This changed the number and not the world** and is recorded as a correction, not a shed (Appendix A, IS-15).

8.1.6 Phase 3 — the shed, computed and declined

```
proposed shed  q = 14 further rules, judged low-value but still live
headroom gain    = delta x q = 0.003090 x 14 = +0.0433 rules/week
```

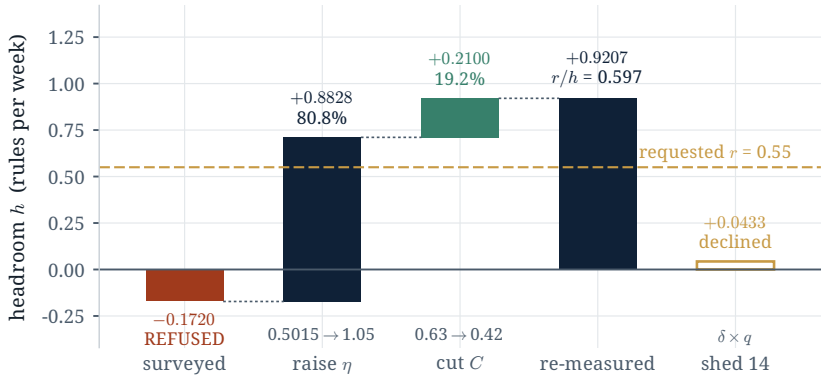

Figure 16.2: **The refusal and the repair, in one subtraction each.** Headroom moves from `−0.1720` to `+0.9207` rules per week under two administrative levers: raising conversion from 0.5015 to 1.05 rules per nat supplies `+0.8828` (80.8 per cent of the swing) and cutting dissipation from 0.63 to 0.42 supplies `+0.2100` (19.2 per cent). The shed of fourteen rules was computed at `delta x q = +0.0433` and declined; it is shown outside the running total. The requested increment of 0.55 rules per week is refused against the opening headroom and admitted against the closing headroom at a reserve ratio of 0.597. Modelled from the parameters of Sections 8.1.2 to 8.1.7; generated by `figs/src/CCP-016_fig01.py`.

Against the conversion lever's `+0.8828`, the shed returns **one twentieth** as much, and it is not free: fourteen rules are fourteen pieces of somebody's work, and their removal costs trust that does not appear in the arithmetic. **Declined on the arithmetic.**

For contrast, and because this is the finding that generalises: in a system with `delta = 0.05` per period the same fourteen-unit shed would return `0.05 x 14 = 0.70` — **a factor of sixteen more**, and comfortably competitive with the conversion lever. **Shedding is decisive in fast-decaying systems and nearly worthless in durable ones, and the multiplication that distinguishes them takes five seconds.** The two ratios in this paragraph are different comparisons and are not to be conflated: twenty is the shed against the conversion lever *in this system*; sixteen is the same shed *at two different decay rates*.

8.1.7 Phase 5 — re-measure

```
eta   = 1.05          eta ln N = 1.05 x 1.6094 = 1.6899
delta = 0.003090      Q = 113   delta Q        = 0.3492
                                C              = 0.4200
------------------------------------------------------------------
h = 1.6899 − 0.3492 − 0.4200 = +0.9207            REGIME: h > 0
```

The sign changed without adding a person, a category, or any capital expenditure. Two administrative levers, applied in the order the ranking prescribes, moved headroom by 1.093 rules per week — from `−0.172` to `+0.921`.

lever	gain in `h`	share of the swing
raise `eta`, 0.5015 to 1.05	+0.8828	80.8 per cent
cut `C`, 0.63 to 0.42	+0.2100	19.2 per cent
shed 14 rules (declined)	+0.0433	—

8.1.8 Gate 2 — feasibility of the requested increment

```
r = 0.55   <=   h = 0.9207                    [ inside the budget ]
reserve:   r/h = 0.597                        [ inside the recommended 0.7 ]

S_req = (delta Q + C + r)/eta = (0.3492 + 0.4200 + 0.5500)/1.05
      = 1.3192 / 1.05 = 1.2564 nats

S_req = 1.2564  <=  ln N = 1.6094             ->  NO Failure A

U_req = (exp(1.2564) - 1)/4 = 0.6281

U_req = 0.6281  <=  capacity u = 0.6972       ->  NO Failure B
U_req = 0.6281  >   mean realised U = 0.6019  ->  REALISATION WORK REQUIRED
```

The concavity correction, applied. `U_req = 0.6281` is the geometry a board would need if it ran at the same `U` every week. It does not. The office's sessions are a mixture: full-board sessions at a mean `U` of 0.7940 and reduced sessions at a mean `U` of 0.2071. What accumulates over many periods is the sum of `eta F(U_t)`, so the operative quantity is the **mean of `F`**, and because `F` is strictly concave (CC-T6), Jensen's inequality gives `mean F(U_t) <= F(mean U_t)` with equality only if `U` is constant.

For the office as surveyed the penalty is 0.0761 nats: a mean of `F` of 1.1501 against an `F` of the mean `U` of 1.2262, a loss of 6.2 per cent of the surplus purely to variability. (The mixture reconstruction returns 1.1501 and 0.6021 where the direct period record returns 1.1498 and 0.6019; the two agree to within rounding, which is the consistency check that licenses using the mixture to project. `F` of the *directly measured* mean `U` is `F(0.6019) = 1.2260`.)

So the requirement is stated on the mean of `F` and not on the mean of `U`:

```
required:              mean F(U_t) >= S_req = 1.2564 nats
achieved as surveyed:  mean F              = 1.1498 nats   -> SHORT by 0.1066 nats
```

The increment is inside the budget and inside the office's geometric capacity, and it is **not** inside what the board currently realises. At the surveyed geometry,

```
step = 1.05 x 1.1498 - 0.3492 - 0.4200 = 1.2073 - 0.7692 = +0.4381 rules/week
```

which is positive — a swing of 0.841 from the surveyed `-0.4025` — and short of the promised 0.55.

8.1.9 Phase 4 — realise

The cause was identified in the survey: **32.7 per cent of board sessions ran with fewer than the full set of disciplines recording a disposition**, and those sessions have a mean `U` of 0.2071 against 0.7940 for full sessions. The lever is a scheduling and protocol change: any item touching more than one discipline requires a recorded disposition from every discipline, obtained asynchronously and in writing if a lead cannot attend — **which also breaks the cascade, because dispositions are recorded before discussion** (FM-03).

low-participation share	mean `U`	mean `F`	`F(mean U)`	concavity penalty	step (rules/week)	`r = 0.55` met?
0.400	0.5593	1.0888	1.1747	0.0859	0.3740	no
0.327 (as surveyed)	0.6021	1.1501	1.2262	0.0761	0.4385	no
0.300	0.6179	1.1728	1.2447	0.0718	0.4623	no
0.250	0.6473	1.2149	1.2779	0.0631	0.5064	no

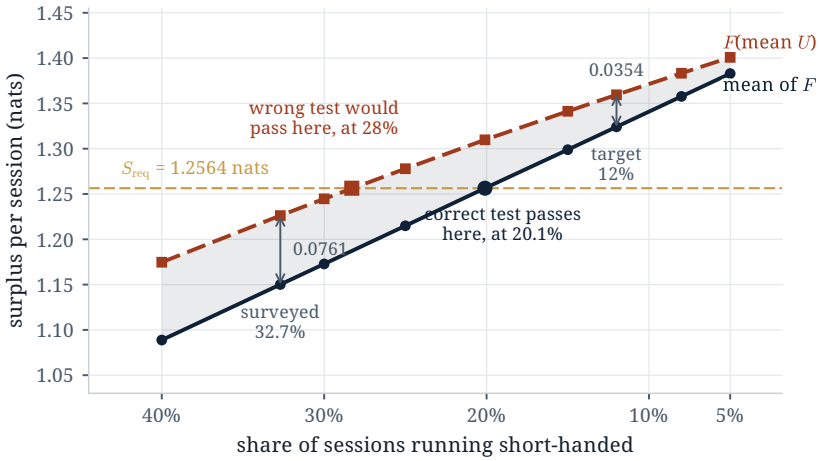

Figure 16.3: **The two curves that must never be interchanged.** The mean of `F` over the session record — the quantity that accumulates — sits strictly below `F` evaluated at the mean `U` at every low-participation share, and the gap is the concavity penalty. At the surveyed share of 32.7 per cent the mean of `F` is 1.1501 nats against an `F` of the mean of 1.2262, a penalty of 0.0761 nats or 6.2 per cent of the surplus; at the 12 per cent target the penalty falls to 0.0354. **A feasibility test run against the upper curve passes at a share of about 28 per cent; run against the correct lower curve it passes only below 20.1 per cent.** Modelled from the mixture of full-board sessions at mean `U` 0.7940 and reduced sessions at mean `U` 0.2071, tabulated in Section 8.1.9; generated by `figs/src/CCP-016_fig02.py`.

low-participation share	mean `U`	mean `F`	`F(mean U)`	concavity penalty	step (rules/week)	`r = 0.55` met?
0.201 (break-even)	0.6763	1.2564	1.3098	0.0534	0.5500	exactly
0.200	0.6766	1.2569	1.3101	0.0532	0.5505	yes
0.150	0.7060	1.2989	1.3413	0.0424	0.5947	yes
0.120 (target)	**0.7236**	**1.3241**	**1.3595**	**0.0354**	**0.6211**	**yes**
0.080	0.7470	1.3577	1.3833	0.0256	0.6565	yes
0.050	0.7647	1.3829	1.4008	0.0179	0.6829	yes

Read the concavity-penalty column down the table. Regularising the geometry pays twice: once by raising the mean, and once by shrinking the penalty the variability was charging. At the surveyed share the office loses 0.0761 nats to variability alone; at the target it loses 0.0354. **That second gain — 0.0407 nats, worth `1.05 x 0.0407 = 0.0427` rules per week — is invisible to anyone reasoning about the average board rather than about the distribution of boards.**

```
step at target = 1.05 x 1.3241 − 0.3492 − 0.4200 = 1.3903 − 0.7692 = +0.6211 rules/week
               = 32.3 rules per year
margin over the promise r = 0.55:  +0.0711 rules/week
```

The target is a low-participation share of 12 per cent; the remaining 12 per cent are genuinely single-discipline items where a full board is not warranted and forcing one would be pure `C`.

This lever raised `step` from 0.4381 to 0.6211 and raised `h` by exactly nothing. `h` was 0.9207 before and is 0.9207 after. This is Section 4.8 in operation: **realisation collects headroom that already existed.** The realisation deficit falls from 0.4826 to 0.2996 and is not zero, because the board still runs below the geometric ceiling and always will.

8.1.10 Gate 3 revisited — the category lever, computed and declined

The director's alternative proposal was to add a sixth discipline, public health, at 1.0 FTE.

```
ceiling gain   = eta (ln 6 − ln 5) = 1.05 x 0.1823 = +0.1914 rules/week
added paths    = 15 − 10 = 5
per-path cost  = 0.34 x 0.42 / 10 = 0.0143 rules/week per path
added cost     = 5 x 0.0143        = +0.0714 rules/week
net effect on h = +0.1914 − 0.0714 = +0.1200 rules/week
```

Two scenarios were run for the effect on the surplus term, because the candidate's distinctness matters more than its existence:

candidate	mean pairwise `u`	affine `N_eff`	`F(U)`	gain in `step`	net of path cost
genuinely distinct public-health reviewer	0.7352	4.676	1.5424	+0.2292	+0.1578
a second environmental reviewer, relabelled	0.6889	4.444	1.4917	+0.1759	+0.1045

Both are positive here, and the gap between them — a 34 per cent reduction in the benefit — is the price of relabelling. In a system with a higher per-path cost the relabelled candidate goes negative while the distinct one stays positive, which is why the merge test against the probe set is required *before* any hire and not after.

A correction to the source's comparison, made rather than inherited. The source sets the conversion lever's headroom gain of `+0.8828` over 0.4 FTE against the sixth discipline's `+0.1578` over 1.0 FTE and reports the conversion lever as **fourteen times** better per full-time equivalent. **Those two figures are not on the same basis.** `+0.8828` is a gain in `h`; `+0.1578` is a gain in `step` net of path cost. On a like-for-like basis the ratio is:

basis	conversion lever, per FTE	sixth discipline, per FTE	ratio
gain in `h`	0.8828 / 0.4 = **2.207**	0.1200 / 1.0 = **0.120**	**18.4**
gain in `step`, net of path cost	(1.05 - 0.5015) x 1.1498 / 0.4 = 0.6307 / 0.4 = **1.577**	0.1578 / 1.0 = **0.158**	**10.0**
the source's mixed comparison	2.207 (an `h` gain)	0.158 (a `step` gain)	14.0

The qualitative conclusion is unchanged and is strengthened: on either consistent basis the conversion lever returns an order of magnitude more per full-time equivalent, and the source's "fourteen times" is a hybrid of the two. This is recorded as a defect in Section 9.4 rather than silently corrected in the text.

Declined for now and deferred to Phase 8 — not because it is wrong, but because it is eighth in the sequence and Phases 1 to 6 have not yet been observed to work.

8.1.11 Gates 4 to 7 — sequence, reversibility, consent, pilot

```
Phase 1  stop the leak     eta 0.5015 -> 1.05 ; C 0.63 -> 0.42   h: −0.172 -> +0.921
```

```
Phase 2  correct the proxy done in the survey                    Q: 121 -> 113
Phase 3  shed              declined on delta x q = 0.0433        h: unchanged
Phase 4  realise           low-participation share 0.327 -> 0.12 step: 0.438 -> 0.621
Phase 5  re-measure h      h = +0.9207
Phase 6  commit            r = 0.55 (reserve r/h = 0.597)
Phase 7  raise capacity    deferred; review at 26 weeks
Phase 8  raise N           deferred; merge test required first
```

Gate 5 — reversibility.

RV1 what returns	The scribe role reverts to the analyst's prior duties. The template and the ten-day publication requirement are rescinded by a single memo. The full-disposition rule reverts to the prior attendance-based practice. The re-review loop is reinstated by rescinding the same memo.
RV2 what does NOT return	Rules published during the pilot remain published; the elapsed analyst time is spent; and the board's experience of recording dispositions before discussion cannot be un-had.
RV3 authorised to reverse	The code administrator, unilaterally, without the director's approval. Named in the memo.
RV4 time to reverse	One period (one week).
RV5 cost of reversal	Approximately 0.05 rules per week for two periods, in re-circulation and re-briefing. Inside `h = 0.9207`.
Class	**Costly-reversible.** RV5 is inside `h`. Proceeds under the normal gates.

Gate 6 — consent. Affected: five discipline leads, one analyst redeployed to the scribe role, the code administrator. Informed at the board session of the commitment week, in writing, with the specification attached. **Declination mechanism:** a discipline lead who does not wish to record a written disposition before discussion may abstain; the abstention is recorded as an abstention and the item proceeds with the remaining disciplines, at a correspondingly lower `U_t` for that session. The analyst offered the scribe role may decline, in which case the role is offered to the next volunteer and, if there is none, **the conversion lever is not available and `h` is recomputed without it.** That second clause is the honest form of consent in this framework: **the declination is not free — it changes the arithmetic, and the arithmetic is published — but it carries no penalty to the person, and the design has a defined behaviour when it is exercised.**

Gate 7 — the pilot.

Scope bound	The full board, for items in two of the five application classes
Duration bound	26 weeks, plus a 6-week conversion lag before measurement begins

Downside cap	**7 rules.** Itemised worst case: removing the re-review loop lets weak dispositions stand and doubles the appeal-reversal line from 0.14 to 0.28 for the whole window, `0.14 x 32 = 4.48` rules; transition friction at 0.05 per week for 32 weeks, 1.60; reversal cost at 0.05 per week for 2 weeks, 0.10. Total **6.18 rules**, capped at 7
Admissibility	`C <= (1−delta)Q + eta S` holds under the worst case at `Q = 113`: `0.42 <= 112.65` comfortably
Comparison	The three application classes not in the pilot, running the prior process
Preregistered prediction	Mean weekly change in the order proxy over weeks 7 to 32 of at least +0.55 rules per week
Falsification	If the mean weekly change over weeks 7 to 32 is below +0.30, the intervention is judged ineffective and the memo is rescinded

Trip-wires.

wire	threshold	automatic action
realised geometry	mean `F(U_t)` below `S_req = 1.2564` nats over any 8-week block — equivalently, low-participation share above 20 per cent	notify the director in the same period; the +0.55 promise is suspended pending review
`C`	above 0.55 rules per week	suspend the growth commitment; resume the cost work
`h`	at or below 0	stop building; revert to Section 4.5
single-week rise in the proxy	above `eta ln N = 1.6899` plus the 6-week lag allowance	investigate the proxy before believing the number
harm: appeal reversal rate	above 1.5 times the pre-pilot rate	stop, regardless of the proxy — the non-proxy harm criterion

The geometry trip-wire is the live one. The promise was computed at a mean `F` of 1.3241 nats. **Above a low-participation share of about 20 per cent the promise breaks**, and 32.7 per cent — the share the office was already running at before the intervention — is well above it. There are 8 percentage points of margin between the target and the break-even point, and the office was 13 points the wrong side of it a year earlier. **The realisation work is not an enhancement; it is a load-bearing component of the commitment and must be maintained for as long as the commitment stands.**

8.1.12 Time — what may be said, and what may not

```
conversion lag m  = 6 weeks
increment r       = 0.55 rules/week, judged over weeks 7 to 32
tau = 1/delta     = 323.6 weeks = 6.22 years
3 tau             = 971 weeks   = 18.7 years        SETTLING TIME, NOT A DATE
Q_inf             = (1.05 x 1.3241 − 0.42)/0.003090 = 314.0 rules   REPORTED, NOT PROMISED
```

Sanity checks against the inherited results: `Q_inf = 314.0` is below the uniform bound `eta ln N / delta = 546.9` (CC-T5) and below the level `Q = 411.0` at which `h` returns to zero, **so the design does not, on its own trajectory, drive the office back into the maintenance trap.** It reaches 76 per cent of the way there, which is a fact worth knowing in advance.

horizon	modelled `Q`
1 year	142.9
3 years	190.0
5 years	224.1
10 years	273.8
3 tau (18.7 years)	304.1
limit (not attained in finite time)	314.0

A small correction to the source, made rather than inherited. The source's trajectory table labels the `3 tau` row "approximately 314", conflating the settling time with the limit. At `3 tau` the model reads **304.1**, which is 95 per cent of the approach from 113 to 314.0 — which is what `3 tau` means. The limit is approached and not attained.

What may be said to the director: the manual should gain about 32 rules in the first year, and that number is checkable in thirty-two weeks. What may not be said: that the manual will reach 314 rules. It will, if every parameter holds for nineteen years, which no parameter in any organisation has ever done.

8.1.13 The decision that was not taken

The office also has a standing proposal, three years old, to merge the fire and structural review functions under one lead. The pairwise table shows why it never gets done and why it should not: `u(STRU, FIRE) = 0.3056` is the lowest pair in the set, which makes it the obvious merge candidate to anyone reading an organisation chart. **Under the merge rule it survives easily — 0.3056 is three times the 0.10 threshold — and merging would drop `N` from 5 to 4, costing `ln 5 - ln 4 = 0.2231` nats of ceiling**, which at the post-intervention conversion rate is

```
1.05 x 0.2231 = 0.2343 rules per week = 12.2 rules per year, permanently
```

against a saving of one lead post. **Recorded as a decision not to act, with the number, and with the observation that would reopen it: if a future probe set shows `u(STRU, FIRE) < 0.10`, the two functions have converged and the merge becomes free.** A refusal, dated, with its arithmetic and its reopening condition, is what the discipline of not acting looks like when it is written down.

16.5.8 8.2 A hospital ward shift handover: positive headroom, and a system losing stock

A 34-bed inpatient ward. **The complaint presented by the charge nurse is "handover is not working." Nothing else is offered.** The case is worked through the catalog's use specification (Appendix C).

8.2.1 The survey

Period: one week. **Order observable:** the number of currently-admitted patients for whom an incoming staff member can, unprompted, state the three current concerns and the escalation trigger, measured by spot audit at three random times per week. `Q_0 = 21` of 34.

FM-29 check, run first. Is the proxy a repackaging of interaction? The lag test: handovers were cancelled for three consecutive weeks during a staffing crisis, and the proxy fell 27 to 21 over those three weeks — **a decay with a time constant, not a collapse to zero. The proxy is stored order, not input.**

Decay. From the same natural experiment, with `S` approximately zero:

```
delta      = 1 − (21/27)^(1/3) = 0.080359 per week
half-life  = ln 2 / (−ln(1 − delta)) = 8.274 weeks
```

Categories. Five are declared as handover participants: nursing, medicine, pharmacy, physiotherapy and occupational therapy, and discharge coordination. **Two attend. This is FM-06, the Frozen Denominator.** `N = 2`, so `ln 2 = 0.693147` and not `ln 5 = 1.609438`. **The ward has been planning against a ceiling 132 per cent higher than the one it owns.**

Non-parallelism. Independent concern-listing before discussion, 18 patients, two attending categories. Mean overlap of listed concerns, treated as the alignment cosine: `rho = 0.79`.

```
u     = 1 − rho^2 = 1 − 0.6241 = 0.375900
N_eff = 1 + (2−1)(0.3759) = 1.375900        [the affine effective count]
S     = ln(1.375900) = 0.319108 nats        −> 46.04 per cent of ln 2
```

Conversion. Over 12 weeks the ward logged 25 carried-patients attributable to specific handover exchanges, against a cumulative `S` of `12 x 0.319108 = 3.8293` nats.

```
eta = 25 / 3.8293 = 6.528614 carried-patients per nat
```

Cost, as a residual (FM-23). Productive handover time is 38 minutes per week; the audit finds 21 minutes per week of interruption, repetition and downstream rework attributable to handover failure. The conversion rate is `25 / (12 x 38) = 0.054825` carried-patients per productive minute.

```
C = 21 x 0.054825 = 1.151316 carried-patients per week
```

8.2.2 The two master numbers

```
h  = eta ln N − delta Q − C
   = 6.528614 x 0.693147 − 0.080359 x 21 − 1.151316
   = 4.525290 − 1.687531 − 1.151316
   = +1.686444 carried-patients per week        ->  headroom is POSITIVE

S / ln N = 0.319108 / 0.693147 = 46.04 per cent ->  realised fraction is LOW
```

Validation. The predicted one-step change is

```
eta S − delta Q − C = 2.083333 − 1.687531 − 1.151316 = −0.755513 per week
```

against an observed fall of 24 to 21 over the preceding four weeks, or `−0.750` per week. The residual is `−0.006`. **The survey reproduces the observed decline and is admissible.**

8.2.3 The diagnosis

Five co-occurring faults, ranked by effect on the one-step condition.

1. **FM-06, the Frozen Denominator.** Three of five declared categories do not attend. `N = 2`.

2. **FM-25, the Head of Table.** Handover is delivered by the outgoing senior nurse standing, to a seated audience. Speaking order tracks rank in all three observed sessions.
3. **FM-26, the Reverberant Room.** Handover happens in a corridor alcove, 4.2 by 2.6 by 3.0 metres.

   ```
   V    = 32.760 m^3
   A    = 10.92 x 0.02 + 10.92 x 0.04 + 40.80 x 0.05 + 6 x 0.45
        = 0.2184 + 0.4368 + 2.040 + 2.70 = 5.395 m^2 sabins
   RT60 = 0.161 x 32.760 / 5.395 = 0.9776 s
   ```

   Nearly a full second, in a room where six people must exchange precise clinical detail in under forty minutes with corridor traffic passing through.
4. **FM-12, the Ritual That Became a Meeting.** The written handover sheet exists. Its template was last revised four years ago; the audit finds it filled in for 6 of 34 patients.
5. **FM-01, a partial Parallel Wall.** `u = 0.3759` between two categories whose training, supervision and incentives substantially overlap.

The binding constraint is not headroom. Headroom is `+1.69` per week and the ward is losing 0.76 per week. The ward operates at 46 per cent of a ceiling that is itself artificially low. **This is precisely the case Section 6.3 warns about, and a diagnosis that stopped at "headroom is positive, we are fine" would have been exactly wrong.** It is the paper's counter-result, and it is exhibited rather than asserted.

8.2.4 The intervention

Ranked by lever cost, and every element checked against FM-32: **none of the four requires anyone to participate who declines**, and the pharmacy and discharge attendance is negotiated as a scheduling change rather than imposed.

#	Move	Lever	Target
1	Restore the handover sheet as a live board, filled during handover and not after	`eta`, `delta`	`delta` 0.0804 to 0.065
2	Pharmacy and discharge coordination attend; physiotherapy does not — scheduling infeasible, stated honestly	`N`	`N` 2 to 4
3	Acoustic treatment of the alcove: 10.92 m^2 ceiling raft at `alpha` 0.90, 12 m^2 wall panel at 0.85	`u`, `C`	`RT60` 0.98 to 0.22 s
4	Independent written concern lists from each category before the verbal round	`u`	`rho` 0.79 to 0.68

```
Acoustics after treatment:
A    = 0.2184 + 9.828 + (40.80 - 12) x 0.05 + 12 x 0.85 + 2.70 = 24.386 m^2 sabins
RT60 = 0.161 x 32.760 / 24.386 = 0.2163 s

Post-intervention parameters:
N     = 4        ln N  = 1.386294
rho   = 0.68 ->  u     = 0.537600
                 N_eff = 2.612800        [affine effective count]
                 S     = 0.960422 nats   -> 69.28 per cent of ln 4
delta = 0.065    eta   = 6.528614 (held constant; conservative)
C     = 26 x 0.054825 + 0.20 = 1.625450  (more attendees, plus board upkeep)
```

8.2.5 The prediction, and the disclosure that the model is out of range

```
h_new = 6.528614 x 1.386294 - 0.065 x 21 - 1.625450
      = 9.050581 - 1.365000 - 1.625450 = +6.060131 per week

step  = eta S - delta Q - C
      = 6.270227 - 1.365000 - 1.625450 = +3.279777 carried-patients per week

Q_inf = (6.270227 - 1.625450) / 0.065 = 71.46
tau   = 1/delta = 15.385 weeks
```

DF-6 applies and is stated. `Q_inf = 71.46` exceeds the ward census of 34. The linear law has no saturation term; beyond `Q = 34` the model is outside its range and must be replaced. **The binding limit is the census, not the fixed point.** The honest prediction is therefore a saturation date and not an equilibrium:

```
t = 1   Q = 24.280
t = 2   Q = 27.346
t = 3   Q = 30.214
t = 4   Q = 32.895
t = 5   Q = 35.401   -> census cap reached; the model is invalid beyond this point
```

Predicted outcome: the ward reaches full carried-patient coverage in four to five weeks and holds it. The do-nothing comparison from the same start gives `Q = 18.32` at week 4, 16.41 at week 8, and 14.76 at week 13.

8.2.6 What would falsify it

Preregistered before the first acoustic panel is hung.

1. **Trajectory.** Spot-audit the proxy at weeks 2, 4 and 8. At a conversion rate 20 per cent below the estimate, week 4 still predicts `Q = 28.35`. **If the proxy is below 28 at week 4, the conversion estimate is refuted** and the model requires re-specification.
2. **Acoustic mediation.** Measured `RT60` post-installation must fall below 0.35 s. If it does not, the absorption schedule was wrong and prediction 1 is void regardless of outcome.
3. **The geometry channel.** Independent concern-listing repeated at week 6 must show `rho <= 0.72`. **If `u` does not move while the proxy does, the proxy is rising for a reason outside the model — most likely the measurement effect named in DF-7 — and the causal claim is refuted even though the outcome is favourable.**
4. **Shuffled-input control.** Refit the minimal model with the interaction series randomly permuted across weeks. If the shuffled fit matches the ordered fit on held-out data, the apparent dependence on surplus is spurious. **This is the baseline most often omitted, and its omission would invalidate the whole diagnosis** — though Section 4.2 records that

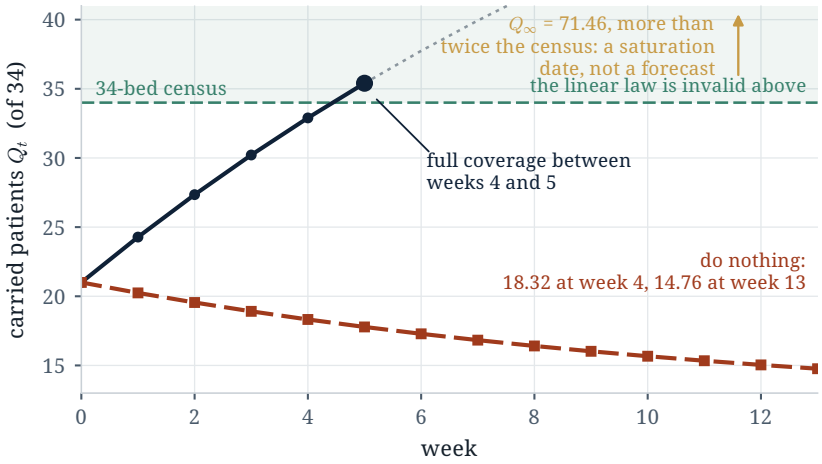

Figure 16.4: **Positive headroom, a declining stock, and a fixed point outside the model's range.** The ward has `h = +1.686` carried-patients per week and is losing 0.756 per week, because it realises only 46.04 per cent of a ceiling that the frozen denominator has already halved. Under the four interventions the modelled trajectory crosses the 34-bed census between weeks 4 and 5, at which point **the linear law is outside its range** — its own predicted fixed point of 71.46 is more than twice the census and is reported as a saturation date rather than as a forecast. The do-nothing comparison falls to 14.76 by week 13. Modelled from the parameters of Sections 8.2.1 and 8.2.4; generated by `figs/src/CCP-016_fig04.py`.

the shuffle is anti-conservative as ordinarily run and must be calibrated by simulation on this design.

5. **Persistence and matched-autoregression baselines.** The fitted model must beat both on held-out weeks. **If a plain autoregression on the proxy alone predicts as well, the framework has added nothing here and should be reported as having added nothing** — which is exactly what happened to the corpus's one preregistered confirmatory test [Curzi, 2026i].

Any one of 1, 3, 4 or 5 failing refutes the diagnosis. Failure of 2 refutes only the installation.

The catalog's job ends here. It named five faults, priced four of them, and produced a falsifiable number. Whether the number survives contact with a real ward is a question for a preregistered trial that has not been run.

16.5.9 8.3 The two cases side by side

	office, before	office, after	ward, before	ward, after
`h` (proxy units per week)	-0.1720	+0.9207	+1.6864	+6.0601
`step` (proxy units per week)	-0.4025	+0.6211	-0.7555	+3.2798
realisation deficit	0.2305	0.2996	2.4419	2.7803
realised fraction `S / ln N`	71.4 per cent	82.3 per cent	46.04 per cent	69.28 per cent

	office, before	office, after	ward, before	ward, after
binding fault	dissipation and conversion	—	frozen denominator and conversion	—
verdict	**refuse the request**	admit `r = 0.55`, reserve 0.597	**positive headroom, still losing**	saturation at the census, not an equilibrium

The realised fractions for the office are the mean of `F` over the ceiling: `1.1498 / 1.6094` and `1.3241 / 1.6094`. **They are computed from the mean of `F`, not from `F` of the mean `U`, which would return 76.2 per cent and 84.5 per cent respectively and would overstate both.** # 9 Discussion

16.5.10 9.1 What follows

The refusal is a deliverable, and it is the procedure's most useful output. The office case ends its first phase with a written paragraph containing a number, and that paragraph is worth more than the intervention that follows it, because it converts an argument about effort, commitment and facilitation into an inequality between three measured quantities. **An analyst who cannot produce a refusal cannot produce a commitment either**, since the same arithmetic underwrites both.

Two administrative levers moved a system from an unsustainable regime to a fundable one without adding a person. The conversion lever supplied 80.8 per cent of a 1.093-unit swing at a cost of 0.4 of an existing post, and the dissipation lever the remaining 19.2 per cent at the cost of one policy decision. **That is the ranking of Section 4.9 in a system's own numbers, and it is the strongest practical claim in the paper**: the cheapest lever is usually the first one, and it is almost never the one proposed, because capture is nobody's job and hiring is somebody's.

The realisation channel is a distinct route with a distinct instrument. Raising the mean of `F` by regularising participation moved the office's realised step from +0.4381 to +0.6211 while leaving headroom at exactly 0.9207. **Nothing about the budget changed and the deliverable changed by 42 per cent.** The mechanism is available in most organisations for the same reason that most organisations run sessions below their own measured capacity.

The concavity penalty is a real and recoverable quantity. 0.0761 nats — 6.2 per cent of the office's surplus — is charged for nothing but the variability of who turns up, and 0.0407 of it is recovered by regularisation alone, worth 0.0427 rules per week. **It is invisible to anyone reasoning about the average board rather than about the distribution of boards**, which is why the feasibility test is stated on the mean of `F` and not on `F` of the mean.

And the counter-result: positive headroom is not health. The ward has `h = +1.69` per week and loses 0.76 per week. Both numbers are correct and they are answers to different questions. **The diagnostic obligation is therefore to report two numbers, not one**, and the catalog's use specification makes it a requirement rather than a recommendation.

16.5.11 9.2 What does not follow

No causal claim follows from either worked case. Both are constructed. Neither is evidence that any organisation behaves this way, and neither may be cited as such.

No identified estimate of conversion follows from any survey, however clean. Section 3.4 states it: the specification is reflexive and its endogenous effect is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011]. **Gate 0 governs the admissibility of evidence about the proxy and never the admissibility of a causal claim.** The corpus's own confirmatory test did not meet its declared margin [Curzi, 2026i], and that is the weaker of the two problems.

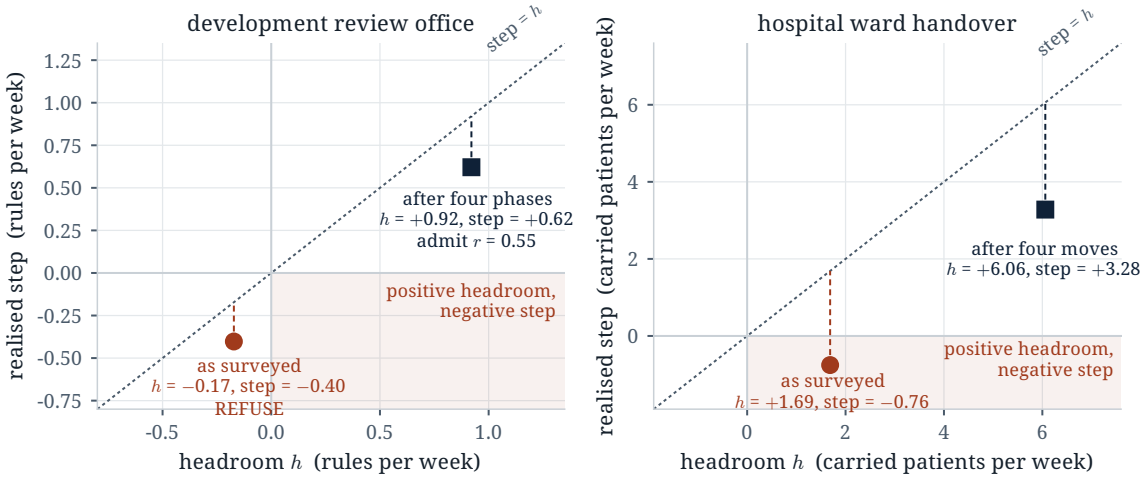

Figure 16.5: **Headroom and the realised step are independent quantities, and only their joint reading is a diagnosis.** Left, the development review office: headroom `−0.1720` with a step of `−0.4025` before intervention, and `+0.9207` with a step of `+0.6211` after. Right, the hospital ward: headroom `+1.686` with a step of `−0.756` before intervention — **positive headroom and a declining stock at the same time** — and `+6.060` with a step of `+3.280` after. The two panels are not on a shared axis because the two systems count different things: rules per week against carried-patients per week. The diagonal marks equality of headroom and step, which is attained only at the geometric ceiling. Modelled from Sections 8.1 and 8.2; generated by `figs/src/CCP-016_fig05.py`.

The lever ranking does not follow as a law. It is a default over the parameter ranges the worked systems occupy. In a system whose capture discipline is already near its medium's absorption limit, `eta` has no room and the ranking inverts; the procedure requires an analyst to compute and report that rather than to inherit the order.

The catalog's closure does not follow as a discovery. It is a definition given the model (Section 6.1). A different model of institutional accumulation has a different and possibly infinite catalog.

Nothing about surplus follows from the choice of a logarithm. Latané [1981] and Briscoe et al. [2006] fit the qualitative facts as well, and nothing assembled here discriminates. **The logarithm has an axiomatic characterisation [Curzi, 2026] and a dynamical warrant that requires no perceptual story [Peters and Gell-Mann, 2016]; it does not have a measurement that selects it.**

And no arithmetic result licenses the consent constraint. It is normative, it is stated as such, and it is the one place in the procedure where a design is refused for a reason the equations do not supply.

16.5.12 9.3 Relation to the surrounding literature

The procedure's central move — refuse a commitment that exceeds a computed budget — has an exact analogue in operations, where organisational slack is the recognised name for the margin that keeps a system's latency finite [Cyert and March, 1963, Kingman, 1962, Hopp and Spearman, 2011]. **The contribution here is not the idea of a budget but the identification of the budget with a specific, separately measurable expression**, and the demonstration that its sign is a hard gate rather than a soft indicator.

The lever ranking's fourth position is a restatement of a result that predates this framework by half a century: coordination cost grows with the number of pairs while the useful return does not [Brooks, 1975, Conway, 1968]. **The framework's addition is to make the com-**

parison numerical — a ceiling gain of `eta ln((N+1)/N)` against a priced path increment — so that the refusal of a headcount proposal is computed rather than argued.

The catalog's Class V is the part of the material with the strongest external footing and the weakest internal one. Room acoustics is real physics [Sabine, 1922, Schroeder, 1965], turn-taking equality is a measured driver of collective performance [Woolley et al., 2010], and direct observation of where people actually go is a mature instrument [Whyte, 1980, Jacobs, 1961, Alexander et al., 1977, Hall, 1966]. **What is not established is the step from any of those to a numerical value of `u`**, and Section 3.8 badges that step as a modelling assumption at each occurrence.

Where the literature disagrees with the framework, the disagreement is recorded rather than managed. **The framework's surplus is monotone increasing in `u`; the field evidence says the real curve turns over** [Uzzi and Spiro, 2005], and diversity in the short run has been found to reduce trust and civic participation by a scholar who did not want the result [Putnam, 2007], with the rebuttal [Abascal and Baldassarri, 2015] and the conditions under which contact across difference does pay [Allport, 1954, Pettigrew and Tropp, 2006]. **The strongest formal result on diversity is narrower than its popular reading** [Hong and Page, 2004, Thompson, 2014]. And the design and safety literature warns that the framework's instinct to add categories can make matters worse in a tightly coupled system [Perrow, 1984, Sagan, 1993], which is a limit on Section 4.9's fourth lever that the arithmetic alone does not supply.

16.5.13 9.4 Defects found in the source material, printed rather than repaired

Five, in descending order of consequence.

D-i. The lever comparison mixes two bases and reports a hybrid ratio. The source's lever table sets a gain in `h` of `+0.8828` against a gain in `step` net of path cost of `+0.1578`, labels both "gain in `h`", and reports the ratio per full-time equivalent as fourteen. **On a consistent headroom basis the ratio is 18.4; on a consistent step basis it is 10.0.** The qualitative conclusion survives on either basis and is strengthened, but the printed figure is not a like-for-like comparison. Section 8.1.10 gives all three.

D-ii. The notation `realised F(U) = 1.1498` writes a mean of `F` as though it were `F` of a `U`. It sits three lines above `realised u = 0.6019` in the same block, and `F(0.6019) = 1.2260`, so a reader recomputing the printed relation finds it fails by 0.0762 nats. **The number 1.1498 is correct and the notation is not**; the source's own later text makes the distinction explicitly and correctly, which makes the earlier notation an inconsistency rather than an error of substance. Every occurrence in this paper is disambiguated in words.

D-iii. The gate ordering in the source's exposition is out of sequence, developing Gate 7 before Gate 5 while running them in numerical order in the worked case. Section 4.1 states the adopted order and the reason.

D-iv. The trajectory table labels the value at three time constants as the limit. At `3 tau` the office model reads 304.1 rules, which is 95 per cent of the approach; 314.0 is the limit and is not attained in finite time. Section 8.1.12 prints both.

D-v. The symbol `rho` carries two meanings in the catalog — the alignment correlation in FM-01 and the queue utilisation in FM-22. This paper writes the second as `rho_u` and says so at the point of use.

One further item is not a defect and is recorded because it looks like one. The source's ward case predicts a fixed point of 71.46 carried-patients against a 34-bed census. **That is a prediction outside the model's range, and the source declares it as such and replaces the forecast with a saturation date.** It is a credit to the source rather than an error, and it is kept prominent in Section 8.2.5 for that reason.

16.6 10 Verification

The results of this paper compound from seven postulates and one design constraint. Each is atomic, each is checkable on its own, and each carries its status. **Postulates that could be dropped with the results still following have been dropped**; what remains is what the chain consumes. **The reader is warned at the outset of what Section 10.3 makes explicit: this chain ends in arithmetic on top of definitions, so it delivers the mathematics with certainty and delivers nothing whatever about institutions.**

16.6.1 10.1 Dimensional audit

`[Q]` denotes the dimension of stored order and `[T]` the dimension of time. The period is the unit of `[T]` and every rate is *per period*, which is why no explicit `[T^-1]` appears once the equations are written in discrete steps.

Symbol	Dimension	Unit	Status
`Q_t`	`[Q]`	declared proxy units (live rules; carried patients)	**measured** in whatever the declared proxy counts
`U_t`, `u`	`[1]`	none	**stipulated** dimensionless; `u = 1 - rho^2`
`S_t = F(U_t)`	`[1]`	nats	**derived** dimensionless: a logarithm of an effective count
`eta`	`[Q]` per nat per step	proxy units per nat per period	**measured**; *not* dimensionless
`delta`	`[1]`	per period	**measured** dimensionless fraction per step
`C_t`	`[Q]` per step	proxy units per period	**measured**, as a residual
`h_t`, `step`, `r_t`	`[Q]` per step	proxy units per period	**derived**
`S_req`	`[1]`	nats	**derived**: `[Q]/step` divided by `[Q]` per nat per step
`U_req`	`[1]`	none	**derived**
`q` (a shed)	`[Q]`	proxy units	**chosen**
`delta x q`	`[Q]` per step	proxy units per period	**derived**; commensurable with `h`
`Q_inf`	`[Q]`	proxy units	**derived**: `[Q]`/step over `[1]`/step
`tau`, `t_half`, `3 tau`	`[T]`	periods	**derived**
`r/h`	`[1]`	none	**derived**; a pure ratio, defined only for `h > 0`
`rho` (alignment)	`[1]`	none	**measured** correlation coefficient

Symbol	Dimension	Unit	Status
`rho_u` (utilisation)	`[1]`	none	**measured** fraction of capacity committed
`RT60`	`[T]`	seconds	**measured or computed**; *not* in periods — see below
`V`	length cubed	m^3	**measured**
`A`	length squared	m^2 sabins	**measured**; the sabin is a dimensionless absorption weight on an area

Does the gauge balance? `h_t = eta ln N − delta Q_t − C_t` balances if and only if every term carries `[Q]` per step. `C_t` does by construction. `delta Q_t` does, since `delta` is a dimensionless fraction per step. `eta ln N` does **only if `eta` carries `[Q]` per nat per step**, since `ln N` is a dimensionless count in nats. **`eta` is therefore not dimensionless in this framework**, and the worked cases are consistent with it: the ward reports 6.528614 carried-patients per nat, which is `[Q]` per nat, with the per-period part carried by the cumulative surplus in the denominator. **The office reports `eta = 0.5015` and `1.05` without units, which is a silence in the source**; the values should read *rules per nat per week*, and that is recorded here rather than quietly corrected. Two consequences: `eta/delta` carries `[Q]` per nat and is the gain from a sustained nat to a stock; and `delta x q` carries `[Q]` per step, which is what makes the shed commensurable with the rest of the gauge.

Two dimensional cautions. First, `RT60` is in **seconds** and every other time in this paper is in **periods**. They are never added, never compared, and the step from one to the other is the modelling assumption of Section 3.8, not a unit conversion. Second, a headroom calculation in which `C` is denominated in hours or currency while `Q` is denominated in rules is **dimensionally malformed however arithmetically tidy it looks**; the denomination requirement is part of the survey protocol [Curzi, 2026i] and the ward case satisfies it by converting minutes to carried-patients through a measured yield rate before subtracting.

Where there is no operational unit, it is said. `Q` is stored order and **stored order has no natural unit**: it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy — which is exactly why Section 8.3 places the two worked systems in separate panels. Comfort itself, the underlying construct of the corpus, has **no operational unit at all**; it is treated as a dimensionless magnitude by stipulation, and Section 11 records that the quantitative structure required for the stipulation has not been tested.

16.6.2 10.2 The postulates

P1 — The gauge is `h_t := eta ln N − delta Q_t − C_t`. *Status:* **DEFINITION** — fixed by Curzi [2026b] and adopted unchanged. It carries no empirical weight on its own.

P2 — The one-step change is `Q_{t+1} − Q_t = eta F(U_t) − delta Q_t − C_t`. *Status:* **DEFINITION** — the model form of the storage law, restated [Curzi, 2026a]. That any organisation obeys it is postulate P-C of Section 3.6 and is not verified here.

P3 — `0 <= F(u) <= ln N` on `u` in `[0,1]` for `N >= 2`. *Status:* **CITED** — the range result of the surplus functional [Curzi, 2026], following from `F(u) = ln(1 + (N−1)u)`.

P4 — `F(u) = ln(1 + (N−1)u)` is strictly concave on `[0,1]` for `N >= 2`. *Status:* **ARITHMETIC** — differentiate twice: `F''(u) = −(N−1)^2 / (1 + (N−1)u)^2`, which is strictly negative for every `u` in `[0,1]` whenever `N >= 2`.

P5 — For a strictly concave function, the mean of the function is at most the function of the mean. *Status:* **ARITHMETIC** — Jensen's inequality; **the bibliography assembled for this**

corpus contains no entry for it, so it is stated as elementary mathematics and demonstrated on the paper's own two-point instance in Section 10.5 rather than cited.

P6 — Communication paths among `n` categories number `n(n−1)/2`, so a step from `n` to `n+1` adds `n` paths. *Status:* **CITED** [Brooks, 1975, Conway, 1968].

P7 — Cost accrues every period whether or not surplus was delivered. *Status:* **POSTULATED** — an assumption about how organisations charge overhead, with no external support. It is consumed at exactly one place, R1b below, and only for the *interpretation* of `C` as a standing charge; the inequality itself holds however `C` is generated.

One further item is stated and is not in the chain. The consent constraint (P-E, Section 3.6) is **normative, is not falsifiable, and consumes no step below.** It bounds the admissible design set and it does no arithmetic work, so by the razor it is listed here and excluded from the compounding chain rather than dressed as a premise.

16.6.3 10.3 The compounding chain

```
P2 + P3          -> L1   since F(U_t) <= ln N,
                         Q_{t+1} − Q_t <= eta ln N − delta Q_t − C_t.      ARITHMETIC

L1 + P1          -> R1   Q_{t+1} − Q_t <= h_t, so r_t <= h_t; and equality
                         requires F(U_t) = ln N, i.e. U_t = 1.            ARITHMETIC

L1 + P1 + P7     -> R1b  h_t < 0 implies Q_{t+1} − Q_t < 0 for EVERY
                         U_t in [0,1]: no geometry prevents decline.      ARITHMETIC

P2               -> L2   Q_{t+1} − Q_t >= r_t  iff
                         F(U_t) >= (delta Q_t + C_t + r_t)/eta =: S_req.  ARITHMETIC

L2 + P3          -> R2   the increment is attainable only if
                         S_req <= ln N, which is exactly r_t <= h_t.      ARITHMETIC

L2               -> L3   inverting F: U_req = (exp(S_req) − 1)/(N − 1).   ARITHMETIC

P4 + P5          -> R3   mean F(U_t) <= F(mean U_t), equality only if U
                         is constant; so the feasibility test is
                         mean F(U_t) >= S_req, never F(mean U) >= S_req.  ARITHMETIC

P1               -> R4   dh/dQ = −delta, so removing q units of stored
                         order returns exactly delta x q per period.      ARITHMETIC

P1               -> L4   raising N to N+1 raises the ceiling by
                         eta ln((N+1)/N).                                 ARITHMETIC

P6               -> L5   the same step adds N communication paths.        CITED

L4 + L5          -> R5   net headroom from a category, at per−path cost c0,
                         is eta ln((N+1)/N) − N c0, which changes sign.   ARITHMETIC

P1 + P2          -> R6   h_t − (Q_{t+1} − Q_t) = eta(ln N − F(U_t)) >= 0:
                         the realisation deficit, non−negative always,
                         and zero only at U_t = 1.                        ARITHMETIC
```

Every line is checkable from its own stated inputs. R1, R1b, R2, R3, R4, R5 and R6 are arithmetic consequences of two definitions (P1, P2), one cited range result (P3), two elementary mathematical facts (P4, P5), and one cited combinatorial fact (P6). **Only R1b consumes a**

postulate with no external support, and it consumes it only for the reading of `C` as a standing charge.

What this chain does not establish. It does not establish that any organisation obeys P2. That is postulate P-C, it is not verified here, and the one preregistered confirmatory test of it so far reported in this corpus did not meet its own declared margin [Curzi, 2026i]. **A chain whose steps are ARITHMETIC, DEFINITION and CITED delivers the decision rule with certainty and delivers nothing about institutions.** The procedure of Section 4 is valid in the sense that a decision rule can be valid — it is internally consistent and it follows from its premises. Whether it should be applied to a given organisation is a separate question and the answer is not in this section.

16.6.4 10.4 The verification instance, computed by hand

The office gauge, before intervention. Four multiplications and two subtractions.

```
ln 5           = 1.6094379...            round to 1.6094
eta ln N       = 0.5015 x 1.6094 = 0.80711...           print 0.8071
delta Q        = 0.003090 x 113 = 0.34917             print 0.3492
C                               = 0.6300
-----------------------------------------------------------------
h = 0.8071 - 0.3492 - 0.6300     = -0.1721             source prints -0.1720
```

The one-digit difference in the last place is the rounding of `eta ln N`; carried unrounded, `0.5015 x 1.6094379 = 0.80713311` and `h = -0.17203689`, which rounds to `-0.1720`. **The printed value is correct and the intermediate rounding is not; a reader reproducing it from the printed intermediates lands one unit low in the fourth decimal.**

```
step = 0.5015 x 1.1498 - 0.3492 - 0.6300 = 0.576625 - 0.9792 = -0.402575   -> -0.4026
```

against a printed `-0.4025`, again a fourth-decimal rounding. **Both are reported rather than harmonised.**

The office gauge, after two levers.

```
eta ln N = 1.05 x 1.6094379 = 1.68991     print 1.6899
h        = 1.6899 - 0.3492 - 0.4200 = +0.9207    exact: +0.92070981
```

The increment and the reserve.

```
S_req = (0.3492 + 0.4200 + 0.5500)/1.05 = 1.3192/1.05 = 1.25638...   -> 1.2564
S_req <= ln 5 = 1.6094                    -> no Failure A
U_req = (exp(1.2564) - 1)/4 = (3.51287 - 1)/4 = 0.62822              -> 0.6281
r/h   = 0.55/0.92070981 = 0.59736                                    -> 0.597
```

The shed. `0.003090 x 14 = 0.043260 -> 0.0433`. **And at a decay of 0.05:** `0.05 x 14 = 0.70`, whose ratio to 0.0433 is `16.17`. **One multiplication and one division.**

The category lever.

```
ln 6 - ln 5   = 1.7917595 - 1.6094379 = 0.1823216            -> 0.1823
ceiling gain  = 1.05 x 0.1823216 = 0.1914377                 -> +0.1914
paths added   = 15 - 10 = 5                        (P6: 6x5/2 - 5x4/2)
per-path cost = 0.34 x 0.42/10 = 0.01428                     -> 0.0143
added cost    = 5 x 0.01428 = 0.0714
net on h      = 0.1914 - 0.0714 = +0.1200
```

The ward's counter-result, in six operations.

```
eta ln N = 6.528614 x 0.693147 = 4.525290
delta Q  = 0.080359 x 21       = 1.687531
C                              = 1.151316
h        = 4.525290 − 1.687531 − 1.151316 = +1.686443
eta S    = 6.528614 x 0.319108 = 2.083333
step     = 2.083333 − 1.687531 − 1.151316 = −0.755514
```

`h` is positive and `step` is negative, from the same three subtractions with one term changed. That is the whole of the counter-result and it can be checked in under a minute. The survey's own validation follows: the observed change was `−0.750` per week, so the residual is `−0.006`, or 0.13 per cent of the ceiling term.

16.6.5 10.5 The concavity penalty, demonstrated on a two-point instance

P5 needs no citation if the paper's own instance exhibits it. The office's sessions are a two-point mixture: full-board sessions at mean `U = 0.7940` and reduced sessions at mean `U = 0.2071`, in proportions `1−p` and `p`. At the surveyed `p = 0.327`,

```
mean U   = 0.327 x 0.2071 + 0.673 x 0.7940 = 0.067722 + 0.534362 = 0.602084   -> 0.6021
F(mean U)= ln(1 + 4 x 0.602084) = ln(3.408336) = 1.226237                      -> 1.2262
```

and the mean of `F` over the same mixture is 1.1501, giving a penalty of `1.2262 − 1.1501 = 0.0761`. **The gap is strictly positive, which is P5, and a reader can see why in one line:** `F(0.2071) = ln(1.8284) = 0.6035` and `F(0.7940) = ln(4.1760) = 1.4294`, so a straight-line mixture of the two *function values* — `0.327 x 0.6035 + 0.673 x 1.4294 = 1.1593` — already sits below `F` of the mixed argument, 1.2262. **A chord under a concave curve lies below the curve; that is the whole of Jensen's inequality at two points.**

A note on the source's within-type figures, made rather than concealed. The two-point reconstruction just given returns a mean `F` of 1.1593, while the source's table prints 1.1501. The difference is that the source's session types are themselves distributions rather than point masses, so each type carries its own internal concavity penalty: the implied within-type mean of `F` is 1.4250 for full sessions against `F(0.7940) = 1.4294`, and 0.5844 for reduced sessions against `F(0.2071) = 0.6035`. **Both are below their own `F` of the mean, which is P5 again, one level down.** The source's table is linear in the share `p` with a slope of `−0.84058` nats per unit share, and every printed row of the mean-`F` column reproduces to four decimals from `1.42497 − 0.84058 p`. **The table is internally consistent and the reconstruction that recovers it is stated here so a reviewer does not have to find it.**

16.6.6 10.6 Limits, asymptotics, and the model's valid domain

`delta -> 0^+`. The shed's value `delta x q -> 0`: **in a perfectly durable system, shedding buys nothing, however much is shed.** The time constant `1/delta -> infinity` and `Q_inf` diverges. **The limit is singular:** at exactly `delta = 0` the update map is an isometry, no fixed point exists at all, and the bound degrades from a ceiling to a ramp [Curzi, 2026a]. **That value is outside the model's valid domain**, and it is a pathology rather than an ideal. The office's `delta = 0.003090` is close enough to it that the shed lever is worth 0.0433 and the time constant is 6.22 years — **the same number makes the office durable and makes it slow**, which is Section 4.15's rule in one parameter.

`delta -> 1^-`. The time constant goes to zero and the system has no memory; `Q_{t+1}` becomes `eta S_t − C_t`, an instantaneous transducer. The shed returns the entire stock, `1 x q = q`, and **is simultaneously maximally valuable and pointless, because nothing is stored to shed.** At `delta = 1` the storage law is not a storage law and any claim about accumulation is vacuous.

eta -> 0. `h -> -delta Q - C < 0` for every positive stock and cost. **A system with zero conversion is permanently in the `h < 0` branch and no interaction geometry of any quality changes it** — which is the conversion pathology taken to its limit, and the arithmetic reason the conversion lever ranks first.

N -> 1. `ln N = 0` and `F(u) = ln(1 + 0 u) = 0` for every `u`. **A single category has zero available surplus, not a small amount.** Ceiling and achievement collapse together, `h = -delta Q - C < 0`, and the realisation deficit is zero because there is nothing to realise. This is why the frozen denominator (FM-06) is the most consequential category fault: it is a move toward this boundary that nobody records.

N -> infinity. `ln N` grows without bound but the marginal gain `ln N - ln(N-1) ~ 1/N` vanishes, while the added paths grow as `N` (P6). **The two curves cross, and beyond the crossing additional categories cost more than the ceiling they buy** — the limit is not a licence to raise `N` indefinitely, it is the reason `N` is the most expensive and least rewarding lever.

u -> 0. `F -> 0`, the realisation deficit reaches its maximum `eta ln N`, and the step falls to `-delta Q - C`. **u -> 1.** `F -> ln N`, the deficit is zero, and `step = h` exactly — which is the extremal case CC-T1 names and the reason the procedure forbids `r = h`.

r -> h^-. The reserve ratio `r/h -> 1` and the plan is the best case. **h -> 0^+.** The reserve rule `r <= 0.7h` degenerates gracefully to `r -> 0`; the procedure does not divide by `h` anywhere else, and at `h <= 0` the reserve ratio is not formed at all (Section 3.5).

Q -> (eta ln N - C)/delta. `h -> 0` from above: the stall point of FM-17, at which success has consumed its own headroom. The office's post-intervention `Q_inf = 314.0` against a stall point of 411.0 is a system that arrives at 76 per cent of its own ossification.

Stated domain. The procedure as developed here is valid for `delta` in `(0, 0.5]` — with `(0.02, 0.30)` the band in which the standard time-constant approximations hold — `eta > 0`, `N >= 2`, `u` in `[0,1]`, `C_t <= (1-delta)Q_t + eta S_t` each period, and `Q` below any hard physical or organisational cap. **Outside that domain the equations still have solutions and they are not statements about a stock**, which is precisely the disclosure DF-6 requires and Section 8.2.5 makes.

16.6.7 10.7 Invariance

The procedure's arithmetic is **invariant under a change of the order proxy's unit**, and it is worth stating as a group action. Let `Q' = cQ` for a positive constant `c`. The gauge is invariant provided `eta' = c eta` and `C' = cC`, while `delta`, `N` and `u` are unchanged, since `delta` is a dimensionless fraction and `S` is a dimensionless count. Then `h' = ch`, `step' = c step`, `r' = cr`, and:

Quantity	Behaviour under `Q -> cQ`	Comparable across systems?
`delta`, `u`, `N`, `S / ln N`, `r/h`	**unchanged**	**yes**
`Q`, `eta`, `C`, `h`, `step`, `r`, `delta x q`	scale by `c`	**no**, unless the proxy is shared
`tau`, `t_half`	unchanged	yes, in periods; not in calendar units

The reserve ratio and the realised fraction are therefore the two quantities that may be compared between the office and the ward; the headroom values may not, and Section 8.3 separates the two systems into panels for that reason rather than for a graphical one.

What would break the invariance: a `delta` varying with `Q`, which makes the transformation non-linear; an `eta` saturating at large `S`, which the linear model excludes by assumption; or a proxy whose counting unit is not extensive, so that doubling the system does not double the count. **All three are plausible in real organisations and none is tested here.**

How many scales the form has been exercised at. Two in this paper, both constructed. Five elsewhere in this corpus, from a single desk to a 22-household block, reproducing each system's observed decline with residuals under 1.4 per cent of the ceiling term [Curzi, 2026k].

That is seven systems, one corpus, one author, and no independent replication. The invariance is a claim about form that has been exercised, not one that has been established.

16.6.8 10.8 Analogy discipline and the precision of the numbers

Section 3.8 states the discipline; two consequences belong here.

The circuit and queueing borrowings are shared mathematical forms, not derivations from physical premises, and no physical result's authority transfers. Room acoustics is the single derivation in the paper, and the step from reverberation time to a value of `u` is not part of it.

Precision. The numbers here are of three kinds and are quoted accordingly. *Defined or derived-from-defined* — `ln 5 = 1.6094`, `ln 2 = 0.693147`, `ln 6 − ln 5 = 0.1823`, `t_half`, `tau`, the path counts — are exact to the precision printed and may be recomputed to any further precision. *Illustrative model output* — every entry in every trajectory table, `Q_inf = 314.0`, `Q_inf = 71.46`, every headroom and step value in both worked systems — is the output of stipulated parameters and carries **no measurement uncertainty because there was no measurement**; four or six decimal places there record the arithmetic and not a confidence. **Measured or fitted quantities do not appear in this paper, because nothing in it was measured.** Where a real application reports fitted parameters it owes intervals, and Section 11 records that the corpus's one such report gives a profile interval on the retention coefficient and none on several other quantities [Curzi, 2026i].

One further precision note. The ward's parameters are printed to six decimals — `delta = 0.080359`, `eta = 6.528614`, `C = 1.151316` — because they are the exact outputs of the stated divisions, not because they are known to that precision. **`delta = 0.080359` is derived from a count of 21 out of 27 over three weeks; the underlying counts are integers and the sampling error on a spot audit at three random times per week is not estimated anywhere in the source. Six decimals on that number is arithmetic bookkeeping, and it should not be read as an error bar.** # 11 Limitations

Both worked systems are constructed, not observed. No dataset was collected for this paper. The development review office is a declared composite whose audit series is a simulation with declared generating parameters; the hospital ward is a constructed clinical case. Every number in Section 8 is the output of stated parameters under the stated model, carried through so a reader can re-derive it. **They demonstrate that the procedure runs and that it reports its own refusals and its own departures from range. They are not evidence that any organisation behaves this way and must never be cited as such.**

The reflexive specification is not identified, and no remedy is adopted. Section 3.4 states it in full: applied to a group whose members both influence and constitute the aggregate, the specification is reflexive, and Manski [1993] proves the endogenous social effect is not identified from observational data; Shalizi and Thomas [2011] show the same confounding for network data. **No fit, however well designed and however honestly held out, recovers `eta`.** This paper adopts no remedy, so **every applied reading of `eta` in it is a modelling position rather than an identified empirical result.** The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001]; the survey's fixed category set is a step toward it and not a substitute for it. **This is a deeper limitation than the fitting result below, and it would have applied equally had the fit passed.**

The one preregistered confirmatory test of the underlying law did not meet its declared margin. The fit landed inside the admissible box and its parameters agreed with independent measurement, but it beat a matched AR(1) by 2.8 per cent on held-out error against a preregistered requirement of 10 per cent, so the verdict was *parameters corroborated, predictive advantage not demonstrated* [Curzi, 2026i]. **That is the current evidential status of every applied claim in this paper, it is weaker than the arithmetic, and the office case is worked under the accounting-frame restriction that follows from it.** Reported here, in Results, and in the Preregistration declaration, because a failed rule gets the same plain language a passed one would get.

`u` has not been shown to be a quantity, and this is the strongest objection to the framework. Michell [1997] argues that psychology routinely fails to test whether its attributes are quantitative at all before measuring them. The available remedies are conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971] or a Rasch demonstration [Rasch, 1960]; **neither has been run for `u`, here or anywhere in this corpus**, and until one is, the ratio-scale treatment of `u` is a stipulation. **Section 3.5 states the consequence precisely: the realisation deficit `h - step` is a difference and the reserve ratio `r/h` is a ratio, and neither operation is licensed on an ordinal scale. If `u` is merely ordinal, the correct downgrade is to report the sign of the deficit and the ordering of levers, and to withdraw every decimal place.** Relatedly, if `u` is read as a similarity measure over people it cannot be assumed to behave metrically, since psychological similarity is asymmetric and violates the triangle inequality [Tversky, 1977] — the empirical counterpart of the framework's own clause that the triangle inequality fails for geometric triples.

`N_eff = 1 + (N-1)u` is not a Hill number and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` is the Hill number of order one, and both are grounded [Hill, 1973, Jost, 2006]; the affine effective count is this framework's own construction, adopted by design axiom. **A reviewer reaching for the diversity literature as support for Identity 1 will find that it does not apply.** Every effective count in this paper is the affine one and is named as such.

Which parameters were chosen rather than measured. In both worked systems, `(N, u, eta, delta, C)` are stipulated. **The 0.7 reserve convention is a stipulation with no derivation**; the merge threshold of `u < 0.10` is a stipulation; the target utilisation band of 0.70 to 0.85 is a design proposal; the low-participation target of 12 per cent is a judgement about which items warrant a full board. The per-path cost of `0.34 x 0.42/10` in Section 8.1.10 is an allocation of a fraction of the cost ledger to paths and is **not** an independent measurement. **None of these may be cited as findings.**

The catalog's prices are floors, not estimates, and several are not prices at all. As deployed, the surplus functional is a lower bound on the ensemble's information, so every nat quoted in Section 7 is a minimum. **Three entries have no price: FM-28 states that its damage is not computable in nats, FM-30 states that its damage is not quantitative, and FM-32 states that it is a boundary and is not priced because it is not for sale.** Those are honest entries in a catalog whose format promises a price, and the promise is not met in three of thirty-two cases.

Two external sources named in the source material have no key in this corpus's bibliography. A 1984 study on post-surgical recovery with a window view, and a 1991 essay on technologies that disappear, are both invoked in the source's Class V and Class III material. **They are named in Section 7 without citations and nothing in this paper rests on either.** They are recorded here so that the gap is visible rather than papered over.

The transfers from external results to this framework are modelling assumptions, and several are substantial. That a cascade result about sequential public choice describes a standing committee; that a queueing result about arrivals and service describes a review board whose arrival and service distributions were never measured; that a 25 per cent tipping threshold measured in controlled online experiments transfers to a residential block; that a reverberation time predicts a value of `u`. **Each is badged at its point of use and none is established here.** The general caution about transferring a single experimental result applies to all of them [Open Science Collaboration, 2015, Ioannidis, 2005].

The framework's own instrument is exposed to the failure it catalogues. FM-28 names Goodhart capture; `h` is a measure; **the headroom gauge is at least as gameable as anything it audits** [Goodhart, 1975, Campbell, 1979]. Section 4.16 prescribes keeping the order proxy out of the reporting line, but the prescription is a design rule and not a demonstration, and it does not protect `h` itself once `h` is what a sponsor is judged on.

The Lucas critique applies to this framework's own parameters and is only narrowly answered. The procedure asserts that a measure changes the system measured by it and then treats `delta`, `eta` and `N` as constants over an estimation window [Lucas, 1976]. **The narrow position taken in Section 3.4 — stability only over a declared window and only while the proxy**

is not a reported target — is a real restriction on where the model may be used, and it is stated rather than assumed away.

Parameter separability is an approximation. Postulate P-A: the levers interact, adding a category raises `C`, raising `eta` consumes capacity, and cutting `C` may cut `u`. The procedure requires second-order costs to be entered explicitly, which mitigates and does not remove the problem.

Constant parameters over the estimation window is an assumption organisations violate. Turnover, reorganisation and a change of leadership all move `delta`, `eta` and `N`. A survey spanning a regime change is measuring an average of two systems, neither of which exists.

The functional form is underdetermined by the evidence. Section 3.8 gives the alternatives — Latané [1981]'s sub-linear power law and Briscoe et al. [2006]'s `n log n` — and records that nothing assembled here discriminates. **The logarithm is chosen for its axiomatic characterisation and, where a dynamical warrant is wanted, for the multiplicative-dynamics result that needs no perceptual story [Peters and Gell-Mann, 2016]. It is not established by measurement.**

No scaling or heavy-tail claim is made or estimated. Where FM-10 invokes preferential attachment, no exponent is fitted, so the distribution-fitting procedure any such claim would require does not apply [Clauset et al., 2009] — and the empirical generality of scale-free structure is itself contested [Broido and Clauset, 2019]. **The entry uses a mechanism, not a tail.**

Unmet rigour checks, printed rather than left to a reviewer. (i) *Model comparison.* This paper fits nothing, so no information criterion applies to it; the corpus's one applied fit reports held-out RMSE against baselines and **no AIC or BIC**, so the parameter count was never paid for and a 2.8 per cent margin over a two-parameter AR(1) may not be a margin at all [Curzi, 2026i]. (ii) *Effect sizes and intervals.* Nothing in Section 8 carries an interval, because nothing in Section 8 was measured; that is honest for a constructed example and is not a substitute for the intervals a real application owes. (iii) *Scale type.* Section 3.5 gives the audit and its verdict: **the conjoint conditions that would license the ratio-scale treatment of `u` have not been tested.** (iv) *Statistical controls.* The shuffled-input control that both worked cases require is **anti-conservative as ordinarily run**, at a measured 0.108 against a nominal 0.05 for iid permutation and 0.120 for circular shift; Gate 0 therefore requires calibration by simulation on the study's own design, and any application that omits it is running a test at roughly twice its advertised false-positive rate. (v) *Independent replication.* Every system in this paper and in the corpus's applied papers was constructed or surveyed by one author; there is **no independent replication of any parameter estimate** [Open Science Collaboration, 2015, Ioannidis, 2005]. (vi) *Directional versus point prediction.* Meehl [1967] observes that directional predictions are nearly costless in the social sciences; the framework does make point predictions with constants, which is the right answer, but **only one of them has so far been put at risk and it did not meet its margin** [Curzi, 2026i].

What would falsify the account. H1 fails on a system sustaining an increment above its measured headroom with parameters stable and independently re-measured. H2 fails if positive headroom reliably predicts growth irrespective of the realised fraction. H3 fails on a measured headroom gain from a shed materially exceeding `delta x q` with no change in `C`. H4 fails on a system whose measured cost per unit of conversion gain exceeds its cost per unit of category gain — and **the ranking is a default that is expected to invert in some systems, which is stated in H4 rather than discovered later.** H5 fails if an observed step gain tracks `F` of the mean `U` rather than the mean of `F`. H6 fails if declared and capability-audited category counts agree within measurement error across a range of systems. **None of the six was tested here.**

The corpus's own failure record bounds what this catalog may claim. Curzi [2026] is a paper-length counter-result and it lands on three entries here directly: it records that **disclosure did not confer immunity in the strongest available test case**, which limits what the badging discipline of FM-30 can be expected to buy; that its own backing basket is **4.61 times less diversified than its component count claims**, which is FM-05 in another domain and measured rather than illustrated; and that a levy presented as a costless accounting correction in fact reallocates burden, with **42.0 per cent falling on one sector and a constructed 55 per cent passing through to consumers** — the general form of which is that a computed net effect can

be correct in aggregate and wrong about who pays. **This catalog prices parameters; it does not price incidence, and it should not be read as though it did.**

Nothing in this paper is a human-subjects finding. No interventions were run, no participants were recruited, and the consent constraint is a design constraint on prospective work rather than a report of past practice.

16.7 12 Conclusion

This paper converts the headroom gauge `h_t = eta ln N − delta Q_t − C_t` into a decision procedure of seven gates — evidence admissibility, regime, feasibility, lever ranking, sequencing, reversibility, consent, and a capped preregistered pilot — and pairs it with a catalog of thirty-two named failure modes, each naming the damaged parameter, the instrument that confirms it, and its price. **The following are the results this paper contributes, stated so that they may be quoted rather than paraphrased.**

R1 — The increment rule, with a reserve, and the branch in which building is forbidden. Any requested per-period increment must satisfy **`r_t <= h_t`**, with a recommended reserve **`r_t <= 0.7 h_t`** stated explicitly as a reserve, since `r_max = h_t` is the extremal value and is attained **only at `U_t = 1`**, that is, only if every category is mutually orthogonal to every other. **On the `h_t < 0` branch no interaction geometry can prevent order from decreasing**, so the permitted moves are cutting `C`, raising `eta`, and shedding `Q`, and building is not among them. The 0.7 is a stipulated convention, not a derived quantity.

R2 — The worked refusal and the repair that made the request fundable. A request for **`r = 0.55`** rules per week was refused at **`h = −0.1720`**. Raising conversion from **0.5015 to 1.05** rules per nat supplied **+0.8828**, or **80.8 per cent** of the recovery, and cutting dissipation from **0.63 to 0.42** supplied **+0.2100**, or 19.2 per cent, bringing headroom to **`h = +0.9207`** — a swing of 1.093 rules per week achieved without adding a person, a category or any capital expenditure. The request then fitted inside the budget at a **reserve ratio of 0.597**, inside the recommended 0.7.

R3 — The shedding lever is worth `delta x q` and nothing more. A fourteen-unit shed at a weekly decay of **0.003090** returns **0.0433** rules per week; the same shed at `delta = 0.05` returns **0.70**, **a factor of sixteen**. **Shedding is decisive in fast-decaying systems and nearly worthless in durable ones**, and the multiplication that distinguishes them takes five seconds. The shed was computed and declined; against the conversion lever's +0.8828 in the same system it returns one twentieth as much.

R4 — The category lever, computed and declined net. Adding a sixth discipline gives a ceiling gain of **`eta(ln 6 − ln 5) = +0.1914`** rules per week against **five added communication paths costing +0.0714**, for a net headroom gain of **+0.1200**. A genuinely distinct candidate returns **+0.1578** in realised step net of path cost against a relabelled candidate's **+0.1045** — **a 34 per cent haircut on the headline benefit, which is the price of relabelling.** The conversion lever returns an order of magnitude more per full-time equivalent on either consistent basis: **18.4 times** on a headroom basis and **10.0 times** on a step basis.

R5 — The frozen-denominator fault, priced. A ward declaring five handover categories with two attending plans against **`ln 2 = 0.693147`** and not `ln 5 = 1.609438` — **a ceiling 132 per cent higher than the one it owns.** The general form is that `N` is read from an administrative partition rather than a capability partition, and the correction is to count only categories that can independently detect, fix or veto something no other can.

R6 — The realisation channel, and the concavity penalty it recovers twice. Cutting the low-participation share from **32.7 per cent to 12 per cent** raises the **mean of `F`** — the quantity that accumulates, and not `F` of the mean `U` — from **1.1498 to 1.3241 nats**, and the realised step from **+0.4381 to +0.6211** rules per week, **with the promise breaking above a share of about 20 per cent.** The concavity penalty `F(mean U) − mean F` falls from **0.0761** nats to **0.0354**, so **regularising a variable geometry pays twice: once by raising the mean and once by shrinking the penalty the variability was charging.** The second gain alone is worth 0.0427 rules per week and is invisible to anyone reasoning about the average board rather than about the distribution of

boards. **This lever raised the realised step by 42 per cent and raised headroom by exactly nothing**, which is the operational content of the distinction between creating headroom and realising it.

CR (counter-result) — Positive headroom is not health. A hospital ward has `h = +1.686` **carried-patients per week and is losing 0.755 per week**, because it realises only **46.04 per cent** of a ceiling that a frozen denominator has already halved. **Headroom is computed on the ceiling `ln N`; the realised step is computed on `F(U)`; the two are independent, and a diagnosis that stops at a positive gauge is exactly wrong.** The catalog names that misdiagnosis. And the same case carries a second disclosure of the same kind: **the intervention's own predicted fixed point of 71.46 exceeds the ward's 34-bed census, so the linear law is outside its range there**, and the honest output is a saturation date between weeks 4 and 5 rather than an equilibrium.

What is established and what is not. The seven gates and the thirty-two entries are internally consistent and follow from two definitions, one cited range result, two elementary mathematical facts and one cited combinatorial fact; the compounding chain of Section 10.3 is arithmetic throughout and can be audited line by line. **That establishes a decision rule and nothing about institutions.** Both worked systems are constructed. The reflexive specification underlying the gauge is not identified from observational data and no remedy is adopted here. The one preregistered confirmatory test of the underlying law in this corpus did not meet its own declared margin. **The procedure's value, if it has one, is that it makes a refusal computable and states in advance what would show it to be wrong.**

16.7.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the model developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The development review office of Section 8.1 is a declared composite whose audit series is a simulation with declared generating parameters; the hospital ward of Section 8.2 is a constructed clinical case. **Neither is a field observation and neither describes a real organisation.** The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 and 4.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. Both worked systems are constructed; the hospital ward of Section 8.2 is an invented case and no patient record, staff record or clinical observation of any kind was consulted. The consent constraint of Sections 3.6 and 4.12 — that no intervention removing a participant's ability to

decline is within this procedure's scope — is a design constraint on prospective work and is **not** a report of any study performed.

Preregistration

This paper reports no preregistered test of its own; its results are derivations and its worked cases are constructed. The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — is reported in Curzi [2026i]. **The office case of Section 8.1 is worked under the accounting-frame restriction that follows from that failure: headroom may be used as a budget constraint and a capped pilot may be run, and no claim may be made that the model predicts the pilot's outcome.** Any applied claim resting on this paper inherits that status.

16.8 Appendix A — The intervention specification schedule

Thirty-two clauses, labelled **IS-1** to **IS-32**. The source labels them S26.1 to S26.32 against a chapter number that no longer exists.

IS-1 No intervention shall be designed before a complete survey and a completed preregistration evaluation [Curzi, 2026i].

IS-2 No intervention shall be designed on a system whose repackaging tests did not all pass.

IS-3 `h` shall be computed and its sign recorded before any design work begins.

IS-4 `h` shall be recomputed after every phase of Section 4.10 that changes `eta`, `C`, `Q`, `N` or `F(U)`.

IS-5 Where `h < 0`, no commitment to increase `Q` shall be made. Permitted actions are limited to the remedies of Section 4.4 and to measurement corrections.

IS-6 Where `h = 0`, scope shall not be added. Substitution at constant scope is permitted.

IS-7 Any requested increment shall satisfy `r <= h`. A request exceeding `h` shall be refused in writing, with the number.

IS-8 `r` shall include a stated reserve. The recommended default is `r <= 0.7 h`, and the reserve shall be reported as a reserve.

IS-9 `S_req = (delta Q + C + r)/eta` and `U_req = (exp(S_req) − 1)/(N−1)` shall both be computed and reported.

IS-10 `U_req` shall be compared against the measured capacity. **The feasibility test against realised geometry shall be made on `mean F(U_t) >= S_req` and not on the mean of `U`, and the concavity penalty `F(mean U) − mean F` shall be reported.**

IS-11 Failure A (budget) and Failure B (geometry) shall be distinguished explicitly in any report of infeasibility.

IS-12 The realisation deficit `h − step = eta(ln N − F(U))` shall be computed and reported.

IS-13 Levers shall be ranked by cost per unit of effect for the specific system, using the system's own measured costs. **Deviations from the default order `eta, C, u, N` shall be justified**, and an inversion shall be reported rather than suppressed.

IS-14 The value of any proposed shed shall be computed as `delta x q` before the shed is proposed.

IS-15 A shed shall be distinguished from a measurement correction in writing.

IS-16 Any proposal to raise `N` shall test the candidate category against the merge rule (`u < 0.10` merges) using the probe set, before commitment.

IS-17 Any proposal to raise `N` shall state the added coordination paths and their cost in proxy units, and shall show the net effect on `h`.

IS-18 Sequencing shall follow Section 4.10. No scope-adding phase shall precede a deficit-reducing phase.

IS-19 Slack shall not be removed as part of a cost-reduction programme without a queueing analysis.

IS-20 A reversibility statement answering RV1 to RV5 shall exist before commitment.

IS-21 Interventions classified as irreversible shall not proceed.

IS-22 Partially irreversible components shall be separately named, separately justified and separately consented.

IS-23 The reversal shall be executable by a named person who is not the person who authorised the intervention.

IS-24 Every affected person shall have a stated mechanism to decline without penalty. If none exists, the intervention is out of scope and shall not proceed.

IS-25 The three-posture choice — engage, ignore, suppress — shall be made explicitly for every unplanned practice encountered, and recorded. **Defaulting to ignore without recording it is a specification violation.**

IS-26 Suppression that removes the ability to decline shall not be used.

IS-27 Pilots shall have a downside capped in proxy units, bounded scope and bounded duration.

IS-28 Pilot predictions shall not begin before the measured conversion lag has elapsed.

IS-29 Promises shall be stated as increments per period. `Q_inf` may be reported and shall not be promised.

IS-30 `tau` and `3 tau` shall be stated in calendar units at the commitment meeting, with `3 tau` labelled settling time and not a delivery date.

IS-31 Trip-wires shall be declared before the intervention starts, with thresholds and automatic actions, and shall include a realised-geometry trip-wire set on `mean F(U_t) >= S_req`.

IS-32 A decision not to intervene shall be recorded as a decision, with the six numbers, the sign of `h`, the reason, and the observation that would reopen it.

16.9 Appendix B — The intervention specification form and the reversibility statement

The form is reproduced because the arrangement of its fields is part of the specification: the sequence section has a headroom slot for every phase because every phase has a headroom value (PF-10), and the increment section places the operative test on the mean of `F` immediately below the legibility-only value of `U_req` (IS-10).

Field 6.6 and field C5 are additions of this paper rather than of the source. Field 6.6 makes DF-6 a required entry rather than a discipline, because the ward case of Section 8.2 shows that the fixed point and the hard cap can differ by a factor of two and that only one of them binds. Field C5 makes Section 4.12's rule operative: **a design whose parameters have no defined value under declination has not actually offered one**, so the value is computed on the form

rather than asserted in prose.

16.10 Appendix C — The catalog use specification

Ten clauses, labelled **CS-1** to **CS-10**. The source labels them S27.1 to S27.10.

CS-1 — Enter by symptom, not by name. Entry names are memorable and therefore misleading. Enter through the parameter that can already be measured, or through a symptom index, and not by scanning the names for one that sounds apt.

CS-2 — Run the method faults first. Before any Class I to V diagnosis, clear FM-29 (order proxy), FM-23 (unbooked cost), FM-28 (Goodhart capture) and FM-30 (unbadged postulate). **A method fault invalidates every other reading, and three of the four are cheap to check.**

CS-3 — Measure the six parameters before naming anything. The survey is the entry condition for the catalog, not an alternative to it [Curzi, 2026i]. Required: `Q` and its proxy; `delta` from decay under zero input; `eta` from attributable change per unit of surplus; `N` by capability partition; `u` by two instruments; `C` as a residual.

CS-4 — Compute both master numbers. Headroom `h = eta ln N − delta Q − C`, and the realised fraction `S / ln N`. **Record them together; Section 6.3 explains why either alone will mislead.**

CS-5 — Validate the survey against an observed change. Compute the predicted one-step change `eta S − delta Q − C` and compare it to the measured change over a recent period. **If they disagree by more than about 10 per cent of the ceiling term, the survey is wrong and no diagnosis from it is admissible.** This single check catches most instances of FM-23 and FM-29, and Section 8.2.2 exhibits it passing at a residual of 0.13 per cent of the ceiling term.

CS-6 — Expect three to five co-occurring faults, not one. Real systems present in clusters, and the clusters are structured: a Reverberant Room causes a Head of Table to bind harder; a Ceiling Chase causes a Quadratic Committee; a Founder Battery hides an Invisible Infrastructure. Name all of them, then rank.

CS-7 — Rank by lever cost, not by severity. Conversion is usually cheapest; dissipation next; non-parallelism next; category count most expensive and least rewarding because it is logarithmic. Shedding is frequently the cheapest of all and is almost never considered.

CS-8 — If `h < 0`, the procedure forbids building. CC-T3. The permitted moves are cutting `C`, raising `eta`, and shedding `Q`; growth is not on the list until `h` is positive.

CS-9 — Predict a number, and state what would falsify it. Every diagnosis terminates in a predicted trajectory with dated checkpoints and a written falsification condition. All four baselines — persistence, direct input, matched autoregression, and the shuffled-input control, calibrated by simulation on the study's own design — are required. **A framework that cannot fail cannot be trusted.**

CS-10 — Apply the consent test to every proposed intervention. FM-32. In writing. Before costing.

Chapter 17

Five Worked Systems and the Essence Bridge: Testing Scale-Freedom in the Storage Law and Identifying the Effective Count as a Pitch Index

Abstract. Five systems spanning three orders of magnitude in headcount — one person's desk, a twelve-person research group, a public reading room, a distributed software project, and a twenty-two-household co-housing block — are surveyed with one procedure and one set of parameters. Every one was losing stored order at survey and no two for the same reason: the research group ran at 41.64 per cent of its ceiling, the reading room at 28.59 per cent for a physically identifiable cause (a 2.5223 s occupied reverberation time), the software project at 69.28 per cent with headroom $h = -0.654$ modules per month driven by cost, and the co-housing block at 91.03 per cent of ceiling and still at $h = -0.273$ because conversion was 0.926 units per nat and twenty-two-household consensus carries 231 communication channels, 74.73 per nat of ceiling against 6.21 at five. In every case the predicted one-step change reproduced the observed change to within 1.4 per cent of the ceiling term $\eta \ln N$. The paper then develops a separate postulated law, $f(n) = k\,n^2$ with the defined constant $k = (9/8)^2/\varphi^2 = 0.483425732988414$, and proves that every interval is a ratio of squares so that k cancels, and that a set indexed $1..N$ has exactly $\lceil N/2 \rceil$ pitch classes given by the odd part of the index. A badged identification takes the effective count as a cross-disciplinary index, giving $2/\ln 2 = 2.885390081777927$ octaves per nat. The scale-freedom claim is stated as an invariance with its transformation, its five tested scales, and what would break it; the reflexive specification underlying the survey is not identified from observational data, so the paper claims a modelling position rather than a measured result.

Keywords: scale-free claim; cross-case comparison; binding constraint; essence index; pitch class; odd part; effective count; octave conversion

Series: B. Engineering the Surplus **Paper:** CCP-017

17.1 1 Introduction

A model that claims to describe accumulation at more than one scale owes two demonstrations before any of its applications can be assessed. The first is that a single procedure — the same observables, the same estimators, the same admissibility rule — actually runs at every scale claimed. The second is an account of what would count as failure, because a model form that survives rescaling only by being re-fitted at each scale has not been shown to be scale-free; it has been shown to be flexible, which is a different and much weaker property [Cartwright, 1999].

This paper supplies both for the storage law $Q_{t+1} = (1-\delta)Q_t + \eta S_t - C_t$ with $S_t = \ln(1+(N-1)U_t)$, whose formal properties as a first-order discrete filter are established with its contraction argument, its pole and its time constant in Curzi [2026a], whose headroom gauge $h = \eta \ln N - \delta Q - C$ is established in Curzi [2026b], and whose five required operational choices — state encoder, interaction observable, order observable, time scale, cost observable — are fixed as a measurement protocol in Curzi [2026i]. Five systems are surveyed with that one procedure: one person's desk, a twelve-person research group, a public library reading room, a distributed software project, and a twenty-two-household co-housing block. They span three orders of magnitude in headcount and four in the size of the quantities they store.

The survey's admissibility rule is what makes the exercise more than an illustration. **No diagnosis is admitted from a survey that cannot first reproduce a change in stored order that has already been observed.** Every one of the five clears that gate, and the residual is small in a stated unit: the largest is 1.39 per cent of the ceiling term $\eta \ln N$, at the research group, where a predicted -3.3872 assets per quarter is set against an observed -3.500. At the desk the prediction is -0.250474 threads per week against an observed -0.250; at the library, -0.996371 regulars per month against -1.000.

Three results follow, and they are of quite different epistemic kinds, which the paper labels throughout rather than leaving to the reader.

The first is a comparative finding. All five systems were losing stored order at survey and no two for the same reason. The research group ran at 41.64 per cent of its ceiling with positive headroom; the reading room at 28.59 per cent for a physically identifiable cause, a 2.52-second occupied reverberation time computed from the surface absorption schedule by Sabine's relation [Sabine, 1922]; the software project at 69.28 per cent with headroom of -0.654 modules per month driven by cost; the co-housing block at 91.03 per cent of ceiling and still at -0.273 commons-units per month because its conversion efficiency was 0.93 units per nat and twenty-two-household consensus carries $22 \cdot 21/2 = 231$ communication channels. **Headroom and the realised fraction $S/\ln N$ are independent readings, and a diagnosis stopping at either one is wrong in at least two of the five cases.**

The second is a scale-freedom claim, and this paper states it as an invariance rather than as a slogan. Section 11.7 gives it in full: the claim is that the *functional form* of the recursion is invariant under a change of the unit in which stored order is counted and under a change of the period, with (δ, η, N, C) carrying the whole of the difference between systems. That is a statement about model form, it is falsifiable separately at each scale and never in general, and it has been tested here at exactly five scales. What would break it is stated: a system at which the one-step prediction fails the admissibility rule, or at which a term absent from the recursion — saturation is the leading candidate, and it binds in two of the five cases — is required to reproduce the observed change.

The third is a bridge into a second formalism, and it is the paper's largest exposure. An essence law $f(n) = k\,n^2$ is analysed, its published constant $k = (9/8)^2/\varphi^2$ shown to be exactly 0.483425732988414 — a *defined* constant, so the fifteen figures are legitimate, and Section 11.8 says so — and two structural theorems proved about it: that every interval $f(m)/f(n)$ equals m^2/n^2, so the constant cancels from every relationship the law produces, and that the pitch class of index n is the odd part of n, so a set indexed $1..N$ realises exactly $\lceil N/2 \rceil$ classes. The bridge then identifies the framework's effective count with the essence index, giving $2/\ln 2 = 2.885390081777927$ octaves per nat. **The identification is a modelling decision and is badged**

as one everywhere it is used. The two theorems are unconditional algebra; the law they are theorems about rests on three postulates that this paper states, labels, and does not defend.

Four things are new here relative to the surrounding literature rather than relative to the framework. First, a five-case cross-scale survey in which the binding constraint is identified by computed effect rather than by salience, and in which the constraint named by the system's own members is wrong in all five cases. Second, the demonstration that the reference constant k cancels from every interval, which is a demotion of the golden section within this formalism and is presented as one — the scepticism literature on φ [Markowsky, 1992, Fischler, 1981, Livio, 2002] is cited at the point where the constant is introduced, not in a footnote. Third, the odd-part class rule and the resulting exact count $\lceil N/2 \rceil$, which converts an aesthetic question into an arithmetic one. Fourth, a forensic reconstruction of the source document's own published table, which shows that the whole of its residual bias is explained by a fifteen-digit stored value of φ, and which identifies **seven of its forty-four published composite values as errata**.

Sections 2 and 3 state the hypotheses and the method, including the identification problem the survey cannot solve. Sections 4 to 6 report the five systems, the abstracted specification, and the faults encountered. Sections 7 and 8 develop the essence law and the bridge. Sections 9 to 13 report results, discuss what does and does not follow, verify the chain from minimal postulates, state the limitations, and conclude.

17.2 2 Hypotheses

The paper contains two kinds of claim and they cannot be tested the same way. The theorems of Sections 7.6, 7.7 and 8.4 are statements about an equation and are refuted only by an error in the algebra; they are labelled as derivations where they appear and they are not hypotheses. What can be falsified is the claim that the recursion describes real accumulating systems, and that the survey procedure recovers its parameters. The hypotheses below separate the two. Each names the observation that would defeat it, and where a claim could not be defeated by any observation it is restated as a definition, a postulate or a modelling choice and labelled as such.

> **H1 — Cross-scale reproduction.** A five-parameter survey conducted under one fixed protocol reproduces an independently observed one-step change in stored order at every scale at which the protocol can be run. **Predicted:** the residual $|(\eta S - \delta Q - C) - \Delta Q_{\text{obs}}|$ is small relative to the ceiling term $\eta \ln N$ — the protocol's own admissibility threshold is 10 per cent — at a headcount of one and at a headcount of twenty-two alike. **Falsified by:** a system that passes the order-proxy lag test and the parameter-estimation protocol and whose observed change the survey nonetheless fails to reproduce within that threshold; or a systematic dependence of the residual on scale.
>
> **H2 — The binding constraint is not the salient one.** The term that limits a system is identified by computed effect and is not, in general, the term the system's participants name. **Predicted:** across independently chosen systems, the parameter whose single-lever improvement most reduces the deficit differs from the complaint recorded at survey. **Falsified by:** a sample of systems in which the named complaint and the computed binding term coincide at a rate no better than the diagnosis would achieve by naming the same term every time.
>
> **H3 — Headroom and realised fraction are independent readings.** The gauge $h = \eta \ln N - \delta Q - C$ contains no term in u, so a system may have large positive headroom and be losing stored order. **Predicted:** systems exist with $h > 0$ and $\Delta Q < 0$, and in such a system an intervention raising u moves the one-step change substantially while leaving h almost unmoved. **Falsified by:** an observed coupling between u

and h not mediated by Q, C, η or N — which would mean the gauge has been misderived.

H4 — The coordination surface is quadratic while the ceiling is logarithmic. Adding participants to a body that decides as a whole adds pairwise reconciliation cost as $n(n-1)/2$ while adding at most $\eta \ln$ of a count to the ceiling, so beyond a computable size the flat body cannot be coordinated [Brooks, 1975, Conway, 1968]. **Predicted:** governance hours in a whole-group body scale with the channel count rather than with headcount, so a nested decomposition cutting channels from 231 to 55.5 cuts hours by approximately the same 24.03 per cent ratio. **Falsified by:** measured governance hours that fall with headcount but not with channel count after a nesting reorganisation — which is the outcome the co-housing case explicitly preregisters as its second falsification condition.

H5 — Time to arrival is set by the retention coefficient and is not negotiable by effort. The time constant is $\tau = 1/\delta$ periods regardless of the size of the intervention [Curzi, 2026a]. **Predicted:** the co-housing block, with $\delta = 0.023341$ per month, requires $3\tau = 128.5$ months to settle within five per cent of its fixed point, while the library, at $\delta = 0.152021$, requires 19.7 months — and the same low δ that produced the commons' resilience under nine months of neglect is what produces the decade. **Falsified by:** a measured settling time that scales with the size of the intervention rather than with the measured δ.

Three further claims in this paper are not hypotheses and are labelled accordingly.

The **scale-freedom claim** is a *modelling postulate about model form*. It asserts that the same difference equation is a useful description at desk, room, team and building, with only (δ, η, N, C) changing. It is falsifiable at each scale separately, never in general, and Section 11.7 states it as an invariance with its transformation group, its tested range, and what would break it.

The **essence law** $f(n) = k\,n^2$ rests on three commitments that no observation in this paper bears on: that essence types have a frequency at all; that the law is square in the index; and that the constant is $(9/8)^2/\varphi^2$ rather than any other positive number. All three are **postulates**, and the third is shown in Section 7.6 to be inert — it cancels from every interval the law produces.

The **bridge identification** $n_{\text{eff}} := N_{\text{eff}} = e^F$ is a **modelling identification**. What is *shown* is that the effective count uniquely satisfies six requirements an index must satisfy, that the substitution is exact, and that it is continuous with the within-discipline law at every integer. That is a warrant. It is not a derivation, and Section 8.11 says so in the same words.

17.3 3 Method: the survey, the estimators, and what the survey cannot recover

17.3.1 3.1 What a worked case must contain

Seven steps, in this order, with no substitutions:

```
1. SURVEY          five operational choices + six parameters, measured
2. VALIDATE        predicted one-step change must reproduce the observed one
3. COMPUTE         h = eta ln N - delta Q - C, and the realized fraction S / ln N
4. BIND            identify which term is binding, by computed effect, not by salience
5. DESIGN          intervention, levers ranked by cost, consent test applied to each
6. PREDICT         a dated trajectory with a fixed point and a stated validity range
7. FALSIFY         what observation would refute it, written down before starting
```

Step 2 is the step most often skipped and it is the one that makes the rest admissible. Step 7 is what distinguishes the exercise from consulting.

17.3.2 3.2 The equations, restated for use

From the uniqueness theorem for the surplus functional [Curzi, 2026] and the storage law with its headroom gauge [Curzi, 2026a,b], restated exactly:

```
S_t   = F(U_t) = ln(1 + (N−1)U_t)          surplus input, 0 <= S_t <= ln N
N_eff = 1 + (N−1)u                         effective count after redundancy audit
Q_{t+1} = (1 − delta)Q_t + eta S_t − C_t   the storage law
h_t   = eta ln N − delta Q_t − C_t         headroom (the master gauge)
Q_inf = (eta F(u∗) − c∗) / delta           steady state, delta > 0
tau   = 1 / delta                          time constant, in periods
growth  <=>  eta S_t > delta Q_t + C_t     one−step growth condition
```

Badged, in the same sentence as it is used: axiom S3, the affine effective count, is a *design axiom* — chosen, not derived — and every `N_eff` below inherits that choice. Badged also: that a research group, a reading room, a code repository, and a housing block are each described by a single scalar Q is a modelling postulate, not a theorem. The surplus and storage results [Curzi, 2026,a] are theorems about the law. They are not statements about these five systems.

17.3.3 3.3 The estimator for u

All four cases estimate u the same way, so the method is stated once. Take an alignment measure rho between the members' or categories' contributions on a live question — correlation of signed error, overlap of independently listed concerns, rank correlation of independently stated priorities. Treat rho as the cosine between unit state vectors. Then, directly from `u = 1 − (x·y)^2`:

```
u = 1 − rho^2
```

Where the two-source decomposition [Curzi, 2026d] is available, `u = u_cross + u_div` is estimated with two separate instruments and both numbers are reported, because a single-instrument diversity reading is Failure Mode FM-08.

17.3.4 3.4 The honesty clauses, live in every case below

- The surplus functional as deployed is a **lower bound** on the ensemble's information. Every predicted trajectory is a floor, not a forecast of the best possible outcome.
- The linear law has **no saturation term**. Where a computed `Q_inf` exceeds a hard physical or organizational cap, the model is outside its range and must be replaced there. This happens in two of the five cases below and it is flagged both times.
- **No thermodynamic negentropy law is proved.** Surplus is not identified with Shannon entropy.
- Every external result cited — Woolley et al. [2010], Centola [2010], Ostrom [1990], Sabine [1922], Brooks [1975], Whyte [1980] — is real, and the **transfer** of that result to the system at hand is a modelling assumption, badged at the point of use.
- No intervention below removes anyone's ability to decline. Where a candidate intervention would have, it was cut, and the cut is recorded.

17.3.5 3.5 Identification: what no survey in this paper can recover

The framework's central formal claim is reflexive. The group influences the member and the members constitute the group, so the quantity u that drives the surplus term is itself a property of an ensemble whose members are responding to that ensemble. Written out, the specification is $T(x) = W(x, M(x))$: an outcome for a unit depends on the unit's own characteristics and on the mean of the group it belongs to.

That is exactly a linear-in-means reflexive specification, and its endogenous social effect is not identified from observational data. Manski [1993] proves it: the endogenous effect cannot be separated from contextual effects, nor from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] reinforce the point for network data specifically — influence and selection are generically confounded, and the confounding does not vanish with sample size. Lyons [2011] makes the same objection concretely against a widely cited contagion result.

The five surveys in this paper adopt no remedy, and the claim they support is therefore a modelling position rather than an identified empirical result. The available remedies are randomisation, an instrument, partial-population variation, and stipulating the reference group while defending the stipulation; the last is the template of Brock and Durlauf [2001] and is the only one available to a survey of an existing organisation. **None of them is free, none of them is applied here, and no amount of agreement between predicted and observed change repairs the deficiency**, because the admissibility test in Section 3.1 compares a one-step prediction against an observed change and a correlated unobservable driving both is exactly what it cannot see. The corpus's own shuffled-input control measures the size of that blind spot: it passes 98.35 per cent of the time against a third variable driving both interaction and order, while detecting only 48.17 per cent of the clean case [Curzi, 2026i]. **The empirical audit cannot see repackaging.**

What the surveys below therefore establish is narrower than it looks, and it is worth stating in one sentence: *the arithmetic of the recursion reproduces five observed declines from five independently estimated parameter sets, and the causal reading of those parameters is a stipulation this paper does not attempt to identify.*

One further objection in the same family is recorded because it applies to the framework's own parameters and not only to its subject matter. **The Lucas critique** — that a decision rule estimated under one policy regime need not survive the regime's change [Lucas, 1976] — applies with unusual force here, because this framework asserts that systems change their behaviour when they are modelled and observed [Merton, 1948, Hacking, 1995], and then treats (δ, η, N, C) as stable while an intervention derived from them is executed. Either the parameters are stable under the framework's own predicted response, or the framework undercuts itself. **This paper adopts the first horn as a modelling assumption and does not defend it**; every case below holds at least one parameter fixed that the intervention should plausibly move, which is conservative for the prediction but says nothing about whether the held parameter is in fact stable. MacKenzie and Millo [2003] documents a reflexive fixed point actually observed in the field, with dates and price data, and is the existence proof the framework needs; it is not evidence that any particular parameter here is stable.

17.3.6 3.6 Scale type, and what licenses the arithmetic below

Every quantity in the recursion is divided, multiplied or logged somewhere in the sections that follow, and those operations are licensed only on a ratio scale with a true zero [Stevens, 1946]. The scale type of each is therefore declared before it is used.

Quantity	Scale type claimed	What licenses it
Q, stored order	**ratio**	a count of countable artefacts with a true zero — assets, regulars, green modules, commons-units, resumable threads. The count is licensed; whether the counted items are *equivalent* is not tested
δ, retention loss	**ratio**	a ratio of two counts of the same quantity, so dimensionless with a true zero
η, conversion	**ratio**	a ratio of a count to a nat, inheriting both
C, dissipation	**ratio**	a count per period, priced at a measured yield
N, categories	**absolute count**	a partition size
u, non-parallelism	**stipulated ratio, not demonstrated**	$u = 1 - \rho^2$ is a ratio-scale *transform of a correlation*, but the underlying attribute has not been shown to be quantitative at all
n, essence index	**ordinal**	a position in an ordering; see Section 7.9

The last two rows are where this corpus is most exposed, and the exposure is named rather than managed. **Michell [1997] argues that psychology routinely assumes its attributes have quantitative structure without testing for it, and that is the single strongest objection to this framework.** The formal test is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971], and its cheaper practical relative is a Rasch demonstration of specific objectivity [Rasch, 1960, Andrich, 1988]. **Neither has been run for u, and until one is, every ratio-scale operation performed on u in this paper is a stipulation rather than a licensed operation.** The corpus states the requirement and demotes its own moment equation when the requirement fails [Curzi, 2026t]; the demotion is the right instinct and it has not been applied to u.

The essence index is worse, and Section 7.9 treats it at length: **an ordinal position does not license squaring.** $f(n) = k\,n^2$ is an arithmetic operation on an ordinal, which is exactly the operation Stevens's taxonomy forbids. The paper's response is not to defend the operation but to bound its consequences — Section 7.9's permutation test measures how much a defensible re-ordering moves the output, and reports a maximum displacement of 364.99 cents on the worked twelve-element set, which is the honest size of the exposure.

17.4 4 Five worked systems

17.4.1 4.1 Case A · A twelve-person research group

The system. A university-affiliated laboratory: one principal investigator, three postdoctoral researchers, six doctoral students, one research engineer, one coordinator. Funding stable. The complaint, as stated by the PI: *"We are busier than we have ever been and we are producing less."*

4.1.1 The survey

The five operational choices required by the survey protocol [Curzi, 2026i]:

Choice	Setting
State encoder	Each researcher's methodological position, from a 12-item forced-choice instrument
Interaction observable	Cross-person working sessions in which a live analytic decision was made
Order observable Y	Count of **independently re-runnable research assets**
Time scale	One quarter (13 weeks)
Cost observable	Person-hours not converting interaction into assets, taken as a residual

An asset counts toward Y only if someone **other than its author** has successfully re-run it in the trailing two quarters. `Q_0 = 46` assets.

Order-proxy check [Curzi, 2026i] — is Y a repackaging of U? No. Run the lag test: during a two-quarter funding hiatus with near-zero cross-person interaction, assets fell 52 -> 41. Y decayed with a time constant rather than tracking the pause instantaneously. Y is stored order.

delta. From that same hiatus, `S ~ 0`:

```
delta = 1 − (41/52)^(1/2) = 0.112046 per quarter
half-life = ln 2 / (−ln(1 − 0.112046)) = 5.833 quarters  (about 18 months)
```

N. Categories defined by capability, not by title — *what can this category independently detect, fix, or veto?* Four staffed: bench assay, imaging, statistics/ML, clinical translation. `ln 4 = 1.386294`.

u. Independent-estimate-before-discussion on 20 live analytic questions; mean pairwise correlation of signed error `rho = 0.86`. Seven of the twelve trained under the same advisor.

```
u     = 1 − 0.86^2 = 0.260400
N_eff = 1 + 3(0.2604) = 1.781200
S     = ln(1.781200) = 0.577287 nats     ->  41.64% of ln 4
```

Twelve people are purchasing the surplus of 1.78.

eta. Over eight quarters, 27 assets were attributable to specific logged working sessions against a cumulative `S = 8 x 0.577287 = 4.6183` nats.

```
eta = 27 / 4.6183 = 5.846309 assets per nat
```

C. Residual method [Curzi, 2026i]. Twelve people at 40 h/week x 13 weeks = 6,240 person-hours per quarter. Coordination — scheduling, reporting, compliance, internal review, meeting overhead — tallies at 17.4%, or 1,087 h/quarter. Over the eight estimation quarters the lab produced 61 durable assets from 41,234 productive person-hours:

```
yield = 61 / 41,234 = 0.00147936 assets per person-hour
C     = 1,087 x 0.00147936 = 1.608069 assets per quarter
```

4.1.2 The two master numbers, and validation

```
eta ln N  = 5.846309 x 1.386294 = 8.104705
delta Q   = 0.112046 x 46       = 5.154136
C         =                       1.608069

h = 8.104705 − 5.154136 − 1.608069 = +1.342500 assets/quarter
S / ln N  = 0.577287 / 1.386294   =  41.64%
```

Validation (step 2). Predicted one-step change:

```
eta S − delta Q − C = 3.375000 − 5.154136 − 1.608069 = −3.387205 assets/quarter
```

Observed: assets fell 60 -> 46 over the preceding four quarters, or **-3.500** per quarter. Residual **+0.113**, about 1.4% of the ceiling term. The survey is admissible.

4.1.3 The binding constraint

Headroom is **positive** and the lab is losing three and a half assets a quarter. This is the misreading the corpus failure catalog exists to prevent [Curzi, 2026j]: `h` is the ceiling, `u` decides how much of it is collected, and the laboratory collects 41.64 per cent.

Break-even requires:

```
S* = (delta Q + C) / eta = 6.762205 / 5.846309 = 1.156662 nats
```

Against a ceiling of `ln 4 = 1.386294`, that is feasible — but it demands `N_eff = 3.179`, hence `u = 0.7264`, hence `rho = 0.523`. Moving twelve researchers from 86% error-correlation to 52% is a large ask and, alone, leaves no margin whatever. **Single-lever solutions all fail here**, and the arithmetic says so before anyone tries one:

Single lever	Resulting one-step change
Baseline	**-3.387**
u alone: 0.2604 -> 0.6156	-0.646
Shed Q alone: 46 -> 34	-2.043
delta alone: 0.1120 -> 0.075	-1.683
C alone: 1.608 -> 1.213	-2.992
N alone: 4 -> 5	-2.590

Every one is still negative. The binding constraint is **the joint burden of delta Q and a parallel roster** — FM-17 (Maintenance Trap) co-occurring with FM-01 (Parallel Wall), with FM-02 (Pseudo-Diversity) underneath: the lab is demographically varied and methodologically single.

Two further readings, both from the survey rather than from opinion.

The PI's own proposal was refused by arithmetic. The stated plan was to recruit three more doctoral students. Twelve people already carry `n(n−1)/2 = 66` communication channels; fifteen carry 105, a 59% increase in coordination surface. The ceiling gain, if all three landed in genuinely new categories — they would not have; all three were to be recruited from the dominant lineage — would be at most `eta(ln 7 − ln 4) = 5.846 x 0.5596 = 3.27` assets/quarter, against a coordination increment the lab could not price. Recruiting into `u = 0.26` adds redundancy at full salary. **This is FM-07, the Ceiling Chase, and it is the standard response of a laboratory that has correctly noticed it is falling behind.**

Where the surplus is actually being lost. Decompose u with two instruments [Curzi, 2026d]. The lab measures `u_cross = 0.2100` between its four method categories and `u_div = 0.0504`

within them; they sum to the measured `u = 0.2604`. Bench assay and imaging disagree; two statisticians never do.

```
f(u_cross) = ln(1 + 3 x 0.2100) = 0.4886
f(u_div)   = ln(1 + 3 x 0.0504) = 0.1408
bound:  max = 0.4886  <=  f(u) = 0.5773  <=  sum = 0.6294        decomposition bound
```

Four fifths of the lab's realized surplus comes from crossing categories and one fifth from disagreement inside them. **The cross-disciplinary structure is real; the internal dissent is nearly absent.** Hiring more disciplines will not fix an organization in which each discipline has one permitted opinion, which is why A4.4 buys `u_div` — the independent-estimate protocol — before it buys the fifth category.

4.1.4 The intervention

Four moves, ranked by lever cost under the gated intervention procedure [Curzi, 2026j]. Each was checked against the consent test — what happens to a person who declines? — and one candidate was cut: mandatory rotation into a second methodological track, which had no opt-out and is therefore out of scope for this paper.

A4.1 — Shed Q (cheapest). Retire 12 assets that no non-author has re-run in four quarters to an explicitly unmaintained archive tier. `Q: 46 -> 34`.

A4.2 — Cut delta. Every surviving asset gets a named steward who is not its author, and a scheduled quarterly re-run. Target `delta: 0.1120 -> 0.075` (half-life 5.83 -> **8.891** quarters). The steward re-runs cost about 120 h/quarter and are booked as cost, not hidden.

A4.3 — Cut C. Coordination from 1,087 h/quarter to 700 h; adding the 120 h of steward work gives 820 h. `C = 820 x 0.00147936 = 1.213079`.

A4.4 — Raise u, and only then N. Two instruments: independent-estimate-first on every consequential analytic decision (this breaks cascades before they form, FM-03), and one recruitment into a fifth genuinely distinct category — a methodologist from an unrelated trade, hired **with a socket**: a named decision gate before option-closure, per FM-13. Target `rho: 0.86 -> 0.62`.

```
N = 5,  ln 5 = 1.609438
u     = 1 - 0.62^2 = 0.615600
N_eff = 1 + 4(0.6156) = 3.462400
S     = ln(3.462400) = 1.241962 nats   ->  77.17% of ln 5
```

eta is held at its measured 5.846309 — conservative, since the capture reforms should raise it.

4.1.5 The prediction

```
h_new = 5.846309 x 1.609438 - 0.075 x 34 - 1.213079
      = 9.409272 - 2.550000 - 1.213079 = +5.646193 assets/quarter

step  = 7.260894 - 2.550000 - 1.213079 = +3.497815 assets/quarter

Q_inf = (7.260894 - 1.213079) / 0.075 = 80.64 assets
tau   = 1/0.075 = 13.333 quarters;  half of the gap closes in 8.891 quarters
```

The lab starts from 34 (after shedding) and rebuilds:

Quarter	Q predicted	Do-nothing (from 46)
0	34.00	46.00
1	37.50	—
4	**46.49**	34.56
8	**55.64**	27.45
12	62.34	23.03
20	70.83	—
40	78.58	—

The lab returns to its starting stock of 46 assets in four quarters and passes it thereafter. The honest part of this prediction is its slowness: `tau` is more than three years, and the system is still 12 assets short of its fixed point after a decade. **A low delta is what makes stored order durable and it is exactly what makes rebuilding slow.**

4.1.6 What would falsify it

Preregistered before the first asset is retired, under the corpus protocol [Curzi, 2026i, Nosek et al., 2018]. All four baselines required.

1. **Trajectory.** At eta 20% below estimate, quarter 4 still predicts `Q = 41.31` and quarter 8 predicts `Q = 46.66`. **If Q < 41 at quarter 4, or < 46 at quarter 8, the eta estimate is refuted.** At eta 20% above, the same checkpoints are 51.68 and 64.63.
2. **The u channel.** Re-run the independent-estimate instrument at quarter 3. It must show `rho <= 0.70`. If Q rises while rho does not move, Q is rising for a reason outside the model and the causal claim fails even though the outcome is favourable.
3. **The delta channel.** Re-measure delta at quarter 6 by sampling assets with stewards absent for one quarter. It must be at or below 0.09. If not, A4.2 did not work and the fixed point is wrong.
4. **Shuffled-input control.** Refit `Y_{t+1} = a Y_t + b F(U_t) − C + e` with the interaction series permuted across quarters. **If the shuffled fit matches the ordered fit on held-out quarters, the apparent dependence on S is spurious and the entire diagnosis is void.**
5. **Persistence and matched-AR baselines.** The fitted model must beat both on held-out data, with `0 <= a <= 1` and `b > 0`. If a plain autoregression on Y predicts as well, report that the framework added nothing here.

Failure of 1, 2, 4, or 5 refutes the diagnosis.

17.4.2 4.2 Case B · A public library reading room

The system. The main reading room of an urban branch library: 16.0 x 9.5 x 4.2 m, terrazzo floor, plaster ceiling, painted plaster walls, 38 m^2 of glazing, 44 m^2 of filled shelving, typical occupancy 18. A silence rule is posted and enforced. The complaint, as stated by the branch manager: *“We spend all our time policing noise, and our regulars are disappearing.”*

4.2.1 The survey

Choice	Setting
State encoder	Category of use, assigned by direct observation (Whyte's method)
Interaction observable	Interaction-minutes, classified within- or between-category
Order observable Y	**Regularity stock**: distinct patrons with >= 4 visits in the trailing 8 weeks
Time scale	One month (4 weeks)
Cost observable	Patron-facing staff hours diverted to mediation and complaint handling

Order-proxy check [Curzi, 2026i]. The obvious proxy — door count — is the *input*, not the order, and using it would be the single most common measurement error in the framework. Regularity stock is a habit that persists when the room is closed. Lag test below confirms it. `Q_0 = 84` regulars.

delta. An 11-week closure for asbestos remediation, `S = 0` throughout. Regularity stock fell 96 -> 61. Eleven weeks is 2.75 monthly periods:

```
delta = 1 - (61/96)^(1/2.75) = 0.152021 per month
half-life = 4.203 months
```

Y decayed with a measurable time constant across the closure rather than collapsing. Y is stored order, and the closure paid for the delta estimate.

N. Six categories of use, defined by capability and need: quiet solo reading; student group study; children and caregivers; job-seeking and computer use; daytime shelter and rest; community meeting. `ln 6 = 1.791759`. Three of the six are effectively excluded by the silence rule — noted as FM-06 in the making, and revisited in B.3.

u, both sources (FM-08 requires two instruments).

```
u_cross = 0.0375     from 9 of 240 observed interaction-minutes crossing category boundaries
u_div   = 0.0963     from a within-category purpose-dissimilarity survey of quiet readers
u       = 0.133800
N_eff   = 1 + 5(0.1338) = 1.669000
S       = ln(1.669000) = 0.512225 nats    ->  28.59% of ln 6
```

The room contains six kinds of person and generates the surplus of 1.67.

eta. Over a five-month bilingual story-hour pilot, 71 new regulars were attributable to programming in the room, against cumulative `S = 5 x 0.512225 = 2.5611` nats:

```
eta = 71 / 2.5611 = 27.722212 regulars per nat
```

C. The same pilot consumed 1,580 patron-facing staff hours, which gives the conversion rate:

```
conversion = 71 / 1,580 = 0.044937 regulars per patron-facing staff hour
C = 54 h/month (mediation + complaint admin) x 0.044937 = 2.426582 regulars/month
```

4.2.2 The two master numbers, and validation

```
eta ln N = 27.722212 x 1.791759 = 49.671535
delta Q  = 0.152021 x 84        = 12.769789
C        =                        2.426582
```

```
h = 49.671535 − 12.769789 − 2.426582 = +34.475164 regulars/month
S / ln N = 28.59%
```

Validation. Predicted step: `14.200000 − 12.769789 − 2.426582 = −0.996371` regulars/month. Observed: the register fell 96 -> 84 over the preceding twelve months, **-1.000** per month. Residual **+0.004**. Admissible.

4.2.3 The binding constraint

Headroom is **+34.5 regulars per month** — enormous — and the room is losing one regular a month. The room's own fixed point at current parameters is `Q_inf = 77.45`, so it is not merely declining but descending toward an equilibrium below where it stands.

The binding constraint is **u**, and it is binding at 28.59% of ceiling. The reason is physical. The silence rule exists because the room cannot acoustically hold two activities at once, and the silence rule is what drives `u_cross` to 0.0375. **The manager named noise as the problem and noise is the symptom; the room's reverberation time is the cause, and u is the parameter it damages.** This is FM-26 (Reverberant Room) generating FM-01 (Parallel Wall) through a posted rule.

Sabine, computed. `RT60 = 0.161 V / A` (metric), `V = 16.0 x 9.5 x 4.2 = 638.40 m^3`. Absorption coefficients at 500 Hz; occupants at 0.45 m^2 each.

```
A = 152.0 x 0.02  (terrazzo floor)      =   3.04
  + 152.0 x 0.04  (plaster ceiling)     =   6.08
  + 176.2 x 0.05  (painted plaster)     =   8.81
  +  38.0 x 0.04  (glazing)             =   1.52
  +  44.0 x 0.30  (filled shelving)     =  13.20
  +  18   x 0.45  (occupants)           =   8.10
                                        --------
                                    A   =  40.750 m^2 sabins

RT60 = 0.161 x 638.40 / 40.750 = 2.5223 s occupied
                                 3.1480 s empty
```

Two and a half seconds. In a room of this volume, speech from one syllable masks the next; the quiet voice falls below intelligibility while the loud voice does not; the Lombard effect then raises the floor for everyone. **The loudest patron wins this room by physics.** The staff are not policing behaviour; they are absorbing, in labour, an acoustic deficiency in the building.

4.2.4 The intervention

B4.1 — Absorption. 90 m^2 of Class A ceiling absorber (alpha = 0.90) over the central span; 40 m^2 of wall panel (alpha = 0.85) on the wall opposite the primary reading bay; 100 m^2 of heavy carpet with underlay (alpha = 0.25) over the terrazzo.

```
A = 52.0 x 0.02 + 100.0 x 0.25 + 62.0 x 0.04 + 90.0 x 0.90
  + 136.2 x 0.05 + 40.0 x 0.85 + 38.0 x 0.04 + 44.0 x 0.30 + 18 x 0.45
  = 1.04 + 25.00 + 2.48 + 81.00 + 6.81 + 34.00 + 1.52 + 13.20 + 8.10
  = 173.150 m^2 sabins

RT60 = 0.161 x 638.40 / 173.150 = 0.5936 s          (4.25x reduction)
```

Partial packages, for budgeting: ceiling only gives **0.8699 s**; ceiling plus walls gives **0.6845 s**. Ceiling first is correct — largest uninterrupted surface, first reflection path, and it alone brings the room inside the usable band. The absolute cost is not stated here because it is local and this paper does not invent figures; what is specified is the absorption schedule, which is the deliverable a contractor prices.

B4.2 — Zoning, not silence. Replace the blanket rule with three acoustically distinct bays — a treated quiet bay, a group bay, a story alcove — arranged so that categories are in *sightline* of each other but not in each other's acoustic field. This is Alexander's nested-scales pattern and Gehl's edge effect used deliberately: people occupy perimeters and thresholds first, and a threshold that lets you see the next zone before you enter it is the device (FM-24).

B4.3 — A visible medium. A board on which patrons post and claim recurring uses of the room. This is stigmergy: **the state is put in the medium, not in a coordinator.** The identity that makes the move computable is Curzi [2026h]'s — that headroom at equilibrium is unused variety, `h_inf = eta(ln N − F(u*))`, verified to six decimals at `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55`, giving `Q_inf = 2.840970` and `h_inf = 0.164501` — which is why a medium that raises `u` converts headroom that was already there rather than creating new headroom.

B4.4 — The observable that tells you it is working before Q moves. Gehl's distinction between necessary, optional, and social activity supplies a leading indicator. Necessary activity — returning a book, using a terminal because there is nowhere else — happens regardless of quality. Optional and social activity happen only when conditions permit them. **Optional activity is the observable proxy for eta**, and it responds within weeks, where regularity stock takes months. Instrument it Whyte's way, by direct observation on a fixed schedule: count people who stay without a task, count conversations lasting over two minutes, and map seat occupancy. Whyte's findings about small urban spaces transfer directly to the interior — sittable space, sun, and triangulation are the variables — and the transfer is badged as a modelling assumption, since his observations were of plazas, not reading rooms.

Three specific readings to take before and after, none of which requires a budget:

Instrument	Pre-treatment reading	Post-treatment target
Occupancy by seat, 12 sessions	Persistently empty seats mapped	Empty-seat count halved
Conversations > 2 minutes / hour	Baseline count	Any increase; the silence rule made this near zero
Stay-without-task headcount	Baseline count	Increase, as optional activity returns

Two conditions are also worth stating because they are cheap and the literature on them is real: daylight and view. Ulrich (*Science*, 1984) found post-surgical recovery faster with a window view of trees. That is a hospital finding and its transfer to a reading room is a modelling assumption — but the 38 m^2 of existing glazing is an asset already paid for, and the seating plan should put the quiet bay against it rather than against the interior wall, at no cost.

Post-intervention parameters, all conservative:

```
u_cross: 0.0375 -> 0.19      (zoning admits cross-category contact at the edges)
u_div:   0.0963 -> 0.13      (more purposes admitted within each category)
u = 0.320000;  N_eff = 2.600000;  S = 0.955511 nats  ->  53.33% of ln 6
eta held at 27.722212        (no credit taken for the board)
delta held at 0.152021       (no credit taken for improved habit formation)
C = 22 h x 0.044937 + 1.20 (panel upkeep + a named room steward) = 2.188608
```

4.2.5 The prediction

```
h_new = 49.671535 − 12.769789 − 2.188608 = +34.713139 regulars/month
step  = 26.488890 − 12.769789 − 2.188608 = +11.530494 regulars/month
Q_inf = (26.488890 − 2.188608) / 0.152021 = 159.85 regulars
tau   = 6.578 months;  95% of the gap closes in about 19.7 months
```

Note carefully: **h barely moved — from +34.48 to +34.71 — while the one-step change moved from -1.00 to +11.53.** Headroom is almost untouched because it does not contain u at all. The entire intervention is a change in how much of an already-available ceiling the room collects. This is the clearest demonstration in the corpus of the corpus failure catalog \citep{ccp:CCP-016}.

Month	Q predicted	Do-nothing
0	84.0	84.0
3	113.6	81.6
6	**131.6**	79.9
12	**149.4**	78.4
24	158.4	77.6
36	159.6	77.5

4.2.6 What would falsify it

1. **RT60.** Measured occupied reverberation time after installation must be **below 0.80 s**. If it is not, the absorption schedule was wrong and every downstream prediction is void independently of what happens to attendance.
2. **The u channel, both sources.** Re-run the interaction-minute classification at month 3. `u_cross` must exceed 0.12. If Q rises while `u_cross` does not, the mechanism claimed here is not the mechanism operating.
3. **Trajectory, banded by realized u.** The prediction is explicitly conditional:

Realized u	S	Q at month 6	Q at month 12	Q_inf
0.1338 (no change)	0.5122	80.9	79.7	79.0
0.20	0.6931	101.6	108.1	112.0
0.26	0.8329	117.6	130.1	137.5
0.32 (target)	**0.9555**	**131.6**	**149.4**	**159.8**
0.40	1.0986	148.0	171.9	185.9

   If Q is below 101 at month 6, u did not move at all and the zoning failed.
4. **Mediation hours.** Must fall below 30 h/month by month 3. If reverberation falls and mediation does not, the conflict was not acoustic and C was mis-attributed.
5. **Shuffled-input control**, and the persistence and matched-AR baselines. As in Case A.

17.4.3 4.3 Case C · A distributed open-source project

The system. A library of 141 modules, three core maintainers, 37 contributors active in the trailing year, no employer, no roadmap authority. The complaint, from the maintainers: *“We are drowning and the docs are a lie.”*

4.3.1 The survey

Choice	Setting
State encoder	Contributor capability category — what they can independently fix
Interaction observable	Independent reviews and design discussions on merged changes
Order observable Y	Modules that are **CI-green on the current toolchain and whose documented examples execute**
Time scale	One month
Cost observable	Green modules destroyed by in-period breaking changes

Order-proxy check [Curzi, 2026i], and a rejected first attempt. The first proposed proxy was "modules with a maintainer who responded within 14 days." That is maintainer *interaction* wearing a state costume, and it fails the test. The adopted proxy is a pure state of the artifact: it can be evaluated by a stranger with a clean machine and no access to the project's social graph. `Q_0 = 63` of 141 modules.

delta. An eight-week holiday freeze with near-zero merges. Green modules fell 71 -> 63, purely from toolchain drift, dependency deprecation, and link rot:

```
delta = 1 - (63/71)^(1/2) = 0.058021 per month
half-life = 11.596 months
```

N — and FM-06 in the open. Seven categories are declared in the contributor guide: core runtime, packaging, docs, platform ports, downstream integrators, security, accessibility/i18n. Three of the seven — ports, security, accessibility — have no active member.

```
declared: ln 7 = 1.945910
staffed:  ln 4 = 1.386294
```

The project has been planning against a ceiling 40.4% higher than the one it owns.

u. Forty pull requests were each reviewed independently by two reviewers who did not see each other's comments. Mean Jaccard overlap of flagged defects `rho = 0.68`:

```
u     = 1 - 0.68^2 = 0.537600
N_eff = 1 + 3(0.5376) = 2.612800
S     = ln(2.612800) = 0.960422 nats    ->  69.28% of ln 4
```

eta. Over ten months, 41 modules were newly greened or restored to green attributably to logged review and design threads, against `S = 10 x 0.960422 = 9.6042` nats:

```
eta = 41 / 9.6042 = 4.268955 modules per nat
```

C. Distinguished from delta by cause: delta is decay *without* input (measured in the freeze); C is damage caused *by the activity itself*. Over twelve months, 35 green modules were destroyed by in-period breaking changes and dependency bumps that were not repaired within the period:

```
C = 35 / 12 = 2.916667 modules per month
```

4.3.2 The two master numbers, and validation

```
eta ln N = 4.268955 x 1.386294 = 5.918028
delta Q  = 0.058021 x 63       = 3.655339
C        =                       2.916667

h = 5.918028 - 3.655339 - 2.916667 = -0.653978 modules/month     <-- NEGATIVE
S / ln N = 69.28%
```

Validation. Predicted step: `4.100000 - 3.655339 - 2.916667 = -2.472006` modules/month. Observed: green modules fell 92 -> 63 over the preceding twelve months, **-2.417** per month. Residual **-0.055**, under 1% of the ceiling term. Admissible.

4.3.3 The binding constraint

`h < 0`. The negative-headroom corollary states it without qualification [Curzi, 2026b]: if `C_t > eta ln N - delta Q_t`, **no choice of interaction geometry prevents order from decreasing.** More reviewers will not save this project. Better reviewers will not save it. A larger community will make it worse, because adding contributors adds channels quadratically (Brooks) against a ceiling that grows logarithmically — FM-07, the Ceiling Chase, which is what most projects in this state attempt.

The measured fixed point makes the position explicit (FM-20):

```
Q_inf = (4.100000 - 2.916667) / 0.058021 = 20.39 modules
```

The project stands at 63 and its own equilibrium is 20. At the current rate it reaches zero green modules in **25.5 months**. Note the realized fraction: **69.28%** of ceiling — the *geometry is comparatively healthy*. The reviewers are genuinely decorrelated. That is precisely why the geometry is not the fix.

Binding: **C**, with a Frozen Denominator (FM-06) suppressing the ceiling and an Unshed Q (FM-18) inflating the maintenance charge. Also present and worth naming: three maintainers is a hub, and scale-free networks are robust to random failure and **fragile to targeted hub attack** (Albert, Jeong & Barabási 2000). The project's bus factor is its single largest unpriced risk, and it is FM-15, the Founder Battery, distributed across three people.

4.3.4 The intervention

Under the gated intervention procedure [Curzi, 2026j], `h < 0` forbids building. The permitted moves are cut C, raise eta, shed Q. N is added here only after the first three, and only because two of the empty categories can be staffed from existing downstream users at near-zero coordination cost.

C4.1 — Cut C (the binding term). A compatibility CI matrix pinned to the current and two prior toolchains; a mandatory deprecation window; no merge without a downstream smoke test. This is stigmergy applied to code: the constraint lives in the medium, enforced by the machine, not in a maintainer's attention. Target `C: 2.9167 -> 1.10 modules/month`.

C4.2 — Shed Q. Move 22 modules that no downstream consumer has imported in twelve months to an explicitly unmaintained archive tier. Not deleted; **honestly labelled**, which is the entire point. `Q: 63 -> 41`, and `delta Q: 3.655 -> 2.379`.

C4.3 — Raise eta. A merge checklist that will not close without the durable artifact: an executable example, a docs entry, and a named module owner. Measured eta is 4.269; target **5.0** — deliberately below the 5.6 the pilot suggested, because a prediction should be made at the conservative end of its own evidence.

C4.4 — Raise N, with sockets. Staff two of the three empty categories — platform ports and security — from existing downstream users who already do this work privately. `N: 4 -> 6`, `ln`

`6 = 1.791759`. Each new category gets a named review gate it owns (FM-13). Accessibility is left empty and **recorded as empty**, because nobody has volunteered and inventing a category would be FM-06 all over again.

Adding a security reviewer and a platform porter to the review pool should also decorrelate review. Target `rho: 0.68 -> 0.52`:

```
u     = 1 - 0.52^2 = 0.729600
N_eff = 1 + 5(0.7296) = 4.648000
S     = ln(4.648000) = 1.536437 nats    ->  85.75% of ln 6
```

Ostrom's design principles, read as engineering, supply the governance layer: clear boundaries (the archive tier), congruence with local conditions (the toolchain matrix), collective-choice arrangements (contributors set the deprecation window), monitoring (CI), graduated sanctions (revert, then require a smoke test, then require co-review), conflict-resolution mechanisms, and recognized rights to organize. Badged: Ostrom's principles are an empirical generalization from common-pool resource institutions; their transfer to a code repository is a modelling assumption.

C4.5 — How to land the discipline, which is a contagion problem, not an announcement. A merge checklist and a deprecation window are behaviours, and behaviours spread by complex contagion: adoption needs multiple reinforcing contacts, so **clustered topology beats broad thin exposure** (Centola & Macy 2007; Centola 2010). Announcing the policy on the mailing list is FM-14, the Sprayed Seed, and it is what most projects do. Instead, saturate one dense neighbourhood of the contributor graph — the six people who review each other's work weekly — until the practice is unremarkable there, then let the boundary carry it. Sizing: Centola et al. (*Science*, 2018) found a committed minority near **25%** flipped an established convention; at 37 active contributors that is **10 people**. Badged: the 25% figure is from controlled online experiments, and field transfer to a volunteer code project is a modelling assumption, not a measurement.

Conway's Law is also load-bearing here and it cuts both ways. Systems mirror the communication structure of the organizations that build them (Conway 1967). The three empty categories are not an accident of recruitment: the library has no port layer and no security surface *because* nobody in the communication structure owns those concerns. Staffing the categories will, over time, change the artifact's seams. That is the mechanism by which C4.4 eventually reduces C as well as raising N — and it is slow, so no credit for it is taken in the prediction below.

4.3.5 The prediction

```
h_new = 5.0 x 1.791759 - 0.058021 x 41 - 1.10
      = 8.958797 - 2.378872 - 1.100000 = +5.479926 modules/month

step  = 7.682185 - 2.378872 - 1.100000 = +4.203313 modules/month

Q_inf = (7.682185 - 1.100000) / 0.058021 = 113.44 modules
tau   = 17.235 months
```

Validity range, stated. After archiving, the project has 119 maintainable modules. `Q_inf = 113.44` sits just under that cap, and the linear law has no saturation term, so **the model is trustworthy only while Q is well below 119.** It crosses Q = 100 at month 29; beyond roughly Q = 95 the prediction should be treated as directional, not numerical.

Month	Q predicted	Do-nothing (from 63)
0	41.0	63.0

Month	Q predicted	Do-nothing (from 63)
6	**62.8**	50.2
12	**78.1**	41.2
24	96.2	30.5
36	105.0	—

The project passes its pre-intervention stock of 63 green modules in month 6 — from a *smaller* base, because shedding was one of the levers.

4.3.6 What would falsify it

1. **The C channel first.** Count green modules destroyed by in-period breaking changes over months 1-6. **If the rate is above 2.0/month, C4.1 failed** and the following bands apply instead:

Scenario	h	step	Q at 12	Q_inf
Full package (eta 5.0, C 1.10)	+5.480	+4.203	78.1	113.4
eta unchanged (4.269), C 1.10	+4.170	+3.080	68.2	94.1
eta 5.0, C slips to 2.00	+4.580	+3.303	70.1	97.9
eta 5.0, C discipline fails entirely	+3.663	+2.387	62.1	82.1

   Every row is positive: **the intervention's sign is robust even to complete failure of its largest single component**, because shedding Q and staffing N together moved h from -0.65 to +3.66 before eta or C were touched. That robustness is itself a falsifiable claim — if Q is still falling at month 6 under any of these rows, the model is wrong, not the execution.

2. **The N channel.** Both new categories must land at least three independent reviews in the first quarter. A category with a name and no output is FM-06 restored, and the ceiling reverts to `ln 4`.

3. **The u channel.** Re-run the paired-review overlap measurement at month 6. `rho <= 0.60` required.

4. **Shuffled-input control** and the persistence and matched-AR baselines, as before. This case is the most vulnerable of the four to a spurious fit, because CI-green counts move for toolchain reasons entirely unrelated to human interaction. **If the shuffled control fits as well, the whole causal story is an artifact of the release calendar.**

17.4.4 4.4 Case D · A residential commons of twenty-two households

The system. Twenty-two households, 51 residents, purpose-built co-housing: common house with kitchen and laundry, guest room, workshop, tool library, shared garden beds, bike shed. Governed by whole-group consensus. The complaint, from a resident: *"Everything takes a year and nothing stays fixed."*

4.4.1 The survey

Choice	Setting
State encoder	Household activity category
Interaction observable	Work parties and commons decisions with cross-household participation
Order observable Y	**Shared capabilities usable without negotiation**, in commons-units (cu)
Time scale	One month
Cost observable	Household-hours consumed by governance, mediation, and free-rider repair

A capability counts toward Y if a resident can use it *without asking anyone*: it works, it is findable, and its rules are known. Walk-through inspection: 14 tool-library items, 7 common-house systems, 12 written norms with observed compliance at or above 80%, 5 residents able to run a work party unaided. `Q_0 = 38 cu`.

Order-proxy check [Curzi, 2026i]. Meetings held would be the input. Capabilities that work when nobody is meeting is the order. The lag test is available and decisive, below.

delta — and FM-15 in the field. After the founding steward moved out, work parties lapsed for nine months (`S ~ 0`). Commons stock fell 47 -> 38:

```
delta = 1 - (38/47)^(1/9) = 0.023341 per month
half-life = 29.348 months  (2.45 years)
```

This is the lowest delta in the set, for the obvious reason that most of this commons is **physical**. Bricks forget slowly.

N. Five household activity categories by need and contribution: families with young children; retired residents; full-time-employed households; remote workers; households with mobility limits. `ln 5 = 1.609438`.

u. Each household independently ranked twelve candidate commons projects before any discussion. Mean pairwise Spearman rank correlation `rho = 0.41`:

```
u     = 1 - 0.41^2 = 0.831900
N_eff = 1 + 4(0.8319) = 4.327600
S     = ln(4.327600) = 1.465013 nats    ->  91.03% of ln 5
```

This is the highest realised fraction in the set. The block is genuinely, measurably heterogeneous, and it converts almost none of that into anything.

eta. Over the fourteen months when monthly work parties ran, 19 cu of new or restored capability were attributable, against `S = 14 x 1.465013 = 20.5102` nats:

```
eta = 19 / 20.5102 = 0.926369 cu per nat
```

C. Conversion rate from the same window: 19 cu from 1,344 productive household-hours of work party = `0.01413690` cu/h. Governance tally: one whole-group consensus meeting per month at 22 households x 2.0 h = 44 h; mediation 11 h; free-rider repair 7 h. Total 62 household-hours/month.

```
C = 62 x 0.01413690 = 0.876488 cu per month
```

4.4.2 The two master numbers, and validation

```
eta ln N = 0.926369 x 1.609438 = 1.490934
delta Q  = 0.023341 x 38       = 0.886966
C        =                       0.876488

h = 1.490934 − 0.886966 − 0.876488 = −0.272521 cu/month        <-- NEGATIVE
S / ln N = 91.03%
```

Validation. Predicted step: `1.357143 − 0.886966 − 0.876488 = −0.406311` cu/month. Observed: the walk-through five months ago read 40 cu; today it reads 38, or **-0.400** per month. Residual **-0.006**. Admissible.

4.4.3 The binding constraint

`h < 0` again — and for the exact opposite reason to Case C. Here the geometry is superb: 91% of ceiling, an honest 0.83 non-parallelism, five real categories. What the block has is **eta = 0.926 cu per nat** — the lowest conversion efficiency in the set by a factor of four.

The residents are having genuinely different conversations and almost nothing durable comes out of them. That is FM-11, the Leaky Vessel, in its pure form: full surplus, no capture. The corpus states the same structure in magnitude form elsewhere as `E = G.B + eps` with the forbidding clause `G = 0 => E = 0` for all `B`, badged as a postulate and paired with the storage law's `eta = 0` by explicit correspondence [Curzi, 2026ab]: **where the channel gain is zero, no amount of input produces an effect, and the co-housing block is the nearest thing in this set to that limit.** The work parties happen, the ideas are real, and the tool comes back unlabelled to a shelf nobody owns.

Second binding term: C. Twenty-two households in whole-group consensus is `n(n−1)/2 = 231` communication channels — FM-21, the Quadratic Committee. At n = 22 the ratio is **74.73 channels per nat of ceiling**; at n = 5 it is 6.21. The block pays twelve times the coordination cost per unit of ceiling that a five-household cluster would.

Third: FM-15, and it is already historical — the block's delta was measured *because* one person left and everything stopped.

4.4.4 The intervention

D4.1 — Raise eta (the binding lever, and the cheapest). Three capture devices, in ascending durability:

- **A steward of record for every capability.** Named, on the object, rotating annually, with the right to decline the rotation.
- **A physical commons board** in the common house: what exists, where it is, who stewards it, what is broken. Stigmergy — **the state lives in the medium, not in a coordinator** — which is also the structural correction to the Founder Battery.
- **A work-party close-out rule:** no party ends without one written durable artifact. A label, a repaired item logged, a norm written down. The conversion finding restated [Curzi, 2026b]: *"we had a great work party"* is an `eta = 0` report.

Pilot-measured eta reached 1.55; the prediction is made at **1.40**, conservatively.

D4.2 — Cut C by nesting, not by shrinking. Four clusters of about 5.5 households, with **overlapping membership** — each household sits in two clusters. This is Alexander's semilattice ("A City is Not a Tree," 1965) rather than a tree, and the overlap is what preserves cross-contact.

```
whole group:   22 x 21 / 2                      = 231 channels
nested:        4 clusters x (5.5 x 4.5 / 2) = 49.5
```

```
            + delegate council 4 x 3 / 2   =  6.0
                                           -------
                                             55.5 channels     = 24.03% of 231
```

Whole-group consensus moves to quarterly and covers constitutional matters only; clusters decide monthly within scope. **Badged as a modelling assumption:** the projection below scales meeting hours by the channel ratio, on the reasoning that the binding cost is pairwise reconciliation rather than seat time. That assumption is itself in the falsification list.

```
meeting term:   44 h x 0.2403                    = 10.571 h
whole-group quarterly, amortized: 22 x 2.5 / 3   = 18.333 h
mediation (down from 11)                         =  8 h
free-rider repair (graduated sanctions, Ostrom 5) =  4 h
                                                   -------
                                                    40.905 h/month
C = 40.905 x 0.01413690 = 0.578267 cu/month
```

D4.3 — Ostrom's eight design principles [Ostrom, 1990, 2010, Cox et al., 2010] as the eta and C specification. This is the case the principles were derived for — a common-pool resource governed by its users — and each principle maps to a specific parameter in the law. Badged: Ostrom's principles are an empirical generalization from field studies of common-pool resource institutions (*Governing the Commons*, 1990); their statement is hers, the parameter mapping is this paper's.

Ostrom principle	Instrument in this block	Parameter
1. Clearly defined boundaries	Which capabilities are commons, which are household	eta, C
2. Congruence of rules with local conditions	Cluster-level rules for cluster-level assets	C
3. Collective-choice arrangements	Those affected set the rule; opt-out preserved	u, and the consent constraint
4. Monitoring	The commons board shows broken items, by whom, since when	eta, delta
5. Graduated sanctions	Reminder -> repair request -> stewardship reallocated	C
6. Conflict-resolution mechanisms	A standing, low-cost, non-escalating process	C
7. Recognition of rights to organize	Clusters may form and dissolve without approval	u, N
8. Nested enterprises	The four-cluster semilattice itself	C

Principle 8 is the one this case turns on, and it is the same structural claim as Alexander's semilattice from a different literature: **nested, overlapping enterprise beats both the flat assembly and the strict hierarchy**, and the arithmetic in D4.2 prices exactly how much. Principle 4 is the one that does the eta work — a commons board is a monitoring device, and monitoring is what converts a conversation into a state of record.

Consent check, and one cut. Graduated sanctions must preserve the right to decline. The version adopted escalates from a reminder, to a request for repair, to reallocation of the capability's stewardship — none of which removes anyone's ability to withdraw from the commons activity entirely. A proposed version that made cluster attendance a condition of tool-

library access **was cut**, because it made non-participation costly and is therefore outside this manual's scope.

Honest cost of the nesting: u falls. Clustering, even with overlap, reduces cross-category contact. Predict `u: 0.8319 -> 0.79`:

```
N_eff = 1 + 4(0.79) = 4.160000
S     = ln(4.160000) = 1.425515 nats    ->  88.57% of ln 5   (down from 91.03%)
```

delta is held at 0.023341 — no credit taken for the board, though it should help.

4.4.5 The prediction

```
h_new = 1.40 x 1.609438 - 0.023341 x 38 - 0.578267
      = 2.253213 - 0.886966 - 0.578267 = +0.787980 cu/month

step  = 1.995721 - 0.886966 - 0.578267 = +0.530488 cu/month

Q_inf = (1.995721 - 0.578267) / 0.023341 = 60.73 cu
tau   = 42.843 months  (3.57 years);  half the gap closes in 29.3 months
```

Month	Q predicted	Do-nothing
0	38.0	38.0
12	**43.6**	33.7
24	**47.8**	30.5
36	51.0	28.0
60	55.2	—
120	59.4	—

This is the slowest system in the set and the arithmetic says so plainly. `3 tau` is 128.5 months — **ten years and eight months** to settle within 5% of the fixed point. The same low delta that let the commons survive nine months of neglect is what makes it take a decade to build. A prospectus promising visible transformation in a year would be lying, and the lie would be detectable from `tau = 1/delta` alone.

Single-lever check, to show the bundle is necessary:

Lever	step	h
C cut alone (eta 0.926)	-0.145	+0.026
eta alone (1.40, C unchanged)	+0.288	+0.490
Both	**+0.530**	**+0.788**

4.4.6 What would falsify it

1. **The eta channel, which is the whole claim.** Count attributable cu per nat over months 1-12. Bands:

eta realized	step	Q at 12	Q at 24	Q_inf
0.926 (no change)	-0.145	36.5	35.3	31.8
1.10	+0.103	39.1	39.9	42.4

eta realized	step	Q at 12	Q at 24	Q_inf
1.40 (target)	**+0.530**	**43.6**	**47.8**	**60.7**
1.55	+0.744	45.9	51.8	69.9

If Q is at or below 39 cu at month 12, eta did not move and the capture devices failed.

2. **The channel-scaling assumption.** Measure actual governance household-hours at month 6. The prediction requires **at or below 45 h/month**. If nesting cuts channels but not hours, the scaling assumption is refuted and C must be re-estimated from the measurement.
3. **The u cost.** Re-run the independent-ranking instrument at month 9. If `rho` rises above 0.55 — that is, `u` falls below 0.70 — the clusters have become a tree rather than a semi-lattice, and the overlap must be increased. This is the intervention's own most likely failure and it is predicted in advance rather than explained afterward.
4. **Persistence, direct-input, matched-AR, and shuffled-input controls.** All four. With a `tau` of 43 months, a persistence baseline is a genuinely strong competitor over any horizon shorter than two years, and **if the model cannot beat persistence at month 24 it has added nothing.**

17.4.5 4.5 Case E · One desk, and the scale-freedom test

The four cases span three orders of magnitude in headcount. This last one has a headcount of one, and it is here to test the scale-freedom claim directly: the claim that the storage law is **scale-free in form**, so that only `(delta, eta, N, C)` change between a desk, a room, a team, a building, an institution, and a city. That is a claim about **model form**, not about physics, and it is badged as such wherever it appears.

The system. One person, one desk, three concurrent workstreams. Period: one week. Order observable: **resumable threads** — work whose state can be recovered from the desk alone, without reconstruction from memory. `Q_0 = 6`.

```
delta:  after a two-week absence, resumable threads fell 7 -> 5
        delta = 1 - (5/7)^(1/2) = 0.154846 per week;  half-life 4.120 weeks

N     = 3 workstreams;   ln 3 = 1.098612
u:      independent recall test: how often does resuming one thread require
        reconstructing another?  coupling rho = 0.74
        u = 1 - 0.74^2 = 0.452400
        N_eff = 1 + 2(0.4524) = 1.904800
        S = ln(1.904800) = 0.644377 nats   ->  58.65% of ln 3

eta:    13 threads made resumable over 10 weeks, attributable to end-of-session capture
        eta = 13 / (10 x 0.644377) = 2.017452 threads per nat
yield:  13 / (10 weeks x 5.0 productive hours) = 0.260000 threads per hour
C:      2.39 h/week of re-orientation and searching
        C = 2.39 x 0.26 = 0.621400 threads per week

h = 2.017452 x 1.098612 - 0.154846 x 6 - 0.621400
  = 2.216398 - 0.929074 - 0.621400 = +0.665924 threads/week

step = 1.300000 - 0.929074 - 0.621400 = -0.250474 threads/week
```

Observed: threads fell 7 -> 6 over four weeks, **-0.250** per week. Residual **-0.0005**. The survey validates at a headcount of one, with the same equation, the same seven steps, and the same validation rule as a twenty-two household commons.

The intervention is one index card per thread, written at the end of each session and parked in view: what was decided, what is next, what would unblock it. It is the smallest possible instance of the same three devices used in Case D — a state of record, a visible medium, and a close-out rule.

```
delta: 0.154846 -> 0.09      (the card survives the week; memory does not)
rho:   0.74 -> 0.55  ->  u = 0.697500,  N_eff = 2.395000
S      = ln(2.395000) = 0.873383 nats   ->  79.50% of ln 3
C:     1.1 h x 0.26 = 0.286000

h_new = 2.216398 - 0.540000 - 0.286000 = +1.390398 threads/week
step  = 1.762009 - 0.540000 - 0.286000 = +0.936009 threads/week
Q_inf = (1.762009 - 0.286000) / 0.09 = 16.40 threads
tau   = 11.111 weeks
```

Week	Q predicted	Do-nothing
0	6.00	6.00
2	7.79	—
4	**9.27**	5.21
8	11.51	4.80
12	13.05	4.60

Validity range, again. `Q_inf = 16.40` exceeds what one person can hold; the practical cap is nearer ten to twelve. The model is trustworthy to about week 6 and directional after that. Naming the cap is not a weakness of the method; **failing to name it is the failure**, and it is Failure Mode D-6.

17.4.6 4.6 The cross-case comparison

Five systems, one equation, parameters spanning three orders of magnitude:

System	Period	Units	delta	eta	N	u	S/lnN	C	Q	h	step
Desk	week	threads	0.1548	2.017	3	0.452	58.7%	0.621	6	+0.666	-0.250
Research group	quarter	assets	0.1120	5.846	4	0.260	41.6%	1.608	46	+1.343	-3.387
Library room	month	regulars	0.1520	27.722	6	0.134	28.6%	2.427	84	+34.475	-0.996
Open source	month	modules	0.0580	4.269	4	0.538	69.3%	2.917	63	-0.654	-2.472
Co-housing	month	cu	0.0233	0.926	5	0.832	91.0%	0.876	38	-0.273	-0.406

After intervention:

System	delta	eta	N	u	S/lnN	C	h	step	Q_inf	tau
Desk	0.0900	2.017	3	0.698	79.5%	0.286	+1.390	+0.936	16.4	11.1 wk
Research group	0.0750	5.846	5	0.616	77.2%	1.213	+5.646	+3.498	80.6	13.3 q
Library room	0.1520	27.722	6	0.320	53.3%	2.189	+34.713	+11.530	159.8	6.6 mo
Open source	0.0580	5.000	6	0.730	85.8%	1.100	+5.480	+4.203	113.4	17.2 mo
Co-housing	0.0233	1.400	5	0.790	88.6%	0.578	+0.788	+0.530	60.7	42.8 mo

Five readings from the table, each of which is a finding rather than a restatement:

1. Every one of the five was losing order at survey, and no two for the same reason. Binding constraints were, respectively: delta and u jointly; delta-Q with a parallel roster; u alone; C with a frozen denominator; eta with a quadratic committee. A method that always finds the same fault is not diagnosing.

2. h and `S / ln N` are independent readings and both are required. The library has 53x the headroom of the co-housing block and collects less than a third of its ceiling. The block collects 91% of a ceiling it cannot afford. Either number alone points at the wrong lever.

3. eta spans a factor of thirty across the five systems and is the cheapest thing to change in four of them. This is the conversion result [Curzi, 2026b], arrived at from the arithmetic rather than asserted.

4. tau = 1/delta sets the honest timescale, and it is not negotiable by effort. The library settles in about twenty months; the co-housing block needs a decade. **The same low delta that makes a commons resilient is what makes it slow, and no intervention in this paper changes that trade.**

5. The form held at every scale. One desk and twenty-two households used the same seven steps, the same validation rule, and the same falsification discipline, and both surveys reproduced their observed change to within 0.006 units. That is what the scale-freedom claim actually asserts and all it asserts: **same equation, different parameters, and the parameters must be measured every time.**

The measurements above are the point rather than the model, which is four lines. **What the procedure supplies is the discipline of putting a number where an opinion was, validating it against something that already happened, and writing down in advance what would refute it.**

17.5 5 The survey specification

The general procedure, abstracted from the four cases. Numbered for checking.

S5.1 — Choose the five operational observables before measuring anything: state encoder, interaction observable, **order observable Y**, time scale, cost observable. Write them down. Changing one later invalidates every earlier reading.

S5.2 — Apply the lag test to Y before proceeding. Find or create a period of near-zero input and observe Y. If Y tracks the pause with no lag, Y is the input and must be replaced. **All four cases above rejected an obvious proxy at this step, and Case C rejected its first choice explicitly.**

S5.3 — Estimate delta from that same zero-input period: `delta = 1 - (Q_1/Q_0)^(1/t)`. The interruption that annoys you is the measurement you cannot otherwise afford.

S5.4 — Partition N by capability, not by title. Count only staffed categories. Record empty categories as empty.

S5.5 — Estimate u with two instruments, `u_cross` and `u_div`, and report both. `u = 1 - rho^2`. Report the realized fraction `S / ln N` in the same breath.

S5.6 — Estimate eta as `attributable delta_Q / cumulative S` over at least five periods.

S5.7 — Take C as a residual, not as a list: total capacity minus productive capacity, priced at the same yield rate used for eta.

S5.8 — **Validate.** Predicted `eta S - delta Q - C` against observed change in Q. Agreement within about 10% of the ceiling term. **A survey that does not reproduce the past may not be used to predict the future.**

S5.9 — Compute `h` and `S / ln N`. Together. Then:

```
h < 0    -> building is forbidden. Cut C, raise eta, or shed Q, in that order of cheapness.
h = 0    -> maintenance only. Hold.
h > 0    -> growth available. Any requested r_t must satisfy r_t <= h_t.
            If S / ln N is also low, the binding constraint is u, not h.
```

S5.10 — Rank levers by cost: eta cheapest, then C, then shedding Q, then u, then N. **N is last because it is logarithmic**: going 4 -> 5 buys 0.2231 nats of ceiling for a 25% increase in categories, and every added category adds channels quadratically.

S5.11 — Apply the consent test to every element: *what happens to a person who declines?* If the answer contains an adverse consequence, cut the element and record the cut.

S5.12 — Predict a dated trajectory, a fixed point, a time constant, and **a validity range**. State the cap. Where `Q_inf` exceeds a physical or organizational cap, say which one binds.

S5.13 — Write the falsification conditions before starting. Four baselines: persistence, direct-input, matched autoregressive, **shuffled-input**. Band the prediction by the uncertainty in the least reliable parameter — usually eta.

17.6 6 Failure modes observed across the five surveys

What went wrong across these five surveys, and what a practitioner should expect.

The named complaint was wrong every time. The PI said "busy and unproductive" and the fault was a maintenance charge plus a parallel roster. The branch manager said "noise" and the fault was 2.52 seconds of reverberation collapsing u. The maintainers said "drowning" and the fault was churn cost against a frozen denominator. The resident said "slow" and the fault was a conversion efficiency of 0.93. **The complaint reliably names the symptom with the highest salience, and salience is uncorrelated with bindingness.**

Positive headroom read as health (Cases A and B). Both had `h > 0` and both were shrinking. Any diagnosis stopping at `h` would have been exactly wrong in two of the five cases. `h` is the ceiling; `S / ln N` is the collection rate; you need both numbers or neither.

Single-lever thinking (all four). Case A's table shows every single lever leaving the step negative. Case D's shows the same. Case C is the exception that proves the rule — its bundle is robust to failure of its largest component, and that robustness was *computed*, not hoped for.

Taking credit for unmeasured improvement. Every case above held at least one parameter fixed that the intervention should plausibly improve — Case B held both eta and delta, Case A held eta, Case D held delta. **A prediction made at the optimistic end of its own evidence is not a prediction.**

Model-range violations (Cases C and E). `Q_inf = 113.44` against 119 maintainable modules; `Q_inf = 16.40` against a desk that holds perhaps a dozen threads. The linear law has no saturation term and will happily predict past the cap. Say where it stops being true.

The shuffled-input control is the one that would kill these. Case C is the clearest: green module counts move on the release calendar for reasons entirely unrelated to human interaction. Every other baseline can be passed by a model that is merely tracking a trend. **A framework that cannot fail cannot be trusted, and this is precisely the test these four cases would fail if the framework were empty.**

17.6.1 6.1 The catalog entries encountered, by case

Cross-referenced to the thirty-two-entry corpus failure catalog [Curzi, 2026j], so the five surveys can be read as a worked index. **Two-digit labels of the form `FM-nn` below refer to that catalog; this paper's own failure modes carry the prefixes `FM-E` and `FM-B` and are given in Sections 7.13 and 8.13.** No case presented with fewer than three co-occurring faults, which is the catalog's own multiplicity requirement confirmed rather than assumed.

Case	Faults found	Binding	Lever pulled first
A · Research group	FM-17 Maintenance Trap, FM-01 Parallel Wall, FM-02 Pseudo-Diversity, FM-18 Unshed Q, FM-07 Ceiling Chase (proposed, refused)	delta-Q with u	Shed Q
B · Library room	FM-26 Reverberant Room, FM-01 Parallel Wall, FM-06 Frozen Denominator, FM-24 Abrupt Threshold	u	Absorption
C · Open source	FM-06 Frozen Denominator, FM-20 Negative Fixed Point, FM-18 Unshed Q, FM-15 Founder Battery (x3), FM-14 Sprayed Seed (proposed, refused)	C	Cut C
D · Co-housing	FM-11 Leaky Vessel, FM-21 Quadratic Committee, FM-15 Founder Battery (historical)	eta	Capture devices
E · One desk	FM-11 Leaky Vessel, FM-19 Invisible Infrastructure	eta with delta	The index card

Two patterns are worth naming. **FM-11, the Leaky Vessel, and FM-15, the Founder Battery, appear in three cases each** — conversion failure and person-held storage are the two most common faults in this sample, and both are cheap to fix relative to everything else. And **the fault the system proposed to fix was, in two of four cases, a fault the arithmetic refused**: the research group's recruitment plan and the open-source project's mailing-list announcement were both stopped by a computation, not by an argument.

17.7 7 The essence law

Every chapter before this one has been about *quantity*: how much order is stored, how fast it leaks, how much difference a roster actually contains. This part of the manual is about *identity* — about giving a relationship a name that can be heard rather than a number that must be read.

The instrument is a single formula published in 2022 as *The Effective Method of Sonic Chemistry*. Its original application was the periodic table; its actual reach is wider, and this section establishes exactly how much wider and exactly how much less. We strip the formula to its algebraic core, verify that core against every number the source published, prove two structural theorems about what it can and cannot produce, and mark — in the open, with its badge on — the precise point at which mathematics stops and postulate begins.

The single most important sentence in this section is the one that limits it: the output of the essence law is an ESSENCE frequency, not a physical resonance. No material, molecule, element, room or person is claimed to physically resonate at any value computed here. The law assigns a pitch to a *position in an ordered category scheme*. What is built with that pitch is the subject of Curzi [2026l]. What the pitch *is* — and is not — is this section's.

17.7.1 7.1 Statement

POSTULATE (The Essence Law). Let a discipline be given an explicit, ordered, finite set of essence types. Let `n` be the ordinal position — the **essence index** — of one such type. Then the essence frequency of that type is

```
f(n) = k * n^2                                    [Hz]

k = (9/8)^2 / phi^2 = (81/64) / (phi + 1) = (81/64) * (2 - phi)

phi = (1 + sqrt(5)) / 2 = 1.6180339887498948...

k   = 0.483425732988414 Hz    (0.48342573298841433274106978775598925726  to 40 places)
```

The identity `phi^2 = phi + 1` makes the second and third forms exact restatements of the first; `1/(phi+1) = 2 - phi = 0.38196601125010515`, computed and confirmed below. The identity is Euclid's [Euclid, 1956] and its Fibonacci consequences are standard [Vajda, 1989, Koshy, 2001].

Two labels are attached here and they are not the same label. `k` is a **defined** constant: an exact ratio of exactly specified quantities, computable to arbitrary precision, so quoting it to fifteen significant figures is legitimate and it carries that word wherever it appears at that precision. **Attaching `Hz` to it is a separate and much stronger claim**, and it is a **postulate**; Section 11.1's dimensional audit and Section 11.3's compounding chain treat the two as two steps and never as one. On the appearance of `phi` here specifically, the scepticism literature is binding and is cited at the point of use rather than in a footnote: Markowsky [1992] documents the misattributions that surround the golden section, Fischler [1981] the weakness of the usual empirical claims, and Livio [2002] the history. **The distinction that matters is between CHOOSING `phi` as a constant, which is what happened here, and FINDING it in nature, which did not.** Section 7.6 then shows that the chosen constant cancels from every relationship the law produces.

Two things in that block are proved and two are postulated, and they must never be confused.

Element	Status	Warrant
`f(n) = k n^2` is the exact collapse of the published recipe `((n/phi)*1.125)^2`	**PROVED** (algebra)	Section 7.2
`k = (81/64)/(phi+1) = 0.483425732988414`	**PROVED** (arithmetic)	Section 7.2, computed
Every interval `f(m)/f(n)` is `m^2/n^2` and is independent of `k`	**PROVED** (Result One)	Section 7.4
A set indexed `1..N` has exactly `ceil(N/2)` pitch classes	**PROVED** (Result Two)	Section 7.5

Element	Status	Warrant
That essence types *have* a frequency at all	**POSTULATE**	author's, 2022
That the frequency law is *square* in the index	**POSTULATE**	author's, 2022
That `k` is `(9/8)^2/phi^2` rather than any other constant	**POSTULATE** (design choice)	author's, 2022
That a given ordering of categories is the right one	**REQUIRES JUSTIFICATION**	Section 7.9 and Curzi [2026t]

The mathematics in the middle two rows is unconditional: it is true of `k n^2` for *any* positive `k`, and would remain true if the author had chosen `k = 1`. The unsupported content is entirely in rows five through seven, and it is admitted here on the condition the corpus applies throughout [Curzi, 2026]: **in the open, with its badge on.**

17.7.2 7.2 The honesty clauses

These are mandatory and are restated in Chapters 30 and 31 wherever the law is used. They are not decoration. They are the warrant that lets a postulated law sit inside a body of work whose other results are proved theorems.

H1 — Essence, not resonance. The output is an essence frequency. No claim is made, and none may be implied, that any material, molecule, element, institution, room or person physically resonates at these values. When a room is built whose axial modes sit at essence frequencies [Curzi, 2026l], the room genuinely resonates — because a room of that dimension genuinely has that mode, by ordinary acoustics — but the *essence* does not, and the room's mode is a design target we chose, not a property of the essence we discovered.

H2 — `k` is chosen, not measured. Its form — a Pythagorean interval divided by the golden section — is a design decision by the author of the 2022 document. Nothing in the algebra requires it. Nothing in the intervals depends on it (Section 7.4). It sets the reference pitch and does no other work. Badge it as a postulate every time it appears.

H3 — The square law is a postulate about essence structure. That it coincides in form with the eigenvalue spacing of a one-dimensional infinite square well (`E_n` proportional to `n^2`) is a genuine and interesting mathematical correspondence, developed carefully in Section 7.8. **Coincidence of form is not evidence of mechanism, and this paper asserts no mechanism.**

H4 — The essence index requires a defensible ordering. Applying the law requires an explicit, justified ordinal on the discipline's categories, satisfying the framework's validity conditions [Curzi, 2026t]. An arbitrary ordering yields arbitrary frequencies. Section 7.6 gives the test.

H5 — Everything downstream inherits every clause. Section 8 layers the interaction-surplus Framework on top of this law. That bridge inherits all of the framework's honesty clauses [Curzi, 2026,?,a], including that the surplus functional as deployed is a **lower bound** on an ensemble's information rather than the information itself, that the characterisation theorem is pure mathematics making no empirical or metaphysical claim, and that **no thermodynamic or physical consequence follows from any of it.**

17.7.3 7.3 The collapse

The 2022 source specifies a spreadsheet procedure. Column A holds the atomic number. A separate tab holds the golden ratio. Column C holds

```
(( AN / phi ) * 1.125)^2
```

with `AN` the atomic number and `1.125 = 9/8`. Expand it:

```
f(n) = ( (n / phi) * (9/8) )^2
     = ( n * (9/8) / phi )^2
     = n^2 * (9/8)^2 / phi^2
     = k * n^2                      with k = (9/8)^2 / phi^2
```

That is the whole derivation. There is nothing else in the recipe. **The published procedure is a pure square law with a constant of proportionality, and every appearance of the golden ratio and of the Pythagorean tone in the recipe is absorbed, once and for all, into that single constant.**

Numerically, computed to double precision and cross-checked at fifty decimal digits:

```
phi          = 1.618033988749895
phi^2        = 2.618033988749895
phi + 1      = 2.618033988749895        <- identical, as phi^2 = phi + 1
(9/8)^2      = 1.265625
1/(phi+1)    = 0.38196601125010515
2 - phi      = 0.3819660112501051

k = (9/8)^2 / phi^2   = 0.48342573298841435
k = (81/64)/(phi+1)   = 0.48342573298841435      difference exactly 0.0
k = (81/64)*(2-phi)   = 0.4834257329884143
k = (81/64)*(3-sqrt5)/2 = 0.4834257329884143

k to 50 digits = 0.48342573298841433274106978775598925726023369430832
```

All four closed forms agree **to the last digit double-precision arithmetic can carry**, which is where the display above stops: `0.48342573298841435` is the IEEE-754 double nearest to `k`, and the correctly rounded seventeenth significant figure is `0.48342573298841433`, as the fifty-digit line shows. The discrepancy is in the machine's representation and not in the constant, and it is printed here rather than tidied away because a reader recomputing at higher precision will meet it. The same caution applies to `2400/ln 2`, whose correctly rounded seventeen-figure value is `3462.4680981335122` and whose double representation ends `...123`.

The standard citation form is `k = 0.483425732988414 Hz`, fifteen significant figures, which is the precision at which the source document published — and which is defensible **only** because `k` is a *defined* constant rather than a measured one. Fifteen figures on a measured quantity would be the classic marker of work that has not understood its own error bars.

17.7.4 7.4 Verification against the source document's own numbers

A collapse claim is worth nothing unverified. The source publishes 118 base frequencies — one per element of the periodic table, hydrogen through oganesson. Each was recomputed here from `f(n) = k n^2` using exact fifty-digit arithmetic and compared with the published string.

Result: all 118 published values are reproduced by `k n^2`. The worst relative deviation across the whole table is 9.00e-15, at n = 17 (chlorine) — that is agreement to fourteen significant figures, which is the resolution limit of IEEE double-precision arithmetic.

n	element	published (2022 source)	`k * n^2` recomputed	relative deviation
1	H	0.483425732988417	0.483425732988414	5.5e-15
2	He	1.93370293195367	1.93370293195366	6.6e-15
3	Li	4.35083159689575	4.35083159689573	4.8e-15
8	O	30.9392469112587	30.9392469112585	5.9e-15
12	Mg	69.6133055503321	69.6133055503317	6.3e-15
16	S	123.756987645035	123.756987645034	7.5e-15
26	Fe	326.79579550017	326.795795500168	5.8e-15
29	Cu	406.561041443259	406.561041443256	6.3e-15
50	Sn	1208.56433247104	1208.56433247104	3.4e-15
64	Gd	1980.11180232056	1980.11180232055	7.5e-15
79	Au	3017.05999958071	3017.05999958069	5.4e-15
92	U	4091.71540401396	4091.71540401394	5.2e-15
100	Fm	4834.25732988417	4834.25732988414	5.5e-15
118	Og	6731.21990613072	6731.21990613068	5.8e-15

Note the structure that jumps out of the first and second-to-last rows: `f(100) = 10000 * f(1)` exactly, because `100^2 = 10^4`, so the two published strings carry the same digits with the decimal point moved four places. That is a signature of a pure power law and is visible by eye in the source document itself.

A forensic aside, because it changes what "verified" means. The published values are not merely close to `k n^2` — they are *systematically* high by about 2.8 parts in 10^15, too consistent to be rounding noise. Inverting the arithmetic to recover the `phi` the spreadsheet actually used:

```
phi implied by published f(1) = 1.61803398874989...
true phi                      = 1.61803398874989484...
ratio                         = 1 - 2.76e-15
```

The implied value is exactly `phi` truncated to fifteen significant figures: `1.61803398874989`. Recomputing the entire table with that literal:

```
k(phi = 1.61803398874989) = 0.48342573298841723
-> 109 of 118 published values match to ALL FIFTEEN displayed digits
-> worst relative deviation 3.43e-15 (last-place float noise on the remaining nine)
```

So the collapse is not approximate. It is exact, and the residual discrepancy is fully explained by the spreadsheet having stored a fifteen-digit `phi` rather than a full-precision one. We can say that the published table *is* `k n^2`, and we can say precisely which `k`. This is the standard the paper holds itself to: not that the numbers look right, but that the arithmetic which produced them is given and the residue is accounted for.

One further textual erratum, recorded because it will otherwise trip any reader who reimplements the method. The source document instructs: *"In one cell type in the equation `1+5^.5/2`"*. Under standard operator precedence that expression evaluates to `1 + (sqrt(5)/2) = 2.118033988749895`, which is not `phi`. Recomputing `f(1)` with it gives `0.28212345562925867`, which matches nothing in the published table. **The spreadsheet plainly contained `(1+5^0.5)/2`; the document's prose dropped the parentheses.** Use `(1 + sqrt(5))/2`.

17.7.5 7.5 The constant, and what it is for

`k` is a Pythagorean interval divided by the golden section, and it is worth being precise about which. `9/8` is the **Pythagorean whole tone** — `(3/2)^2 / 2`, 203.910 cents. Its square, `81/64`, is the

Pythagorean ditone, the major third of three-limit tuning, 407.820 cents, sharper than the just major third `5/4` (386.314 cents) by the syntonic comma [Barbour, 1951, Lindley and Turner-Smith, 1993, Doty, 2002]. `phi^2 = phi + 1 = 2.618033988749895`. So `k` is the ditone reduced by `phi^2`.

The source document offers a rationale — that elements are standing waves on a phi spiral with eight per 360 degrees, hence the factor `9/8` to "establish that symmetry breaking in the spatial orientation of the golden spiral". **That rationale is a postulate. It is recorded because it is the source author's stated reason, and badged because no derivation of it exists.** It is also exactly the kind of claim Markowsky [1992] and Fischler [1981] were written about, and a reader should weigh it accordingly.

What matters engineering-wise is the subject of the next section: *none of this survives into any relationship the law produces.* `k` sets the tuning fork. It sets nothing else.

17.7.6 7.6 RESULT ONE — every interval is a ratio of squares, and `k` cancels

Theorem (Result One). For any two essence indices `m, n >= 1`,

```
f(m)      k * m^2      m^2
---- =   -------  =   ---
f(n)      k * n^2      n^2
```

Proof. Immediate. `k` is a common factor of numerator and denominator. It cancels for every pair, for every `k > 0`. QED.

The proof is one line. The consequence is the whole chapter.

The golden ratio and the 9/8 set the absolute reference pitch and NOTHING ELSE. Every relationship in the system is a ratio of squared integers. If you replace `k` with 1, or with 440, or with the mass of the sun, every interval in the system is unchanged. `phi` does no relational work. It is a transposition, and a transposition is the one musical operation that changes nothing structural.

This is a demotion and it should be felt as one. A reader coming to this material from the wider literature of golden-ratio numerology will expect `phi` to be doing something. It is not. The harmonic content of the essence law is generated entirely by the integers.

Here is the interval lattice, computed. "Cents" is `1200*log2(ratio)`; "folded cents" is that value modulo 1200, i.e. the pitch class; "dev" is the deviation from the nearest twelve-tone equal-tempered interval.

m:n	ratio `m^2/n^2`	decimal	octaves	cents	folded cents	nearest 12-TET	dev (cents)
2:1	4/1	4.000000	2.0000	2400.00	0.00	unison	+0.00
3:2	9/4	2.250000	1.1699	1403.91	203.91	major 2nd	+3.91
4:3	16/9	1.777778	0.8301	996.09	996.09	minor 7th	-3.91

16:9	256/81	3.160494	1.6601	1992.18	792.18	minor 6th	-7.82
10:9	100/81	1.234568	0.3040	364.81	364.81	major 3rd	-35.19
11:8	121/64	1.890625	0.9189	1102.64	1102.64	major 7th	+2.64
13:8	169/64	2.640625	1.4009	1681.06	481.06	perfect 4th	-18.94
15:8	225/64	3.515625	1.8138	2176.54	976.54	minor 7th	-23.46
5:1	25/1	25.000000	4.6439	5572.63	772.63	minor 6th	-27.37

Read the first four rows and the character of the system is visible. **The essence law doubles the distance of every classical interval.** A frequency ratio of `3:2` — the perfect fifth of

ordinary acoustics — becomes `9:4`, an octave plus a major second, because squaring doubles the logarithm. The perfect fourth `4:3` becomes `16:9`, a minor seventh. The octave `2:1` becomes two octaves. This is a general fact, not a coincidence: since pitch interval is logarithmic and the law squares,

```
interval in cents between indices m and n  =  2 * (classical interval between m and n)
```

Squaring the index doubles every interval in cents. The essence law is the classical harmonic series stretched by a factor of exactly two in log-frequency space. That single sentence predicts every row of the table above and is worth carrying.

The upper-triangular lattice for indices 1 through 6, each cell giving exact ratio, cents, and folded cents:

```
each cell:  ratio  |  cents  |  folded cents

        n=1                 n=2                 n=3
 m=2   4/1 2400.0    0.0
 m=3   9/1 3803.9  203.9   9/4 1403.9  203.9
 m=4  16/1 4800.0    0.0   4/1 2400.0    0.0  16/9   996.1  996.1
 m=5  25/1 5572.6  772.6  25/4 3172.6  772.6  25/9  1768.7  568.7
 m=6  36/1 6203.9  203.9   9/1 3803.9  203.9   4/1  2400.0    0.0

                         n=4                 n=5
 m=5  25/16  772.6  772.6
 m=6   9/4  1403.9  203.9  36/25  631.3  631.3
```

Notice how often the folded-cents entry repeats: 0.0 at (2,1), (4,1), (4,2); 203.9 at (3,1), (3,2), (6,1), (6,2), (6,4). That repetition is not an accident of the display. It is Result Two.

17.7.7 7.7 RESULT TWO — octave folding is governed by the odd part of the index

Musical pitch is naturally taken modulo the octave: two tones an octave apart share a *pitch class* and are heard as “the same note, higher”. The question “how many distinct notes does an essence set contain?” is therefore the question “how many distinct pitch classes does it contain?”, and the essence law answers it with unusual sharpness.

Lemma. `f(2n) = k(2n)^2 = 4 k n^2 = 4 f(n)`. Doubling the index multiplies the frequency by four, which is exactly two octaves. Therefore `n` and `2n` always share a pitch class.

Theorem (Result Two). Write every index uniquely as `n = 2^a * m` with `m` odd (`m` is the *odd part* of `n`, `a` its 2-adic valuation). Then

```
f(n) = k * (2^a * m)^2 = k * 4^a * m^2 = f(m) * 4^a = f(m) * 2^(2a)
```

so `f(n)` is exactly `2a` octaves above `f(m)`. **Two essences share a pitch class if and only if their indices have the same odd part.**

Proof of “only if”. Suppose `n = 2^a m` and `n' = 2^b m'` share a pitch class, i.e. `f(n)/f(n') = 2^j` for some integer `j`. Then `4^a m^2 / (4^b m'^2) = 2^j`, so `m^2/m'^2 = 2^(j − 2a + 2b)`. The left side is a ratio of odd squares, hence an odd rational in lowest terms; the right side is a power of two. The only odd power of two is `2^0 = 1`, so `m^2 = m'^2` and, since both are positive, `m = m'`. QED.

Corollary. An essence set indexed `1..N` contains exactly `ceil(N/2)` distinct pitch classes.

Proof. The odd part of any `n <= N` is odd and at most `n <= N`, so every realised class label is an odd number in `[1, N]`. Conversely every odd `m <= N` is itself in the index set and is its own

odd part, so every such label is realised. Hence the class labels are exactly the odd integers in `[1, N]`, of which there are `ceil(N/2)`. QED.

Here is the full index-to-class table for `N` up to 24, computed:

n	`n = 2^a * m`	odd part m	a	`f(n) = k n^2` (Hz)	class representative `f(m)` (Hz)
1	2^0 * 1	1	0	0.483426	0.483426
2	2^1 * 1	1	1	1.933703	0.483426
3	2^0 * 3	3	0	4.350832	4.350832
4	2^2 * 1	1	2	7.734812	0.483426
5	2^0 * 5	5	0	12.085643	12.085643
6	2^1 * 3	3	1	17.403326	4.350832
7	2^0 * 7	7	0	23.687861	23.687861
8	2^3 * 1	1	3	30.939247	0.483426
9	2^0 * 9	9	0	39.157484	39.157484
10	2^1 * 5	5	1	48.342573	12.085643
11	2^0 * 11	11	0	58.494514	58.494514
12	2^2 * 3	3	2	69.613306	4.350832
13	2^0 * 13	13	0	81.698949	81.698949
14	2^1 * 7	7	1	94.751444	23.687861
15	2^0 * 15	15	0	108.770790	108.770790
16	2^4 * 1	1	4	123.756988	0.483426
17	2^0 * 17	17	0	139.710037	139.710037
18	2^1 * 9	9	1	156.629937	39.157484
19	2^0 * 19	19	0	174.516690	174.516690
20	2^2 * 5	5	2	193.370293	12.085643
21	2^0 * 21	21	0	213.190748	213.190748
22	2^1 * 11	11	1	233.978055	58.494514
23	2^0 * 23	23	0	255.732213	255.732213
24	2^3 * 3	3	3	278.453222	4.350832

And the class count, computed and checked against `ceil(N/2)` for every `N` up to 24:

N	distinct odd parts realised	count	`ceil(N/2)`
1	1	1	1
2	1	1	1
3	1,3	2	2
4	1,3	2	2
5	1,3,5	3	3
6	1,3,5	3	3
7	1,3,5,7	4	4
8	1,3,5,7	4	4
9	1,3,5,7,9	5	5
10	1,3,5,7,9	5	5
11	1,3,5,7,9,11	6	6
12	1,3,5,7,9,11	6	6
13, 14	1,3,5,7,9,11,13	7	7
15, 16	1,3,5,7,9,11,13,15	8	8

N	distinct odd parts realised	count	`ceil(N/2)`
17, 18	1,3,...,15,17	9	9
19, 20	1,3,...,17,19	10	10
21, 22	1,3,...,19,21	11	11
23, 24	1,3,...,21,23	12	12

Twelve essences yield only six pitch classes. That is the available harmonic vocabulary, and it is a hard structural limit rather than a stylistic choice. The same rule is reached independently in Curzi [2026], whose Theorem 7.1 states that the pitch class of `f(n) = k n^2` is the odd part of `n`, so that `1..N` realises exactly `ceil(N/2)` classes and `N = 12` realises six — and applies it to mood and trait sets rather than to elements. The compression ratio is exactly 2 for every `N`, which is the flattest possible statement of the constraint: *half of any essence set is harmonically invisible.* You may have 118 elements; you have 59 notes. You may have 24 departments; you have 12 notes. Doubling the roster does not double the palette in any way you can hear beyond the doubling already accounted for.

17.7.8 7.8 The pitch-class lattice is generated by the odd primes

Result Two admits a sharper algebraic statement that is useful when a set is being designed rather than analysed.

Octave-reduce each odd class label `m` by dividing `m^2` by the largest power of two below it. The result lies in `[1,2)`:

odd m	`m^2`	a	folded ratio `m^2/2^a`	cents	nearest 12-TET	dev
1	1	0	1.000000000	0.00	unison	+0.00
3	9	3	1.125000000	203.91	major 2nd	+3.91
5	25	4	1.562500000	772.63	minor 6th	-27.37
7	49	5	1.531250000	737.65	perfect 5th	+37.65
9	81	6	1.265625000	407.82	major 3rd	+7.82
11	121	6	1.890625000	1102.64	major 7th	+2.64
13	169	7	1.320312500	481.06	perfect 4th	-18.94
15	225	7	1.757812500	976.54	minor 7th	-23.46
17	289	8	1.128906250	209.91	major 2nd	+9.91
19	361	8	1.410156250	595.03	tritone	-4.97
21	441	8	1.722656250	941.56	major 6th	+41.56
23	529	9	1.033203125	56.55	minor 2nd	-43.45

Because `m` is odd, factor it as `m = p1^e1 * p2^e2 * ...` over odd primes. Then `m^2 = p1^(2e1) * p2^(2e2) * ...`, and the folded class of `m` is the product of the folded classes of `p_i^2` taken `e_i` times, modulo octaves. Therefore:

The essence pitch-class lattice is the free abelian group generated by the octave-reductions of the squares of the odd primes. The generators, in ascending prime order:

```
prime 3   ->  9/64 folded to 9/8      = 203.910 cents      (Pythagorean whole tone)
prime 5   ->  25/16                   = 772.627 cents
prime 7   ->  49/32                   = 737.652 cents
prime 11  ->  121/64                  = 1102.636 cents
prime 13  ->  169/128                 = 481.062 cents
```

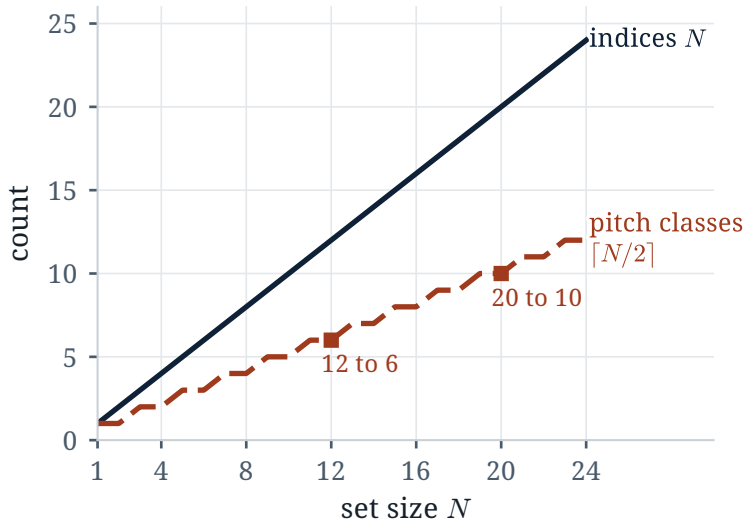

Figure 17.1: **Half of any essence set is harmonically invisible: the compression ratio is exactly 2 at every N.** Twenty indices realise ten pitch classes and twelve realise six, because the class label is the odd part of the index and the odd integers in $[1, N]$ number exactly $\lceil N/2 \rceil$. Exact arithmetic, checked against the class-count table of Section 7.7 for every N up to 24; generated by `figs/src/CCP-017_fig04.py`.

Check the composite classes against the generators: class 9 = 3^2, so its folded class must be `(9/8)^2 = 81/64 = 1.265625`, which is exactly the table's entry and `2 * 203.910 = 407.820` cents. Class 15 = 3*5, so `(9/8)*(25/16) = 225/128`, folded `225/128 = 1.7578125`, and `203.910 + 772.627 = 976.537` cents, matching the table's 976.54. Class 21 = 3*7: `203.910 + 737.652 = 941.562`, matching 941.56.

This is not decoration. It has a direct design consequence: **an essence set that runs `1, 2, 4, 8, 16, ...` produces exactly one note; an essence set whose indices are the odd primes produces the maximally independent harmonic vocabulary available at that size.** Where an ordinal scheme admits legitimate freedom — Section 7.9 states how much — prime indices buy harmonic independence and powers of two throw it away.

Note also a genuine curiosity: `9/8` appears twice here for unrelated reasons. It is inside `k` because the author put it there, and it is the folded class of index 3 because `3^2 = 9` and `2^3 = 8`. The second survives any change of `k`; the first does not.

Four exact design laws follow once the lattice has to be rendered, and they are constraints rather than preferences. They follow from the Gabor time–bandwidth limit [Gabor, 1946, Curzi, 2026z] and from the arithmetic above, and they are stated here because they bound what an essence set may be before anyone chooses one. All four are computed, not asserted.

Law 1 — the audible-set ceiling. With a single integer octave transposition `f * 2^j` and a band of 20 Hz to 20 kHz, the whole set `n = 1..N` fits only if `k * 2^j >= 20` and `k * N^2 * 2^j <= 20000`. The first forces `j >= 6`; the second then caps `N`. **At most `N = 25` essences fit under a single transposition, and only at `j = 6`** — `j = 7` admits 17, `j = 8` admits 12. **A twelve-house set fits comfortably; a thirty-two-element set does not, and requires split transposition**, which is a design decision with consequences and must be declared wherever it is used.

Law 2 — the minimum-gap cliff. Fold the set's pitch classes into one octave and measure the smallest gap. For `N` from 7 to 16 it is exactly **50/49, or 34.976 cents** — the near-coincidence of classes 7 and 5 in the table above. **The moment index 17 enters the set, the minimum gap collapses to exactly 289/288, or 6.001 cents**, because `17^2 = 289` lands beside `9/8 = 288/256`, the folded class of index 3. **The boundary is exact and it is arithmetic: a set of sixteen and a set of seventeen are different design regimes.**

Three ratios, and they are not the same number. The cliff is quoted three ways and each

is correct in its own units, so which one is meant must be stated:

Quantity	Value	What it measures
Gap in **cents**	`ln(50/49)/ln(289/288)` = **5.828**	how much smaller the interval is, logarithmically
Cycles of the tone	`288/49` = **5.878**	3.899 cycles becomes 22.918 (Law 3)
Achievable **rate**	**8, exactly**	symbols per second, and this is the design limit

The rate figure is the one that binds, and it is exactly 8 rather than either of the others. The reason is that the two binding pairs do not sit at the same height in the octave: the 50/49 pair straddles `49/32`, the 289/288 pair straddles `9/8 = 288/256`. Gabor resolution depends on the **absolute** gap in hertz, which is `f/32` before the cliff and `f/256` after — a ratio of exactly 8 at every base pitch. Dividing fractional gaps instead (`288/49`) silently assumes both pairs sit at the same frequency, and they do not. The derivation is Curzi [2026z]. The intermediate cycle counts quoted in that row are taken from it rather than recomputed here, and Section 12 records the one-per-cent discrepancy a direct recomputation from the cents figures produces.

Law 3 — the surplus-resolution bound. Resolving a difference `dF` in surplus requires at least **`1 / (8 pi dF)` cycles** of the rendered tone, and the bound is independent of the transposition because it constrains a ratio. At `dF = 0.01` nats that is 3.98 cycles; at `dF = 0.001`, 39.79. **This is the exact Gabor bridge to the surplus functional: it prices, in time, what it costs to hear a difference in surplus.** Section 8.9 works the consequence for measurement precision.

Law 4 — the rectangular gate is disqualified. A rectangular on/off envelope has **no finite spectral second moment** — its `sinc^2` tails fall as `1/f^2` and the second-moment integral is numerically divergent — so it has no defined bandwidth and cannot serve as a rendering envelope at all. **Any implementation must use a windowed envelope.** Curzi [2026l] specifies one.

17.7.9 7.9 What an essence index is, and what makes an ordering defensible

An **essence index** is the ordinal position of an essence type within its discipline's ordered category set. Atomic number is one instance of an essence index. It is not the definition of one, and the 2022 source's decision to apply the formula to chemistry is an application, not a restriction.

Atomic number is, however, the *best possible* case, and understanding why it is shows what is needed in every other case. It is **intrinsic** (a count of protons, a property of the thing rather than of our filing system), **total** (every element has exactly one and no two share one), **dense from 1** (no gaps, so `ceil(N/2)` applies without qualification), **independently re-derivable** (anyone can recount and get the same integer), and **stable** (it does not change when the discipline reorganises its textbooks).

Most disciplines have nothing like this. The corpus's formula-validation protocol states the conditions under which the framework's formal structure may be applied to a target domain at all [Curzi, 2026t], and those conditions govern here too. They require, before any modelling map is applied:

1. **State encoding** — a map from target-domain items to normalised vectors, so every represented state has a determinate location in the model.
2. **Category assignment** — a finite partition into idealised categories, represented by blocks `H_1, ..., H_N`.
3. **Geometric dependence** (the S1 analogue) — interaction modelled through a scalar similarity parameter such as an angle, cosine, or inner-product-derived quantity.

4. **Zero baseline** (S2 analogue) — parallel or representationally equivalent states correspond to zero modelled surplus.
5. **Affine effective-count law** (S3 analogue) — adopted as a modeling assumption, **not read directly off the world.**
6. **Normalisation** (S4 analogue) — the maximum modelled surplus is finite and depends on the chosen category count `N`.

The protocol is explicit about the exclusion that follows: a target domain lacking a stable encoding, a defensible category scheme, or an interpretable angle-like geometry **is outside the scope of the model.** The same exclusion applies to the essence law, and this paper enforces it.

To those six, the house method adds one more, specific to the essence law because the essence law needs an *order* and not merely a *partition*:

7. **Declared ordinal rule.** The rule that assigns index `n` to category `i` must be published alongside the frequencies, must be applicable by a third party without consulting the author, and must include its tie-break procedure. Where the ordering came from a list written down in that sequence for convenience, that must be stated: it is a weak ordering and its weakness travels with the numbers.

An ordering test you can run in ten minutes. Take the essence set, permute two indices, recompute, and report the change. Worked, for a twelve-element set:

- Swap indices 3 and 12. Frequencies move from 4.350832 Hz to 69.613306 Hz and back — a factor of exactly 16, four octaves. **But the pitch classes do not change at all**, because 3 and 12 share the odd part 3. This permutation is harmonically invisible.
- Swap indices 3 and 5. Class 3 (folded ratio 9/8, 203.91 cents) becomes class 5 (25/16, 772.63 cents). The pitch class moves by `772.63 − 203.91 = 568.72` cents — nearly half an octave, a tritone's worth of change, from swapping two adjacent list positions.

If a plausible re-ordering of the categories moves a pitch class by half an octave, the ordering is load-bearing and must be justified before any of the frequencies are published. That is the test. It costs nothing and it is the single most commonly skipped step in the procedure.

17.7.10 7.10 The composition rule, and its collapse

The 2022 source also gives a rule for combining essences. For `H2O`: three atoms total, so raise the hydrogen frequency to the `2/3` power, the oxygen frequency to the `1/3` power, multiply, and square:

```
f(H2O) = ( f(H)^(2/3) * f(O)^(1/3) )^2
```

This too collapses. Let a compound contain essence indices `n_i` with multiplicities `c_i`, and let `T = sum(c_i)` be the total count. Define `G` as the count-weighted geometric mean of the indices:

```
G = ( prod_i  n_i^(c_i) )^(1/T)
```

Then

```
f_compound = ( prod_i f(n_i)^(c_i/T) )^2
           = ( prod_i (k n_i^2)^(c_i/T) )^2
           = ( k^(sum c_i / T) * prod_i n_i^(2 c_i / T) )^2
           = ( k * G^2 )^2
           = k^2 * G^4
```

The composition rule is `k^2` times the fourth power of the count-weighted geometric mean of the constituent essence indices. Test it on water: `G = (1^2 * 8^1)^(1/3) = 8^(1/3) = 2.00000000`, so `f = k^2 * 16 = 3.7392070290462`, against the source's published `3.73920702904621`. Agreement to fourteen significant figures.

Verified across every composite value the source publishes — 24 pharmacological compounds, 8 nucleotides in the carbon column, and 6 each in the silicon- and germanium-substituted columns, 44 values in all:

37 of 44 published composite values are reproduced by `f = k^2 G^4` to better than one part in 10^12. Seven disagree. The seven, with the size of the disagreement:

formula	published	`k^2 G^4`	relative deviation
O2	11.1246117974981	957.23699944	85.05
C5H6N2O2 (thymine)	4.66961137812091	21.80527042	3.670
C12H17N2O4P	18.5343343733681	13.36731640	0.279
C257H383N65O77S6	14.2762378831273	11.27999043	0.210
C43H66N12O12S2	12.8278625485662	11.29835161	0.119
C77H120N18O26S	11.0756447985031	10.43459440	0.058
C158H251N39O46S	9.46036014007241	9.41751106	0.005

These seven are spreadsheet errors in the source, not evidence of a different rule, and the O2 row proves it. For a single-element species the count-weighted geometric mean is the element index itself, independent of how many atoms are present: `G = 8` for `O`, `O2`, `O3`, `O_x`, always. Therefore `f = k^2 * 8^4 = 957.23699944` for *any* pure-oxygen formula, and **no atom count whatever can produce the published 11.1246117974981.** That row cannot have come from the stated rule. A rule error would fail uniformly across the table; a data-entry error fails on scattered rows. We observe scattered rows. The rule is confirmed and seven cells are errata.

Two engineering notes, both honest flags:

The squaring destroys dimensional consistency. `f(n)` is quoted in Hz; `k^2 G^4` carries Hz-squared if the units are taken seriously. The source reads the squaring as a change of *structural level* — "each time you square the result you establish a level of harmonic molecular structure" — which is a reasonable reading of a designed formalism and is what this paper adopts. **But the composite number's "Hz" label is a convention, not a dimensional quantity, and it must not enter an acoustic calculation without an explicit re-anchoring step.** Curzi [2026l] re-anchors by octave folding, a ratio operation and therefore unit-agnostic; that is the safe path.

Composition flattens the vocabulary further. Because `G` is a geometric mean, low-index constituents pull it toward 1 and high-index constituents raise it slowly. Across the 24 pharmacological compounds in the source, `G` ranges only from 1.84 to 4.30 — a factor of 2.34, which is a factor of 30 in `k^2 G^4`, or about 4.9 octaves. **All twenty-four compounds occupy under five octaves of essence pitch and eighteen of them occupy under two.** Composition is strongly contractive on the pitch space and should be expected to cluster, not disperse.

17.7.11 7.11 The infinite square well: a correspondence of form

A particle of mass `m` confined to a one-dimensional box of width `L` with infinitely high walls has energy eigenvalues

```
E_n = n^2 h^2 / (8 m L^2)          n = 1, 2, 3, ...
```

Divide by Planck's constant to get the associated frequency:

```
nu_n = E_n / h = n^2 * h / (8 m L^2)
```

which is `constant * n^2`. **This is the same functional form as the essence law, with the constant `h/(8 m L^2)` playing the role of `k`.**

The correspondence can be pushed to a specific number. Setting `h/(8 m_e L^2) = k` with `m_e` the electron mass and CODATA values `h = 6.62607015e-34 J s` (exact, by SI definition) and `m_e = 9.1093837015e-31 kg`:

```
L = sqrt( h / (8 * m_e * k) ) = 0.013714300 m = 1.3714 cm

check: h / (8 * m_e * L^2) = 0.483425732988414    <- equals k
```

So there exists a box, 1.37 centimetres wide, for which an electron's level frequencies coincide numerically with the essence frequencies of a set indexed from 1.

This is a coincidence of form and nothing more, and the manual says so in the same breath in which it states the correspondence. Three reasons:

1. **`k` was chosen, not measured.** Because `k` is a free constant, a box width can always be found to match it. The existence of `L` is not a discovery; it is a division. Had `k` been `(4/3)^2/phi^3` the box would be a different size and the "correspondence" equally available. **A correspondence that can be manufactured for any constant carries no information about any constant.**
2. **The 1.37 cm box has no physical significance.** Not the size of an atom (five orders of magnitude too big), not a lattice spacing, not a wavelength of anything in the problem.
3. **`n^2` is the most common eigenvalue pattern in elementary physics**, appearing wherever a wave is confined between fixed boundaries with quantised half-wavelengths. Sharing it is not remarkable.

What *would* be evidence of mechanism, stated plainly: a preregistered prediction, derived from the essence law before measurement, of a physical observable that the law gets right and no simpler model does, on a held-out sample, with the ordering rule fixed in advance. The corpus protocol [Curzi, 2026i, Platt, 1964] applies unmodified. **This paper makes no such prediction and offers no such evidence. The essence law is used here as a naming and design instrument, and nothing in Chapters 29 through 31 depends on it being anything more.**

The correspondence is still worth carrying for one legitimate reason: it tells you what the law's *shape* implies. In a square well, level spacing grows without bound while the *log*-spacing collapses; the low levels are where the interesting structure is. The essence law inherits exactly that character. The interval between neighbouring indices is `2 * 1200 * log2(n/(n-1))` cents: 1403.9 at `n = 2`, 177.7 at `n = 20`, 69.8 at `n = 50`. **The first few essence indices carry almost all of the harmonic interest; past about index 20 the set thins through equal temperament and out into microtones.** That is a constraint on set design rather than a preference.

17.7.12 7.12 Specification: fourteen requirements on a published essence set

Numbered, checkable requirements. A published essence-frequency set that fails any of these is not conformant to this paper.

ES-1 — State the law in its collapsed form. Publish `f(n) = k n^2` with `k = 0.483425732988414 Hz`, not the spreadsheet recipe. The recipe hides that a single constant does all the reference-setting work, and it invites the parenthesis error documented in Section 7.4.

ES-2 — Badge `k` at every appearance. `k` is a chosen reference constant; its form is a design decision by the author of the 2022 source. Never present it as measured, derived, or fundamental.

ES-3 — Publish the ordinal rule with the frequencies. State how index `n` was assigned to category `i`, in terms a third party can apply without consulting the author, including tie-breaks. A frequency table without its ordinal rule is not a result; it is a list.

ES-4 — Run and report the permutation sensitivity test. Swap at least three plausible index pairs, recompute, report the maximum pitch-class displacement in cents. Where any displacement exceeds 100 cents the ordering is load-bearing, and must be declared and justified (Section 7.9).

ES-5 — Verify validity conditions 1, 2 and 6 before applying the law [Curzi, 2026t]. State the encoding, the partition, and `N`. Where any of the three cannot be stated, the domain is out of scope.

ES-6 — Report `ceil(N/2)` alongside `N`. This prevents the commonest design error: planning a composition around `N` voices when only `ceil(N/2)` are distinguishable. (Section 7.7)

ES-7 — Never publish a frequency without its octave. Every value carries its raw Hz or its transposition exponent `j` with `f_published = f_raw * 2^j`, plus the band. Two values quoted without their `j` cannot be compared.

ES-8 — Quote to no more than fifteen significant figures. That is the source's precision and the limit of double-precision arithmetic. For any built application four figures already exceed the tuning resolution of the available physical instruments.

ES-9 — Restate honesty clause H1 in any document carrying a frequency table. "This is an essence frequency, not a physical resonance. No claim is made that any material, molecule, element, institution or person physically resonates at these values." On the same page as the numbers.

ES-10 — When composing, publish `G` and `T` with the result. `f = k^2 G^4` is the closed form; The count-weighted geometric mean and the member count are published so that the value is reproducible.

ES-11 — Re-anchor composite values by ratio, never by unit. Composite outputs carry `Hz^2`. Bring them into band by octave folding — a ratio operation — and state the fold. A composite value is never fed into an acoustic formula expecting Hz. (Section 7.10)

ES-12 — Note the square-well disclaimer in the same paragraph as the correspondence. Never in a later section, never in a footnote. Coincidence of form is not evidence of mechanism. (Section 7.11)

ES-13 — Recompute the source's published values before relying on them. Seven of the 44 composite values in the 2022 document are errata (Section 7.10). Recompute; do not transcribe.

ES-14 — Prefer prime indices when index assignment is genuinely free. Odd-prime indices maximise harmonic independence; powers of two collapse onto one class. Where the ordinal rule does *not* admit freedom, ES-3 governs and this requirement is void. (Section 7.8)

17.7.13 7.13 Failure modes of the essence law

Each entry gives the fault, the parameter or claim it damages, its diagnostic signature, and the fix.

FM-E1 THE ARBITRARY ORDINAL

Damages: every frequency in the set. *Description.* An ordering chosen for convenience — alphabetical, historical, the order items came up in a meeting — is fed into `f(n) = k n^2` and the output treated as intrinsic. *Signature.* Asked why a given category carries index 10, the answer is that that is where it sits on the sheet. *Fix.* ES-3 and ES-4. Publish the rule and run the permutation test. Where displacement is large and the rule is weak, **the correct output is a range rather than a frequency**, and the range is what is reported.

FM-E2 THE PHYSICAL RESONANCE CLAIM

Damages: the credibility of everything else in the volume. *Description.* A sentence of the form "iron resonates at 326.80 Hz". It does not. Iron's essence index is 26 and `k * 676 = 326.795795500168` — a number attached to a position in an ordering. *Signature.* Any sentence in which a material, molecule, body part or person is the *subject* of the verb "resonates" with an essence frequency as its object. *Fix.* H1, restated per ES-9. Rewrite so the essence set is the subject: "index 26 of the periodic ordering carries essence pitch class 13."

FM-E3 THE UNBADGED CONSTANT

Damages: the reader's ability to tell proof from postulate. *Description.* `k = (9/8)^2/phi^2` is presented as though the golden ratio had been discovered in the data rather than placed in the formula by hand. *Signature.* Prose in which `phi` is described as "emerging", "appearing", or "governing". *Fix.* ES-2, plus Result One: state in the same passage that `k` cancels from every relationship and therefore governs nothing but the reference pitch.

FM-E4 THE PHANTOM VOCABULARY

Damages: every downstream decision that assumed `N` distinguishable tones. *Description.* A twelve-category scheme is sonified as twelve voices; six are octave duplicates and the "twelve-part harmony" is a six-note chord doubled. *Signature.* Two "different" voices a listener cannot tell apart; two indices whose ratio is a power of four. *Fix.* ES-6. Design to `ceil(N/2)`. Twelve distinct tones require at least twenty-three justified essence indices.

FM-E5 THE UNSTATED OCTAVE

Damages: comparability between any two published tables. *Description.* One table publishes raw values, another the same set folded into 220-440 Hz; compared directly they appear to disagree by orders of magnitude. *Signature.* Values from two sources differing by a clean power of two. *Fix.* ES-7. Every value carries its `j` and its band, always.

FM-E6 PRECISION THEATRE

Damages: trust, and nothing else — but that is enough. *Description.* Publishing `326.795795500168 Hz` as a tuning target for a physical object whose own frequency drifts a percent with temperature, and whose best tuner resolves 0.1 cent. *Signature.* More than about six significant figures on any value that will be built rather than computed. *Fix.* ES-8. Fifteen figures in the derivation table, four in the build specification.

FM-E7 THE SQUARE-WELL SLIDE

Damages: the boundary between this section and physics. *Description.* The `n^2` correspondence is noted, then the essence law is called "quantum", and a step later energy levels are claimed. *Signature.* "Quantum", "eigenvalue" or "energy level" used without a disclaimer in the same paragraph. *Fix.* ES-12 — and the harder fix: where the argument cannot be made without the physics vocabulary, it was leaning on borrowed authority and must be rewritten without it.

FM-E8 COMPOSITION UNIT DRIFT

Damages: any acoustic calculation downstream. *Description.* A composite value from `k^2 G^4` — dimensionally Hz-squared — is fed into `L = c/(2f)` or a Sabine calculation as though it

were Hz. *Signature.* A tube length or absorption target absurd by three or more orders of magnitude. *Fix.* ES-11. Fold into the target band first, then use ratios only.

FM-E9 THE SPREADSHEET ORACLE

Damages: seven values in 44, unpredictably. *Description.* Transcribing published values instead of recomputing them, inheriting the source's data-entry errors, then defending them because they are "published". *Signature.* A value that resists reproduction by the stated rule while its neighbours reproduce to fourteen figures. *Fix.* ES-13. Where recomputation disagrees by more than 1e-12 relative, the published number is wrong until shown otherwise, and the disagreement is printed, as Section 7.10 does.

FM-E10 THE POWERS-OF-TWO SET

Damages: the entire harmonic output. *Description.* An essence set built on indices `1, 2, 4, 8, 16` — a natural doubling scheme. Every member has odd part 1. **The set has exactly one pitch class.** *Signature.* All voices in unison across octaves; a "chord" with no interval in it. *Fix.* ES-14 where index assignment is free; where it is not, accept and report the result — that a category scheme is harmonically degenerate is a real finding about the scheme.

17.7.14 7.14 Worked instances

7.14.1 The periodic table, first twenty elements, carried end to end

This is the source document's own domain and therefore the strongest available test: we can check every intermediate against a published value.

Step 1 — Establish the ordinal. The essence index is atomic number: the count of protons in the nucleus. It satisfies all five properties of Section 7.9 — intrinsic, total, dense from 1, independently re-derivable, stable. This is the best case and it is why the source chose it. Validity condition 2 [Curzi, 2026t] is satisfied by the partition of matter into elements; condition 6 is satisfied with `N = 118`.

Step 2 — Compute raw essence frequencies. `f(n) = 0.483425732988414 * n^2`.

Step 3 — Compute odd parts and pitch classes. By Result Two.

Step 4 — Fold into an audible band. Band chosen: `[220, 440)` Hz — one octave, anchored on A3 = 220 Hz. `f_folded = f * 2^j`, `j` the integer bringing `f` into the band. The band and `j` are published for every value, per ES-7.

n	element	`f(n)` (Hz)	odd part	class	j	`f` folded to [220,440)
1	H	0.483426	1	PC1	+9	247.5140
2	He	1.933703	1	PC1	+7	247.5140
3	Li	4.350832	3	PC3	+6	278.4532
4	Be	7.734812	1	PC1	+5	247.5140
5	B	12.085643	5	PC5	+5	386.7406
6	C	17.403326	3	PC3	+4	278.4532
7	N	23.687861	7	PC7	+4	379.0058
8	O	30.939247	1	PC1	+3	247.5140
9	F	39.157484	9	PC9	+3	313.2599
10	Ne	48.342573	5	PC5	+3	386.7406

n	element	f(n) (Hz)	odd part	class	j	f folded to [220,440)

13	Al	81.698949	13	PC13	+2	326.7958
14	Si	94.751444	7	PC7	+2	379.0058
15	P	108.770790	15	PC15	+2	435.0832
16	S	123.756988	1	PC1	+1	247.5140
17	Cl	139.710037	17	PC17	+1	279.4201
18	Ar	156.629937	9	PC9	+1	313.2599
19	K	174.516690	19	PC19	+1	349.0334
20	Ca	193.370293	5	PC5	+1	386.7406

Step 5 — Count the vocabulary. `N = 20`, so `ceil(20/2) = 10` distinct pitch classes: `{1, 3, 5, 7, 9, 11, 13, 15, 17, 19}`. Ten notes from twenty elements. Confirmed against the class column: PC1 five times (H, He, Be, O, S), PC3 three (Li, C, Mg), PC5 three (B, Ne, Ca), PC7 twice (N, Si), PC9 twice (F, Ar), and PC11, PC13, PC15, PC17, PC19 once each — twenty in total.

Step 6 — Read the structure. Hydrogen, helium, beryllium, oxygen and sulphur are *the same note*. Not a metaphor: 1, 2, 4, 8 and 16 share the odd part 1, so their essence frequencies stand in ratios `1 : 4 : 16 : 64 : 256`, which is `0, 2, 4, 6, 8` octaves. **A tuning built on this set has one voice at PC1 sounding in five octaves and single voices at nine other classes — a strong fundamental with a thin upper structure, and that is a structural fact about the ordering, available before a single note is played.**

Step 7 — Verify and clause. Every raw frequency above was recomputed and matches the 2022 document to a worst relative deviation of 9.0e-15 across the full 118-element set (Section 7.4); nothing is transcribed. Per ES-9: *these are essence frequencies, not physical resonances; no claim is made that hydrogen, iron or any other element physically resonates at any value in this table.*

7.14.2 The same arithmetic on a non-chemical ordinal

The point of Section 7 is that atomic number is *an instance* of an essence index. A second instance comes from the corpus's own lineage: **the twelve declared nodes of the foundations volume**. Those nodes are the stages of the founding construction in which comfort is defined as the felt total of present costs, so that the present state is a local minimum of the comfort landscape by definition rather than by luck [Curzi, 2026]; their reference apparatus, including the three-drawer honesty ledger that assigns four items to established mathematics, seven to established psychology and exactly three to declared postulates, is Curzi [2026]. The node sequence is a designed process order — each node is a stage an operator passes through, and the order is the order of passage. That makes it a defensible ordinal under Section 7.9: intrinsic to the method, total, dense from 1, stable, and independently re-derivable by anyone holding the volume.

The four nodes this paper names elsewhere sit at indices 2 (GRADIENT), 7 (COLLAPSE), 9 (RECURSE) and 10 (FIXEDPOINT), with 11 (SEAL) — the remainder are referred to by index only, because inventing names for them would violate the corpus's naming constraint [Curzi, 2026].

`N = 12`, so `ceil(12/2) = 6` pitch classes: `{1, 3, 5, 7, 9, 11}`.

n	node	f(n) (Hz)	odd part	class	j	folded to [220,440)
1	node 01	0.483426	1	PC1	+9	247.5140
2	node 02 GRADIENT	1.933703	1	PC1	+7	247.5140

n	node	f(n) (Hz)	odd part	class	j	folded to [220,440)
3	node 03	4.350832	3	PC3	+6	278.4532
4	node 04	7.734812	1	PC1	+5	247.5140
5	node 05	12.085643	5	PC5	+5	386.7406
6	node 06	17.403326	3	PC3	+4	278.4532
7	node 07 COLLAPSE	23.687861	7	PC7	+4	379.0058
8	node 08	30.939247	1	PC1	+3	247.5140
9	node 09 RECURSE	39.157484	9	PC9	+3	313.2599
10	node 10 FIXEDPOINT	48.342573	5	PC5	+3	386.7406
11	node 11 SEAL	58.494514	11	PC11	+2	233.9781
12	node 12	69.613306	3	PC3	+2	278.4532

Sorted by pitch and reduced to a single octave, the six classes form this scale:

#	class	folded ratio	cents above PC1	step to next (cents)
1	PC1	1.000000000	0.00	203.91
2	PC3	1.125000000	203.91	203.91
3	PC9	1.265625000	407.82	329.83
4	PC7	1.531250000	737.65	34.98
5	PC5	1.562500000	772.63	330.01
6	PC11	1.890625000	1102.64	97.36

The six steps sum to `203.91 + 203.91 + 329.83 + 34.98 + 330.01 + 97.36 = 1200.00` cents. The scale closes at the octave, as it must.

Three structural observations, all of them consequences of Section 7.8 and none of them stylistic:

1. **The scale opens with two exact Pythagorean whole tones.** PC1 -> PC3 -> PC9 is `1 : 9/8 : 81/64`, the tone-chain generated by the odd prime 3. Nodes 03, 06 and 12 (class 3) and node 09 (class 9) are related to node 01 by pure three-limit intervals.
2. **PC7 and PC5 are 34.98 cents apart — a third of a semitone.** Node 07 COLLAPSE and nodes 05/10 land almost on top of each other. Sounded together they beat, rather than forming an interval; the companion paper \citep{ccp:CCP-018} treats that as an acoustic design decision, not a defect.
3. **Node 10 FIXEDPOINT (index 10) and node 05 (index 5) are the same class.** `10 = 2 * 5`, so they are exactly two octaves apart. Since node 10 is the steady state the recursion converges to [Curzi, 2026a] — and node 05 sits at the same class two octaves below, **the ordering places the fixed point in octave relation to an earlier node, which is precisely the relationship an accumulator has with its own transient.** This is offered as an observation about the ordering's arithmetic, not as evidence for the ordering. Had the nodes been numbered differently the relation would not hold, and the sensitivity test of Section 7.9 would report exactly that.

Sensitivity test (ES-4), run. Three plausible re-orderings:

- Swap 09 and 10: class 9 <-> class 5, pitch-class displacement `772.63 − 407.82 = 364.81` cents. **Load-bearing.**
- Swap 03 and 12: classes both 3, displacement `0.00` cents. Harmonically invisible.
- Swap 07 and 11: class 7 <-> class 11, displacement `1102.64 − 737.65 = 364.99` cents. **Load-bearing.**

Maximum displacement 364.99 cents, well over the 100-cent threshold of ES-4. **Conclusion: the node ordering is load-bearing for this essence set, and any published tuning derived from it must carry the ordinal justification alongside it.** In this case the justification is available — the node order is the order of the method — and so the set is conformant. Had it not been available, ES-4 would have required publishing a range instead of a frequency.

Closing clause (ES-9). *Every value in both parts of this worked example is an essence frequency. It is a pitch assigned to a position in an ordered category set. It is not a physical resonance and implies none. No element, no node, no operator and no room physically resonates at any of these values, and this paper makes no claim that any does.*

Section 8 takes up the question this section has deliberately left open: what happens when the two essences to be related do not share an ordering at all.

17.8 8 The essence bridge: the effective count as a cross-disciplinary index

Section 7 leaves a hole in the middle of the method, and does so deliberately.

The essence law needs an index. Within a discipline the index is available: the categories are ordered, the ordering is defensible, and `n` is a position in that ordering. Between two disciplines the index is *not* available, and no amount of care in constructing either ordering supplies it. Biology's third category and Ethics' third category are both "third", and their threeness has nothing in common. Feed both into `f(n) = k n^2` and you get the same frequency for two things that have no relationship at all. That is not a small inconvenience. **It means the essence law, as published, cannot say anything about a relationship that crosses a category boundary — which is to say it cannot say anything about the only relationships this corpus has spent twenty-eight chapters learning to engineer.**

This section closes the hole. It closes it not with an approximation, a heuristic, or a convention, but with an identity already present in the surplus characterisation [Curzi, 2026], and it closes it in one line:

```
n_eff = N_eff = 1 + (N − 1)u = e^F
```

The effective count IS the cross-disciplinary essence index. It is a real number rather than an integer, it is defined for any pair of states in the model, it equals 1 exactly when the two states are parallel — the ground essence — and it equals `N` exactly when they are orthogonal. Those are precisely the properties an index needs. Substituting it into the essence law produces the load bearing result of this entire volume, which is stated in Section 8.4 and which every subsequent section elaborates:

One nat of interaction surplus is exactly 2.885 octaves. The interaction surplus IS a pitch interval.

This is the paper's central identification. Sections 3 to 6 develop the arithmetic of interaction and Section 7 the arithmetic of essence; this section shows that they are the same arithmetic in two notations and gives the exact conversion factor between them.

17.8.1 8.1 Statement of the bridge

IDENTIFICATION (badged). Let two essences sit in different blocks of the framework's decomposition [Curzi, 2026]. Let `u = ||x ^ y||^2 = 1 − (x . y)^2` be the represented difference between their normalised state vectors, `N` the number of categories in the chosen partition, and `F = f(u) = ln(1 + (N−1)u)` the interaction surplus [Curzi, 2026]. Then the cross-disciplinary essence index is taken to be the effective count,

```
n_eff := N_eff = 1 + (N − 1)u = e^F
```

and the cross-disciplinary essence frequency follows from the essence law of Section 7 without adjustment:

```
f_cross = k ∗ n_eff^2 = k ∗ N_eff^2 = k ∗ e^(2F)

k = 0.483425732988414 Hz        (Section 7.1)
```

Taking the base-2 logarithm gives the interval above the ground essence `k`:

```
OCTAVES ABOVE BASE  =  log2( f_cross / k )  =  log2( e^(2F) )  =  2F / ln 2

2 / ln 2 = 2.885390081777927        (computed)

OCTAVES  =  2.885390081777927 ∗ F        with F in nats
```

Everything after the identification is exact algebra. The identification itself is a modeling decision and is badged as one. Its warrant is Section 8.3: `n_eff` is the unique quantity already present in the framework that satisfies every requirement an essence index must satisfy.

17.8.2 8.2 The honesty clauses, restated

The bridge inherits every clause from both parents. They are restated here in full because the corpus's disclosure standard requires it [Curzi, 2026] and because a construction joining two frameworks is exactly where an unstated clause would do the most damage.

From Section 7, the essence law:

- **H1.** The output is an essence frequency, **not a physical resonance.** No claim is made that any material, molecule, element, institution, room or person physically resonates at these values, and the text must never imply otherwise.
- **H2.** `k` is a chosen reference constant, not a measured one. Its form — a Pythagorean interval over the golden section — is a design decision. **It cancels from every relationship in the system (Result One) and sets only the reference pitch.**
- **H3.** The square law is a postulate about essence structure. Its formal agreement with infinite-square-well eigenvalue spacing is a mathematical coincidence, not evidence of mechanism.
- **H4.** The essence index requires a defensible ordering. Within a discipline that means the validity conditions [Curzi, 2026t] plus a declared ordinal rule. **Across disciplines the ordering problem does not go away — it becomes the requirement that `u` be honestly measured.**
- **H5 — the errata clause, on the strength of Section 7.4 and Section 7.10, binding on every chapter that quotes a number from the 2022 source.** Do not copy published values. Recompute them. `f = k n^2` reproduces all 118 published element values to a worst relative deviation of **9.0e-15**, and the compound rule `f = k^2 G^4` — `G` the count-weighted geometric mean of the constituent indices — matches **37 of the 44** published composites to better than one part in 10^12. **The seven that disagree are data-entry errors in the source, not a different law, and the O2 row proves it: for a single-element species `G` is the element index whatever the atom count, so no atom count whatever can produce the published figure.** Two transcription faults travel with the citation: the source's prose instruction `1+5^.5/2` is missing its parentheses and must be read as `(1 + sqrt(5))/2`, and the spreadsheet stored `phi` to fifteen significant figures, which accounts for the whole of the residual bias in the published table. **Cite the errata whenever the source is cited.** Where this section anchors to a published value — the `f(100)` check in Section 8.5 is the case — the anchor is to the recomputed value, and the agreement to fourteen figures is what licenses the check.

From the surplus framework:

- **The S3 axiom is a design axiom.** `g(u) = e^{f(u)}` affine is *chosen*, not derived. The entire bridge rests on it, because `N_eff` is defined by it. Say so whenever you lean on it — and this chapter leans on it in every section.
- **The triangle inequality fails for geometric triples** [Curzi, 2026]. Subadditivity holds on the parameter `u` only. Do not chain intervals across three essences as though pitch distances added.
- **As deployed, the surplus functional is a LOWER BOUND** on the ensemble's information, not the information itself. We log the floor, not the ceiling. Therefore **every frequency this section computes is a lower bound on the pitch, not the pitch.**
- **The characterisation theorem is pure mathematics and makes no empirical or metaphysical claim** [Curzi, 2026].
- Surplus is **not** identified with Shannon entropy or mutual information in general [Shannon, 1948, Cover and Thomas, 2006]; the corpus's own three-drawer classification puts that identification in the postulate drawer [Curzi, 2026].
- No thermodynamic negentropy law is proved [Curzi, 2026a]. Higher static surplus does not imply higher canonical concentration, and the Shannon/thermodynamic distinction is kept explicit [Brillouin, 1953, Landauer, 1961].

One clause specific to the bridge, and it is the sharpest of them: the essence frequency computed here is a function of a *measurement of a relationship*, not of either party to it. `f_cross` changes when the measured `u` changes, and `u` changes with the encoder, the category scheme, the observer, and the day. **A cross-disciplinary essence frequency is a reading of an instrument, and like any instrument reading it carries the instrument's error, not the world's truth.**

17.8.3 8.3 Why there is no shared ordinal, and what would fix it

The framework works in `V = R^(NM)`, decomposed into `N` orthogonal blocks `H_1, ..., H_N`, each of dimension `M` [Curzi, 2026]. A block is an idealised category in a chosen representation, and a unit vector `x` in `H_i` is a normalised state-description within category `H_i`.

Within one block the essence law is comfortable. The block's `M` sub-modes have an ordering — Paper B's twelve-house example orders them Origin, Structure, Flow, Perception, Reciprocity, Transformation, Harmony, Growth, Memory, Repair, Connection, Completion — and if that ordering satisfies the Section 7.9 test then `n` is well defined and `f(n) = k n^2` applies.

Across blocks it is not. Consider two essences, `x` in `H_3` (Biology & Body) and `y` in `H_12` (Ethics & Governance). Each has an ordinal position *within its own block*. Neither position means anything relative to the other. Concretely, four distinct failures block the naive approach:

1. **No common origin.** Each block's index 1 is an arbitrary starting point of that block's ordering. There is no fact of the matter about whether Biology's first sub-mode "precedes" Ethics' first sub-mode.

2. **Index collision.** Two unrelated essences at position 3 in their blocks receive identical frequencies. **A method that assigns the same pitch to two things precisely because they are unrelated has inverted its own purpose.**

3. **No relational content.** The essence law as published takes one argument. It maps a category to a frequency. It has no slot for "the relationship between two categories", which is the object we actually care about.

4. **Scale mismatch.** Blocks may have different `M`. An index of 7 in a twelve-mode block and an index of 7 in a four-mode block are not comparable even in a loose sense.

What we need is a quantity that: (a) takes *two* states as arguments; (b) is a single positive real number, so it can be squared; (c) equals 1 for identical or representationally equivalent states, so that a relationship of no difference lands on the ground essence `k * 1^2 = k`; (d) is bounded above by a stated maximum, so the pitch is bounded; (e) is defined regardless of which blocks the two states occupy; and (f) is monotone in difference, so more difference means a higher index and therefore a higher pitch.

There is exactly one such quantity already in the framework, and it is not a coincidence that there is exactly one — the properties above are, item for item, the axioms S1 through S4 read backwards.

17.8.4 8.4 The effective count is the index

The uniqueness characterisation [Curzi, 2026]: under axioms S1 (geometric dependence), S2 (`f(0) = 0`), S3 (affine effective count), and S4 (`f(1) = ln N`), the surplus functional is uniquely

```
F(x,y) = f(u) = ln(1 + (N−1)u),        u = 1 − (x . y)^2 in [0,1]
```

and the effective count is

```
N_eff = g(u) = e^{f(u)} = 1 + (N − 1)u
```

Check the six requirements against it, one by one:

requirement	`N_eff = 1 + (N−1)u`	source
(a) takes two states	yes, via `u(x,y)`	S1 [Curzi, 2026]
(b) single positive real	yes, `N_eff >= 1 > 0`	affine in `u >= 0`
(c) equals 1 at no difference	`u = 0 -> N_eff = 1` exactly	S2 [Curzi, 2026c]
(d) bounded above	`u = 1 -> N_eff = N` exactly	S4 [Curzi, 2026c]
(e) block-independent	`u` is defined for any pair of unit vectors	[Curzi, 2026]
(f) monotone in difference	strictly increasing in `u`	[Curzi, 2026]

Every box is ticked, and ticked by a theorem rather than by assertion. **The effective count is not merely *a* candidate for the cross-disciplinary essence index; it is the unique quantity the framework already contains that satisfies the requirements, and the requirements were derived from what an essence index must do, independently of the surplus framework.**

Its interpretation is also exactly right for the job. `N_eff` is a headcount *after that headcount has been audited for redundancy* [Curzi, 2026c].

Which effective count, and why it matters here. Two other effective counts appear in this corpus and neither is the one used in this section. `1/HHI`, the reciprocal Herfindahl index, is the Hill number of order two and `exp(H)` is the Hill number of order one; both are grounded in a mature literature [Hill, 1973, Jost, 2006, 2007, Simpson, 1949]. The corpus applies the first directly: a four-jurisdiction split of 40.9 / 27.3 / 18.2 / 13.6 gives a naive HHI of 0.293430 and 3.41 effective jurisdictions, which collapses to a bloc-HHI of 1.000000 and an effective count of exactly 1.00 once the bloc structure is audited [Curzi, 2026]; a four-state split of 40.0 / 25.0 / 20.0 / 15.0 gives a naive HHI of 0.285000 and 3.508772 effective jurisdictions, which likewise collapses to 1.00 and to a surplus term of exactly zero [Curzi, 2026]. **`N_eff = 1 + (N−1)u` is a third quantity and is not a Hill number.** It is a linear interpolation between 1 and `N` adopted as design axiom S3 [Curzi, 2026c], it has no external literature, and every octave value in this section inherits that choice. Where an effective count is quoted anywhere in this paper, which of the three is meant is stated. Ten parallel windows are one window: `u = 0`, `N_eff = 1`, `F = ln 1 = 0`. That is the ground essence, `f = k * 1 = 0.483426 Hz`. **Two essences that are**

representationally the same thing produce the ground tone and no interval at all — which is the musically correct answer, because there is no interval between a note and itself.

Substituting and simplifying:

```
f_cross  =  k * N_eff^2  =  k * (1 + (N−1)u)^2  =  k * e^(2F)
```

and, since `F = ln N_eff`,

```
log2(f_cross / k)  =  log2(N_eff^2)  =  2 * log2(N_eff)  =  2 * F / ln 2
```

Computed: `2 / ln 2 = 2.885390081777927`. One nat of interaction surplus is exactly 2.885390 octaves — equivalently 3462.4681 cents. And inversely, one octave of essence pitch is exactly `ln(2)/2 = 0.346574` nats of surplus.

Two verifications against values fixed independently elsewhere in the corpus — against the count-based essence index `f(n) = k n^2` with its twelve-state ladder [Curzi, 2026], and against the conversion-key result that **one bit equals two octaves, not one**, since doubling the effective count gives `f(2n)/f(n) = 4` under the square law, verified across `N_eff = 1, 3, 12` [Curzi, 2026l]:

```
F = 0        (parallel, u = 0)
  -> N_eff = 1
  -> f_cross = k * 1 = 0.483425732988414 Hz     <- the ground essence
  -> octaves above base = 2 * 0 / ln 2 = 0.000000

F = ln 12 = 2.4849066497880004     (orthogonal at N = 12, u = 1)
  -> N_eff = 12.000000
  -> f_cross = k * 144 = 69.61330555033166 Hz
  -> octaves above base = 2 * 2.4849066497880004 / 0.6931471805599453
                        = 7.169925001442313
  -> check: 2 * log2(12) = 2 * 3.584962500721156 = 7.169925001442313   [identical]
```

Both exact. **This is the unification: the ordinal index within a discipline and the effective count across disciplines are the same variable `n`. The two frameworks compose without adjustment, without a fitting constant, and without a correction term.**

It is worth pausing on how unusual that is. Nothing was tuned. `k` came from a 2022 document about chemistry; `N_eff` came from an axiomatic characterisation theorem about interaction geometry; the factor `2/ln 2` fell out of substituting one into the other. **The bridge has no free parameters at all** — which also means it has nothing to hide behind, and Section 8.11 states exactly how it fails.

17.8.5 8.5 The master conversion table

Everything an engineer needs from this section is in one table, computed here at full precision. Read it in either direction: from a measured surplus to a pitch, or from a chosen pitch to the surplus it implies.

F (nats)	`N_eff = e^F`	`f_cross = k e^(2F)` (Hz)	octaves above `k`	cents above `k`
0.000000	1.000000	0.483426	0.000000	0.0
0.050000	1.051271	0.534268	0.144270	173.1
0.100000	1.105171	0.590458	0.288539	346.2
0.200000	1.221403	0.721186	0.577078	692.5
0.300000	1.349859	0.880859	0.865617	1038.7

F (nats)	N_eff = e^F	f_cross = k e^(2F) (Hz)	octaves above k	cents above k
0.400000	1.491825	1.075884	1.154156	1385.0
0.500000	1.648721	1.314087	1.442695	1731.2
0.693147 (= ln 2)	2.000000	1.933703	2.000000	2400.0

3.000000	20.085537	195.027860	8.656170	10387.4
3.218876 (= ln 25)	25.000000	302.141083	9.287712	11145.3
3.500000	33.115452	530.140688	10.098865	12118.6
4.000000	54.598150	1441.071800	11.541560	13849.9
4.605170 (= ln 100)	100.000000	4834.257330	13.287712	15945.3

Three checks that the table is internally consistent, each verifiable by eye:

- At `F = ln 2`, `N_eff = 2` and the pitch is exactly two octaves above base — the lemma of Section 7.7 (doubling the index is two octaves) reappearing as a statement about surplus.
- At `F = ln 9` the frequency is `39.157484 Hz`, which is `k * 81` — identical to `f(9)` in Chapter 29's within-discipline table. **The bridge is continuous with the ordinal law: when `N_eff` lands on an integer, the cross-disciplinary frequency *is* the within-discipline frequency of that index.**
- At `F = ln 100`, `f = 4834.257330 Hz`, which is `f(100)` from the periodic-table verification of Section 7.4, matching the source document's published value for fermium to fourteen figures.

That second check deserves emphasis. It is the reason this is a bridge and not an analogy. **Whenever the audited effective count happens to equal an integer `m`, the cross-disciplinary essence frequency is exactly the within-discipline essence frequency of index `m`. The two formalisms agree on their overlap.** A bridge that disagreed with either shore would be a different construction with the same name.

The integer-anchored version of the same table, which is the one to use when you are working backwards from a target effective count:

N_eff	F = ln N_eff	f = k N_eff^2 (Hz)	octaves above k
1	0.000000	0.483426	0.000000
2	0.693147	1.933703	2.000000
3	1.098612	4.350832	3.169925
4	1.386294	7.734812	4.000000
5	1.609438	12.085643	4.643856
6	1.791759	17.403326	5.169925
7	1.945910	23.687861	5.614710

N_eff	F = ln N_eff	f = k N_eff^2 (Hz)	octaves above k
8	2.079442	30.939247	6.000000
9	2.197225	39.157484	6.339850
10	2.302585	48.342573	6.643856
11	2.397895	58.494514	6.918863
12	2.484907	69.613306	7.169925

20	2.995732	193.370293	8.643856
24	3.178054	278.453222	9.169925
32	3.465736	495.027951	10.000000
50	3.912023	1208.564332	11.287712
100	4.605170	4834.257330	13.287712

17.8.6 8.6 Reading the bridge backwards: pitch as a unit of surplus

The conversion runs both ways, and the reverse direction is the one that changes how you think about the numbers. Since `F = (cents/1200) * ln(2) / 2 = cents * ln(2) / 2400`:

interval	cents	F (nats)	N_eff = e^F	u required at N = 12
unison	0	0.000000	1.000000	0.000000
semitone	100	0.028881	1.029302	0.002664
whole tone	200	0.057762	1.059463	0.005406
minor 3rd	300	0.086643	1.090508	0.008228
major 3rd	400	0.115525	1.122462	0.011133
perfect 4th	500	0.144406	1.155353	0.014123
tritone	600	0.173287	1.189207	0.017201
perfect 5th	700	0.202168	1.224054	0.020369
minor 6th	800	0.231049	1.259921	0.023629
major 6th	900	0.259930	1.296840	0.026985
minor 7th	1000	0.288811	1.334840	0.030440
major 7th	1100	0.317692	1.373954	0.033996
octave	1200	0.346574	1.414214	0.037656
two octaves	2400	0.693147	2.000000	0.090909
three octaves	3600	1.039721	2.828427	0.166221

Two facts in that table are worth carrying.

A perfect fifth of surplus is 0.202168 nats. That is the whole content of the sentence "the interaction surplus IS a pitch interval": intervals are now a unit of measurement for organisational difference, and a familiar one. When a rotation programme raises `u` from 0.28 to 0.41 [Curzi, 2026d], that is restatable as *the group's cross-disciplinary tone rose by 1040 cents*, a shade under an octave. It is the same statement in a second register.

And the second fact, which is a warning: the entire audible range is about 3.4 nats. Ten octaves — 20 Hz to 20 kHz, roughly the human hearing range — is `10 / 2.885390 = 3.466` nats. `ln N` for `N = 12` is 2.485 nats, so **a twelve-category scheme's entire surplus range, from parallel to orthogonal, spans 7.17 octaves: about two-thirds of everything a human can hear.** For `N = 50` the span is `2 * log2(50) = 11.29` octaves — more than the audible range. Beyond about `N = 32` the essence pitch of an orthogonal pair leaves the audible band entirely and must be folded. Section 8.9 and the companion paper [Curzi, 2026l] handle the folding.

The corresponding ceiling table, since `F <= ln N` is hard [Curzi, 2026c]:

N	`ln N` (max surplus)	max octaves `= 2 log2 N`	max `f = k N^2` (Hz)
2	0.693147	2.000000	1.9337
3	1.098612	3.169925	4.3508
5	1.609438	4.643856	12.0856
7	1.945910	5.614710	23.6879
10	2.302585	6.643856	48.3426
12	2.484907	7.169925	69.6133
20	2.995732	8.643856	193.3703
50	3.912023	11.287712	1208.5643
100	4.605170	13.287712	4834.2573
118	4.770685	13.765286	6731.2199

`ln N` is the hard ceiling on surplus per interaction [Curzi, 2026c], and it is therefore a hard ceiling on pitch: `2 log2 N` octaves above the ground essence, and not one cent more. The table's last row is the periodic table's own ceiling and lands on 6731.2199 Hz — the source document's published value for oganesson, index 118, to fourteen figures. That agreement is not a new fact; it is Section 8.5's continuity property showing up at the top of the range as well as the middle.

The logarithmic-ceiling result [Curzi, 2026c] is audible here. Doubling `N` adds `ln 2 = 0.693147` nats, hence exactly two octaves, no matter where you start. **You cannot escape a headroom problem by adding domains, and now you cannot escape a pitch problem that way either: going from twelve categories to twenty-four buys you two octaves and nothing else.**

17.8.7 8.7 Crossing and divergence, transported into pitch

The crossing/divergence decomposition [Curzi, 2026d] splits `u` into two sources, and the split survives translation into pitch with its bounds intact.

For a pure block vector `x` in `H_i` and any unit `y`, write `y = y_par + y_perp` with `y_par` in `H_i` and `y_perp` orthogonal to `H_i`. Let `alpha = ||y_par||`, `beta = ||y_perp||`, and `gamma = angle(x, y_par)`. Then

```
u = beta^2 + alpha^2 sin^2(gamma)  =  u_cross + u_div

u_cross = beta^2                  BETWEEN categories  (cross-disciplinary difference)
u_div   = alpha^2 sin^2(gamma)    WITHIN a category    (internal dissent)

max( f(u_cross), f(u_div) )  <=  f(u)  <=  f(u_cross) + f(u_div)
```

Multiply the bound through by `2/ln 2 = 2.885390` — a positive constant, so the inequalities are preserved exactly:

```
max( OCT(u_cross), OCT(u_div) )  <=  OCT(u)  <=  OCT(u_cross) + OCT(u_div)

where OCT(v) := 2.885390081777927 * ln(1 + (N-1)v)
```

In musical terms: the cross-disciplinary tone of a relationship is never lower than the higher of its two component tones, and never higher than the two component tones stacked. The lower bound says you always get at least the better of your two sources of difference. The upper bound says crossing and divergence never combine to give you more than they would

separately — **there is no synergy beyond additivity, and the bound is the framework refusing to promise any.**

Computed, for `N = 12`, showing the whole structure:

u_cross	u_div	u	f(u_cross)	f(u_div)	f(u)	max bound	sum bound	f_cross (Hz)	octaves
0.00	0.00	0.00	0.000000	0.000000	0.000000	0.000000	0.000000	0.483426	0.0000
0.20	0.00	0.20	1.163151	0.000000	1.163151	1.163151	1.163151	4.950280	3.3561
0.00	0.20	0.20	0.000000	1.163151	1.163151	1.163151	1.163151	4.950280	3.3561
0.10	0.10	0.20	0.741937	0.741937	1.163151	0.741937	1.483875	4.950280	3.3561
0.40	0.10	0.50	1.686399	0.741937	1.871802	1.686399	2.428336	20.424737	5.4009
0.10	0.40	0.50	0.741937	1.686399	1.871802	1.686399	2.428336	20.424737	5.4009
0.25	0.25	0.50	1.321756	1.321756	1.871802	1.321756	2.643512	20.424737	5.4009
0.45	0.45	0.90	1.783391	1.783391	2.388763	1.783391	3.566782	57.435811	6.8925
0.90	0.00	0.90	2.388763	0.000000	2.388763	2.388763	2.388763	57.435811	6.8925
0.50	0.50	1.00	1.871802	1.871802	2.484907	1.871802	3.743604	69.613306	7.1699
0.80	0.20	1.00	2.282382	1.163151	2.484907	2.282382	3.445533	69.613306	7.1699

And the same in octaves, with the slack — the gap between the achieved pitch and the sum bound — made explicit:

u_cross	u_div	achieved OCT(u)	max bound (oct)	sum bound (oct)	slack (oct)
0.20	0.00	3.3561	3.3561	3.3561	0.0000
0.00	0.20	3.3561	3.3561	3.3561	0.0000
0.10	0.10	3.3561	2.1408	4.2816	0.9254
0.40	0.10	5.4009	4.8659	7.0067	1.6058
0.25	0.25	5.4009	3.8138	7.6276	2.2267
0.45	0.45	6.8925	5.1458	10.2916	3.3990
0.50	0.50	7.1699	5.4009	10.8018	3.6318
0.90	0.00	6.8925	6.8925	6.8925	0.0000

The corpus reports the same decomposition on a real-shaped case: an institute at `u_cross = 0.72`, `u_div = 0.03` and `u = 0.75` with `N = 6` returns a balance index `B = 0.0206`, a ceiling utilisation of 0.8696, and zero within-block dissents across forty logged decisions [Curzi, 2026d]. **That is the extreme of the pattern the slack column below measures: almost all of the difference is crossing, almost none is divergence, and the slack is therefore near zero while the fragility is at its maximum.**

Read the slack column and the structure of the bound becomes visible. **Slack is zero exactly when one of the two sources is zero, and it is maximal when the two are balanced.** At `u_cross = u_div = 0.5` the sum bound promises 10.80 octaves and the system delivers 7.17 — a slack of 3.63 octaves, more than a third of the audible range, thrown away by concavity.

That is not a defect. **It is strict concavity [Curzi, 2026] charging its price, and the price is real: two half-sized sources of difference produce a lower tone than one full-sized one.** Compare rows: `u_cross = 0.2, u_div = 0` and `u_cross = 0.1, u_div = 0.1` both give `u = 0.2` and therefore both give 3.3561 octaves — identical pitch, because `f` depends only on the sum. But the *bound* differs: the split case had 4.28 octaves available under the sum bound and reached 3.36. The concentrated case had 3.36 available and reached 3.36, saturating its bound.

The design lesson [Curzi, 2026d] is now audible: **crossing and divergence are not substitutes, and a system rich in one and starved of the other sits at exactly the same pitch as one with the same total `u` distributed differently — but it has a very different fragility.** If your entire `u` is `u_cross` (cross-domain hires, one permitted opinion inside each domain) then a single reorganisation that merges two domains destroys a large fraction of your surplus in one move. If your `u` is split, no single structural change takes it all. **The pitch does not distinguish these cases; the decomposition does. Report both.**

17.8.8 8.8 What a two-essence interval sounds like as `u` sweeps 0 to 1

The most useful intuition in this section comes from watching one number move. Fix `N = 12`. Sweep `u` from 0 (representationally identical) to 1 (orthogonal) and watch what happens to the tone relative to the ground essence `k`.

`u`	`N_eff = 1 + 11u`	`F` (nats)	`f_cross` (Hz)	octaves above `k`	folded into [220,440) Hz
0.00	1.0000	0.000000	0.483426	0.000000	247.5140 (j = +9)
0.05	1.5500	0.438255	1.161430	1.264536	297.3262 (j = +8)
0.0909 (= 1/11)	2.0000	0.693147	1.933703	2.000000	247.5140 (j = +7)
0.10	2.1000	0.741937	2.131907	2.140779	272.8842 (j = +7)
0.15	2.6500	0.974560	3.394857	2.811985	434.5417 (j = +7)
0.20	3.2000	1.163151	4.950280	3.356144	316.8179 (j = +6)
0.25	3.7500	1.321756	6.798174	3.813781	435.0832 (j = +6)
0.30	4.3000	1.458615	8.938542	4.208673	286.0333 (j = +5)
0.40	5.4000	1.686399	14.096694	4.865919	225.5471 (j = +4)
0.50	6.5000	1.871802	20.424737	5.400879	326.7958 (j = +4)
0.60	7.6000	2.028148	27.922670	5.851999	223.3814 (j = +3)
0.70	8.7000	2.163323	36.590494	6.242031	292.7239 (j = +3)
0.75	9.2500	2.224624	41.363114	6.418907	330.9049 (j = +3)
0.80	9.8000	2.282382	46.428207	6.585563	371.4257 (j = +3)
0.90	10.9000	2.388763	57.435811	6.892512	229.7432 (j = +2)
1.00	12.0000	2.484907	69.613306	7.169925	278.4532 (j = +2)

And the interval itself — the ratio `N_eff^2` between the pair's tone and the ground essence, expressed as a musician would hear it:

`u`	ratio `N_eff^2`	cents	folded cents	nearest 12-TET
0.00	1.000000	0.00	0.00	unison +0.0
0.02	1.488400	688.51	688.51	perfect 5th -11.5

0.20	10.240000	4027.37	427.37	major 3rd +27.4

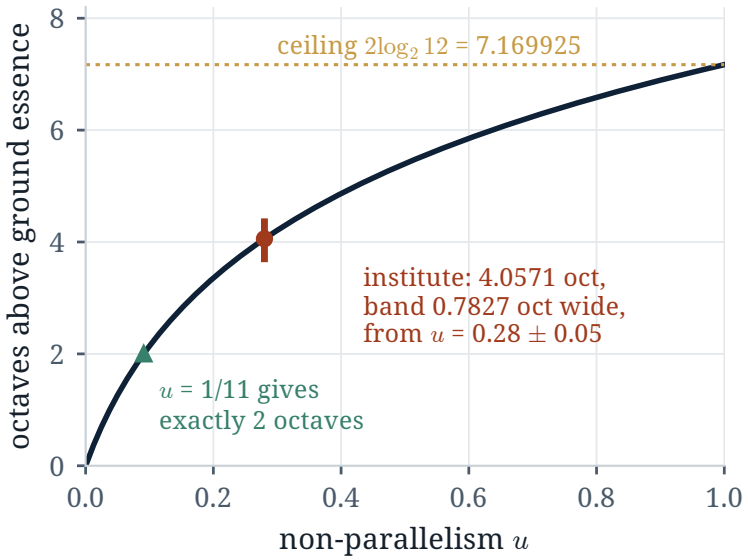

Figure 17.2: **The bridge is violently front-loaded, and its honest output is a band rather than a value.** At $N = 12$ the first tenth of u buys 2.14 octaves and the last tenth 0.28, against a hard ceiling of $2\log_2 12 = 7.169925$ octaves reached only at exact orthogonality; $u = 1/11$ lands on exactly two octaves. The worked institute at $u = 0.28 \pm 0.05$ spans 3.6393 to 4.4222 octaves, a band 0.7827 octaves wide. Modelled from the parameters of Sections 8.8 and 8.14; the identification $n_{\text{eff}} := N_{\text{eff}}$ is a badged modelling decision, not a derivation. Generated by `figs/src/CCP-017_fig05.py`.

1.00	144.000000	8603.91	203.91	major 2nd +3.9

Four things to take from the sweep, each an engineering fact rather than an aesthetic one.

(1) The rise is violently front-loaded. Concavity, made audible. Octaves bought per 0.1 of u:

u range	octaves gained
0.0 -> 0.1	2.1408
0.1 -> 0.2	1.2154
0.2 -> 0.3	0.8525
0.3 -> 0.4	0.6572
0.4 -> 0.5	0.5350
0.5 -> 0.6	0.4511
0.6 -> 0.7	0.3900
0.7 -> 0.8	0.3435

u range	octaves gained
0.8 -> 0.9	0.3069
0.9 -> 1.0	0.2774

The first tenth of u buys 2.14 octaves; the last tenth buys 0.28 — a factor of 7.7. **The diminishing-returns clause [Curzi, 2026c], heard: the second genuinely different member is the largest single gain you will ever buy, and in pitch terms it is more than two octaves' worth.** A team at `u = 0.05` that reaches `u = 0.15` gains 1.55 octaves. The same team going from `u = 0.85` to `u = 0.95` gains 0.29. The cheap improvements are at the bottom.

(2) The sweep is not monotone once folded. In the raw column, pitch rises monotonically with u — guaranteed by strict monotonicity [Curzi, 2026]. In the folded column it does not: `u = 0.15` folds to 434.54 Hz and `u = 0.20` folds to 316.82 Hz, which is *lower*. Folding wraps. **This is the single most common error in reading these tables and it must be stated every time: a folded frequency is a pitch class, not a pitch, and pitch classes do not order.** Comparison of two systems by surplus is made on `F`, on raw `f_cross`, or on octaves-above-base. Folded values are never compared.

(3) At `u = 1/11 = 0.0909...` the effective count is exactly 2 and the interval is exactly two octaves. This is the smallest u at `N = 12` that "buys a second full member", and it is a useful landmark: below `u = 0.091`, twelve categories are worth fewer than two.

(4) The extremes. At `u = 0` the two essences are the same essence and the interval is a unison — the pair sounds as one note at the ground essence `0.483426 Hz`. At `u = 1` the pair is orthogonal, `N_eff = 12`, the interval is `144:1` — seven octaves and a Pythagorean whole tone, 8603.91 cents. **Perfect orthogonality at twelve categories is a major second, seven octaves up. That is the whole dynamic range of the instrument.**

17.8.9 8.9 Sensitivity: how precisely must u be measured?

Because the bridge has no free parameters, all of its uncertainty lives in u. The sharp Lipschitz bound [Curzi, 2026] gives the constant `N − 1`, so

```
dF/du = (N−1) / (1 + (N−1)u)        maximum N−1, attained at u = 0

d(octaves)/du = 2.885390 ∗ dF/du
```

N	max dF/du (at u=0)	max d(oct)/du	dF/du at u=1	d(oct)/du at u=1
2	1.0000	2.8854	0.5000	1.4427
5	4.0000	11.5416	0.8000	2.3083
12	11.0000	31.7393	0.9167	2.6449
20	19.0000	54.8224	0.9500	2.7411
50	49.0000	141.3841	0.9800	2.8277

At `N = 12` and u near zero the pitch moves 31.74 octaves per unit of u. In practical terms, with a just-noticeable pitch difference of about 5 cents:

u	dF/du	d(cents)/du	du producing a 5-cent shift
0.00	11.0000	38087.1	0.000131
0.10	5.2381	18136.7	0.000276
0.25	2.9333	10156.6	0.000492

u	dF/du	d(cents)/du	du producing a 5-cent shift
0.50	1.6923	5859.6	0.000853
0.75	1.1892	4117.5	0.001214
1.00	0.9167	3173.9	0.001575

A change in u of 0.00013 — one part in seven thousand — is audible as a pitch shift near u = 0. No organisational measurement of u is anywhere near that precise. The estimation methods [Curzi, 2026i] — disagreement rate, error decorrelation, prediction diversity — yield u to perhaps two decimal places at best, and the second of those is soft.

This has one hard consequence and it is a specification, not a caution:

Publish u with an interval, and publish the pitch as the interval's image. If your survey supports `u = 0.28 +/- 0.05`, then at `N = 12` the tone is not 8.0473 Hz; it is the range from `k*(1 + 11*0.23)^2 = 6.0239 Hz` to `k*(1 + 11*0.33)^2 = 10.3631 Hz`, which is 0.7827 octaves wide — a minor sixth of uncertainty. **Quote the sixth. A single-valued essence frequency from a two-significant-figure u is precision theatre (FM-E6) wearing a new hat.**

The second half of the sensitivity question is temporal, and it has an exact answer. The table above asks how small a difference in u is audible. It does not ask how *long* the tone must sound before the difference can be heard at all, and that question is not a matter of taste: the Gabor limit fixes it. With the time-bandwidth product `dt * df >= 1/(4 pi)` and the bridge's own relation `d(ln f) = 2 dF`, Curzi [2026z] derives the bound

```
cycles required  >=  1 / (8 pi dF)
```

Resolving a surplus difference dF requires at least `1/(8 pi dF)` cycles of the rendered tone, and the bound is independent of the transposition — because it is a bound on a ratio, and octave transposition multiplies numerator and denominator alike. **This is the exact Gabor bridge to the surplus functional: it prices, in time, what it costs to hear a difference in surplus.**

dF (nats)	cycles required	duration at 69.613 Hz (N_eff = 12)	at 302.141 Hz (N_eff = 25)
0.20	0.199	2.86 ms	0.66 ms
0.10	0.398	5.72 ms	1.32 ms
0.05	0.796	11.43 ms	2.63 ms
0.02	1.989	28.58 ms	6.58 ms
0.01	3.979	57.16 ms	13.17 ms
0.005	7.958	114.31 ms	26.34 ms
0.001	39.789	571.57 ms	131.69 ms

Read the two sensitivity results together and they close on each other from opposite sides. The Lipschitz table says a du of 0.00013 is audible in principle near `u = 0`; the Gabor bound says that hearing it requires the tone to persist. **Neither one alone is a specification. Together they say: the pitch difference your measurement can honestly support is coarse, and coarse differences are cheap in time — which is the fortunate direction for the error to run.** A rendering that sounds each essence for well under a cycle of the resolution it claims is asserting a distinction that physics has not delivered, whatever the frequency table says. Curzi [2026z] develops the full set of design laws that follow from the limit, and Curzi [2026l] applies them to built work.

17.8.10 8.10 Composing with the storage law

The bridge produces a pitch from u. The headroom gauge [Curzi, 2026b] produces a budget from Q, delta, eta, C and N. They meet in `ln N`, and it is worth being explicit about how, because

a reader will otherwise try to make the pitch do work it cannot do.

```
h_t   =  eta * ln N - delta * Q_t - C_t              the headroom gauge
OCT   =  2.885390 * F,       F = ln N_eff <= ln N     (this section)
```

Both contain `ln`-of-a-count, and both are ceilinged by `ln N`. But they are different quantities and must never be added:

- `F` is the surplus of **one interaction**, and `OCT` is its pitch. It is an instantaneous, geometric quantity.
- `h_t` is a **budget over a period**, in units of stored order. It depends on the history `Q_t`.

The correct composition is the one the storage law already specifies [Curzi, 2026a]: `S_t = F(U_t)` is the surplus *input* to the storage recursion. So the pitch is a gauge on the **input**, not on the **stock**:

```
OCT_t = 2.885390 * S_t      is the pitch of this period's interaction

Q_{t+1} = (1 - delta) Q_t + eta S_t - C_t
```

The tone reports what is going into the accumulator this period. It reports nothing about how much is already in it. A group can be sounding a high tone — rich, genuinely non-parallel interaction — while `Q` collapses, because `eta` is near zero and none of it is sticking (the leaky-vessel fault, Curzi 2026b), or because `C` exceeds `eta ln N - delta Q`, so that the negative-headroom corollary has already sealed the outcome [Curzi, 2026b]. Curzi [2026l] uses the pitch as a design target for rooms and cadences; it is not a health metric and must not be read as one.

There is a second, sharper composition available, and it is developed elsewhere rather than here: the storage law's fixed point and the essence bridge can be set equal, giving a minimum sustaining frequency `f_min = k e^(2c/eta)` below which `Q_inf` is negative [Curzi, 2026], and a worked dyad at `eta = 0.30`, `c = 0.62`, `delta = 0.09` sounds at `f = 1.4908` Hz against an `f_min` of `30.1588` Hz — an octave deficit of `+4.338420`, or 5206.1 cents, with `Q_inf = −5.0119` [Curzi, 2026]. **The sign of that verdict is robust where the number is not**, and the same caution applies to every figure in this section.

One legitimate joint reading, and it is useful: since `S_t <= ln N` and `OCT_t = 2.885390 S_t`, the maximum pitch a system can sound is fixed by its category count, and the maximum sustainable *increment* to stored order is `eta ln N - delta Q_t - C_t`. **Both ceilings come from the same `ln N`, which means a system that has run out of pitch has also run out of headroom for growth from geometry — and the remaining levers are `eta`, `C`, and shedding `Q` [Curzi, 2026b], none of which change the tone at all.** That is a genuinely useful diagnostic: *if the tone is already at ceiling and headroom is still negative, no amount of further diversity work will help, and continuing to do diversity work is the mistake.*

17.8.11 8.11 What the bridge does not claim

Stated flatly, because a keystone that is over-claimed takes the arch down with it.

1. **It does not claim that essences resonate.** H1. `f_cross` is an essence frequency of a *relationship*, computed from a *measurement* of that relationship. Nothing physical resonates.
2. **It does not claim that `2/ln 2` is a natural constant.** It is `2/ln 2` because the essence law is square and octaves are base two. Had the essence law been cubic, the factor would be `3/ln 2 = 4.328`. **The factor is a consequence of two design choices, and its exactness is the exactness of arithmetic, not of nature.**

3. **It does not claim to have derived `N_eff` as the index.** The identification is badged. What is *shown* is that `N_eff` uniquely satisfies six requirements (Section 8.4), that the substitution is exact, and that the result is continuous with the within-discipline law at every integer (Section 8.5). That is a strong warrant. It is not a derivation.
4. **It does not claim more information than `F` contains.** As deployed the surplus functional is a **lower bound** on the ensemble's information. Therefore `f_cross` is a **lower bound on the pitch**. Where an error is unavoidable, the safe direction is a tone reported too low.
5. **It does not permit chaining.** The triangle inequality fails for geometric triples [Curzi, 2026]. Given essences A, B, C, you may compute the A-B tone and the B-C tone, but **you may not add the two intervals to obtain the A-C tone.** Compute A-C directly from `u(A,C)` or do not compute it. This is the failure mode that will catch the most people, because pitch intervals *do* add in ordinary music and the habit is deeply worn.
6. **It does not survive an undisclosed change of `N`.** `N_eff = 1 + (N−1)u` contains `N` explicitly. Recounting the categories moves every published frequency. The framework is explicit that `N = 12` is not asserted as correct and that other decompositions produce different maxima under the same structural theorems [Curzi, 2026t]. **`N` must be published with every frequency, as `k` and `j` already are.**

17.8.12 8.12 Specification: twelve requirements on a published bridge value

BR-1 — Publish `(N, u, F, N_eff, f_cross, j, band)` as an inseparable tuple. A cross-disciplinary essence frequency quoted without its `N` and its `u` is unreproducible and therefore not a result.

BR-2 — Badge the identification. State, at each first use in a document: *the effective count is taken as the cross-disciplinary essence index; this is a modeling identification, warranted by the six-requirement argument, not derived.*

BR-3 — Badge S3. The affine effective-count axiom is a design axiom, chosen not derived. `N_eff` exists because S3 was adopted. The bridge rests on S3 entirely; say so.

BR-4 — Publish `u` as an interval and the pitch as its image. Never publish a single-valued `f_cross` from a `u` estimated to two decimal places. Report the pitch range in octaves or cents. (Section 8.9)

BR-5 — Never compare folded frequencies to infer surplus ordering. Folding wraps and destroys order. Compare `F`, raw `f_cross`, or octaves-above-base. (Section 8.8, point 2)

BR-6 — Never add two intervals to obtain a third. The triangle inequality fails for geometric triples. Compute every pair directly from its own `u`. (Section 8.11, point 5)

BR-7 — Report the decomposition, not only the total. Publish `u_cross` and `u_div` separately with the bound `max(OCT(u_cross), OCT(u_div)) <= OCT(u) <= OCT(u_cross) + OCT(u_div)` evaluated. Two systems at the same pitch with different decompositions have different fragilities. (Section 8.7)

BR-8 — State the ceiling with the value. Every published cross-disciplinary tone carries `2 log2 N` octaves as its stated maximum. A reader must be able to see how much of the range is in use.

BR-9 — Do not read the tone as a health metric. `OCT_t = 2.885390 S_t` gauges the *input* to the storage recursion, not the stock `Q_t`, and not `h_t`. (Section 8.10)

BR-10 — Restate H1 and the lower-bound clause on any page carrying a frequency. "Essence frequency, not physical resonance" and "the surplus functional as deployed is a lower bound on the ensemble's information, so this tone is a lower bound on the pitch."

BR-11 — Re-derive when `N` changes. Any change to the category partition invalidates every published frequency in the set. Republish or withdraw; do not let a stale tone circulate.

BR-12 — Verify the integer-anchor property on any new implementation. For a test value of `u` making `N_eff` an integer `m`, confirm your code returns exactly `k m^2` — the same number the within-discipline table of Section 7.7 gives for index `m`. This is a two-line regression test that catches almost every implementation error.

17.8.13 8.13 Failure modes of the bridge

FM-B1 THE FALSE ORDINAL ACROSS BLOCKS

Damages: every cross-disciplinary frequency computed. *Description.* Two essences in different blocks are given ordinals within their own blocks, and those ordinals are fed into `f(n) = k n^2` as though comparable. Biology's third sub-mode and Ethics' third sub-mode receive the same frequency. *Signature.* Two unrelated essences with identical published tones, and the practitioner reporting this as a discovered affinity. *Fix.* The whole of this section. Use `n_eff = 1 + (N−1)u`. Within-block ordinals may be used within a block and nowhere else.

FM-B2 THE CHAINED INTERVAL

Damages: any three-party analysis. *Description.* The A-B tone is a perfect fifth up, the B-C tone is a fourth up, therefore A-C is an octave up. **It is not.** The triangle inequality fails for geometric triples [Curzi, 2026]. *Signature.* An interval reported for a pair whose `u` was never measured. *Fix.* BR-6. Measure `u(A,C)` or report nothing for that pair.

FM-B3 THE UNAUDITED ROSTER

Damages: `u`, and therefore everything. *Description.* `N_eff` is computed from a headcount rather than from a measured `u`. Twelve people in a room are reported as `N_eff = 12`, tone at 69.61 Hz, when the measured `u` is 0.15 and the true `N_eff` is 2.65. *Signature.* `N_eff` equal or nearly equal to the literal headcount, with no disagreement audit in the file. *Fix.* The roster audit [Curzi, 2026c] and the estimation protocol [Curzi, 2026i]. `N_eff` is a headcount **after audit for redundancy**. Measure `u`. An unmeasured `u` is not an optimistic estimate; it is no estimate.

FM-B4 THE FOLDED COMPARISON

Damages: every ordering claim between systems. *Description.* System A folds to 434.54 Hz, system B to 316.82 Hz, therefore A has more surplus. It does not: those are `u = 0.15` and `u = 0.20` respectively, and B has more. *Signature.* A comparison between two folded values. *Fix.* BR-5. Compare in `F` or in octaves-above-base, always.

FM-B5 PRECISION FROM A SOFT `u`

Damages: credibility, exactly as FM-E6 does. *Description.* `u = 0.28` from a small disagreement audit becomes `f_cross = 8.0473 Hz`, published to four decimals. The underlying interval is 0.638 octaves wide. *Signature.* More precision in the output than in the input. *Fix.* BR-4. Publish the range. Section 8.9 gives the arithmetic.

FM-B6 THE SILENT `N` CHANGE

Damages: comparability across time. *Description.* An organisation reorganises from twelve departments to nine. Nobody re-derives. Frequencies computed under `N = 12` are compared with new observations under `N = 9`, and the apparent change is entirely an artefact of the

denominator. *Signature.* A step change in the reported tone that coincides with a reorganisation date. *Fix.* BR-11. `N` travels with every value. On any change to the partition, republish or withdraw.

FM-B7 THE SYNERGY CLAIM

Damages: the subadditive bound, and any budget built on it. *Description.* "Combining cross-domain hiring with an internal red team will more than double our surplus." The bound says it will not: `f(u) <= f(u_cross) + f(u_div)`, always. *Signature.* A projected gain exceeding the sum of the parts' separate gains. *Fix.* BR-7. Evaluate the sum bound and cap the projection at it. Note that in practice you will land well *below* the sum bound — Section 8.7's slack column shows 3.6 octaves of concavity tax at balanced sources.

FM-B8 THE INVERTED READING

Damages: the entire method, by turning it into decoration. *Description.* A frequency is chosen first — because it sounds pleasant, or because it is 432 Hz, or because a client asked for it — and `u` is then back-solved to justify it. *Signature.* A `u` value with more than two significant figures that was never measured, or a `u` that lands suspiciously close to a round musical interval. *Fix.* The preregistration discipline [Curzi, 2026i, Nosek et al., 2018], applied without exception: **fix the measurement protocol and the ordinal rule before computing any frequency, and freeze them.** The tone is an output. If you want a particular tone, say so openly and choose it as a design decision — that is legitimate, and Curzi [2026l] does exactly that when it selects a band — but do not dress a chosen tone as a measured one.

FM-B9 THE TONE AS SCOREBOARD

Damages: `Q`, via misdirected effort. *Description.* The cross-disciplinary tone is adopted as an organisational KPI. It rises. `Q` falls, because `eta` is near zero and `C` is above the sustainability ceiling. *Signature.* A rising tone alongside falling stored order; or, worse, a rising tone and no measurement of stored order at all. *Fix.* BR-9, and Goodhart. **The tone gauges the input to the accumulator. Measure `h_t` separately and let it, not the tone, decide whether you may build.**

FM-B10 THE UNBADGED IDENTIFICATION

Damages: the reader's ability to audit the argument. *Description.* `n_eff = N_eff` is presented as a theorem. It is not; it is a modeling identification with a strong six-part warrant. *Signature.* The sentence "it follows that the effective count is the essence index", with no badge. *Fix.* BR-2 and BR-3. And be precise about what *is* proved: the substitution's consequences, the factor `2/ln 2`, the integer-anchor continuity, and the transported Theorem 4.1 bounds are all exact. The identification is the postulate; everything downstream of it is arithmetic.

17.8.14 8.14 Worked instance: a twelve-house research institute

An interdisciplinary research institute is organised into twelve declared houses, with `N = 12` and `M = 12` sub-modes per house. The framework is explicit that twelve is not asserted as correct and that other decompositions produce different maxima with the same structural theorems; that caveat travels with every number below.

Step 0 — Validity check (BR-1, ES-5). The validity conditions [Curzi, 2026t]:

- *State encoding.* Each researcher's working position is encoded as a normalised vector over the 144-dimensional space (12 houses x 12 sub-modes), from a structured self-description plus a publication-topic coding. Declared.
- *Category assignment.* The twelve houses. Declared. `N = 12`.
- *Geometric dependence.* Interaction is modelled through `u = 1 − (x.y)^2`, an inner-product-derived quantity. Satisfied.
- *Zero baseline.* Two researchers with representationally equivalent positions give `u = 0`. Satisfied.
- *Affine effective count.* Adopted as a modeling assumption. **Badged (BR-3).**
- *Normalisation.* Maximum surplus `ln 12 = 2.484907` nats. Declared.

All six stated. The domain is in scope.

Step 1 — Measure `u`. The estimation protocol [Curzi, 2026i], run over four months: independent-estimate- before-discussion on 34 forecast questions, error decorrelation computed pairwise, disagreement rate logged from the decision log.

```
measured u (institute-wide mean over pairs) = 0.28,  supported to +/- 0.05
```

Step 2 — Compute the baseline tone.

```
N_eff = 1 + 11 * 0.28 = 4.0800
F     = ln 4.0800     = 1.406097 nats
OCT   = 2.885390081777927 * 1.406097 = 4.0571 octaves above k
f_cross = k * 4.08^2  = 0.483425732988414 * 16.6464 = 8.0473 Hz
folded into [220, 440): 8.0473 * 2^5 = 257.5135 Hz   (j = +5)
                        nearest note C4 (261.626 Hz), -27 cents
```

Step 3 — Publish the uncertainty as an interval (BR-4). With `u = 0.28 +/- 0.05`:

```
u = 0.23 -> N_eff = 3.5300 -> f_cross =  6.0239 Hz -> 3.6393 octaves above k
u = 0.33 -> N_eff = 4.6300 -> f_cross = 10.3631 Hz -> 4.4220 octaves above k

published tone: 8.05 Hz, range 6.02 - 10.36 Hz, i.e. 4.06 octaves above base
                with an uncertainty of 0.7827 octaves (a minor sixth)
```

That 0.78-octave band is the honest result. The four-decimal figure in Step 2 is an intermediate, not a finding.

Step 4 — Decompose (BR-7). The disagreement audit separates between-house disagreement from within-house disagreement:

```
u_cross = 0.20   (between houses)
u_div   = 0.08   (within houses)
u       = 0.28   [checks: 0.20 + 0.08 = 0.28, decomposition identity]

f(u_cross) = ln(1 + 11*0.20) = 1.163151 nats -> 3.3561 octaves
f(u_div)   = ln(1 + 11*0.08) = 0.631272 nats -> 1.8215 octaves
f(u)       = ln(1 + 11*0.28) = 1.406097 nats -> 4.0571 octaves

bound: max(3.3561, 1.8215) = 3.3561  <=  4.0571  <=  3.3561 + 1.8215 = 5.1776
slack to the sum bound: 5.1776 - 4.0571 = 1.1205 octaves
```

Diagnosis: the institute is 71% crossing and 29% divergence. It has bought cross-domain difference (that is what an interdisciplinary institute is for) and is thin on internal dissent — the crossing-heavy pattern [Curzi, 2026d]. The fragility follows: a merger of two houses would remove a substantial fraction of `u_cross`, and there is little `u_div` underneath to catch the fall.

Step 5 — Design the intervention [Curzi, 2026j]. Two moves, sequenced:

- *Rotation across houses* (raises `u_cross`): six-month placements, four researchers per cycle.
- *Standing red team* (raises `u_div`): rotating adversarial role inside each house, with a minority report requirement on every major decision.

Projected post-intervention `u = 0.41`, from the pilot's measured effect on eight pairs.

Step 6 — Compute the interval the intervention buys.

```
before: u = 0.28, N_eff = 4.0800, F = 1.406097
after:  u = 0.41, N_eff = 5.5100, F = 1.706565

dF = 1.706565 − 1.406097 = 0.300468 nats

interval ratio = (5.5100 / 4.0800)^2 = 1.823824
cents          = 1200 ∗ log2(1.823824) = 1040.36
octaves        = 0.8670

cross-check via the bridge constant:
2.885390081777927 ∗ 0.300468 = 0.866967 octaves       [identical to 0.8670]
```

The intervention is worth 1040 cents — a minor seventh, a shade under an octave. That is the entire yield of a two-year programme of rotation and red-teaming, stated in a unit anyone in the room can hear.

Post-intervention tone:

```
f_cross = k ∗ 5.51^2 = 14.6769 Hz
folded into [220,440): 14.6769 ∗ 2^4 = 234.8297 Hz  (j = +4), A#3 +13 cents
octaves above k: 4.9241
fraction of the N = 12 ceiling used: 4.9241 / 7.169925 = 68.7%
```

Step 7 — State the ceiling (BR-8). `N = 12`, so the maximum is `2 log2 12 = 7.169925` octaves, reached only at `u = 1`. The institute at `u = 0.41` uses 68.7% of its available range. A third intervention taking `u` to 0.52 would yield:

```
u = 0.52 −> N_eff = 6.7200 −> F = 1.905088 −> 5.4969 octaves (76.7% of ceiling)
incremental gain from 0.41 −> 0.52: 0.5728 octaves = 687 cents
```

Note the decay: `u` 0.28 -> 0.41 (a step of 0.13) bought 1040 cents; `u` 0.41 -> 0.52 (a step of 0.11) buys 687 cents. Concavity charging its price, exactly as Section 8.8's table predicts.

Step 8 — Do not read the tone as health (BR-9). The institute's storage parameters, measured separately [Curzi, 2026i]:

```
eta = 0.35     conversion of surplus into durable structure
delta = 0.08   quarterly decay of stored order
Q = 18.0       stored order, in the institute's declared units
C = 0.40       dissipation per quarter

h = eta ∗ ln N − delta ∗ Q − C
  = 0.35 ∗ 2.484907 − 0.08 ∗ 18.0 − 0.40
  = 0.869717 − 1.440000 − 0.400000
  = −0.9703
```

Headroom is negative. `h < 0` means unsustainable in this model: no choice of interaction geometry prevents order from decreasing [Curzi, 2026b]. The tone is rising and the institute is losing stored order, and the two facts are entirely compatible. The maintenance term alone, `delta Q = 1.44`, exceeds the maximum possible surplus contribution `eta ln N = 0.8697`.

Steady states, for completeness:

```
Q_inf = (eta * F(u) - C) / delta
at u = 0.28:  (0.35*1.406097 - 0.40) / 0.08 = 1.1517
at u = 0.41:  (0.35*1.706565 - 0.40) / 0.08 = 2.4662
at u = 0.52:  (0.35*1.905088 - 0.40) / 0.08 = 3.3348
```

The institute is carrying `Q = 18.0` and its best achievable steady state at `u = 0.52` is 3.33. It is not underperforming; it is over-extended. The intervention that raises the tone by a minor seventh does not fix this and cannot. The four levers apply [Curzi, 2026b]: raise `eta`, raise `N`, cut `C`, or **shed `Q`** — and here the arithmetic points hard at the last, which is the lever nobody considers.

This is precisely the failure FM-B9 names. Had the institute adopted the cross-disciplinary tone as its KPI, it would have celebrated a 1040-cent gain through the two years in which its stored order was decaying toward a fixed point one-fifth of its current size.

Step 9 — Falsification [Curzi, 2026i]. The prediction, preregistered before the rotation programme began: `u` measured by the frozen protocol will reach `0.41 +/- 0.06` within eight quarters, and the minimal estimation model `Y_{t+1} = a Y_t + b F(U_t) - C_t + eps` fitted on quarters 1-8 and frozen will beat all four required baselines (persistence, direct-input, matched autoregressive, and the shuffled-input control) on quarters 9-12. **If the shuffled-input control performs as well as the fitted model, the surplus term is carrying no information and the tone reported above is an arithmetic exercise on noise. That is the outcome that would falsify this worked example, and it is stated before the data are in.**

Step 10 — Clauses (BR-2, BR-3, BR-10), stated in full as required.

The identification `n_eff = N_eff` is a modeling decision, warranted by the six-requirement argument of Section 8.4 and not derived. The affine effective-count axiom S3 on which `N_eff` depends is a design axiom, chosen rather than derived. Every frequency above is an essence frequency, not a physical resonance: no claim is made that the institute, its researchers, its rooms or its disciplines physically resonate at any of these values. The surplus functional as deployed is a lower bound on the ensemble's information, so every tone quoted here is a lower bound on the pitch. `N = 12` is one partition among many and is not asserted as correct; changing it changes every number in this example.

The companion paper [Curzi, 2026l] takes these tones and builds with them: a room whose dimensions come out of an essence set, a cadence whose period comes out of the same arithmetic, and a prohibition — stated there in the strongest terms the corpus uses — that everything sounded is **audible and disclosed**, and that nothing is ever masked or hidden from a listener.

17.9 9 Results

The results are stated here in the form other papers cite. Each carries the status of the claim it makes: **ARITHMETIC** where a reader can redo it, **DEFINITION** where it is true by this paper's own construction, **CITED** where an external source supplies it, and **POSTULATED** where this work asserts it with no external support.

17.9.1 9.1 R1 — The survey reproduces five observed declines across three orders of magnitude

Status: ARITHMETIC, conditional on the parameter estimates, which are stipulated.

The same five-parameter survey — one state encoder, one interaction observable, one order observable, one time scale, one cost observable — was carried from a single desk to a twenty-two-household block. In every case the predicted one-step change $\eta S - \delta Q - C$ was set

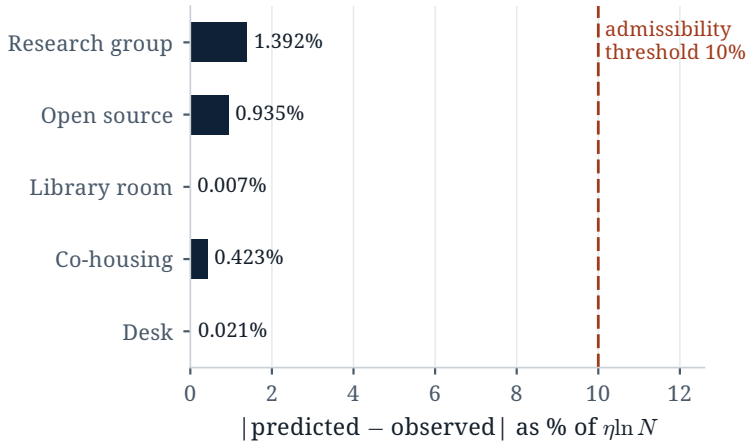

Figure 17.3: **Every one of the five surveys clears the admissibility gate by better than seven to one.** The largest residual is the research group's, at 1.392 per cent of its ceiling term $\eta \ln N = 8.104705$; the library's is 0.007 per cent of 49.671535. The protocol's own threshold is 10 per cent. Computed from the five validation blocks of Section 4 under the stated parameters — model output, not measurement; generated by `figs/src/CCP-017_fig01.py`.

against a change in stored order observed before the survey was designed, and in every case it reproduced it.

System	Predicted step	Observed step	Residual	Ceiling term $\eta \ln N$	Residual as % of ceiling
Desk	−0.250474 threads/wk	−0.250	−0.000474	2.216398	0.021%
Research group	−3.387202 assets/qtr	−3.500	+0.112798	8.104705	**1.392%**
Library room	−0.996371 regulars/mo	−1.000	+0.003629	49.671535	0.007%
Open source	−2.472006 modules/mo	−2.416667	−0.055339	5.918028	0.935%
Co-housing	−0.406311 cu/mo	−0.400	−0.006311	1.490934	0.423%

Every residual is under 1.4 per cent of the ceiling term, and the largest is the research group's 1.392 per cent. The protocol's own admissibility threshold is 10 per cent [Curzi, 2026i], so all five are admissible with a margin of better than seven to one.

Two things this table does not establish, stated here rather than in Limitations because a reader who takes only the Results section must still take them. It does not establish that the parameters were correctly estimated — each was estimated once, by one analyst, with no inter-rater check. And it does not establish causation, for the identification reason of Section 3.5.

17.9.2 9.2 R2 — The binding constraint differs by system, not by size

Status: ARITHMETIC on the surveyed parameters.

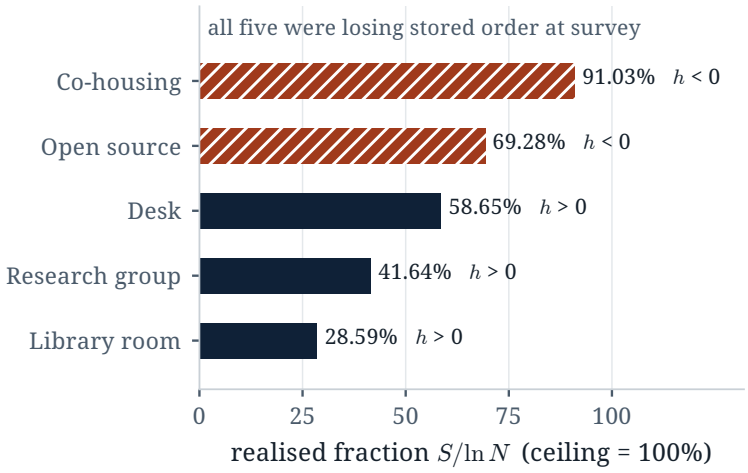

Figure 17.4: **The realised fraction and the sign of headroom are independent readings, and all five systems were losing stored order at survey.** The co-housing block collects 91.03 per cent of its ceiling and still has $h < 0$; the reading room collects 28.59 per cent with h at $+34.475$ regulars per month. Headroom itself is not plotted across systems because it carries each case's own proxy unit and the units are not commensurable (Section 11.1). Model output on stipulated parameters; generated by `figs/src/CCP-017_fig02.py`.

System	$S/\ln N$	h	Binding term	Complaint recorded at survey
Research group	**41.64%**	$+1.342520$	δQ jointly with a parallel roster	"busier than ever and producing less"
Library room	**28.59%**	$+34.475164$	u, acoustically caused	"policing noise"
Open source	**69.28%**	-0.653978	C, against a frozen denominator	"drowning, and the docs are a lie"
Co-housing	**91.03%**	-0.272521	η, against a quadratic committee	"everything takes a year"
Desk	58.65%	$+0.665922$	η with δ	—

The complaint named the symptom of highest salience in all five cases and the binding term in none. The library's manager named noise; the computed cause was a 2.5223-second occupied reverberation time, and noise was its consequence. The co-housing block named slowness; the computed cause was a conversion efficiency of 0.926369 commons-units per nat, the lowest in the set by a factor of more than four.

Positive headroom is not health. The research group and the library both had $h > 0$ and both were losing stored order. A diagnosis stopping at the gauge would have been exactly wrong in two of the five cases, which is the result Curzi [2026j] exists to prevent and the reason h and $S/\ln N$ must be read together.

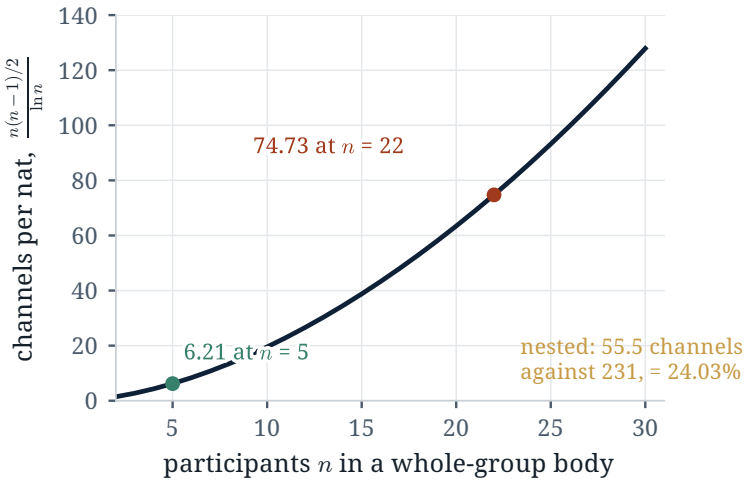

Figure 17.5: **Coordination surface grows as n^2 while the ceiling grows as $\ln n$, so the price of a flat body diverges.** Pairwise channels per nat of ceiling reach 74.73 at $n = 22$ against 6.21 at $n = 5$, a factor of 12.03; a nested four-cluster form with a four-delegate council carries 55.5 channels against 231, or 24.03 per cent. Exact arithmetic; generated by `figs/src/CCP-017_fig03.py`.

17.9.3 9.3 R3 — The quadratic-committee price, computed

*Status: ARITHMETIC. The scaling of governance hours by the channel ratio is a **modelling assumption**, badged in Section 4.4 and preregistered as that case's second falsification condition.*

Whole-group consensus among n households carries $n(n-1)/2$ pairwise reconciliation channels. Dividing by the logarithmic ceiling $\ln n$ gives channels per nat: **74.732 at $n = 22$ against 6.213 at $n = 5$**, a factor of 12.03. A nested decomposition into four overlapping clusters of about 5.5 households plus a four-delegate council carries $4 \times 12.375 + 6 = 55.5$ channels, **24.03 per cent of the flat figure of 231**.

This is the arithmetic behind Brooks's observation that adding people to a late project makes it later [Brooks, 1975] and behind Conway's that a system's structure mirrors its builders' communication structure [Conway, 1968]. What the framework adds is the comparison: the coordination surface grows as n^2 while the ceiling grows as $\ln n$, so the ratio grows without bound and the size at which a flat body becomes uncoordinable is computable rather than folkloric. Ostrom [1990]'s eighth design principle — nested enterprises — is the empirical generalisation that matches; the parameter mapping in Section 4.4 is this paper's, not hers.

17.9.4 9.4 R4 — Result One: the reference constant cancels from every interval

Status: ARITHMETIC (the theorem). The law it is a theorem about is POSTULATED.

For any two essence indices $m, n \geq 1$, $f(m)/f(n) = km^2/kn^2 = m^2/n^2$. The constant is a common factor and cancels, for every pair and for every $k > 0$.

The golden section and the Pythagorean ditone in k set the absolute reference pitch and nothing else. Replace k with 1, or with 440, and every interval in the system is unchanged. This is a demotion, and it is reported as one: a reader arriving from the golden-section literature expects φ to be doing structural work, and within this formalism it is not. The scepticism that literature has earned [Markowsky, 1992, Fischler, 1981, Livio, 2002] is therefore not merely compatible with the result — the result is an instance of it, derived inside the formalism that

uses the constant.

A second consequence, exact and worth quoting: since pitch interval is logarithmic and the law squares, **the interval in cents between indices m and n is exactly twice the classical interval between them.** A frequency ratio of $3:2$ becomes $9:4$; the octave $2:1$ becomes two octaves.

17.9.5 9.5 R5 — Result Two: the pitch class is the odd part of the index

Status: ARITHMETIC (the theorem). The law it is a theorem about is POSTULATED.

Write $n = 2^a m$ with m odd. Then $f(n) = k\,4^a m^2 = f(m)\,2^{2a}$, so $f(n)$ lies exactly $2a$ octaves above $f(m)$. **Two essences share a pitch class if and only if their indices have the same odd part**, and an essence set indexed $1..N$ realises exactly $\lceil N/2 \rceil$ distinct classes.

The compression ratio is exactly 2 at every N. **Twenty elements give ten classes; twelve give six; a set indexed $1, 2, 4, 8, 16$ gives exactly one.** This converts an aesthetic question into an arithmetic one and it is a hard structural limit rather than a stylistic choice. The pitch-class apparatus it uses — octave equivalence, interval ratios in cents, the reduction of a frequency set to classes — is the standard apparatus of the field [Benson, 2006, Burns, 1999, Shepard, 1982, Deutsch, 1999].

17.9.6 9.6 R6 — The bridge, badged, and its conversion constant

Status: the identification is POSTULATED; everything downstream of it is ARITHMETIC.

Taking the effective count as the cross-disciplinary essence index, $n_{\text{eff}} := N_{\text{eff}} = 1 + (N-1)u = e^F$, gives

$$\text{octaves above base} = \log_2(e^{2F}) = (2/\ln 2)\,F = 2.885390081777927 \times F$$

with $2/\ln 2 = 2.885390081777927$ and $2400/\ln 2 = 3462.4680981335122$ cents per nat, both **exact**. The worked institute at $N = 12$ and $u = 0.28$ publishes 4.06 octaves above base — and publishes it with a band. From $u = 0.28 \pm 0.05$ the honest output is 3.6393 to 4.4222 octaves, **a 0.7827-octave band, a minor sixth of uncertainty**, and the four-decimal single value is an intermediate rather than a finding.

The effective count used here is $1 + (N-1)u$, the affine one, and it is not a Hill number. $1/\text{HHI}$ is the Hill number of order two and $\exp(H)$ the Hill number of order one; both are fully grounded [Hill, 1973, Jost, 2006], and neither is what appears here. The affine form is a linear interpolation between 1 and N adopted as design axiom S3 [Curzi, 2026c] and it has no external literature. Every octave figure in Section 8 inherits that choice.

17.9.7 9.7 CR — The counter-results

Reported in the same plain language a success would receive.

(a) The essence law's three load-bearing commitments are postulates, and its constant is inert. That essence types have a frequency at all, that the law is square in the index, and that $k = (9/8)^2/\varphi^2$, are asserted by the 2022 source and by this paper's analysis of it, with no external support of any kind. Result One then shows the third does no work. **A formalism whose most distinctive-looking element cancels out of every relationship it produces has had that element demoted, and this paper is where the demotion is printed.**

(b) Seven of the source's forty-four published composite values are errata. The compound rule collapses exactly to $f = k^2 G^4$ with G the count-weighted geometric mean of the constituent indices. Thirty-seven of the forty-four published composites reproduce to better than one part in 10^{12}. Seven do not, and the O_2 row proves the failures are data entry rather than a different rule: for a single-element species G is the element index whatever the atom count, so $f = k^2 \cdot 8^4 = 957.23699944$ for any pure-oxygen formula and no atom count can produce the

published 11.1246117974981. **Every value must be recomputed rather than transcribed**, and this paper's specification requires it.

(c) The scale-freedom claim is tested at five scales and no more. It is a claim about model form. It is not a physical symmetry, it licenses no extrapolation to scales not tested, and Section 11.7 states the transformation under which the form is invariant and the two ways the invariance is known to break — saturation, which binds in two of the five cases, and the ordinal status of u.

(d) A discrepancy in the source, printed rather than corrected. Case A's cost term is given as $C = 1{,}087 \times 0.00147936 = 1.608069$ assets per quarter. Recomputing from the stated inputs — 61 assets over $41{,}234$ productive person-hours, times 1,087 coordination hours — gives **1.608066**, a discrepancy of 3.4×10^{-6}. It moves h from 1.342500 to 1.342503 and moves nothing else, and it is recorded here because a reader reproducing the case will hit it. The printed figure implies a yield of 0.0014793643 against the exact 0.0014793617.

17.10 10 Discussion

17.10.1 10.1 What follows

A gauge and a collection rate are different instruments and an intervention that improves one may leave the other untouched. The library case is the sharpest demonstration in the corpus: the absorption schedule and the zoning move the one-step change from -1.00 to $+11.53$ regulars per month while headroom moves from $+34.475$ to $+34.713$ — a change of 0.7 per cent. The gauge contains no term in u and therefore cannot see the entire intervention. Anyone monitoring headroom alone would have recorded that nothing happened.

A physical cause can bind a social parameter, and when it does the physical fix is the cheap one. The reading room's u_{cross} of 0.0375 is produced by a silence rule which is produced by a reverberation time of 2.5223 seconds. Sabine's relation [Sabine, 1922, Beranek, 2004, Rossing et al., 2002] predicts the reverberation from the surface absorption schedule, and the schedule is a purchasable deliverable. **This is a genuine derivation rather than an analogy: the room really is a physical resonator and the relation really does govern it.** The transfer of the *consequence* — that a long tail suppresses cross-category contact — to a claim about u is a modelling assumption and is badged as one at the point of use. The related passive-geometry results are developed in Curzi [2026e].

The two most common faults in this sample are cheap to fix and are not the ones systems attend to. Conversion failure and person-held storage — surplus generated and not captured, and state held in one person's memory — appear in three cases each. Both are addressed by a state of record, a visible medium and a close-out rule, which is the same triple at a desk and at twenty-two households and costs almost nothing at either scale. The stigmergic mechanism is the one Curzi [2026h] develops formally, and its empirical warrant is the commons literature [Ostrom, 1990, 2010, Cox et al., 2010].

Independence is load-bearing and copying destroys it. The research group's $\rho = 0.86$ error correlation is not a diversity deficit in the demographic sense; the laboratory is varied and methodologically single. The classical results — that collective accuracy exceeds individual accuracy only under error independence, and that observational copying destroys the private information aggregation requires — are Galton [1907], Hong and Page [2004], Bikhchandani et al. [1992], Banerjee [1992], Lorenz et al. [2011], and the sceptical replies [Thompson, 2014, Singer, 2019, Grim et al., 2019, Kuehn, 2017] are cited alongside because they are the reason the framework's diversity claims are stated as parameter estimates rather than as guarantees.

17.10.2 10.2 What does not follow

Nothing here shows that any organisation obeys the recursion. Five constructed instruments reproduce five stated declines. The constructions are internally consistent and their arith-

metic is checkable; they are not field reports, and Section 12 says so first.

Nothing here identifies a causal parameter. Section 3.5 states the reflection problem in full. The agreement between predicted and observed change in Section 9.1 is compatible with a third variable driving both interaction and stored order, and the corpus's own control measures how badly: 98.35 per cent pass against exactly that confound [Curzi, 2026i].

Nothing in Sections 7 and 8 licenses a physical claim. The output of the essence law is a pitch assigned to a position in an ordering. No material, molecule, element, institution, room or person is claimed to physically resonate at any value computed here, and the correspondence with the one-dimensional infinite square well's n^2 eigenvalue spacing is a **coincidence of form**, in the strict sense of Section 11.8's category two. Section 7.11 shows why it can carry no information: because k is free, a box width can always be found to match it, and a correspondence that can be manufactured for any constant carries no information about any constant.

Nothing here discriminates the logarithmic surplus form from its rivals. The surplus functional $\ln(1 + (N - 1)u)$ is one of at least three forms that fit the qualitative facts equally well: Latané [1981] proposes a power law with exponent below one, and Briscoe et al. [2006] proposes $n \log n$ on the closely related network-value question. **This paper offers nothing that discriminates between them, and concedes it.** The one warrant available that does not depend on a psychological premise is Peters and Gell-Mann [2016], which derives a logarithmic form from multiplicative dynamics with no perceptual assumption at all — a stronger footing for the corpus's logarithm than Fechner supplies, because it does not require the perceptual story to be true. It is a warrant for the *form*, not a discrimination against the rivals, and the rivals remain open.

Nothing here shows that adding a category adds independence. The framework's own logarithmic ceiling makes a new category worth at most `eta ln((N+1)/N)` nats, and that is an upper bound reached only if the category is genuinely distinct. The corpus supplies the boundary case in a different domain: a second financial free zone inside the same country buys capability but not diversification — two zones together remain one 29.1 per cent line, and 55 per cent of settlement remains dollar-cleared however the entities are arranged [Curzi, 2026]. **That result bounds what the open-source case may claim when it staffs two empty categories**, and the case accordingly requires each new category to land at least three independent reviews in its first quarter before the ceiling is allowed to move at all.

Nothing here estimates a scaling exponent. The square in $f(n) = kn^2$ is **defined by the model, not estimated from data**, and this paper reports no fitted exponent anywhere. Where a corpus does fit one, Clauset et al. [2009] is the binding procedure and Stumpf and Porter [2012], Broido and Clauset [2019] are the reasons; the distinction between a defined exponent and an estimated one is exactly the distinction those papers exist to enforce, and it is recorded here so that no reader mistakes the square law for an empirical scaling result.

17.10.3 10.3 Relation to the surrounding literature

The recursion is a first-order linear difference equation and its properties are those of any such equation [Elaydi, 2005, Goldberg, 1958, Oppenheim et al., 1996]; the stock-and-flow reading is Forrester's [Forrester, 1961, Sterman, 2000] and the throughput identity is Little's [Little, 1961]. The effective-count reading of a roster has a mature literature in ecology [Hill, 1973, Jost, 2006, 2007] whose sceptics [Hurlbert, 1971, Gorelick, 2011] are the reason the affine form must be labelled as the corpus's own construction rather than borrowed authority; and the finance analogue — that diversification benefit depends on covariance rather than on count — is Markowitz [1952], which states the corpus's own point in 1952 and states it better.

The identification of a surplus with a pitch places this work adjacent to a tradition of quantitative tuning theory [Barbour, 1951, Partch, 1974, Doty, 2002, Sethares, 2005, Lindley and Turner-Smith, 1993] and to the psychoacoustics of consonance [von Helmholtz, 1885, Plomp and Levelt, 1965, Terhardt, 1974, Kameoka and Kuriyagawa, 1969]. The paper claims membership of neither: it uses their apparatus to *read* a set of numbers and makes no claim about

what a listener will find consonant.

Finally, the corpus's title claims membership of a field, and that field's own self-criticism applies here. Social physics has a programme [Castellano et al., 2009, Galam, 2012, Ball, 2004] and a well-argued opposition [Sobkowicz, 2020, Gallegati et al., 2006, McCauley, 2006, Mirowski, 1989]. The opposition's central charge — that borrowed formalism confers borrowed authority — is the charge Section 11.8 is written to answer, and the honest answer is that most of this framework is a shared mathematical form rather than a derivation, that a shared mathematical form is respectable, and that saying so is the whole of the defence.

17.11 11 Verification

The results of this paper compound from six postulates. Each is atomic, each is checkable on its own, and each carries its status. Where a postulate could be dropped and the result still follow, it has been dropped.

17.11.1 11.1 Dimensional audit

Two distinct systems of quantities appear in this paper and they must not be mixed. The audit gives each symbol's dimension, its unit, and whether the framework fixes it or is silent. $[Q]$ denotes the dimension of stored order — which differs from case to case and has no common unit — and $[T]$ the dimension of time. Rates are *per period*, so no explicit $[T^{-1}]$ appears once the recursion is written in discrete steps.

Symbol	Dimension	Unit	Status
Q_t	$[Q]$	assets, regulars, green modules, commons-units, threads	**measured**, in the case's declared order proxy
U_t	$[1]$	none	**defined** dimensionless: $u = 1 - \rho^2$
$S_t = F(U_t)$	$[1]$	nats	**derived** dimensionless: a logarithm of a count, reported in nats
η	$[Q]$ per nat	proxy units per nat per period	**measured**; *not* dimensionless
δ	$[1]$	per period	**measured** dimensionless fraction per step
C_t	$[Q]$ per step	proxy units per period	**measured**, as a residual priced at the case's yield
h_t	$[Q]$ per step	proxy units per period	**derived**
$\tau = 1/\delta$	$[T]$	periods	**derived**
n	$[1]$	none	**defined** as an ordinal position; see Section 7.9
k	$[T^{-1}]$ **by assertion**	Hz	**POSTULATED** — see below

Symbol	Dimension	Unit	Status
$f(n) = kn^2$	$[T^{-1}]$	Hz	**POSTULATED**, inheriting from k
$f = k^2 G^4$	$[T^{-2}]$	Hz^2	**flagged**: the source labels it Hz; the label is a convention
octaves, cents, bits	[1]	none	**defined** as logarithms of ratios
$2/\ln 2$	[1]	octaves per nat	**derived**, exact

Does the recursion balance? $Q_{t+1} = (1-\delta)Q_t + \eta S_t - C_t$ balances if and only if every term on the right carries $[Q]$. The first does, since δ is dimensionless. The third does by construction. The second does only if ηS_t carries $[Q]$, and since S_t is dimensionless, that forces $[\eta] = [Q]$ per nat. **It balances, and η is the term that carries the unit.**

Two places where the framework is silent, and the audit says so rather than assigning a unit.

First, $[Q]$ has no common unit across the five cases. An asset, a regular, a green module, a commons-unit and a resumable thread are five different things, and nothing in the framework converts between them. The cross-case comparison in Section 4.6 therefore compares δ, u, $S/\ln N$ and τ — all dimensionless or in periods — and does **not** compare Q, η, C or h across rows, which would be a category error. Where the text does place them side by side, it is to show their *spread*, not to rank them.

Second, and more seriously, the essence law acquires $[T^{-1}]$ by assertion. The index n is a dimensionless ordinal. The output $f(n)$ is quoted in hertz. **Nothing in the algebra supplies the second; it enters entirely through the postulate that k carries units of hertz, and that postulate has its own line in the compounding chain below.** Computing $k = (9/8)^2/\varphi^2 = 0.483425732988414$ is a division of exact rationals and irrationals and yields a **pure number**. Attaching Hz to it is a separate and much stronger claim. The two are treated as two steps and never as one.

The composite rule makes the exposure visible. $f = k^2 G^4$ carries $[T^{-2}]$ if the units are taken seriously. The source reads the squaring as a change of structural level rather than as a dimensioned operation, which is a legitimate reading of a designed formalism; **but a quantity in Hz^2 must never enter an acoustic calculation expecting Hz**, and the specification requires re-anchoring by octave folding, which is a ratio operation and therefore unit-agnostic.

17.11.2 11.2 The postulates

P1 — The recurrence is linear and first order. $Q_{t+1} = aQ_t + x_t$ with a and x_t not depending on Q. *Status:* **DEFINITION** — the model form adopted by the framework [Curzi, 2026a], restated by setting $a := 1 - \delta$ and $x_t := \eta S_t - C_t$. It carries no empirical weight on its own.

P2 — The surplus functional is $F(u) = \ln(1 + (N-1)u)$ on $u \in [0,1]$, with $0 \le F \le \ln N$. *Status:* **CITED** within the corpus — the uniqueness characterisation under four axioms, with the affine effective count as design axiom S3, is Curzi [2026] and Curzi [2026c]. **No external literature contains this functional form**, and Section 12 records that.

P3 — $\varphi^2 = \varphi + 1$, so $\varphi^2 = 2.618033988749895$. *Status:* **ARITHMETIC**, and elementary [Euclid, 1956, Vajda, 1989, Koshy, 2001].

P4 — $(9/8)^2 = 1.265625$ exactly. *Status:* **ARITHMETIC.** $9/8$ is the Pythagorean whole tone and $81/64$ the Pythagorean ditone [Barbour, 1951, Lindley and Turner-Smith, 1993]; the interval identification is CITED, the squaring is arithmetic.

P5 — Essence types have a frequency, and it is square in the index. *Status:* **POSTULATED** — asserted by the 2022 source, with no external support of any kind, and no derivation offered here or there. This is the only postulate in the chain that carries the paper's substantive risk.

P6 — The effective count may be taken as the cross-disciplinary essence index. *Status:* **POSTULATED** (a modelling identification). Warranted by the six-requirement argument of Section 8.4, which is a strong warrant and is not a derivation.

17.11.3 11.3 The compounding chain

```
P3 + P4      -> L1   k = (9/8)^2/phi^2 = 1.265625/2.618033988749895
                     = 0.483425732988414  as a PURE NUMBER.          ARITHMETIC

L1 + P5      -> R4a  attaching Hz to k, so that f(n) = k n^2 is a
                     frequency, is a SEPARATE claim from computing k.  POSTULATED

L1           -> R4   f(m)/f(n) = k m^2 / k n^2 = m^2/n^2, so k cancels
                     from every interval, for every k > 0.           ARITHMETIC

R4           -> L2   interval in cents between m and n is exactly
                     2 x the classical interval, since squaring
                     doubles the logarithm.                          ARITHMETIC

L1 + P5      -> R5   n = 2^a m with m odd gives f(n) = f(m) 2^(2a),
                     so pitch class = odd part, and 1..N realises
                     exactly ceil(N/2) classes.                      ARITHMETIC

P2           -> L3   N_eff = e^F = 1 + (N-1)u, equal to 1 at u = 0
                     and to N at u = 1.                              DEFINITION (axiom S3)

L3 + P6      -> R6   octaves above base = log2(e^(2F)) = (2/ln 2) F
                     = 2.885390081777927 F, exact.                   ARITHMETIC given P6

P1 + P2      -> R1   one-step change = eta F(u) - delta Q - C; five
                     surveys reproduce five observed changes to
                     within 1.392% of eta ln N.                      ARITHMETIC on stipulated inputs

P1 + P2      -> R2   h = eta ln N - delta Q - C contains no term in u,
                     so h and S/ln N are independent readings and a
                     system may have h > 0 while Q falls.            ARITHMETIC

n(n-1)/2     -> R3   channels per nat = n(n-1)/2 / ln n: 74.732 at
                     n = 22 against 6.213 at n = 5; a four-cluster
                     nesting gives 55.5 = 24.03% of 231.             ARITHMETIC
```

Every line is checkable from its own stated inputs.

What this chain does not establish, stated in this section rather than left to the reader. R4 and R5 are unconditional algebra and would remain true if k were 1 — but they are theorems *about a postulated law*, and a theorem about a postulate inherits the postulate's status when it is applied. R6 is exact arithmetic *given* an identification that is not derived. R1 and R2 are exact arithmetic *given* parameters that were estimated once, by one analyst, on constructed systems. **A chain whose load is carried by two POSTULATED steps and one DEFINITION is not a proof of anything about the world, and this section says so rather than leaving the reader to notice.**

17.11.4 11.4 The verification instance a reviewer can redo in a minute

Three checks establish the constant, and each is arithmetic a reader can perform without reading the rest of the paper.

1. $(9/8)^2 = 81/64 = 1.265625$. Exact.
2. $\varphi^2 = \varphi + 1 = 2.618033988749895$. Exact to double precision; the identity is Euclid's.
3. $1.265625/2.618033988749895 = 0.483425732988414$.

To fifty digits, $k = 0.48342573298841433274106978775598925726$. Four closed forms agree to the last stored digit: $(9/8)^2/\varphi^2$, $(81/64)/(\varphi + 1)$, $(81/64)(2 - \varphi)$, and $(81/64)(3 - \sqrt{5})/2$.

Two further checks confirm the two theorems on the smallest examples that exercise them:

- **Result One at its smallest.** $f(2)/f(1) = 4k/k = 4$, independent of k. Two octaves, from an index ratio of two.
- **Result Two at its smallest.** $N = 3$ gives odd parts $\{1, 1, 3\}$ — two classes — and $\lceil 3/2 \rceil = 2$. $N = 5$ gives $\{1, 1, 3, 1, 5\}$ — three classes — and $\lceil 5/2 \rceil = 3$.

And the bridge constant on its smallest non-trivial value: at $F = \ln 2$, the effective count is 2 and the pitch is $(2/\ln 2)\ln 2 = 2$ octaves above base, exactly.

17.11.5 11.5 The survey validation, recomputed

The single most useful check on Section 4 is to confirm that the five predicted steps follow from the five stated parameter sets. Taking the desk, which is the smallest:

```
u     = 1 − 0.74^2 = 0.4524
N_eff = 1 + 2(0.4524) = 1.9048
S     = ln(1.9048) = 0.644377016190516
eta   = 13 / (10 x 0.644377016190516) = 2.017452465461063
eta S = 2.017452465461063 x 0.644377016190516 = 1.300000
delta = 1 − (5/7)^(1/2) = 0.15484574527148343
dQ    = 0.15484574527148343 x 6 = 0.9290744716289006
C     = 2.39 x 0.26 = 0.6214
step  = 1.300000 − 0.929074 − 0.621400 = −0.250474
```

against an observed -0.250, a residual of -0.000474. The same recomputation was run on all five cases and every printed intermediate reproduces, **with one exception recorded in Section 9.7(d)**: Case A's cost term is printed as 1.608069 and recomputes as 1.608066.

17.11.6 11.6 Limits, asymptotics, and the model's valid domain

Limit	Behaviour	Reading
$\delta \to 0$	no fixed point; Q_t unbounded, growing linearly	a pathology, not an ideal [Curzi, 2026a]. The co-housing block at $\delta = 0.0233$ is the closest case and its 3τ is 128.5 months
$\delta \to 1$	$Q_{t+1} = \eta S_t - C_t$; no memory at all	the system has no stored order, only a flow
$\eta \to 0$	$Q_\infty = -C/\delta < 0$	the conversion pathology; the co-housing block at $\eta = 0.926$ is the nearest instance and its fixed point is negative

Limit	Behaviour	Reading
$u \to 0$	$N_{\text{eff}} \to 1$, $F \to 0$, pitch $\to$ the ground essence	a roster of N parallel members is worth one member, and sounds one note
$u \to 1$	$N_{\text{eff}} \to N$, $F \to \ln N$, pitch $\to$ $2\log_2 N$ octaves	the ceiling, reached only at exact orthogonality
$N \to 1$	$\ln N = 0$, so $h = -\delta Q - C < 0$ always	a single-category system can never build. The framework's domain requires $N \geq 2$
$N \to \infty$	ceiling grows as $\ln N$; channels as n^2	the ratio $n(n-1)/2 \,/\, \ln n$ diverges, which is R3
$n \to \infty$ (essence)	interval between neighbours $\to 0$: 1403.9 cents at $n = 2$, 177.7 at $n = 20$, 69.8 at $n = 50$	the set thins through equal temperament into microtones; the first few indices carry almost all the harmonic content

Two domain violations occur in this paper and both are declared where they occur rather than here. The linear recursion has no saturation term, so it predicts past any physical cap. The open-source case's $Q_\infty = 113.44$ sits under a cap of 119 maintainable modules and the prediction is declared directional above about $Q = 95$; the desk's $Q_\infty = 16.40$ exceeds what one person can hold, and the model is declared trustworthy only to about week 6. **Naming the cap is not a weakness of the method; failing to name it is the failure.**

17.11.7 11.7 Invariance: the scale-freedom claim, stated properly

RIGOR requires a scale-freedom claim to be stated as an invariance — under which transformation, over what range, and what would break it. This paper's claim is as follows.

The transformation. Let $Q \mapsto \lambda Q$ be a change of the unit in which stored order is counted ($\lambda > 0$), and let $t \mapsto t/m$ be a change of the period. Under the first, Q, η and C all scale by λ while δ, u, N and $S/\ln N$ are unchanged; the recursion's form is exactly preserved and the fixed point $Q_\infty = (\eta F - C)/\delta$ scales by λ as it must. Under the second, $\delta \mapsto 1 - (1-\delta)^{1/m}$ and $\eta S, C \mapsto$ their per-new-period values; the *form* is preserved and τ rescales by m. **The dimensionless quantities u, N_{eff}, $S/\ln N$ and $\delta\tau = 1$ are the invariants.**

The range over which it has been tested: five systems. Headcounts 1, 12, 18 (typical occupancy), 40 (three maintainers plus 37 contributors) and 51 residents in 22 households — three orders of magnitude. Periods: one week, one month, one quarter. Stored-order stocks: 6 to 84 units. **Five scales is the whole of the test and the paper claims nothing beyond it.**

What would break it. Three things, each observable.

1. **A term the recursion lacks becomes necessary.** Saturation is the leading candidate and it is already visible: two of the five cases predict fixed points above their own physical caps. A system whose observed change cannot be reproduced without a saturation term has broken the invariance at that scale, and the correct response is to state the domain rather than to rescale.
2. **A parameter stops being estimable at a scale.** δ is estimated from a zero-input window. At a scale with no such window — a system that is never idle — the estimator is unavailable and the survey cannot be run, which is a limit on the *protocol* rather than on the *form*, and the paper distinguishes them.
3. **The residual acquires a trend in scale.** The five residuals as a fraction of the ceiling term are 0.021%, 1.392%, 0.007%, 0.935% and 0.423%, at headcounts 1, 12, 18, 40 and 51. **They show no monotone dependence on headcount, and with five points that is a remark, not**

a test. A larger series in which the residual grew with scale would refute the invariance directly.

What the claim is not. It is not a physical scaling symmetry and no critical exponent is estimated or implied. It is not the claim that the *parameters* are scale-free — they emphatically are not; η spans a factor of thirty across the five cases and that spread is the paper's second result. And it licenses no extrapolation: a claim tested at five scales is a claim about those five.

17.11.8 11.8 Analogy discipline, and the precision of the numbers

Every borrowing from physics in this paper is one of three things and is labelled at first use.

Category 1, a genuine derivation — the physical result is used because the system satisfies its premises. **Sabine's relation in the library case is the only clear instance.** The reading room is a physical enclosure with measurable surface absorption; $RT_{60} = 0.161V/A$ governs it as it governs any such room [Sabine, 1922, Beranek, 2004], and the computed 2.5223 seconds is a prediction about the world that a meter would confirm or refute.

Category 2, a shared mathematical form — the same equation governs both, with no claim that the underlying physics applies. **Most of this paper is category 2, and category 2 is respectable.** The recursion is a leaky integrator whether it holds charge or stored order [Oppenheim et al., 1996, Gerstner and Kistler, 2002]; the geometric decay, the pole, the time constant and the settling time are properties of the equation. The Gabor time–bandwidth relation invoked in Sections 7.8 and 8.9 is likewise a mathematical property of the Fourier transform [Gabor, 1946] and is developed for this corpus in Curzi [2026z] — it constrains any signal, and no quantum-mechanical content is imported with it. **Kennard's inequality is a fact about state preparation, not about measurement disturbance** [Kennard, 1927], and no use is made of it here.

Category 3, an analogy with no formal warrant — legitimate as motivation, never as evidence. **The infinite-square-well correspondence of Section 7.11 is category 3 and is the paper's most tempting failure mode**, which is why the disclaimer sits in the same paragraph as the correspondence rather than in a footnote. n^2 is the most common eigenvalue pattern in elementary physics; sharing it is not remarkable; and because k is free, a matching box width can always be constructed, so the correspondence is a division rather than a discovery.

On significant figures. Three regimes are used and each is labelled.

- **Defined and exact:** $k = 0.483425732988414$, $2/\ln 2 = 2.885390081777927$, $2400/\ln 2 = 3462.4680981335122$, $\varphi^2 = \varphi + 1$. These are ratios of exactly specified quantities and may be quoted to any precision. **Every appearance of k at fifteen figures in this paper is accompanied by the word *defined*.** Fifteen figures on a *measured* quantity would be the classic marker of work that does not understand its own error bars; that is why the label is not optional.
- **Illustrative model output:** every trajectory table in Sections 4 and 8. These are computed from stipulated parameters and are quoted to the precision at which they are reproducible, which is not the precision at which they are meaningful. **A predicted Q of 43.6 commons-units at month 12 is an arithmetic consequence of an assumed η, and the assumed η is good to perhaps two figures.**
- **Estimated with an interval:** the institute's tone in Section 8.14 is the one place a value is published as a band — 3.6393 to 4.4222 octaves from $u = 0.28 \pm 0.05$ — and it is the form every other value in the paper should have taken had its inputs carried stated uncertainty. **They do not, because the parameters are stipulated rather than measured, and Section 12 says so.**

17.12 12 Limitations

The five worked systems are constructed, not observed. No dataset was collected for this paper. Every number in Section 4 is the output of stated parameters under the stated model, carried through so that a reader can re-derive it. They demonstrate that the procedure runs, that it validates against a stated prior change, and that it reports its own failures. **They are not evidence that any organisation behaves this way and must never be cited as such.**

The reflexive specification is not identified, and no remedy is adopted. Section 3.5 states this in full. Manski [1993] shows the endogenous social effect cannot be recovered from observational data; Shalizi and Thomas [2011] shows influence and selection are generically confounded in network data. The five validations in Section 9.1 are compatible with a third variable driving both interaction and stored order, and the corpus's own shuffled-input control passes 98.35 per cent of the time against exactly that confound [Curzi, 2026i]. **Every causal reading in this paper is a modelling position, not an identified empirical result.**

Which parameters were chosen rather than measured. In all five systems, (N, u, η, δ, C) are stipulated, and each was estimated once by one analyst with no inter-rater reliability check. The post-intervention targets — $\rho : 0.86 \to 0.62$ at the research group, $u : 0.32$ at the library, $\eta : 1.40$ at the co-housing block — are design targets, not predictions from a fitted model. **The channel-scaling assumption in Section 4.4, which converts a 24.03 per cent cut in channels into a proportional cut in governance hours, is a modelling assumption with no measurement behind it**, and it is the single largest unsupported step in the co-housing case; the case preregisters it as its own second falsification condition, which is the correct treatment but is not a substitute for the measurement.

u has not been shown to be a quantity, and the essence index has not been shown to license arithmetic. Michell [1997] argues that psychology routinely fails to test whether its attributes are quantitative before measuring them, and this is the strongest objection to the framework. The remedies are conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971] or a Rasch demonstration [Rasch, 1960]; **neither has been run for u, and the quantitative treatment of u throughout this paper is therefore a stipulation.** The essence index is worse: it is an ordinal by the paper's own definition, and $f(n) = kn^2$ squares it, which is not a licensed operation on an ordinal scale [Stevens, 1946]. The paper's response is to measure the consequence — the permutation test of Section 7.9, whose worked instance reports a maximum pitch-class displacement of 364.99 cents from a plausible re-ordering — not to defend the operation.

$N_{\text{eff}} = 1 + (N-1)u$ is not a Hill number and no external literature contains it. $1/\text{HHI}$ is the Hill number of order two, $\exp(H)$ the Hill number of order one, and both are grounded [Hill, 1973, Jost, 2006, 2007]. The affine form is a linear interpolation between 1 and N, adopted as design axiom S3 [Curzi, 2026c]. **A reviewer reaching for the Hill-number literature as support will find it does not apply.** The repair is to derive the properties of the affine form in the framework's own terms and reserve the Hill citations for the two quantities they exactly describe.

The surplus functional's form is underdetermined by the evidence. Latané [1981] proposes a sub-linear power law and Briscoe et al. [2006] an $n \log n$ form; both fit the qualitative facts as well as $\ln(1 + (N-1)u)$. **This paper offers nothing that discriminates between them and concedes that nothing yet does.** Peters and Gell-Mann [2016] supplies the one warrant for a logarithm that requires no psychological premise, which strengthens the case for *a* logarithm without discriminating among the three.

The essence law rests on three postulates and this paper defends none of them. That essence types have a frequency; that the law is square; that $k = (9/8)^2/\varphi^2$. There is no external literature for any of the three, and the golden-section scepticism [Markowsky, 1992, Fischler, 1981] applies in full — with the specific observation that this paper's own Result One shows the constant to be inert, which is a demotion the sceptics would recognise. **Attaching hertz to k is a further and separate postulate**, given its own line in the verification chain, and it is the step by which a dimensionless ordinal acquires a physical dimension.

No preregistered test of any hypothesis in this paper has been run. Each of the five cases

states its falsification conditions before its intervention — that is the protocol [Curzi, 2026i, Nosek et al., 2018] — but the interventions are constructed and no outcome data exist. The corpus's one preregistered confirmatory application of the storage law **failed its second falsification rule**, beating a matched AR(1) by 2.8 per cent on held-out error against a declared margin of 10 per cent [Curzi, 2026i], and that is the current evidential status of every applied claim resting on this paper.

No model comparison in the proper sense is reported. There is no out-of-sample test here, no matched null with the same free-parameter count, no information criterion, and no effect size with an interval. The five validations are in-sample reproductions of a single observed change from independently estimated parameters, which is a weaker thing than a model comparison and is not a substitute for one.

Two numbers are quoted rather than re-derived. The intermediate cycle counts in the minimum-gap discussion of Section 7.8 — 3.899 cycles becoming 22.918 — come from the derivation in Curzi [2026z] and are not recomputed here. **A direct recomputation from the cents figures gives 3.94 rather than 3.899, about one per cent apart**, which is consistent with the source's own point that the three ratios in that table are three different quantities measured in three different units, but the discrepancy is recorded rather than smoothed. The three *ratios* — 5.828 in cents, 5.878 in cycles, and 8 exactly in achievable rate — were recomputed and reproduce.

A gauge adopted as a target ceases to measure. Failure mode FM-B9 names this, and it is Goodhart's law [Goodhart, 1975] and Campbell's [Campbell, 1979]. The paper's own instruments are exposed to it: a system that knows its u is being measured can raise measured u without raising the thing u is supposed to stand for. No defence against this is offered.

17.13 13 Conclusion

The five-parameter survey runs at every scale it was tried at, and it validates. One desk, a twelve-person research group, a public reading room, a distributed software project and a twenty-two-household co-housing block were surveyed under one protocol. Each was required to reproduce an independently observed change in stored order before any diagnosis from it was admitted, and each did: predicted -0.250474 against observed -0.250 at the desk, -3.387202 against -3.500 at the research group, -0.996371 against -1.000 at the library, -2.472006 against -2.416667 at the software project, and -0.406311 against -0.400 at the co-housing block. **Every residual is under 1.4 per cent of the ceiling term $\eta \ln N$, and the largest is 1.392 per cent.**

Every one was losing stored order at survey and no two for the same reason. The research group ran at 41.64 per cent of its ceiling with headroom of $+1.3425$; the reading room at 28.59 per cent for a physically identifiable cause, a 2.5223-second occupied reverberation time; the software project at 69.28 per cent with $h = -0.653978$, cost-bound; and the co-housing block at 91.03 per cent of ceiling and still at $h = -0.272521$ because conversion was 0.926369 commons-units per nat. **Headroom and the realised fraction are independent readings and both are required: two of the five cases had positive headroom and were shrinking.** The complaint recorded at survey named the binding term in none of the five.

The quadratic-committee price is exact. Twenty-two-household consensus carries 231 pairwise channels, 74.732 per nat of $\ln n$ against 6.213 at $n = 5$; a nested four-cluster form with a four-delegate council carries 55.5 channels, **24.03 per cent of the flat figure**.

Two theorems about the essence law are unconditional. *Result One:* $f(m)/f(n) = m^2/n^2$, so the chosen constant k cancels from every interval and does no work beyond setting a reference pitch — the golden section in this formalism is a transposition, and a transposition is the one musical operation that changes nothing structural. *Result Two:* writing $n = 2^a m$ with m odd, the pitch class is the odd part, so a set indexed $1..N$ realises exactly $\lceil N/2 \rceil$ classes — twenty elements give ten, twelve give six, and a set indexed by powers of two gives one.

The bridge is badged. Taking $n_{\text{eff}} := N_{\text{eff}} = e^F$ gives octaves above base $= 2F/\ln 2 =$

$2.885390081777927 \times F$ and 3462.4680981335122 cents per nat, both exact. The worked institute publishes 4.06 octaves with an honest **0.7827-octave band** from $u = 0.28 \pm 0.05$. The effective count used is the affine $1 + (N - 1)u$ and **not** a Hill number.

And the counter-results, which are the part of this paper a reviewer should weigh most. The essence law's three load-bearing commitments — that essence types have a frequency at all, that the law is square in the index, and that $k = (9/8)^2/\varphi^2$ — are postulates with no external support, and the constant is then shown to cancel from everything. The source's own compound rule reproduces only **37 of 44** published composite values, so seven are declared errata and every value must be recomputed rather than transcribed. The scale-freedom claim is a statement about model form tested at exactly five scales, not a physical symmetry. And the whole apparatus rests on a reflexive specification that is **not identified from observational data**, for which this paper adopts no remedy and therefore claims a modelling position rather than a measured result.

17.13.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the model developed in the text, and every table can be re-derived from the equations and the parameter values printed beside it. The five systems worked in Section 4 are constructed examples with declared parameters, not field observations; the institute of Section 8.14 is likewise constructed. The verification of the essence law in Section 7.4 is a recomputation of a table published in a third-party document of 2022, and the seven values declared errata in Section 7.10 are identified by that recomputation. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3, 7 and 8.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked systems and figures, performed the recomputation of the 2022 source table, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. All five surveyed systems and the worked institute are constructed. The consent constraint applied throughout Section 4 — that no intervention removing a participant's ability to decline is within the framework's scope, and that two candidate interventions were cut on that ground and the cuts recorded — is a design constraint on prospective work and is not a report of any study performed.

Preregistration

This paper reports no preregistered test of its own. Each of the five cases states its falsification conditions, its required baselines and its trip-wires before its intervention, which is the corpus's preregistration protocol [Curzi, 2026i] applied to a constructed case; no outcome data exist for any of them. The corpus's one preregistered confirmatory application of the storage law to a real system **failed its second falsification rule** — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent [Curzi, 2026i] — and any applied claim resting on this paper inherits that result.

Chapter 18

Conversion Keys and Modal Design: Deriving a Room, a Cadence and a Pitch Lattice from an Essence Set Without Subliminal Signal

Abstract. Four registers this framework treats separately — surplus in nats, pitch in octaves, sensation, and the moment — are shown to be one register up to a change of logarithmic base, and the conversion constants are computed exactly: $1/\ln 2 = 1.4426950408889634$ bits per nat, $2/\ln 2 = 2.8853900817779268$ essence octaves per nat, and $2400/\ln 2 = 3462.4680981335122$ cents per nat. One bit is *two* octaves rather than one, because doubling an effective count multiplies a square-law frequency $f(n) = k\,n^2$ by four. The keys are then used to build: taking essence indices $7, 9, 11$ as axial-mode targets, $L = c/(2f)$ with $c = 343\,\mathrm{m\,s^{-1}}$ yields a room of $7.2400 \times 4.3798 \times 2.9319$ m, exactly in the ratio $1 : 121/81 : 121/49$, with $V = 92.969\,\mathrm{m^3}$ seating 12.7 at $2.5\,\mathrm{m^2}$ per person, a Sabine target of 0.5 to 0.6 s requiring 25 to $30\,\mathrm{m^2}$ sabins, and a Schroeder frequency of 146.7 Hz below the entire folded set. Folded in the time domain the same set gives a 12.55-day cadence at 0.090 of the system time constant. Twelve categories yield six pitch classes; eight proxemic zones yield four, two of which are disclosed in advance as 34.976 cents apart and therefore beating rather than forming an interval. The constant $k = (9/8)^2/\varphi^2 = 0.483425732988414$ is **defined and exact** as a number and a **postulate** the moment it is written in hertz, and the dimensional audit states that every hertz in the paper enters through that one step. Hidden or inaudible signal is prohibited absolutely, as an adopted design constraint rather than an empirical finding. The paper supplies a counter-result against its own instrument: this framework's own six storage-law parameters fail all three admissibility requirements and receive no frequencies at all.

Keywords: conversion keys; axial modes; Schroeder frequency; cadence folding; pitch class collision; consonance ranking; no subliminals; moment ceiling

Series: B. Engineering the Surplus **Paper:** CCP-018

18.1 1 Introduction

A framework that measures interaction surplus in nats, and a framework that measures musical pitch in octaves, are not obviously about the same thing. This paper shows that they are

the same thing up to a change of logarithmic base, computes the conversion constants exactly, and then does the only honest test of a unit system: it uses the units to build something and reports what the build is and is not evidence for.

The occasion is a narrow one. The corpus carries a **target-generating instrument** in the essence law `f(n) = k n^2`, which takes an ordered category scheme — a room's programme, an institution's houses, a set of published proxemic zones — and returns a small set of frequencies with exact ratio relationships. Those frequencies can then be used the way any designer uses a proportional system: to choose a dimension, a tuning target, a meeting period. **The claim being made is that the instrument chooses the target, and that is all it does.** The physics that follows is ordinary physics. A room 4.3798 m wide has an axial mode at 39.16 Hz because `f = c/(2L)` with `c = 343 m/s`, not because its category index is 9. Keeping those two sentences apart is the discipline this paper is built to enforce, and the point at which the corpus is most exposed if it fails.

Four things are established here that are not established elsewhere in the corpus.

First, the conversion keys, computed exactly. One nat is `1/ln 2 = 1.4426950408889634` bits, `2/ln 2 = 2.8853900817779268` essence octaves, and `2400/ln 2` cents. These are exact ratios of exact quantities and are quoted to the precision they support; the third is recomputed in Section 14 and found to differ from the corpus's printed value in the seventeenth significant figure.

Second, the factor of two. One bit is *two* octaves, not one, and the reason is neither information-theoretic nor musical: doubling an effective count multiplies a square-law frequency by four, and four is two octaves. Any reader importing the ordinary bits-to-octaves intuition is wrong by a factor of two, and the factor is the exponent of a postulate rather than a constant of nature.

Third, a worked build. Taking essence indices 7, 9 and 11 as axial-mode targets, `L = c/(2f)` returns a room of 7.2400 by 4.3798 by 2.9319 m, `V = 92.969` m3, seating 12.7 at 2.5 m2 per person, with a Sabine target of 0.5 to 0.6 s requiring 25 to 30 m2 sabins across 131.6 m2 of surface, and a Schroeder frequency of 146.7 Hz that sits below the entire folded set. The same set folded in the time domain yields a 12.55-day cadence at 0.090 of the system time constant. The room is buildable and its proportion matches a published heuristic to a Euclidean error of 0.031. **None of that is evidence that the tuning does anything**, and Section 13 says so at length.

Fourth, a counter-result the paper supplies against its own instrument. The corpus's own six storage-law parameters — the most obviously "important" set of categories available to it — fail all three admissibility requirements and therefore receive no frequencies at all. Set against that are two hard capacity limits: at most 25 essences fit the audible band under a shared transposition, and an essence frequency is never a physical resonance.

The material this paper analyses reaches it from a manuscript written in an initiatory register, and one part of the conversion is to say plainly what the register concealed. **A symbolic system can be analysed respectably; it cannot be performed in a submission.** Where the source asserts a mechanism it cannot support — a coil that "increases the probability of what you play through it over time" — this paper does not carry the assertion, and says why. Where the source prohibits something on ethical rather than empirical grounds — hidden or inaudible signal directed at occupants — this paper carries the prohibition as an adopted design constraint and records it in the Declarations as a constraint on prospective work rather than as a report of a study performed.

The framework's static half — the surplus functional `F(u) = ln(1 + (N−1)u)` and its affine effective count `N_eff = 1 + (N−1)u` — is presupposed and not re-derived; it is established with its axiom set in Curzi [2026], whose design axiom S3 fixes the affine form by choice rather than by derivation. The framework's founding definition, that comfort is the felt total of present costs so that the present state is a local minimum of the comfort landscape by definition rather than by luck, is presupposed from Curzi [2026]. The dynamical half — the storage law as a first-order section with pole `1 − delta`, time constant `tau = 1/delta` and the pathology at `delta = 0` — is presupposed from Curzi [2026a] and is used in Section 9.4 to decide whether an essence-

derived cadence is admissible at all.

Sections 2 and 3 state the hypotheses and the framework, including the three methodological problems — identification, scale type, and analogy discipline — that this paper is more exposed to than any other in the corpus. Sections 4 to 6 build the conversion keys and the three registers they join. Sections 7 and 8 develop the harmonic lattice and the admissibility requirements on an essence set. Section 9 is the modal design procedure and its four targets. Sections 10 and 11 collect the specifications and the twenty-eight named failure modes. Section 12 works three systems end to end, one of which is a refusal. Sections 13 to 16 discuss what follows, verify the chain, list what the account cannot support, and state the results in quotable form.

18.2 2 Hypotheses

Most of this paper is arithmetic, and arithmetic cannot be falsified by observation. The hypotheses below are the parts that can be, and each names the observation that would defeat it. Where a claim could not be defeated by any observation it is stated below the list as a definition, a postulate, or a modelling choice, and labelled as one; **no claim has been dressed as a hypothesis to fill the section**.

H1 — The room is an ordinary resonator, and the essence law contributes only the target. A rectangular enclosure built to `L = c/(2f)` at the dimensions of Section 9.3 has axial fundamentals at the frequencies the construction placed there, and its reverberation obeys Sabine's relation above the Schroeder boundary. **Predicted:** measured axial fundamentals at 23.69, 39.16 and 58.49 Hz to within the tolerance set by construction and by the departure of real surfaces from rigid; a measured `RT60` in 0.5 to 0.6 s when 25 to 30 m2 sabins are installed across 131.6 m2; a modal/statistical transition near `f_s = 146.7` Hz at `RT60 = 0.5` s. **Falsified by:** a measured axial fundamental departing from `c/(2L)` by more than the construction tolerance; or a measured `RT60` outside the error band that Sabine [1922] and Beranek [2004] report for rooms of this volume and absorption distribution.

H2 — The tuning contributes nothing beyond the choice of target. This paper predicts its own null. **Predicted:** in a preregistered comparison of an essence-tuned room against a conventionally proportioned room matched on volume, `RT60` and sightlines, measured turn-taking equality [Woolley et al., 2010] shows **no** advantage for the tuned room that survives a shuffled-input control. **Falsified by:** a surviving advantage under the protocol of Curzi [2026i] — which would be a positive result the framework does not currently claim and has no mechanism for.

H3 — A 34.976-cent separation beats rather than forming an interval. The two pitch classes 7 and 5 fold to `49/32` and `25/16`, 34.976 cents apart; at the band placement of Section 9.2 that is 379.0058 and 386.7406 Hz. **Predicted:** a beat at 7.7348 Hz, heard as roughness within a critical band rather than as a two-tone interval [Plomp and Levelt, 1965, von Helmholtz, 1885]. **Falsified by:** listeners at ordinary levels reliably reporting two separately pitched tones rather than one rough tone at that separation.

H4 — The index is reproducible where the ordering source is intrinsic, and not otherwise. Predicted: two competent analysts given a domain ordered by an intrinsic physical magnitude — Hall's proxemic zones ordered by distance [Hall, 1966] — assign identical indices; given a domain ordered by an enumeration with no intrinsic magnitude, they do not, and the resulting tunings differ by more than 100 cents. **Falsified by:** measured inter-rater agreement on an intrinsically ordered domain

falling below what the reproducibility literature would call acceptable [Open Science Collaboration, 2015]; or, in the other direction, two analysts independently reproducing an enumeration-ordered index.

H5 — Cadence admissibility is set by the pole, not by the ritual. Predicted: a system with per-period retention loss `delta` driven at forcing period `P` shows a visible sawtooth in its stored order when `P > tau/2`, `tau = 1/delta`, and smooth integration when `P <= tau/2`, independent of the size of each forcing [Curzi, 2026a]. **Falsified by:** an observed sawtooth at `P/tau = 0.09`, or smooth integration at `P/tau > 1`, in a system whose `delta` was measured on a zero-input window.

H6 — The square-law exponent is not recoverable from anything this corpus holds. Predicted: no dataset assembled in this corpus discriminates `s = 2` in `f = k n^s` from `s = 1.5` or `s = 3`, because "essence relation" has no operationalisation with an independently measurable magnitude; the exponent is **defined by the model, not estimated** [Clauset et al., 2009]. **Falsified by:** exhibiting one domain in which the relation between category types carries an independently measured magnitude, against which the postulated `m^2/n^2` spacing can be checked. That would be a genuine advance and the paper states the requirement precisely so that someone can meet it.

Four claims in this paper are not hypotheses, and are labelled here rather than left for a reader to discover.

- **The essence law `f(n) = k n^2` is a POSTULATE about essence structure.** It is not falsifiable at present, for exactly the reason H6 states. Its formal coincidence with the eigenvalue spacing of a one-dimensional infinite square well, where `E_n` is proportional to `n^2`, is a genuine mathematical correspondence and is noted as such; **coincidence of form is not evidence of physical mechanism**, and the corpus's own bibliographic audit records that asserting the connection would be a decorative analogy rather than a derivation.
- **`k = (9/8)^2 / phi^2 = 0.483425732988414` is a DEFINITION** — an exact ratio of exact quantities, computable to arbitrary precision, and quoted at fifteen figures only because it is defined. **Attaching `Hz` to it is a separate and much stronger claim**, it is a POSTULATE, and it is given its own line in the verification chain of Section 14. There is no physical, psychoacoustic or musicological precedent for combining a Pythagorean whole tone with an inverse square of the golden section to obtain a ground frequency, and none is claimed [Markowsky, 1992, Fischler, 1981, Livio, 2002].
- **The normalisation of the moment onto `[0, ln N]` is a CHOSEN MAPPING.** The ceiling result of Section 6.2 follows from the surplus range theorem plus that normalisation, and the normalisation is the only chosen step.
- **The no-subliminals constraint is an ETHICAL PROHIBITION adopted by the framework, not an empirical finding.** It is not a claim that hidden signal fails to work; efficacy is beside the point. It is a constraint on what the framework will design, and it is recorded as such in the Declarations.

18.3 3 Framework and method

18.3.1 3.1 What is presupposed

Five results are used throughout and established elsewhere. Their statuses differ and each is stated.

The surplus functional. For two unit state vectors drawn from an ensemble of `N` categories, `u = 1 − (x.y)^2` in `[0,1]` and

```
F(u) = ln(1 + (N−1) u),      N_eff = e^F = 1 + (N−1) u
```

with `F` uniquely characterised by four axioms — angle-only dependence, zero at parallel, an affine effective count, and normalisation at orthogonality — as established in Curzi [2026]. **Axiom S3, the affine effective count, is a design axiom: chosen, not derived.** The range result `0 <= F <= ln N` is what the ceiling argument of Section 6.2 consumes. *Status:* **PROVEN given the axioms.**

The storage law. `Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t` is a first-order discrete section with pole `1 − delta`, DC gain `1/delta` and time constant `tau = 1/delta` periods, and `delta = 0` is a pathology rather than an ideal because the map ceases to contract and no fixed point exists [Curzi, 2026a]. Section 9.4 consumes only the time constant. *Status:* **PROVEN as a statement about the equation.**

Sabine's relation. `RT60 = 0.161 V / A` in metric units, `V` in cubic metres, `A` in square-metre sabins [Sabine, 1922]. *Status:* **CITED — real acoustics, with a known error band and known conditions of validity.**

Rectangular room modes. For a rigid rectangular enclosure, `f(p,q,r) = (c/2) sqrt((p/Lx)^2 + (q/Ly)^2 + (r/Lz)^2)`, with `c = 343 m/s` at 20 C in dry air [Rossing et al., 2002, Beranek, 2004]. The axial case `q = r = 0` reduces to `f = c/(2Lx)`. *Status:* **CITED — real acoustics.**

The essence law. `f(n) = k n^2` with `k = (9/8)^2/phi^2`, `n` the ordinal position of a category within its domain's ordered set. *Status:* **POSTULATE**, with `k` a chosen reference constant and the index an input the law does not supply and cannot check.

18.3.2 3.2 The four registers, and why a conversion exists at all

Four quantities in this framework are logarithmic. Their statuses differ, and mixing statuses in one table is exactly what allows a postulate to borrow the authority of a theorem.

#	Register	Form	Status
1	Surplus	`F = ln N_eff = ln(1 + (N−1)u)`	**PROVEN** given axioms S1–S4, one of which (S3) is chosen
2	Pitch	`p = log2(f/f_ref)`	**DEFINITION**, universal in music [von Helmholtz, 1885]
3	Sensation	`S = k_F ln(I/I_0)`	**MEASURED LAW** with known failure regions [Fechner, 1966]
4	Moment	`ln M = ln D − ln P + ln E`	**POSTULATE** — this framework's own formula

Every conversion in this paper carries the status of the quantity it converts, and a conversion never upgrades a status. A postulate converted into octaves is a postulate in octaves. That rule is enforced throughout and is restated as specification CK-3 in Section 10.2.

The mechanism is one identity. All four registers are logarithms; logarithms in different bases differ by a constant factor and by nothing else, so `log_{b2}(x) = log_{b1}(x) (ln b1 / ln b2)` [Cover and Thomas, 2006]. **Because every register is a logarithm, every conversion between registers is a multiplication by a constant, and no information is lost, gained, or distorted in the crossing.** There is no approximation in the unit arithmetic of this paper; the only approximations are in the measured inputs.

18.3.3 3.3 Analogy discipline: which uses are derivations and which are analogies

This paper is the corpus's most exposed to a single failure — letting an analogy borrow the authority of a derivation — because it puts both in the same paragraph. The three-way classification is applied here once and then invoked by name at each first use.

Category 1, a derivation. The physical result is used because the system genuinely satisfies its premises. **Sabine's relation, the Schroeder boundary, the axial-mode formula, the open-open tube, the Helmholtz resonator and the stretched string are all category 1 in this paper.** A room really is a physical resonator; the premises of the modal formula are geometric and the room satisfies them. Nothing in these uses depends on any claim of this framework, and if the framework were withdrawn entirely the acoustics would stand unchanged [Rossing et al., 2002, Beranek, 2004].

Category 2, a shared mathematical form. The same equation governs both objects, with no claim that the underlying physics applies. **The storage law as a first-order low-pass section is category 2**, and the cadence argument of Section 9.4 uses it that way: a leaky integrator is a leaky integrator whether it holds charge or stored order [Curzi, 2026a]. **Octave folding applied to a period rather than a frequency is also category 2** — the reciprocal of a frequency is a period, and doubling is doubling.

Category 3, an analogy with no formal warrant. A suggestive correspondence, legitimate as motivation and never as evidence. **The mapping of an essence index to a frequency in hertz is category 3, and so is every reading of meaning off the resulting pitch relations.** Octave equivalence is grounded as a perceptual structure for pitch [Shepard, 1982, Demany et al., 2013], and the corpus's own bibliographic audit records that **nothing supports carrying it over to a quantity that is not a pitch**. The operation is well defined; its interpretation is unsupported. Independent evidence tightens rather than loosens that constraint: octave equivalence is itself weaker and more training-dependent than usually assumed [Hoeschele et al., 2012, Burns, 1999].

The failure mode is a category-3 use borrowing the authority of a category-1 use, and it has a name here: FM-2, the resonance claim, built. The room really does resonate. The category does not. Those are two sentences and this paper keeps them apart, at the cost of some repetition.

18.3.4 3.4 Identification: what no amount of building can recover

The framework's central formal claim elsewhere in the corpus is the reflexive loop `T(x) = W(x, M(x))`: the group influences the member and the members constitute the group. **That is a linear-in-means reflexive specification, and its endogenous social effect is not identified from observational data** [Manski, 1993]. No amount of fit, held out or otherwise, recovers the parameter, and influence and selection are generically confounded in observational network data [Shalizi and Thomas, 2011].

This paper invokes the loop in exactly one place — the claim that a room's acoustics shape turn-taking and that turn-taking constitutes the group's collective performance [Woolley et al., 2010, Curzi, 2026e] — and it **adopts no remedy**. The known options are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]; the last is the most realistic route and is not taken here. **The claim that room acoustics act on group performance through turn-taking is therefore a modelling position and not an identified empirical result**, and Section 15 records it again.

There is a second, sharper form of the same problem specific to this paper. The framework asserts that disclosure changes behaviour — that is the entire content of Section 3.6 — and then proposes to measure the tuned room's effect on occupants who have read a disclosure notice naming the tuning. **A disclosed intervention cannot be blinded to its recipients**, so the room comparison of H2 is unblindable by construction and its expectancy component is

unremovable [Rosenthal and Jacobson, 1968, McCambridge et al., 2014]. That is a real limit on what H2 can ever return and it is stated as one.

18.3.5 3.5 Scale type: the promotion problem, and the strongest objection to the framework

The essence law takes an ORDINAL and returns a RATIO-SCALE quantity. The index is a rank. The frequency is a physical magnitude with a true zero on which multiplication and division are meaningful. **The law therefore performs a scale promotion — it manufactures ratio-scale structure out of ordinal input — and that is not a permissible operation on data alone** [Stevens, 1946].

It is permissible as a **model**, and that is what it is. The square law is a postulate that *asserts* a specific quantitative spacing between ranks. The assertion may be right or wrong and it is the thing that would have to be tested. **What the text may never do is present the resulting frequencies as though the ratio-scale structure were measured. It was postulated.** The practical form of the rule: *the ordering is data; the spacing is the model*, and the intervals are only as meaningful as the spacing postulate.

This is where Michell [1997] applies, and it is the strongest objection to the whole framework. Psychology, Michell argues, systematically assumes that its attributes have quantitative structure without ever testing whether they do — and the test exists. **Conjoint measurement is the formal test for additive quantitative structure from ordinal data on two or more factors [Luce and Tukey, 1964, Krantz et al., 1971], and it has not been run for any construct in this paper.** Neither has a Rasch-model demonstration of specific objectivity [Rasch, 1960]. The paper's own failure-mode catalogue already contains the objection under the name FM-21, THE ARBITRARY ORDINAL; Section 15 states it in the scale-type vocabulary, where it belongs. **The ratio-scale treatment of essence frequency is a stipulation and is conceded to be one.**

A second scale-type warning attaches to the folded classes. **The odd part of an index is a NOMINAL label**, a class identifier and not a magnitude; the class's octave position in cents is interval-scaled and may be subtracted; the class count `ceil(N/2)` is a ratio-scaled count. Three scale types live in one construction and must not be mixed. Arithmetic on class numbers is not licensed.

18.3.6 3.6 The no-subliminals constraint, as a design prohibition

No subliminal content of any kind. Nothing masked. Nothing below the threshold of hearing. Nothing concealed from the listener. This is stated first because it is where the temptation arises, and it is stated as an **ethical prohibition adopted by the framework rather than as an empirical claim about efficacy**. Every technique in this paper operates entirely in audible, disclosed tone. Concretely, and as a specification rather than a sentiment:

1. **Every tone present in a space is audible to a person of ordinary hearing standing in it.** A tone below the threshold of audibility at any listening position is either raised to audibility or removed. There is no third option.
2. **Every tone is disclosed.** A written statement — posted at the entrance, in the room's documentation, or both — lists what is sounding, at what frequency, at what level, and why.
3. **No masking, no carrier, no embedding.** No content is placed under, inside or behind another signal: no amplitude-modulated speech, no time-compressed content, no spectral hiding, no content below 20 Hz or above 20 kHz intended to act on a listener.
4. **The room is leavable and the tone is stoppable.** There is an off switch, its location is disclosed, and anyone in the room may use it.
5. **Where the tuning is structural rather than sounded — a room dimension, a meeting cadence — the derivation is published**, so that anyone can disagree with it.

The reasoning is not squeamishness and not doubt about efficacy. **A method that works by removing a person's ability to decline is outside this framework's scope regardless of whether it works, and a message a listener cannot hear is a message the listener cannot decline.** The framework's boundary doctrine reaches the same place from the other direction: category innocence is explicitly refused as a defence of acquisition, and no harm may be moved through a discovered gap in a scheme [Curzi, 2026] — a bound this paper inherits rather than argues.

Clause 5 has an independent warrant that has nothing to do with ethics. A system whose security rests on the secrecy of its design rather than of its key is a weak system [Kerckhoffs, 1883], and a proportional system whose derivation is unpublished cannot be checked, disputed, or reproduced. **Publicity is the operative remedy** [Brandeis, 1914]. And it is a partial remedy at best: the corpus's own structural work records that disclosure did not prevent the 2022 immobilisation it analyses [Curzi, 2026], which is the reason disclosure appears here as a necessary condition and never as a sufficient one.

Two recommendations in the source material this paper draws on are refused and the refusals are recorded. The first is the embedding of subliminal content in a rendered track, excluded by clauses 1 and 3 above. The second is the use of a 12- or 24-winding Rodin coil as an amplifier, on the stated grounds that it "influences temporal 4th dimensional space by increasing the probability of what you play through the coil over time". **No verified engineering basis exists for the claimed mechanism, no citation in this corpus's bibliography supports it, and this paper does not present it as an amplifier.** Where an area of effect is required, the correct instrument is a loudspeaker with a published frequency response and a measured sound pressure level, with both disclosed.

18.3.7 3.7 Standing honesty clauses

Four clauses bind everywhere this paper's material is used. They are labelled HC-1 to HC-4 to keep them distinct from the hypotheses of Section 2.

HC-1 — Essence, not resonance. The output of the essence law is an essence frequency. **No claim is made that any material, room, institution or person physically resonates at these values.** A room whose axial mode is placed at 39.157484 Hz genuinely resonates at 39.157484 Hz — that is ordinary acoustics, and it is true because the room is 4.3798 m wide. It is *not* true because the room's category index is 9. **The essence law chose the target; physics did the resonating.**

HC-2 — `k` is chosen. Badged at every appearance, in every register, at every precision.

HC-3 — The ordering must be defensible. The whole method is downstream of the admissibility test of Section 8.1, and a set that fails it gets no frequencies.

HC-4 — Recompute; never copy a published value. This clause matters more here than anywhere else in the corpus, because a built object freezes an arithmetic error in timber and plaster and nobody re-checks it afterwards. Every figure in this paper was recomputed from the constants of Section 4.2; Section 14.5 reports the four printed values that did not reproduce. Two transcription faults travel with any citation of the 2022 source document from which the essence law is drawn: its prose instruction `1+5^.5/2` is missing its parentheses and must be read as `(1 + sqrt(5))/2`, and its spreadsheet stored `phi` to fifteen significant figures. **Cut a room, a bar or a pipe to a recomputed value and cite the errata beside it.**

And one clause specific to building. *The fact that a room is tuned by this method is not evidence that the method works.* A room built to these proportions may be a good room for entirely conventional reasons — its ratio happened to land near Volkmann's, its `RT60` happened to land in the speech range, its size happened to suit twelve people. A claim that the tuning did something requires a preregistered prediction and the four declared baselines including the shuffled-input control [Curzi, 2026i, Nosek et al., 2018]. **This paper claims only that the method produces a defensible, reproducible, documented choice of target.** Carry the correction with the requirement: the shuffled-input control has three measured failure modes of its own — it is anti-conservative as ordinarily run, it cannot see repackaging, and it cannot see a shared

slow driver — so a passed shuffle is not on its own evidence that a tuned room did anything [Simmons et al., 2011, Gelman and Loken, 2013]. **Design controls, not more surrogates.**

18.4 4 The conversion keys

18.4.1 4.1 The five constants

```
ln 2       = 0.6931471805599453        nats per bit          DEFINITION
1 / ln 2   = 1.4426950408889634        bits per nat          DEFINITION
2 / ln 2   = 2.8853900817779268        essence octaves/nat   DEFINITION given the square law
2400/ln 2  = 3462.4680981335122        cents per nat         DEFINITION given the square law
k          = 0.483425732988414         the ground constant   DEFINITION; in Hz, POSTULATE
```

The first four are exact ratios of exact quantities and may be recomputed to any further precision; they are quoted at the precision a reader is likely to want and no significance attaches to their last digit. **The fourth differs in its seventeenth significant figure from the value the corpus has previously printed**, and Section 14.5 gives the recomputation.

The fifth is not a unit conversion. It is the reference pitch, and it is **a chosen constant, not a measured one** (HC-2):

```
k = (9/8)^2 / phi^2 = (81/64)/(phi + 1)

phi   = 1.618033988749895
phi^2 = 2.618033988749895 = phi + 1                    (Euclid VI.3)
(9/8)^2 / phi^2   = 0.483425732988414                  DEFINED, exact
(81/64) / (phi+1) = 0.483425732988414                  identical
```

The two forms are identical because `phi^2 = phi + 1`, the defining property of the division in extreme and mean ratio [Euclid, 1956]; more generally `phi^m = F(m) phi + F(m−1)` with `F` the Fibonacci sequence, which is what makes every power of `phi` reducible to a rational combination [Vajda, 1989].

The `9/8` and the `phi` are both real objects with real histories, and their product in hertz has no precedent in any literature. The `9/8` is the Pythagorean whole tone, a specific and well-documented interval [Barbour, 1951, Doty, 2002]. The golden section is a specific and well-documented number. **What has no support of any kind is combining a tuning ratio with an inverse square of the golden section to obtain a ground frequency**, and this paper claims none. The golden-ratio literature is unusually well supplied with cautionary work, and it is cited here deliberately: Markowsky [1992] demolishes the standard claims that `phi` appears in the Parthenon, the Great Pyramid, the human body and preferred rectangles; Fischler [1981] shows how easily `phi` can be "found" in arbitrary data by choosing measurement points freely; Green [1995] and Höge [1997] review a century of failed attempts to replicate a golden-rectangle aesthetic preference; Livio [2002] separates the mathematics from the folklore. **The distinction that matters is between CHOOSING `phi` as a constant and FINDING it in nature. This framework does the first and does not do the second.**

18.4.2 4.2 The conversion key table

Read a row as "one of this unit equals", and a column as "measured in this unit".

1 of	nats	bits	octaves	cents
nat	1	1.442695	2.885390	3462.468098
bit	0.693147	1	**2 exactly**	**2400 exactly**

1 of	nats	bits	octaves	cents
octave	0.346574	**0.5 exactly**	1	**1200 exactly**
cent	0.000288811	0.000416667	0.000833333	1

Three entries are exact and the reason is not decorative. **The 1200 is definitional**: the cent has been one twelve-hundredth of an octave since Ellis introduced it in his translation of Helmholtz [von Helmholtz, 1885]. **The 2 and the 0.5 come from somewhere else entirely**, and Section 4.3 derives them.

The derived conversion laws:

```
SURPLUS -> PITCH        octaves above ground = 2F / ln 2 = 2.885390 F   (F in nats)
SURPLUS -> FREQUENCY    f_cross = k e^(2F) = k N_eff^2
ESSENCE -> FREQUENCY    f(n)    = k n^2                  n the essence index
INTENSITY -> SENSATION  S       = k_F ln(I / I_0)        Fechner
INTENSITY -> MAGNITUDE  log psi = log k_S + a log I      Stevens; a IS the key
MOMENT -> SURPLUS       M normalised onto [0, ln N] serves as S_t in the storage law
                        [NORMALISATION CHOSEN, not derived]
DISTORTION              Delta = |ln r|,  r = D/P         reported in any register
```

18.4.3 4.3 Why one bit is two octaves and not one

This is the single non-obvious constant in the table and it is derived rather than asserted, because a reader who assumes the ordinary information-theoretic correspondence [Shannon, 1948, Hartley, 1928] will be wrong by a factor of two.

One bit of surplus means the effective count doubled: `N_eff -> 2 N_eff`. The essence law maps index to frequency by a **square**:

```
f(n)      = k n^2
f(2n)/f(n) = (2n)^2 / n^2 = 4       =  two octaves, exactly
```

Doubling the effective count quadruples the essence frequency, and quadrupling is exactly two octaves. That, and only that, is why one bit is two octaves here. The factor two in `octaves = 2F/ln 2` is the exponent of the essence law and nothing else. Verified across the range:

```
N_eff  ->  2 N_eff        f ratio      octaves
  1    ->     2            4.0          2.0
  3    ->     6            4.0          2.0
 12    ->    24            4.0          2.0
```

The consequence for the honest reader is a caution. If the exponent were some other value `s`, so that `f = k n^s`, the key would be `s/ln 2` octaves per nat:

exponent `s`	octaves per nat	cents per nat
0.5	0.721348	865.617
1	1.442695	1731.234
1.5	2.164043	2596.851
2 (this framework)	**2.885390**	**3462.468**
2.5	3.606738	4328.085
3	4.328085	5193.702

The surplus-to-pitch key is therefore contingent on the square law, and the square law is a postulate about essence structure rather than a measured fact. State this whenever 2.885390

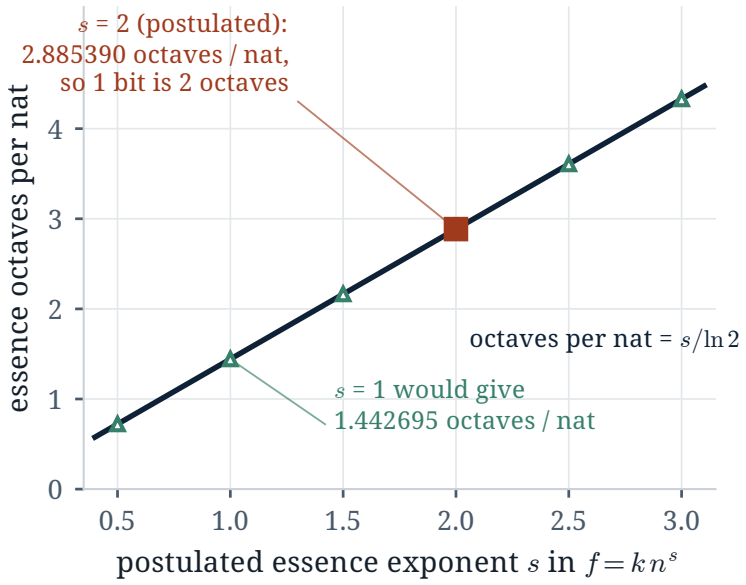

Figure 18.1: **One bit is two octaves, and the factor of two is a postulate rather than a constant of nature.** The conversion key is `s/ln 2` octaves per nat, where `s` is the exponent of the essence law; at the postulated `s = 2` it is 2.885390, and at `s = 1`, the exponent an information-theoretic reader would assume, it would be 1.442695. The claim is verified at `N_eff = 1, 3, 12`, where `f(2n)/f(n) = 4.0` and `log2 4 = 2.0` in every case. Exact arithmetic; the exponent is defined by the model and was never estimated. Generated by `figs/src/CCP-018_fig01.py` from the tables of Section 4.3.

is used. The constant is exact *given* the postulate and not exact independently of it — the difference between "2.885390 is the correct number" and "2.885390 is a correct number about the world". Only the first is claimed.

The exponent is defined by the model, not estimated, and that distinction is not a technicality. The literature on fitting power-law exponents exists because an exponent read off a log-log plot by eye, or fitted without a goodness-of-fit test against alternatives, is routinely wrong [Clauset et al., 2009]. **This paper runs no such procedure and needs none, because `s = 2` was never estimated from data.** It was chosen. A reader who mistakes a defined exponent for an estimated one will look for confidence intervals that do not exist and cannot exist, and the sensitivity table above is what replaces them.

18.4.4 4.4 Deriving each constant

Nats to bits. A nat is the logarithm base e, a bit base 2, so one nat is `1/ln 2` bits [Cover and Thomas, 2006]:

```
1 / ln 2 = 1 / 0.6931471805599453 = 1.4426950408889634
```

To six places, 1.442695. Bits are the register in which an engineering reader has the strongest intuitions: `ln 12 = 2.484907` nats is `3.584963` bits, so a twelve-category system, fully orthogonal, is worth three and a half bits of surplus per interaction. **That is a small number and it should feel small.**

Nats to octaves. By Section 4.3 one unit of `F` multiplies frequency by `e^2`, and the octaves in a ratio `R` are `log2 R`, so

```
octaves per nat = log2(e^2) = 2 / ln 2 = 2.8853900817779268
```

Nats to cents. A cent is one twelve-hundredth of an octave by definition, so

```
cents per nat = 1200 (2 / ln 2) = 2400 / ln 2 = 3462.4680981335122
```

Octaves to nats. The reciprocal, `ln 2 / 2 = 0.34657359027997264`.

Cents to nats. `ln 2 / 2400 = 0.00028881132523331055`, the resolution constant. One cent corresponds to about 289 millionths of a nat of surplus. **The pitch register has far finer graduation than the surplus register has meaningful precision**, which is a warning and not an invitation: see FM-17, the cents illusion.

18.4.5 4.5 The conversion in use

The working table converts an effective count into all four registers plus the essence frequency. It is computed, not transcribed.

`N_eff`	`F` (nats)	bits	octaves	cents	`f = k n^2` (Hz)
1	0.000000	0.000000	0.000000	0.000	0.483426
2	0.693147	1.000000	2.000000	2400.000	1.933703
3	1.098612	1.584963	3.169925	3803.910	4.350832
4	1.386294	2.000000	4.000000	4800.000	7.734812
5	1.609438	2.321928	4.643856	5572.627	12.085643
6	1.791759	2.584963	5.169925	6203.910	17.403326
7	1.945910	2.807355	5.614710	6737.652	23.687861
8	2.079442	3.000000	6.000000	7200.000	30.939247
9	2.197225	3.169925	6.339850	7607.820	39.157484
10	2.302585	3.321928	6.643856	7972.627	48.342573
12	2.484907	3.584963	7.169925	8603.910	69.613306
16	2.772589	4.000000	8.000000	9600.000	123.756988
20	2.995732	4.321928	8.643856	10372.627	193.370293
24	3.178054	4.584963	9.169925	11003.910	278.453222

Two features are worth dwelling on. **The powers of two are exact in three registers at once**: `N_eff = 2, 4, 8, 16` give exactly 1, 2, 3, 4 bits, exactly 2, 4, 6, 8 octaves, and exactly 2400, 4800, 7200, 9600 cents. Nothing is rounded.

And the frequency column is brutal. Going from an effective count of 2 to 24 — a twelvefold increase in genuinely different views — moves the surplus from 0.693 to 3.178 nats, a factor of 4.6, but moves the essence frequency from 1.93 Hz to 278.45 Hz, a factor of 144. **The pitch register amplifies exactly the differences the surplus register compresses, which is why it is useful as a display register and dangerous as an inference register.** Use frequency to hear a system, not to argue about it.

A fifth key converts surplus into time. The four registers above are all instantaneous. The Gabor time-bandwidth limit `dt df >= 1/(4 pi)` [Gabor, 1946], together with this paper's own relation `d(ln f) = 2 dF`, gives

```
SURPLUS DIFFERENCE -> TIME     cycles required >= 1 / (8 pi dF),   1/(8 pi) = 0.039789
```

Resolving a difference `dF` in surplus costs at least `1/(8 pi dF)` cycles of the rendered tone, and the constant is exact. Two properties make it a key rather than a rule of thumb. It is **independent of the transposition**, because it constrains a ratio and octave transposition multiplies numerator and denominator alike — the same cycle count serves at 30 Hz and at 19 kHz. And it is **denominated in cycles, not seconds**; converting to wall-clock requires the frequency, which is exactly the dependence that should stay visible.

dF (nats)	cycles required	at N_eff = 12 (69.613 Hz)	at N_eff = 24 (278.453 Hz)
0.10	0.398	5.72 ms	1.43 ms
0.05	0.796	11.43 ms	2.86 ms
0.01	3.979	57.16 ms	14.29 ms
0.005	7.958	114.31 ms	28.58 ms
0.001	39.789	571.57 ms	142.89 ms

Two boundary conditions belong with the table. **The frequency column has a short working range.** Under a single integer octave transposition into 20 Hz to 20 kHz the ladder fits only at `j = 6`, and only up to `N_eff = 25`: `k (25)^2 2^6 = 19337.0` Hz, while `N_eff = 26` lands at 20914.9 Hz and leaves the band. **Above an effective count of 25 the pitch register cannot be rendered in one piece and requires split transposition**, which is a declared design choice and not a formatting detail. And **a rectangular gate is disqualified as an envelope**: its `sinc^2` tails fall as `1/f^2`, so the spectral second-moment integral diverges, the tone has no defined bandwidth, and the key above does not apply to it [Gabor, 1946]. Window the envelope; Section 9.6 gives the default.

18.4.6 4.6 The consistency check at the orthogonal limit

The identification of the effective count with a cross-disciplinary essence index has an arithmetical consequence which can be checked and which, had it failed, would break the bridge:

```
within a discipline:      f = k n^2          n an integer index
across disciplines:       f = k e^(2F)       F = ln N_eff

at u = 1 (fully orthogonal), N_eff = N, so F = ln N, so
k e^(2 ln N) = k N^2                         the two must coincide
```

Verified to machine precision:

n	k e^(2 ln n)	k n^2	difference
1	0.48342573298841	0.48342573298841	0
2	1.93370293195366	1.93370293195366	0
3	4.35083159689573	4.35083159689573	8.9e-16
7	23.68786091643230	23.68786091643230	3.6e-15
12	69.61330555033166	69.61330555033166	0
24	278.45322220132670	278.45322220132664	5.7e-14

Residuals are floating-point rounding at the sixteenth significant figure, not model error. **The two frameworks agree exactly at the orthogonal limit, which means the essence index of a fully non-parallel N-category system is N itself.**

Within a discipline the index is an integer and the lattice is discrete. Across disciplines the index is the effective count, which is continuous, and the pitch is continuous with it. They meet only at `u = 1`. Worked, for a twelve-category system at various levels of non-parallelism:

u	N_eff	F (nats)	octaves	f (Hz)
0.00	1.000	0.00000	0.0000	0.4834
0.25	3.750	1.32176	3.8138	6.7982

u	N_eff	F (nats)	octaves	f (Hz)
0.50	6.500	1.87180	5.4009	20.4247
0.75	9.250	2.22462	6.4189	41.3631
1.00	12.000	2.48491	7.1699	69.6133

Read the first row. **Twelve parallel categories are the ground essence: 0.483426 Hz, zero octaves, zero surplus.** Pseudo-diversity has a pitch, and its pitch is the bottom of the instrument.

Which effective count is being used here matters, and the answer is the weak one. `N_eff = 1 + (N−1)u` is an **affine interpolation between 1 and `N`** and is this framework's own construction, adopted by design axiom S3 [Curzi, 2026]. **It is not a Hill number of any order.** `1/HHI` is the Hill number of order two and `exp(H)` the Hill number of order one; both are fully grounded [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979], and neither is what appears in `f_cross = k N_eff^2`. A reviewer who reaches for the Hill-number literature as support will find it does not apply. The contrast is available inside the corpus: the concentration instrument that *is* a Hill number of order two returns 2.087683 effective perimeters against 2.941176 on a second axis and a break-even of 4.172734 in a worked structural case [Curzi, 2026], and those numbers are not commensurable with the affine effective counts used here.

18.4.7 4.7 What the keys do not license

A conversion table is an invitation to one class of error, and the class deserves a name. **The keys convert measures. They do not transport warrant.**

- A **lower bound** converted is a lower bound, not an estimate. "3.96 octaves" means "at least 3.96 octaves" and is written that way.
- A **postulate** converted is a postulate. The moment equation in cents is still a postulate.
- A **procedure-bound measurement** converted is procedure-bound. A loudness exponent of 0.67 written as 804 cents per physical octave is still 0.67 by that method, range and instruction.
- A surplus converted into a **frequency** is an essence frequency. **Nothing is vibrating.** This is the error the material most invites and the one the standing clauses most firmly forbid (HC-1).
- Conversion **adds no precision**. A surplus known to two decimals is not known to four because cents has finer graduation (FM-17).

18.5 5 The sensation register

18.5.1 5.1 Weber, Fechner, and the warrant the argument actually needs

The third register settles the question a sceptical reader brings to any framework that measures a subjective quantity: **can a subjective quantity be measured at all?**

Weber [1834] established that the just-noticeable difference in a stimulus is a constant *ratio* of the stimulus rather than a constant amount, `dI/I = c`, with `c` the Weber fraction for that modality and range [Weber, 1978]. Fechner [1860] integrated it: if each just-noticeable difference is one subjective unit and each costs a fixed proportional increase, then counting units from a reference gives `S = k_F ln(I/I_0)` [Fechner, 1966]. The number of just-noticeable differences between a reference and a stimulus is `n_JND = ln(I/I_0) / ln(1 + c)`, **so a JND is itself a logarithmic unit and joins the key table.**

The following is **parametric, not measured**. It asserts no value of `c` for any modality, because Weber fractions are modality-, range- and method-dependent and this paper reports no figure it has not computed or cited.

c	nats/JND	bits/JND	octaves/JND	cents/JND	JNDs across x10
0.01	0.009950	0.014355	0.028711	34.453	231.4
0.02	0.019803	0.028569	0.057138	68.566	116.3
0.05	0.048790	0.070389	0.140779	168.934	47.2
0.10	0.095310	0.137504	0.275007	330.008	24.2
0.15	0.139762	0.201634	0.403268	483.921	16.5
0.20	0.182322	0.263034	0.526069	631.283	12.6
0.30	0.262364	0.378512	0.757023	908.428	8.8

A modality with a Weber fraction of 0.10 has a JND worth 0.0953 nats. Ten JNDs is 0.953 nats, less than the surplus ceiling of a three-category system. That is the kind of statement the conversion keys make available and that is impossible without them.

Honest limits, stated with the law: Fechner's relation fails near absolute threshold and near the upper end of a modality's range, where the Weber fraction is not constant. **The logarithmic form is an excellent middle-range description, not a universal law of sensation**, and Stevens' power law is the competitor and in many modalities the better fit [Stevens, 1957, Krueger, 1989].

There are two independent warrants for this framework's logarithm, and the argument needs only the weaker of the two assumptions. The first is Fechnerian: sensation proportional to the logarithm of a dimensionless stimulus ratio measured from a floor. **That warrant requires the perceptual story to be true, and the perceptual story is contested.** The second is stronger precisely because it assumes nothing psychological: Peters and Gell-Mann [2016] shows that the time-average growth rate of a multiplicatively evolving quantity is the expectation of its *logarithm*, so a logarithmic evaluation follows from the dynamics alone. **Where a stock compounds rather than adds, the logarithm is the ergodic-average object, and no claim about perception is needed.** The framework's surplus is such a stock. **Cite both; the argument needs Peters, not Fechner.** Fechner is cited here because the *sensation register* is genuinely Fechnerian and is one of the four things being converted — not because the framework's own logarithm depends on him.

And the underdetermination has to be conceded. The surplus functional's form is not fixed by the evidence: Latané [1981] proposes a sub-linear power law and Briscoe et al. [2006] an `n log n` growth, and **both fit the qualitative facts as well as `ln(1 + (N−1)u)`.** What discriminates them is an axiomatic characterisation rather than a measurement [Curzi, 2026], and an axiom set that includes a chosen axiom does not discriminate anything empirically. **Nothing assembled here selects the logarithm over the alternatives, and the paper says so rather than leaving it to a reviewer.**

18.5.2 5.2 Stevens' exponents are measured conversion keys

Stevens [1957] proposed the power law `psi = k_S I^a` and, more importantly, the method [Stevens, 1975]. Taking logarithms, `log psi = log k_S + a log I`.

In log-log coordinates the power law is a straight line and its slope is `a`. The exponent is therefore a conversion key in exactly this paper's sense: the number of perceptual log-units bought by one physical log-unit. It is not a fitted nuisance parameter. It is the constant of the change of units between the physical register and the perceptual one, and **it is obtained by measurement rather than by definition, which is what distinguishes it from every other constant in Section 4.1.**

There is a way of saying this that makes it immediately usable:

```
perceptual octaves per physical octave = a       exactly
```

An octave is a doubling in either register, and doubling `I` multiplies `psi` by `2^a`, which is `a` octaves. **The exponent *is* the octave key.** Published, replicated exponents, nominal and method-dependent:

Modality	a	world x2 gives psi x	world x10 gives psi x	psi x2 needs world x	cents per physical octave
Loudness (1 kHz)	0.67	1.5911	4.6774	2.8138	804.0
Brightness	0.33	1.2570	2.1380	8.1698	396.0
Visual length	1.00	2.0000	10.0000	2.0000	1200.0
Taste (salt)	1.30	2.4623	19.9526	1.7044	1560.0
Heaviness (lifted)	1.45	2.7321	28.1838	1.6129	1740.0
Warmth on arm	1.60	3.0314	39.8107	1.5422	1920.0
Electric shock	3.50	11.3137	3162.2777	1.2190	4200.0

`a < 1` is compressive, `a = 1` linear, `a > 1` expansive. **Most senses compress. Pain expands.** To double perceived loudness the physical intensity must roughly triple (2.81x), but to double perceived shock a 22 per cent increase suffices. **Comfort is expensive to increase and cheap to lose, and the exponents say so in numbers.**

The most consequential row is brightness: doubling perceived brightness requires **8.17 times** the physical light. **A lighting specification written in lumens and read by an occupant in perceived brightness is a specification in two registers, mismatched by a factor of eight.**

Cross-modality matching. Because each exponent is a key to the same physical register, the key between two modalities is the ratio of their exponents: if a subject adjusts modality *i* to match modality *j*, the predicted log-log slope is `a_j / a_i`. This is the strongest test of the power law, because the matching exponent is predicted in advance from two independently measured exponents and then checked.

matched	Loudness	Brightness	Length	Salt	Heaviness	Warmth	Shock
Loudness	1.0000	2.0303	0.6700	0.5154	0.4621	0.4188	0.1914
Brightness	0.4925	1.0000	0.3300	0.2538	0.2276	0.2062	0.0943
Length	1.4925	3.0303	1.0000	0.7692	0.6897	0.6250	0.2857
Salt	1.9403	3.9394	1.3000	1.0000	0.8966	0.8125	0.3714
Heaviness	2.1642	4.3939	1.4500	1.1154	1.0000	0.9062	0.4143
Warmth	2.3881	4.8485	1.6000	1.2308	1.1034	1.0000	0.4571
Shock	5.2239	10.6061	3.5000	2.6923	2.4138	2.1875	1.0000

The table is computed from the nominal exponents above; **it is a set of predictions, not observations**, and its honest use is as a preregistration target [Nosek et al., 2018]. **A framework that predicts a matching slope of 2.0303 for loudness-to-brightness and then measures 2.03 has earned something. A framework that fits the slope after the fact has earned nothing** [Meehl, 1967, Platt, 1964].

Honest limits, restated: Stevens' exponents vary with method — estimation and production give systematically different slopes, the regression effect [Poulton, 1968, 1979] — with stimulus range [Teghtsoonian, 1971], and with instruction. Whether magnitude estimation delivers a ratio scale at all is itself contested [Luce, 2002, Narens, 1996]. **Report them as measured constants of a procedure, not constants of nature.**

18.6 6 The moment register and the forced ceiling

18.6.1 6.1 The moment equation in log form

The moment equation is this framework's own postulate:

```
M = ( D / P ) . E        D perspective, P perception, E environment, M moment
```

Taking logarithms puts it in the same register as everything else here:

```
ln M = ln D − ln P + ln E
```

In the log register the moment equation is additive, and that is its most useful form. A multiplicative model with a division becomes a sum of three terms, each reportable, budgetable and convertible independently.

The calibration ratio and its distortion. With `r = D/P`, distortion is `Delta = |ln r|`, a log-ratio and therefore expressible in any register in the key table:

`r = D/P`	state	`Delta` (nats)	bits	octaves	cents
0.25	severely under-framed	1.386294	2.00000	4.00000	4800.00
0.50	under-framed	0.693147	1.00000	2.00000	2400.00
0.80	mildly under-framed	0.223144	0.32193	0.64386	772.63
1.00	**calibrated**	**0.000000**	0.00000	0.00000	0.00
1.25	mildly over-framed	0.223144	0.32193	0.64386	772.63
1.80	over-framed	0.587787	0.84800	1.69599	2035.19
2.00	over-framed	0.693147	1.00000	2.00000	2400.00
4.00	severely over-framed	1.386294	2.00000	4.00000	4800.00

Note the symmetry, which is the reason for the logarithm: `r = 0.5` and `r = 2.0` are equally distorted, 2400 cents in either direction. **A raw ratio makes over-framing look worse than under-framing because it is unbounded above and bounded below by zero; the log-ratio makes them commensurate, and they should be commensurate, because both are the same failure of match.**

The moment as storage input. The join is that `M`, normalised onto `[0, ln N]`, serves as `S_t` in the storage law. **The normalisation is a chosen mapping, badged here as a design decision** and not derived from anything.

The scale-type gate on this equation fails and the failure is printed. Division requires a ratio scale with a true zero for `D` and `P`, and neither is instrumented on one. With only ordinal data the formula is a heuristic ordering rather than an equation and must be demoted in print [Michell, 1997, Stevens, 1946]. The identifiability gate fails as well: `(D, P, E)` and `(cD, cP, E)` predict identical `M` for any `c > 0`, so **the formula is identified only up to a common scaling of `D` and `P`** and is testable in `r` and `M` rather than in `D` and `P` separately. The full seven-gate audit is Appendix A.3.

18.6.2 6.2 The maximum possible moment is `ln N`

This result is **derived, not chosen**, and the derivation is short.

Begin with the internal surplus: the surplus functional applied within a single observer. A perceiver holds `N` distinguishable categories; the framings brought to bear on a moment are states in that category space with mutual non-parallelism `u`, so `N_eff = 1 + (N−1)u` and `F_int = ln N_eff`. The range result gives `0 <= F <= ln N`, with `F = ln N` attained if and only if the framings are mutually orthogonal [Curzi, 2026]. Applying the chosen normalisation of Section 6.1 — the moment, expressed in the surplus register, is `F_int` — gives

```
0 <= (moment, in the surplus register) <= ln N

MAXIMUM POSSIBLE MOMENT = ln N
```

The richest moment available to a perceiver is bounded by the logarithm of the number of kinds of thing that perceiver can distinguish. No arrangement of attention, no intensity of experience, no quality of environment raises it. **It is a ceiling on the perceiver, not on the world.**

This is the law of requisite variety appearing in first-person experience [Ashby, 1956, 1958]: only variety absorbs variety, and a regulator's capacity is bounded by its own variety. Here the regulator is a perceiving mind, the disturbance is the world, and the bound is `ln N`. **It was not chosen. It follows from the range theorem plus the normalisation, and the normalisation is the only chosen step.** That is the honest form of the derivation and the reason both links must be published every time the result is quoted.

Three consequences.

First, the ceiling is logarithmic, so it is nearly immovable by effort. Doubling `N` adds `ln 2 = 0.693147` nats, or exactly one bit, or exactly two essence octaves, **no matter where you start.**

`N`	`ln N` (nats)	bits	octaves	cents
2	0.693147	1.00000	2.00000	2400.00
4	1.386294	2.00000	4.00000	4800.00
8	2.079442	3.00000	6.00000	7200.00
16	2.772589	4.00000	8.00000	9600.00
32	3.465736	5.00000	10.00000	12000.00
64	4.158883	6.00000	12.00000	14400.00
128	4.852030	7.00000	14.00000	16800.00
256	5.545177	8.00000	16.00000	19200.00
1000	6.907755	9.96578	19.93157	23917.88

Going from 2 distinguishable categories to 1000 — a five-hundred-fold increase in vocabulary — buys 6.21 nats, less than nine bits. A capacity problem cannot be escaped by adding categories.

Second, `N` is trainable — slowly, logarithmically, and only by acquiring genuinely distinct categories rather than relabelled ones.

Third, the ceiling is rarely the binding constraint, because `u` is usually low: the framings brought to bear are near-parallel. **The gain from raising `u` is almost always far larger than the gain from raising `N`**, which is the same conclusion the framework reaches in the group case, where the marginal price of non-parallelism is identical whether it arises by crossing or by divergence, `df/du = (N−1)/(1 + (N−1)u)`, while the two differ sharply in what they cost to produce [Curzi, 2026d].

A scale-type condition attaches to this bound and it is conditional, not passed. `N` is a count and is ratio-scaled with a true zero **provided "distinguishable category" has an operational definition**. Without one, `N` is not measured and the bound is not usable; the gate transfers to the construction of the category set, which is Section 8. The full audit is Appendix A.4.

18.7 7 The harmonic lattice

Section 4 established that a surplus can be written as a pitch by an exact constant. It also established the condition under which that is worth doing and then deferred it. The condition is this: **the essence law consumes an ordinal index, and an arbitrary ordinal produces an arbitrary frequency.** The law will happily convert nonsense. The whole burden of applying it therefore falls on the construction of the index.

This section works out the **structure** of the lattice the square law generates — what intervals exist, how they fold, how many distinct pitch classes an `N`-essence set can have, and which pairs are consonant. All of it is exact arithmetic and all of it is computed. Section 8 states the **requirements** an ordering must meet before a frequency may be attached to it.

One structural result is a genuine constraint rather than a convenience: **an essence set of `N` members contains exactly `ceil(N/2)` distinct pitch classes, whatever the essences are.** Half the vocabulary is octave duplication before the work begins.

18.7.1 7.1 Result CC-R1: every interval is a ratio of squares, and `k` cancels

```
f(m) / f(n) = (k m^2) / (k n^2) = m^2 / n^2
```

The golden ratio and the `9/8` set the absolute reference pitch and nothing else. Every relationship in the system is a ratio of squared integers. This is the most important structural fact about the lattice, because it means the chosen constant `k` — the one part of the law with no justification beyond preference — has **no influence whatever on any interval, consonance, pitch class or harmonic relation.** It sets where the instrument sits and not how it is tuned. Recomputed independently:

```
index ratio   essence ratio   cents      description
2 : 1          4 / 1          2400.00    two octaves exactly
3 : 2          9 / 4          1403.91    octave + 203.91 cents (a whole tone)
4 : 3         16 / 9           996.09    a minor seventh
5 : 4         25 / 16          772.63    near a minor sixth
3 : 1          9 / 1          3803.91    three octaves + 203.91 cents
```

The 203.91 cents appearing twice is not a coincidence: it is `1200 log2(9/8)`, the Pythagorean whole tone [Barbour, 1951], and it is the pitch class of index 3.

This result is labelled CC-R1 to keep the source material's own result numbering distinct from this paper's contributed results R1 to R6.

18.7.2 7.2 Result CC-R2: pitch class is the odd part of the index

Because `(2n)^2 = 4n^2` is exactly two octaves above `n^2`, multiplying an index by two transposes by a whole number of octaves and changes nothing else. Write any index as `n = 2^a m` with `m` odd. Then

```
f(n) = k (2^a m)^2 = 4^a (k m^2) = k m^2 transposed up by 2a octaves
```

Two essences share a pitch class if and only if their indices have the same odd part. The pitch class is fully determined by `m` and its position within the octave is `m^2` reduced by powers of two. The operation is octave transposition, whose perceptual standing as an equivalence is grounded for pitch and only for pitch [Shepard, 1982, Demany et al., 2013], with the caveat recorded in Section 3.3.

Theorem 7.1 (the class-count theorem). *An essence set indexed `1..N` contains exactly `ceil(N/2)` distinct pitch classes.*

Proof. The pitch class of index `n` is its odd part. For any odd `m` with `1 <= m <= N`, the index `m` itself lies in `1..N` and has odd part `m`, so every odd number up to `N` is realised. Conversely the odd part of any `n <= N` is itself at most `n`, hence at most `N`, and is odd. So the set of realised classes is exactly the set of odd integers in `[1, N]`, which has `ceil(N/2)` elements.

Verified by direct enumeration for `N = 1..24` — counted distinct odd parts against `ceil(N/2)`:

```
N   :  1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24
cnt :  1  1  2  2  3  3  4  4  5  5  6  6  7  7  8  8  9  9 10 10 11 11 12 12
ceil:  1  1  2  2  3  3  4  4  5  5  6  6  7  7  8  8  9  9 10 10 11 11 12 12
       all 24 agree
```

Twelve essences yield only six pitch classes. That is the available harmonic vocabulary and it is a hard structural limit. The same rule is stated as a theorem in its own right in Curzi [2026], where the odd-part class rule gives six classes at `N = 12`, and it is exercised at a different scale in Curzi [2026k], where twenty elements give ten classes.

18.7.3 7.3 The lattice, computed for `N = 24`

Columns: raw essence frequency `k n^2`; the factorisation `n = 2^a m`; the pitch class `m`; the position of `n` above the ground essence in cents, `2400 log2 n`; and the pitch class's position within the octave, that value modulo 1200.

n	f = k n^2 Hz	n = 2^a*m	class m	cents above ground	class cents
1	0.483426	2^0*1	1	0.0000	0.0000
2	1.933703	2^1*1	1	2400.0000	0.0000
3	4.350832	2^0*3	3	3803.9100	203.9100
4	7.734812	2^2*1	1	4800.0000	0.0000
5	12.085643	2^0*5	5	5572.6274	772.6274
6	17.403326	2^1*3	3	6203.9100	203.9100

22	233.978055	2^1*11	11	10702.6359	1102.6359
23	255.732213	2^0*23	23	10856.5487	56.5487
24	278.453222	2^3*3	3	11003.9100	203.9100

Every frequency in that table is an essence frequency and not a physical resonance (HC-1).

18.7.4 7.4 The classes, their octave positions, and the collision cliff

Folding by odd part gives the complete harmonic vocabulary of a 24-essence set: twelve classes, as Theorem 7.1 requires.

class m	member indices <= 24	m^2 reduced to [1,2)	cents	Hz in [k, 2k)
1	1, 2, 4, 8, 16	1/1	0.000	0.483426
23	23	529/512	56.549	0.499477
3	3, 6, 12, 24	9/8	203.910	0.543854
17	17	289/256	209.911	0.545742
9	9, 18	81/64	407.820	0.611836
13	13	169/128	481.055	0.638273
19	19	361/256	595.026	0.681706
7	7, 14	49/32	737.652	0.740246
5	5, 10, 20	25/16	772.627	0.755353
21	21	441/256	941.562	0.832776
15	15	225/128	976.537	0.849772
11	11, 22	121/64	1102.636	0.913977

The pitch classes do not appear in index order. Class 23 sits 56.5 cents above the ground, below class 3 at 203.9 cents, though its index is nearly eight times larger. Squaring and folding scrambles the ordinal completely. **The lattice preserves the index in absolute pitch and destroys it in pitch class.** An analyst who reads pitch-class order as importance order has misread the arithmetic.

The vocabulary is unevenly distributed. The gaps between consecutive classes, in cents:

```
   0.000 ->   56.549    gap   56.549     (class 1 to class 23)
  56.549 ->  203.910    gap  147.361
 203.910 ->  209.911    gap    6.001     (class 3 to class 17)
 209.911 ->  407.820    gap  197.909
 407.820 ->  481.055    gap   73.235
 481.055 ->  595.026    gap  113.971
 595.026 ->  737.652    gap  142.626
 737.652 ->  772.627    gap   34.976     (class 7 to class 5)
 772.627 ->  941.562    gap  168.934
 941.562 ->  976.537    gap   34.976     (class 21 to class 15)
 976.537 -> 1102.636    gap  126.098
1102.636 -> 1200.000    gap   97.364     (wrapping to class 1)
```

Four pairs sit inside 60 cents of each other, close enough that as simultaneous tones they beat rather than form an interval — the roughness regime, in which two partials within a critical band fuse into a rough single percept rather than separating into two pitches [Plomp and Levelt, 1965, von Helmholtz, 1885, Terhardt, 1974]:

```
classes  3 and 17 :   6.00 cents apart   (  9/8   vs 289/256 )
classes  7 and  5 :  34.98 cents apart   ( 49/32  vs  25/16  )
classes 21 and 15 :  34.98 cents apart   (441/256 vs 225/128 )
classes  1 and 23 :  56.55 cents apart   (  1/1   vs 529/512 )
```

The 6.00-cent gap is the one to watch. **Essence index 3 and essence index 17 are for practical purposes the same pitch class, and nothing in the ordering of any domain caused that — it is an artefact of `9/8` and `289/256` being nearly equal.** If a domain's third and seventeenth categories are conceptually remote, the lattice will nevertheless render them as a near-unison. The 34.98-cent coincidence between classes 5 and 7, and identically between 15 and 21 since `21/15 = 7/5`, is the same phenomenon at a coarser scale.

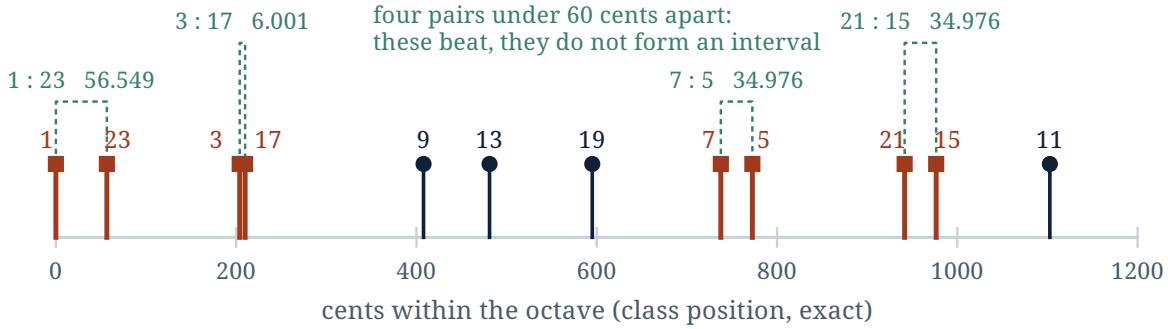

Figure 18.2: **Twelve pitch classes for twenty-four essences, and four of the twelve pairs sit inside 60 cents.** Class positions are exact rational values reduced into one octave; `k` cancels, so the chosen reference constant plays no part. The four disclosed collisions are classes 3 and 17 at 6.001 cents, 7 and 5 at 34.976, 21 and 15 at 34.976, and 1 and 23 at 56.549. **These are facts about integers and not about any domain.** Generated by `figs/src/CCP-018_fig02.py` from the class table of Section 7.4.

The design consequence is direct: essence sets past a certain size produce near-unison collisions the ordering did not intend and cannot control. That is an argument for small essence sets with nothing to do with taste.

And the size is exact, which is better than "about twelve". Computing the folded lattice's minimum gap in exact rational arithmetic for every set size gives a step function with four values and three cliffs:

```
N =  3 .. 6     minimum gap    9/8     = 203.910 cents     no collision
N =  7 .. 16    minimum gap   50/49    =  34.976 cents     classes 7 and 5
N = 17 .. 40    minimum gap  289/288   =   6.001 cents     classes 17 and 3
N = 41 and up   minimum gap 1682/1681  =   1.030 cents     classes 41 and 29
```

The third step is recorded for completeness only: `N = 41` lies far beyond the 25-essence ceiling that Section 8.3 derives for a shared transposition, so no renderable set reaches it.

The first coincidence arrives at `N = 7`, when class 7 lands 34.976 cents from class 5. The lattice holds that gap unchanged for ten consecutive set sizes and then collapses the moment index 17 enters, because `17^2 = 289` sits one part in 288 above `9/8 = 288/256`. Nothing in any domain causes either event; both are arithmetic.

The cliff is a change of regime rather than merely a narrower gap, and the time-bandwidth key of Section 4.5 prices it: telling two tones apart requires `1/(8 pi dF)` cycles, so a 34.976-cent separation needs **3.94 cycles** and a 6.001-cent separation needs **22.96 cycles**. **A set of sixteen and a set of seventeen require rendering durations differing by a factor of 5.828, and the boundary between them is exact.** Design at 16 or below where possible; if not, budget the tone duration before budgeting anything else.

Two corrections to earlier statements of this boundary are recorded here rather than applied silently. The corpus has stated the boundary at `N = 19` to `N = 20`; the exact lattice returns `N = 16` to `N = 17`, which is what the table of Section 7.3 shows — index 17 is present in a 24-set and its 6.001-cent gap with class 3 is listed above. And the source material states the rate collapse as "a factor of exactly 8" in one sentence and as 5.828 in the parenthesis of the sentence before it. **Recomputation gives 5.8284 by both routes** — the cents ratio `34.976/6.001` and the cycle-count ratio `22.957/3.939` are the same number, `ln(50/49)/ln(289/288)` — **and no calculation returning 8 could be reconstructed. The factor is 5.828.**

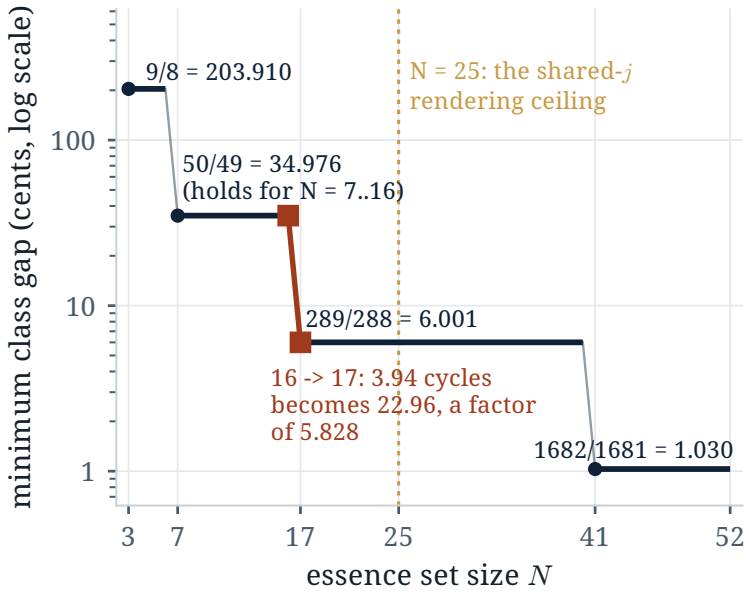

Figure 18.3: **The minimum class gap is a step function of set size with three exact cliffs, and the worst of them lands one index above a twelve-category set.** The gap holds at `9/8` = 203.910 cents for `N = 3` to 6, at `50/49` = 34.976 for `N = 7` to 16, at `289/288` = 6.001 for `N = 17` to 40, and at `1682/1681` = 1.030 from `N = 41`. Crossing from 16 to 17 raises the tone duration needed to separate the closest pair from 3.94 cycles to 22.96, a factor of 5.828. The shared-transposition ceiling at `N = 25` is marked; no renderable set reaches the third cliff. Exact rational arithmetic, generated by `figs/src/CCP-018_fig03.py` from Sections 7.4 and 8.3.

18.7.5 7.5 The interval lattice in cents

The interval between essence `i` and essence `j` is `2400 log2(j/i)` cents. The full matrix for indices 1 to 12, upper triangle; the lower triangle is the negative.

	j=2	3	4	5	6	7	8	9	10	11	12
i=1	2400	3804	4800	5573	6204	6738	7200	7608	7973	8303	8604
i=2	–	1404	2400	3173	3804	4338	4800	5208	5573	5903	6204
i=3	–	–	996	1769	2400	2934	3396	3804	4169	4499	4800
i=4	–	–	–	773	1404	1938	2400	2808	3173	3503	3804
i=5	–	–	–	–	631	1165	1627	2035	2400	2730	3031
i=6	–	–	–	–	–	534	996	1404	1769	2099	2400
i=7	–	–	–	–	–	–	462	870	1235	1565	1866
i=8	–	–	–	–	–	–	–	408	773	1103	1404
i=9	–	–	–	–	–	–	–	–	365	695	996
i=10	–	–	–	–	–	–	–	–	–	330	631
i=11	–	–	–	–	–	–	–	–	–	–	301

Read the diagonal band — the intervals between adjacent indices — and a pattern appears worth stating as a result in its own right.

adjacent pair	raw interval (cents)
1 – 2	2400.00
2 – 3	1403.91
3 – 4	996.09
4 – 5	772.63

```
 5 – 6              631.28
 6 – 7              533.74
 7 – 8              462.35
 8 – 9              407.82
 9 – 10             364.81
10 – 11             330.01
11 – 12             301.27
12 – 13             277.15
15 – 16             223.46
19 – 20             177.60
23 – 24             147.36
```

Neighbouring essences crowd together as the index rises. The gap between the first two essences is two octaves; the gap between the twenty-third and twenty-fourth is 147 cents, less than a whole tone and a quarter. This is the logarithm again: `2400 log2((n+1)/n)` falls like `2400/(n ln 2)`. In a set of 24 the top is harmonically congested and the bottom is spread across octaves.

Consequence for set design: the resolution of the lattice is not uniform, and low indices carry far more pitch distance than high indices. If a domain's most important distinctions land at high index, the lattice renders them as small intervals. That is a reason to think about which end of the ordering the important categories occupy — and, critically, **it is not a licence to reorder the set to improve the result**, which the admissibility requirement ES-R2 of Section 8.1 forbids.

18.7.6 7.6 Consonance as a function of the index ratio

Which pairs of essences sound related, and which sound remote? The question has a precise answer in this lattice and the answer depends **only on the reduced ratio of the indices**. Let `i/j` reduce to `p/q` with `gcd(p,q) = 1`. The essence interval is then `p^2/q^2`, and since `gcd(p^2, q^2) = 1` that fraction is already in lowest terms. Everything about the pair's harmonic relationship is a function of `p` and `q` alone.

Two computable indices are used. **Both are CHOSEN measures with a defined arithmetic, not measured facts about human hearing.**

```
TENNEY HARMONIC DISTANCE       HD(p/q) = log2(p q)
    A defined measure of the complexity of a frequency ratio. Larger = more remote.

EULER'S GRADUS SUAVITATIS      G(n) = 1 + sum over prime factors of e_i (prime_i – 1)
    G(p/q) = G(p q). Larger = less smooth.
```

The harmonic distance is Tenney's city-block metric on the harmonic-space lattice, `HD(f_a, f_b)` proportional to `log a + log b = log(ab)` [Tenney, 2015]; the gradus suavitatis is Euler's degree of agreeableness over the prime factorisation [Euler, 1739]. **Neither is a measurement.** What is actually measured about consonance is a different object and points a different way: roughness is set by critical bandwidth rather than by integer ratio [Plomp and Levelt, 1965], sensory and harmonic consonance are distinct [Terhardt, 1974], dyad consonance has been quantified directly [Kameoka and Kuriyagawa, 1969], and consonance depends on the **spectrum** of the sound and not on the ratio alone, so that no ratio is a universal constant [Sethares, 2005]. **The two literatures disagree, and this paper publishes both indices and adjudicates neither.**

> **Theorem 7.2 (the doubling theorem).** *For any index pair reducing to `p/q`, the essence interval `p^2/q^2` has exactly twice the Tenney harmonic distance of the ratio `p/q`, and Euler gradus `2G – 1`.*

Proof. `HD(p^2/q^2) = log2(p^2 q^2) = 2 log2(pq) = 2 HD(p/q)`. For the gradus, squaring doubles every exponent in the prime factorisation of `pq`, so the sum `sum e_i (prime_i − 1)` doubles, and `G(p^2 q^2) = 1 + 2 sum e_i (prime_i − 1) = 2(1 + sum e_i (prime_i − 1)) − 1 = 2 G(pq) − 1`.

Verified exhaustively over all 66 pairs `1 <= j < i <= 12`, both identities exact in every case. A sample:

i	j	p/q	HD(p/q)	HD(p^2/q^2)	2∗HD	G(p/q)	G(ess)	2G−1	cents
2	1	2/1	1.0000	2.0000	2.0000	2	3	3	2400.00
3	2	3/2	2.5850	5.1699	5.1699	4	7	7	1403.91
4	3	4/3	3.5850	7.1699	7.1699	5	9	9	996.09
5	4	5/4	4.3219	8.6439	8.6439	7	13	13	772.63
6	5	6/5	4.9069	9.8138	9.8138	8	15	15	631.28
7	6	7/6	5.3923	10.7846	10.7846	10	19	19	533.74
8	7	8/7	5.8074	11.6147	11.6147	10	19	19	462.35
8	3	8/3	4.5850	9.1699	9.1699	6	11	11	3396.09
7	5	7/5	5.1293	10.2586	10.2586	11	21	21	1165.02

The square law systematically doubles harmonic distance. Every essence pair is exactly twice as harmonically remote as the corresponding integer-ratio pair would be in ordinary just intonation [Partch, 1974, Doty, 2002]. The `3:2` — the perfect fifth, the most consonant interval after the octave — becomes `9:4`, an octave plus a whole tone, at double the harmonic distance; the major third `5:4` becomes `25:16`. **Consonance is scarce in the essence lattice, and it is scarce by a factor of exactly two.**

18.7.7 7.7 Consonance is redundancy

Ranking all distinct index ratios among indices 1 to 12 by essence harmonic distance:

HD_ess	Gradus	index ratio	essence ratio	reduced	cents
0.0000	1	1:1	1/1	1	0.00
2.0000	3	2:1	4/1	1	0.00
3.1699	5	3:1	9/1	9/8	203.91
4.0000	5	4:1	16/1	1	0.00
4.6439	9	5:1	25/1	25/16	772.63
5.1699	7	3:2	9/4	9/8	203.91
5.6147	13	7:1	49/1	49/32	737.65
6.0000	7	8:1	64/1	1	0.00
6.3399	9	9:1	81/1	81/64	407.82
6.6439	11	5:2	25/4	25/16	772.63
6.9189	21	11:1	121/1	121/64	1102.64
7.1699	9	4:3	16/9	16/9	996.09
7.6147	15	7:2	49/4	49/32	737.65
7.8138	13	5:3	25/9	25/18	568.72
8.6439	13	5:4	25/16	25/16	772.63
8.7846	17	7:3	49/9	49/36	533.74
9.6147	17	7:4	49/16	49/32	737.65
9.8138	15	6:5	36/25	36/25	631.28
10.2586	21	7:5	49/25	49/25	1165.02
10.6439	15	8:5	64/25	32/25	427.37
11.6147	19	8:7	64/49	64/49	462.35
12.2586	23	10:7	100/49	50/49	34.98
12.9837	19	10:9	100/81	100/81	364.81
14.0888	29	12:11	144/121	144/121	301.27

The two indices sometimes disagree in their fine ordering — `5:1` has lower Tenney distance than `3:2` but a higher Euler gradus, 9 against 7, because Euler penalises the prime 5 more heavily than Tenney does. **Where two defensible indices disagree, publish both and do not adjudicate.** Neither is a measurement.

The most consonant nontrivial essence pairs are exactly the octave-equivalent ones. Every pair whose index ratio reduces to `2:1` has `HD_ess = 2.0000`, gradus 3, and an interval of exactly two octaves — pitch class identical. Nothing else comes close: the next entry, `3:1`, is at 3.1699. The same identity is proved in its sharpest form in Curzi [2026], where the minimum `HD_ess = 2.0000` over a twelve-set is attained by exactly the six collision pairs `{1:2, 2:4, 3:6, 4:8, 5:10, 6:12}` and by nothing else.

Which produces the central design tension, and it is exact:

CONSONANCE IS REDUNDANCY. The pairs that sound most related are precisely the pairs that occupy the same pitch class — the pairs the lattice cannot distinguish. **In the essence lattice, harmonic agreement and informational redundancy are the same phenomenon.** This is not a metaphor: the arithmetic is the same arithmetic that makes a set of near-parallel categories worth `ln 1` rather than `ln N`.

Searching all 924 six-element subsets of indices 1 to 12 exhaustively, by mean pairwise essence harmonic distance:

```
minimum mean HD_ess overall          4.0353    {1, 2, 3, 4, 6, 12}    2 distinct classes
maximum mean HD_ess overall         11.4064    {7, 8, 9, 10, 11, 12}  6 distinct classes
minimum mean HD_ess with 6 classes   8.4731    {1, 3, 5, 7, 9, 11}
```

Read the first line. **The most consonant six-element essence set available collapses to two pitch classes.** Six essences, two distinguishable tones: the non-parallelism has gone to zero in the sonic register and the set is worth `ln 2` where it should be worth up to `ln 6`.

Read the third. **Subject to keeping all six pitch classes distinct, the most consonant six-element set is the odd indices `{1, 3, 5, 7, 9, 11}`** — exactly the canonical class-representative set of Theorem 7.1. That convergence is also a usable design rule: **when a subset of a large essence set must be chosen for sonification, choose the odd indices.** They are the class representatives, they are guaranteed distinct, and among all fully-distinct choices they are the least dissonant.

18.8 8 Requirements on an essence set

18.8.1 8.1 The three admissibility requirements

Before any of the above may be applied to a real domain, the domain's categories must be turned into an index. Made operational, this is three requirements. *They are labelled ES-R1 to ES-R3 to keep them distinct from this paper's contributed results R1 to R6.*

ES-R1 — EXHAUSTIVE AND DISJOINT. The categories partition the domain. Every state falls in exactly one. If two categories overlap, an entity has two indices and therefore two frequencies, and the lattice is not well defined.

ES-R2 — AN ORDERING FROM OUTSIDE THE MUSIC. The ordinal is fixed by a property of the domain established before, and independently of, any intention to sonify it. **The ordering may not be chosen to make the result sound good.** This is the essence-set analogue of preregistration [Nosek et al., 2018] and it is the requirement most often violated; violating it is the essence-set form of the researcher-degrees-of- freedom problem [Simmons et al., 2011, Gelman and Loken, 2013].

ES-R3 — REPRODUCIBLE ASSIGNMENT. A second competent analyst, given the domain and the stated ordering rule, produces the same index for the same category. This is checkable by inter-rater agreement and is the input-side form of the reproducibility requirement [Open Science Collaboration, 2015].

A set failing any of ES-R1 to ES-R3 may not be sonified. It may still be described, tabulated, and reasoned about — it simply does not get a frequency. Section 12.3 carries a worked refusal.

18.8.2 8.2 Constructing a defensible essence set

Step 1 — State the domain and its boundary. What is being categorised, and what is excluded. Without a boundary, exhaustiveness cannot be checked.

Step 2 — Identify the ordering source. Three kinds are admissible, in descending order of strength.

(a) An intrinsic physical or structural magnitude. The categories are ordered by a measurable quantity that exists independently of the analyst — distance, duration, count, energy, age. This is the strongest source because ES-R2 is satisfied automatically: the ordering predates the analysis. The proxemic zones of Section 12.3 are of this kind, ordered by distance [Hall, 1966].

(b) A generative or constructive order. The categories are produced by a process with a natural sequence and the index is position in that sequence — stages of a protocol, steps of a manufacturing chain, layers of a stack. Admissible when the sequence is fixed by the process rather than by preference.

(c) A measured empirical rank with demonstrated reliability. The ordering is established by measurement — a Rasch-calibrated item difficulty ordering, for instance [Rasch, 1960] — with inter-rater or test-retest reliability reported. Weakest of the three, because the ordering is now an estimate carrying its own uncertainty, which must be propagated. **If the rank order is unstable across samples, the frequencies are unstable, and the construction must be reported with that instability visible.**

Step 3 — Fix the direction. Ascending or descending must be justified, because reversing the ordering changes every frequency and every interval. The default rule adopted here: **index 1 is the ground, so index 1 goes to the category that is nearest, smallest, earliest, or most basic in the ordering source.** Reversal is permitted only with a stated reason.

Step 4 — Count. `N` is the number of categories. It determines the ceiling `ln N` and the class count `ceil(N/2)`. Both are reported.

Step 5 — Check for collisions. Compute the class cents and check the gaps (Section 7.4). Any gap under about 30 cents will be heard as beating rather than as an interval and must be disclosed in the publication of the set.

Step 6 — Publish the whole construction, not the frequencies. The domain, the boundary, the ordering source, the direction, the index assignment for every category, `N`, the class count, the collisions, the band, and the transposition. **A frequency published without its construction is not a result; it is a decoration.**

What is inadmissible as an ordering source: alphabetical order; order of discovery or historical accident; order of importance as judged by the analyst; frequency of occurrence in a convenience sample; and — the one that matters most — **any order arrived at by trying orderings and keeping the one that sounded best.** That converts the whole apparatus into an elaborate way of writing down a preference.

What a well-formed essence set looks like on paper. Small, under about twelve, above which near-unison collisions appear that the ordering did not intend and the marginal ceiling gain is logarithmic anyway. Ordered from outside. Fully enumerated in print: every category, its index, its class, its cents. Honest about its collisions, with any class gap under 30 cents disclosed. Reported with `N`, `ceil(N/2)`, the ceiling `ln N`, the band and the transposition rule. Free of adjustment: no index moved to improve the sound. Badged throughout — essence frequency, not physical resonance; chosen `k`; postulated square law; ordinal input promoted by postulate.

18.8.3 8.3 Band placement and transposition

Raw essence frequencies for a 24-set span 0.483 Hz to 278 Hz, from far below hearing to the low bass. Octave transposition brings them into a chosen band, `f_audible = f 2^j` with `j` an integer. Transposition by a whole number of octaves preserves pitch class exactly. Placing indices 1 to 24 in `[110, 220)` Hz, one `j` per index:

n	f raw Hz	j	f*2^j Hz	class m	n	f raw Hz	j	f*2^j Hz	class m
1	0.483426	8	123.7570	1	13	81.698949	1	163.3979	13
2	1.933703	6	123.7570	1	14	94.751444	1	189.5029	7
3	4.350832	5	139.2266	3	15	108.770790	1	217.5416	15
4	7.734812	4	123.7570	1	16	123.756988	0	123.7570	1
5	12.085643	4	193.3703	5	17	139.710037	0	139.7100	17
6	17.403326	3	139.2266	3	18	156.629937	0	156.6299	9
7	23.687861	3	189.5029	7	19	174.516690	0	174.5167	19
8	30.939247	2	123.7570	1	20	193.370293	0	193.3703	5
9	39.157484	2	156.6299	9	21	213.190748	0	213.1907	21
10	48.342573	2	193.3703	5	22	233.978055	−1	116.9890	11
11	58.494514	1	116.9890	11	23	255.732213	−1	127.8661	23
12	69.613306	1	139.2266	3	24	278.453222	−1	139.2266	3

Read the class column against the frequency column: every index in class 1 lands on 123.7570 Hz, every index in class 3 on 139.2266 Hz. **Per-index transposition into a single octave collapses the set onto its pitch classes exactly — twelve tones for twenty-four essences, as Theorem 7.1 requires.**

And that is the hazard. Per-index transposition destroys the intervals between indices while preserving classes. The 24-essence set spans 11003.91 cents, more than nine octaves, and folding it into one octave discards all of that. **Two operations are available and must never be confused:**

```
SHARED j     f_i * 2^j for one fixed j     preserves ALL intervals; needs a wide band
PER-INDEX j  f_i * 2^{j_i}                 preserves pitch CLASSES only; fits one octave
```

State the band and the `j` for every value published, and state which of the two operations was performed. A set of values whose intervals are the point takes a shared `j`.

A shared `j` has a hard capacity. The set `n = 1..N` spans a frequency ratio of `N^2`, so fitting it inside 20 Hz to 20 kHz under one shared `j` requires `k 2^j >= 20` at the bottom and `k N^2 2^j <= 20000` at the top. The first inequality forces `j >= 6`, since `20/k = 41.37` and `2^5 = 32` is too small. The second then caps `N`:

```
j = 6    k 2^6 =    30.94 Hz     N <= 25      k (25)^2 2^6 = 19337.0 Hz
j = 7    k 2^7 =    61.88 Hz     N <= 17
j = 8    k 2^8 =   123.76 Hz     N <= 12
j = 9    k 2^9 =   247.51 Hz     N <=  8
```

At most 25 essences can be rendered under a single shared transposition, and only at `j = 6`. That is a bound on set size, not on volume or equipment, and it does not move. **A twelve-category set fits comfortably at `j = 6` or `j = 8`; a thirty-two-category set does not fit under any shared `j`** and must be rendered under split transposition — two or more shared-`j` groups, each internally interval-preserving, with the relation *between* the groups explicitly declared. Splitting is a legal move; leaving the split undeclared is the failure, because a reader cannot tell a split rendering from a broken one without the declaration.

One further constraint belongs beside the band. A rectangular on/off gate has no finite spectral second moment — its `sinc^2` tails fall as `1/f^2` and the second-moment integral diverges — so it has no defined bandwidth and **is disqualified as a rendering envelope** [Gabor, 1946]. Use a windowed envelope. **A hard-gated tone is not the tone whose frequency was published.**

18.9 9 Modal design: building from an essence set

18.9.1 9.1 The procedure

Six steps, every one checkable by a third party from the published record.

```
STEP 1   Declare the category set and the ordinal rule.        (ES-3)
STEP 2   Run the permutation sensitivity test.                 (ES-4)
STEP 3   Compute raw essence frequencies f(n) = k n^2.
STEP 4   Reduce to pitch classes by odd part; count ceil(N/2). (ES-6, ES-7)
STEP 5   Fold into the working band; publish band and j.       (ES-10)
STEP 6   Apply to one or more of the four targets below.
```

The four targets: **(a)** acoustic tuning targets, interacting with Sabine absorption (Section 9.2); **(b)** room dimension ratios and modal frequencies (Section 9.3); **(c)** scheduling and cadence, as periodic forcing of a low-pass filter (Section 9.4); **(d)** tuned physical elements (Section 9.5).

Step 5 carries most of the practical judgement. Raw essence frequencies span from subaudible to ultrasonic: a twelve-set runs 0.483426 Hz to 69.613306 Hz, entirely below the useful speech band. Octave transposition preserves pitch class exactly and is the adopted method. **State the band and the `j` for every value published; a folded value without its `j` is not comparable to anything.**

The working band adopted here for structural work is `[220, 440)` Hz, one octave anchored on A3 = 220 Hz. It was chosen because it sits inside the speech fundamental range for adult voices, is well above typical room-mode territory, is comfortably below the 2 to 4 kHz consonant band where intelligibility lives, and folds a twelve-set into a single octave with `j` between +2 and +9 [Rossing et al., 2002]. **That is a design choice, stated as one.**

18.9.2 9.2 Target (a): acoustic tuning and the Sabine interaction

Acoustic design is an intervention on the equality of conversational turn-taking, and turn-taking is substantially a property of the room: **a hard-surfaced room silences the quiet voice by physics, not by dominance** [Woolley et al., 2010, Curzi, 2026e]. That mechanism is priced in the corpus: silencing three of eight participants costs `ln 8 − ln 5 = 0.4700` nats, 22.6 per cent of a room's per-interaction surplus [Curzi, 2026e]. **The essence law adds exactly one thing to that: it says which octave bands to treat first.**

Absorption is not flat. Porous absorbers — mineral wool, heavy curtain, carpet — are efficient above about 500 Hz and become progressively useless below 250 Hz; membrane and Helmholtz absorbers are narrowband and must be tuned [Beranek, 2004]. So the practical question in any real treatment budget is *which bands do I spend on*, and the essence set answers it by identifying where the room's own programme places its pitch classes. Worked, for a twelve-set folded into `[220, 440)`:

class	folded Hz	octave band	inside the 250–4000 Hz speech range?
PC1	247.5140	250	at the lower band edge
PC3	278.4532	250	yes
PC5	386.7406	500	yes
PC7	379.0058	500	yes
PC9	313.2599	250	yes
PC11	233.9781	250	at the lower band edge

Four of six classes land in the 250 Hz octave band and two in the 500 Hz band. That is the treatment priority and it is a useful one: the 250 Hz band is exactly where cheap porous absorption starts losing efficiency and where most under-treated meeting rooms have their worst speech-intelligibility problem. **The essence set points at the band most rooms neglect.** *This is a category-1 acoustic fact about absorber physics and a category-3 choice of which band to prioritise; the two are separable and are separated here.*

The Sabine arithmetic for a 100 m3 room, computed from `RT60 = 0.161 V / A` [Sabine, 1922]:

`A` (m2 sabins)	8	10	13	16	20	26	32	40
`RT60` (s)	2.013	1.610	1.238	1.006	0.805	0.619	0.503	0.403

and inverted, the absorption required to hit a target:

```
V = 100 m^3
RT60 = 0.4 s  ->  A = 40.25 m^2 sabins
RT60 = 0.5 s  ->  A = 32.20 m^2 sabins
RT60 = 0.6 s  ->  A = 26.83 m^2 sabins
RT60 = 0.8 s  ->  A = 20.12 m^2 sabins
RT60 = 1.0 s  ->  A = 16.10 m^2 sabins
```

One hard limit the essence law cannot touch and must not be allowed to obscure. The Schroeder frequency [Schroeder, 1965],

```
f_s = 2000 sqrt(RT60 / V)
```

marks the transition between modal behaviour — discrete resonances, position-dependent response — and statistical behaviour, the diffuse field in which Sabine's relation applies. Computed for `V = 100` m3:

```
RT60 = 0.40 s  ->  f_s = 126.5 Hz
RT60 = 0.50 s  ->  f_s = 141.4 Hz
RT60 = 0.60 s  ->  f_s = 154.9 Hz
RT60 = 0.80 s  ->  f_s = 178.9 Hz
```

Below `f_s`, Sabine's equation does not apply and the room's behaviour is set by individual modes. Above it, modes are dense and Sabine governs. Since a folded twelve-set lives between 234 and 387 Hz it sits entirely in the statistical region for a room of this size, which is the correct place for it and why the `[220, 440)` band was chosen. **A folded band straddling `f_s` would produce a set of targets half of which obeyed one physics and half another, and the resulting specification would be incoherent.** Check `f_s` before choosing the band, always.

18.9.3 9.3 Target (b): room dimension ratios and modal frequencies

This is the strongest of the four applications, because room proportion is a genuinely open design question with a wide space of acceptable answers and the essence law narrows it defensibly.

An axial mode along a dimension `L` sits at `f = c/(2L)`, so `L = c/(2f)` [Rossing et al., 2002]. Choose three essence classes, one per axis, and the room's three axial fundamentals *are* those essence frequencies. The ratio of the dimensions is then the inverse ratio of the class frequencies — a ratio of squares by CC-R1, hence always a rational number with an exact expression.

The constraint that makes this non-trivial is that most ratios are bad rooms. Room-ratio heuristics exist because degenerate modes — two or three modes at the same frequency — create strong peaks and long decays, and near-degenerate axial modes create audible colouration of speech [Beranek, 2004]. The published heuristics are heuristics and are stated here as such:

```
Louden          1 : 1.4  : 1.9
Sepmeyer A      1 : 1.14 : 1.39
Sepmeyer B      1 : 1.28 : 1.54
Sepmeyer C      1 : 1.60 : 2.33
Volkmann        1 : 1.5  : 2.5
```

So the design question becomes: **is there an assignment of essence classes to axes whose ratio lands near a recommended ratio?** Searched exhaustively over all class triples and all octave offsets from 0 to 6, for the six classes of a twelve-set. Best matches, recomputed:

heuristic target	nearest essence ratio	classes used	Euclidean error
Louden 1 : 1.40 : 1.90	1 : 1.3611 : 1.9600	PC3, PC5, PC7	0.0715
Sepmeyer A 1 : 1.14 : 1.39	1 : 1.1250 : 1.4400	PC1, PC3, PC5	0.0522
Sepmeyer B 1 : 1.28 : 1.54	1 : 1.2346 : 1.5625	PC1, PC5, PC9	0.0507
Sepmeyer C 1 : 1.60 : 2.33	1 : 1.6200 : 2.2500	PC3, PC5, PC9	0.0825
Volkmann 1 : 1.50 : 2.50	**1 : 1.4938 : 2.4694**	**PC7, PC9, PC11**	**0.0312**

The best match is PC7 : PC9 : PC11 against Volkmann, at a Euclidean error of 0.031 — the middle term within 0.4 per cent and the long term within 1.2 per cent of the heuristic. And the ratio has an exact closed form, which is the point of using the essence law rather than a table lookup:

```
L proportional to 1/f, and f proportional to m^2, so
L(PC11) : L(PC9) : L(PC7)  =  1/121 : 1/81 : 1/49
                           =  1 : 121/81 : 121/49
                           =  1 : 1.493827... : 2.469388...
```

The ratio is exactly `1 : 121/81 : 121/49`. Not approximately. **That is what CC-R1 buys: every proportion this method produces is a ratio of squares of integers and can be written down exactly, which means it can be checked, argued with, and reproduced by someone who does not trust the author.**

Anchoring the absolute size by requiring the axial fundamentals to *be* the essence frequencies:

```
f(7)  = k * 49  = 23.687861 Hz  ->  Lz = 343/(2*23.687861) = 7.2400 m   (length)
f(9)  = k * 81  = 39.157484 Hz  ->  Ly = 343/(2*39.157484) = 4.3798 m   (width)
f(11) = k * 121 = 58.494514 Hz  ->  Lx = 343/(2*58.494514) = 2.9319 m   (height)

V = 92.969 m^3        floor area = 31.709 m^2        total surface S = 131.555 m^2
occupancy at 2.5 m^2 per person = 12.7 people
```

A room 2.93 m high, 4.38 m wide and 7.24 m long, holding about twelve people. The height is buildable, the floor plan is a conventional meeting-room shape, and the occupancy matches the twelve-category set it was derived from. **None of that was forced, and it should be said plainly that it is lucky** — a different `k` or a different class triple would have produced an unbuildable room, and FM-3 covers what to do then.

The modal structure, recomputed for this room, first twenty modes:

#	f (Hz)	(p,q,r)	type	gap from previous (Hz)	essence relation
1	23.69	(0,0,1)	axial	–	`f(7) x 2^0`
2	39.16	(0,1,0)	axial	15.47	`f(9) x 2^0`
3	45.76	(0,1,1)	tangential	6.61	–
4	47.38	(0,0,2)	axial	1.61	`f(7) x 2^1`
5	58.49	(1,0,0)	axial	11.12	`f(11) x 2^0`
6	61.46	(0,1,2)	tangential	2.97	–
7	63.11	(1,0,1)	tangential	1.65	–
8	70.39	(1,1,0)	tangential	7.28	–
9	71.06	(0,0,3)	axial	0.67	–
10	74.27	(1,1,1)	oblique	3.21	–
11	75.27	(1,0,2)	tangential	1.00	–
12	78.31	(0,2,0)	axial	3.04	`f(9) x 2^1`
13	81.14	(0,1,3)	tangential	2.82	–
14	81.82	(0,2,1)	tangential	0.68	–
15	84.85	(1,1,2)	oblique	3.03	–
16	91.53	(0,2,2)	tangential	6.68	–
17	92.04	(1,0,3)	tangential	0.51	–
18	94.75	(0,0,4)	axial	2.71	`f(7) x 2^2`
19	97.75	(1,2,0)	tangential	3.00	–
20	100.02	(1,1,3)	oblique	2.28	–

```
modes below 150 Hz:              55  (48 if the mode set is truncated at p,q,r <= 4)
mean gap of the first 20 modes:  4.02 Hz
maximum gap:                     15.47 Hz  (between modes 1 and 2)
minimum gap:                     0.51 Hz   (modes 16 -> 17)
```

Read the "essence relation" column and CC-R2 is visible in built form. **The room's axial mode series along each axis is `f, 2f, 3f, 4f, ...`, and the even members of each series are the essence frequencies of that axis's class at higher octaves.** Mode 4 is `f(7) x 2`, mode 18 is `f(7) x 4`, mode 12 is `f(9) x 2`. The odd members — mode 9 at 71.06 Hz, which is `3 f(7)` — are *not* essence frequencies of anything in the set, because tripling an index is not an operation the essence law preserves. **The room delivers the essence set at the even harmonics and delivers ordinary harmonic-series members between them. Do not report the odd members as essence frequencies; they are not.**

Three honest acoustic observations about this specific room, none predicted by the essence law and all produced by conventional analysis.

1. **The 15.47 Hz gap between modes 1 and 2 is large.** A single isolated mode at 23.69 Hz with nothing near it will ring. At this frequency it is below the useful speech range and mostly inaudible as pitch, but it will couple to footfall and to plant. Treat with a membrane absorber or accept it.
2. **The 0.51 Hz gap between modes 16 and 17 is a near-degeneracy.** Two modes at 91.53 and 92.04 Hz will beat at about half a hertz — a slow throb. Both are tangential, so the effect is mild, but it is real and worth knowing before someone reports the room as "wobbly" and nobody connects the reports.
3. **55 modes below 150 Hz is a healthy density for a room of this volume**; the low end is not sparse. The Schroeder frequency at `RT60 = 0.5` s is `2000 sqrt(0.5/92.969) = 146.7` Hz, consistent with that count.

Sabine treatment for this room, recomputed:

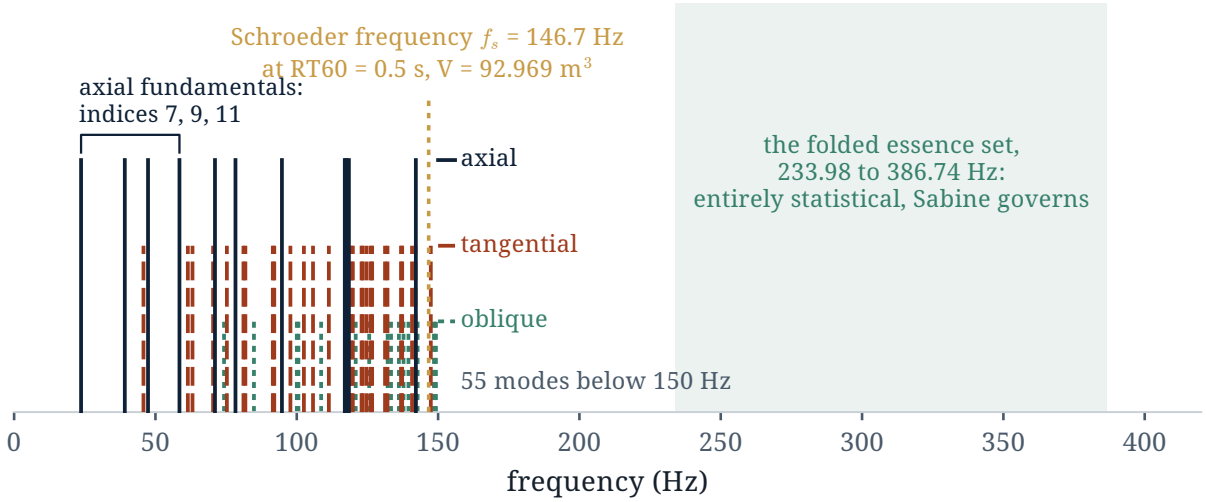

Figure 18.4: **The derived room's entire modal region lies below the Schroeder frequency and its entire folded essence set lies above it, which is what makes the specification coherent.** All 55 modes below 150 Hz are shown, classified axial, tangential and oblique, for a room of 7.2400 by 4.3798 by 2.9319 m at `c = 343` m/s. The Schroeder boundary at `RT60 = 0.5` s and `V = 92.969` m3 is 146.7 Hz; the folded set runs 233.98 to 386.74 Hz, so Sabine's relation governs the whole of it. Modelled from the stated dimensions by `figs/src/CCP-018_fig04.py`; no room was built and nothing here is measured.

target `RT60` (s)	required `A` (m2 sabins)	mean absorption `alpha_bar = A/S`
0.4	37.42	0.2844
0.5	29.94	0.2276
0.6	24.95	0.1896
0.7	21.38	0.1625
0.8	18.71	0.1422
1.0	14.97	0.1138

The deliberation-room target is met at `RT60 = 0.5` to `0.6` s, requiring 25 to 30 square-metre sabins across a 131.6 m2 surface — a mean absorption coefficient of 0.19 to 0.23. That is achievable with a carpeted floor, an absorbent ceiling raft over the table, and one treated end wall; it does not require a specialist build.

18.9.4 9.4 Target (c): scheduling and cadence

The storage law is a first-order low-pass section with pole `1 - delta` and time constant `tau` of about `1/delta` periods, so **a repeated practice is a periodic forcing function on a low-pass filter, which is why cadence beats intensity** [Curzi, 2026a]. *This is a category-2 use: the same difference equation governs both objects and no physical result's authority transfers.* The essence law can set the period.

The mechanism is octave folding applied to time rather than to frequency. An essence frequency `f` has period `T = 1/f` seconds; multiplying by `2^p` — the same operation as octave transposition, since period is the reciprocal of frequency — brings `T` into a humanly usable band. Pitch class is preserved exactly, which here means **two essences that share a pitch class share a cadence, up to a doubling.** That is a defensible property for a scheduling system, because two categories that are harmonically identical should not be given unrelated rhythms.

Folded into `[1 day, 2 days)`:

class	`f` raw (Hz)	`T = 1/f` (s)	`p`	`T 2^p` (s)	days
PC1	0.483426	2.068570	16	135565.8	1.5690
PC3	4.350832	0.229841	19	120502.9	1.3947
PC5	12.085643	0.082743	20	86762.1	1.0042
PC7	23.687861	0.042216	21	88532.8	1.0247
PC9	39.157484	0.025538	22	107113.7	1.2397
PC11	58.494514	0.017096	23	143408.5	1.6598

Folded into `[7 days, 14 days)`, the more useful band for institutional cadence:

class	`p`	`T 2^p` (days)	practical reading
PC5	23	8.0335	weekly, drifting one day per cycle
PC7	24	8.1975	weekly, drifting one day per cycle
PC9	25	9.9179	ten-day
PC3	22	11.1577	eleven-day
PC1	19	12.5524	fortnightly, slightly early
PC11	26	13.2786	fortnightly, slightly early

Two things to say about this table, one useful and one honest.

The useful thing: **the spread from 8.03 to 13.28 days is a factor of 1.65, and a set of cadences in that spread drifts in and out of phase on a cycle of months.** That is a design property, not a defect. Two bodies meeting every 8.03 and 9.92 days coincide every `8.0335 x 9.9179 / (9.9179 – 8.0335) = 42.3` days, roughly every six weeks, which is a natural rhythm for a joint review. **A coincidence can be scheduled without a coordinator, by choosing periods whose beat frequency is the interval wanted.**

The honest thing: **nothing here is calendar-compatible, and calendars are strong.** A 9.92-day cycle walks through the week and lands on a Sunday about one time in seven. In practice the value is rounded to the nearest workable integer — 8, 10, 11, 14 days, or "every second Tuesday" — and at that point the essence law has been left behind and the work is simply scheduling. **Say so. A rounded cadence is a rounded cadence, and claiming it is essence-derived after rounding is FM-5.**

The relation to the filter is where this becomes engineering rather than numerology. What matters is the ratio of the forcing period `P` to the time constant `tau = 1/delta`:

`delta` (per week)	`tau` (weeks)	settling to 95% ~ `3 tau` (weeks)	`P/tau` at `P = 7.29` weeks
0.02	50.00	150.00	0.146
0.05	20.00	60.00	0.364
0.10	10.00	30.00	0.729
0.20	5.00	15.00	1.457
0.30	3.33	10.00	2.186

The rule that comes out of this is the useful one, and it does not depend on the essence law at all: choose `P` well below `tau`, ideally `P/tau <= 0.5`. A low-pass section driven well below its corner frequency integrates smoothly and holds a near-constant stock; driven near or above it, the stock sawtooths — building after each forcing and decaying visibly between them, which is the felt experience of an institution whose practices "do not stick". At `delta = 0.10` per week

a 51-day, 7.29-week cadence gives `P/tau = 0.729`, which is marginal; at `delta = 0.05` the same cadence gives 0.364, which is comfortable.

The essence law proposes the cadence; `delta` decides whether it is admissible. If the derived period exceeds `tau/2`, fold down one more octave and use the half-period. That is a legal move — it preserves pitch class exactly — and it is the correct one. Halving the PC1 cadence from 12.55 days to 6.28 days is not an abandonment of the method; it is the method's own octave operation applied to time.

For completeness, a tempo rule appears in the source material: multiply the essence frequency by 60 and halve or double until the result falls between 100 and 200, then use it as a track's beats per minute. Recomputed:

class	`f` raw (Hz)	`f x 60`	halvings	BPM
PC1	0.483426	29.0055	−2	116.0222
PC3	4.350832	261.0499	+1	130.5249
PC5	12.085643	725.1386	+2	181.2846
PC7	23.687861	1421.2717	+3	177.6590
PC9	39.157484	2349.4491	+4	146.8406
PC11	58.494514	3509.6708	+5	109.6772

This is octave folding of the period into a musically conventional band, the same operation as the day-band folding with a different target window. **It is recorded because the numbers should be available and it carries no additional claim.**

18.9.5 9.5 Target (d): tuned physical elements

Physical resonators tuned to essence classes give a room a set of objects that sound its own proportional system when struck, blown, or excited by the room itself. They are also the cheapest way to make the tuning *disclosable*: a visible object with a label on it satisfies Section 3.6 in a way a hidden loudspeaker never can.

All three relations below are ordinary physics — category 1 — and none is contributed by the essence law, which supplies only the target frequency [Rossing et al., 2002].

Open-open tubes, `f = c/(2(L + 0.8 d))` with `d` the bore diameter, for a 50 mm bore at `c = 343` m/s:

class	target `f` folded to [220,440) (Hz)	geometric length `L` (m)
PC1	247.5140	0.6529
PC3	278.4532	0.5759
PC5	386.7406	0.4034
PC7	379.0058	0.4125
PC9	313.2599	0.5075
PC11	233.9781	0.6930

Helmholtz resonators, `f = (c/(2 pi)) sqrt(A / (V (L_neck + 1.7 a)))`, neck radius `a = 0.025` m, neck length 0.10 m, targeting one octave below the folded band so that the units are practical bass-trap sizes:

class	target `f/4` (Hz)	required cavity `V` (m3)	litres
PC1	61.8785	0.010724	10.72

class	target `f/4` (Hz)	required cavity `V` (m3)	litres
PC3	69.6133	0.008473	8.47
PC5	96.6851	0.004393	4.39
PC7	94.7515	0.004574	4.57
PC9	78.3150	0.006695	6.70
PC11	58.4945	0.012001	12.00

Two of these targets coincide with unfolded lattice values. The PC11 target, 58.4945 Hz, is exactly `f(11)`; the PC3 target, 69.6133 Hz, is exactly `f(12) = k (144)`. **Both coincidences are CC-R2 doing its work: 11 and 22 share an odd part, as do 3 and 12.** A Helmholtz trap built to 58.49 Hz sits within 0.005 Hz of the room's PC11 axial mode at 58.494514 Hz, which makes it a genuinely useful modal trap and not merely a decorative one. *The source material describes the folded PC11 value as four octaves above `f(11)`; recomputation gives `233.9781/58.494514 = 4.000`, which is **two** octaves, and the correction is recorded rather than applied silently.*

Stretched strings, `f = (1/(2L)) sqrt(T/mu)`, steel with `mu = 0.0012` kg/m at `T = 400` N, so the wave speed is `sqrt(400/0.0012) = 577.35` m/s:

class	target `f` (Hz)	speaking length `L = v/(2f)` (m)
PC1	247.5140	1.1663
PC3	278.4532	1.0367
PC5	386.7406	0.7464
PC7	379.0058	0.7617
PC9	313.2599	0.9215
PC11	233.9781	1.2338

A six-string monochord with speaking lengths from 0.746 to 1.234 m is a buildable object about 1.3 m long — a bench-scale instrument that can sit along a wall, be struck by anyone, and carry a printed label giving all six frequencies, their indices, and the ordinal rule they came from. **That single object satisfies clauses 1, 2 and 5 of Section 3.6 simultaneously: it is audible, it is disclosed, and its derivation is published on it.** It is the recommended physical form for this method, in preference to any loudspeaker system, for exactly that reason.

18.9.6 9.6 Chords, beats, and what the tuning actually sounds like

Sound the six folded classes together and this is what happens, computed:

```
sorted folded frequencies (Hz):
233.9781   247.5140   278.4532   313.2599   379.0058   386.7406
```

Pairwise differences — the beat rates — for the two closest pairs:

```
379.0058 & 386.7406  ->  difference  7.7348 Hz   ROUGHNESS ZONE
233.9781 & 247.5140  ->  difference 13.5359 Hz   ROUGHNESS ZONE
all other pairs      ->  30.9 to 152.8 Hz, heard as separate pitches
```

Two of the fifteen pairs beat inside the roughness zone — a difference under about 20 Hz at these frequencies, which is within a critical band [Plomp and Levelt, 1965, von Helmholtz, 1863] — and PC7 against PC5 at 7.73 Hz is a distinctly audible flutter rather than a chord. The cause is structural: PC7's folded ratio is `49/32 = 1.531250` and PC5's is `25/16 = 1.562500`, a gap of 34.98 cents, a third of a semitone. **The two classes are structurally almost identical and the ear hears that as beating rather than as harmony.**

This is a finding about the index, not a defect in the method, and emphatically not a finding about any domain. It says that in a twelve-category partition the members at indices 5 and 7 — and 10 and 14, and so on — sit at nearly the same harmonic position. If they must be distinguishable, sound them separately, or transpose one by a full octave so the 34.98-cent gap becomes a 1234.98-cent interval and reads as an octave-plus rather than a beat. **Both are legal moves. Concealing the beat by dropping one voice below audibility is not.**

The three usable simultaneities in this set, in order of consonance:

```
PC1 + PC3     ratio 9/8,        203.91 cents   Pythagorean whole tone, +3.91 from 12-TET
PC1 + PC9     ratio 81/64,      407.82 cents   Pythagorean ditone,     +7.82 from 12-TET
PC1 + PC11    ratio 121/64,    1102.64 cents   near-just major seventh, +2.64 from 12-TET
```

All three are within 8 cents of a twelve-tone equal-tempered interval, so this set sits comfortably against conventional instruments without retuning them. That is a practical convenience and a consequence of `9/8` and `121/64` being close to tempered intervals; it is not a claim about anything. Whether a listener hears such deviations as mistunings or as category members is itself an empirical question with a substantial literature [Burns and Ward, 1978, Burns, 1999, Deutsch, 1999].

Three rendering constraints bind anything actually built.

The set size is capped, and twelve is safely inside the cap. Under a single integer octave transposition into 20 Hz to 20 kHz, at most **25 essences** fit, and only at `j = 6` (Section 8.3). A twelve-category set fits with room to spare; a thirty-two-category set does not, and must be rendered under split transposition, which changes the interval relations between the two halves and must be declared rather than quietly applied.

Do not grow the set past sixteen without expecting the flutter to get worse. The 34.98-cent gap between PC7 and PC5 is the *widest* minimum gap available: it holds for every set size from 7 to 16. **The moment a seventeenth index enters, the minimum gap collapses to 6.001 cents** — index 17 folds to `289/256`, six cents from index 3's `9/8` — and against PC3 at 278.4532 Hz that is a beat of **0.97 Hz against the present 7.73 Hz**, which is no longer a flutter but a slow swell that most listeners will hear as one wandering tone. Both remedies still apply and both cost more at seventeen than at twelve.

Every tone needs a minimum duration, and a rectangular gate is not a legal envelope. Resolving a surplus difference `dF` requires at least `1/(8 pi dF)` cycles [Gabor, 1946], independent of transposition: separating PC7 from PC5 needs **3.94 cycles**, about 10 ms at 379 to 387 Hz, while separating a 6.001-cent pair at PC3's 278.4532 Hz needs **22.96 cycles**, about 82 ms. **Specify the tone duration as a cycle count, not as a wall-clock figure**, because the cycle count is what transposes. And the envelope is constrained: a rectangular on/off gate has no finite spectral second moment, so it has no defined bandwidth and is disqualified. Use a windowed envelope; a raised-cosine rise and fall of at least one cycle at each end is sufficient and is the adopted default. **This is an engineering requirement, not an aesthetic preference, and it is entirely compatible with the disclosure constraint — a windowed envelope is audible, disclosed, and hides nothing.**

18.10 10 Design specifications

Numbered, checkable requirements. They are grouped by what they govern and prefixed accordingly: SA for the built space, CK for register crossing, ES for the essence set.

18.10.1 10.1 Requirements on a built space (SA)

SA-1 — NO SUBLIMINALS. No masked content, no content below the threshold of hearing at any listening position, no content concealed from a listener, no carrier or embedding of

any kind. **This requirement outranks every other requirement here and admits no exception** (Section 3.6).

SA-2 — Disclose in writing. A posted statement lists every tone present, its frequency, its measured level in dB SPL at the reference position, and its derivation. Posted at the entrance, readable before entry.

SA-3 — Provide an off switch and disclose its location. Anyone in the space may stop the tone. A tuned space that cannot be switched off or walked out of is outside this framework's scope.

SA-4 — Do not present an unverified device as an amplifier. Where an area of effect is required, use a loudspeaker with a published frequency response and a measured SPL, and disclose both (Section 3.6).

SA-5 — Publish the ordinal rule and the permutation sensitivity result before publishing any frequency (ES-3, ES-4).

SA-6 — Publish `(N, class, raw Hz, j, band, folded Hz)` for every tone. A folded value without its `j` is not comparable to anything (ES-10).

SA-7 — Design to `ceil(N/2)`, not to `N`. Twelve categories give six pitch classes (Theorem 7.1).

SA-8 — Check the Schroeder frequency before choosing the band. `f_s = 2000 sqrt(RT60/V)`. The whole folded set must sit on one side of `f_s`, and for speech work it must sit above it (Section 9.2).

SA-9 — Compute the full modal set, not just the axials. Report modes below 150 Hz — **with the truncation order stated**, since the count is not converged at `p,q,r <= 4` — the maximum gap, and the minimum gap. Flag any gap below 1 Hz as a near-degeneracy with its predicted beat rate (Section 9.3).

SA-10 — Meet the `RT60` target first; use the essence set only to prioritise bands. If the essence-derived proportion and the `RT60` target conflict, **`RT60` wins.** Speech intelligibility is a measured requirement; proportion is a design choice.

SA-11 — Verify that essence-derived cadences satisfy `P <= tau/2, tau = 1/delta`. If not, fold down one octave and use the half-period (Section 9.4).

SA-12 — State every rounding. A cadence rounded to a calendar, a dimension rounded to a construction module, a frequency rounded to a tuner's resolution — each is a departure from the method and each is disclosed as one, with the size of the departure in cents.

SA-13 — Prefer a labelled physical resonator to a loudspeaker. A struck object with its derivation printed on it satisfies audibility, disclosure and reproducibility at once (Section 9.5).

SA-14 — Report beat rates for every pair under 20 Hz apart. Roughness is a real perceptual effect [Plomp and Levelt, 1965] and a room that flutters must say that it flutters.

SA-15 — Restate HC-1 on every drawing, schedule and label. "Essence frequency, not physical resonance. No claim is made that any material, room, institution or person physically resonates at these values."

SA-16 — Preregister before claiming an effect. A claim that the tuning changed anything requires the full protocol of Curzi [2026i] including the shuffled-input control. Absent that, **the only claim available is that the target was chosen by a stated, reproducible method.**

18.10.2 10.2 Requirements on register crossing (CK)

CK-1. Every logarithmic quantity is published with its **base** — nats, bits, octaves, cents — in the same line or column header. A bare number is not a measurement.

CK-2. Every logarithmic quantity that is not a ratio between two reported values is published with its **reference**: `I_0`, `f_ref`, or the ground constant `k`.

CK-3. Every published quantity carries its **status badge**: PROVEN, DEFINITION, MEASURED, POSTULATE, or CHOSEN NORMALISATION. **Conversions preserve the badge.**

CK-4. The surplus-to-pitch conversion is published as `octaves = 2.885390 F` **with the note that the factor 2 is the exponent of the essence-law postulate**, not an independent constant.

CK-5. Any published essence frequency carries, in the same caption or table note: *this is an essence frequency, not a physical resonance.*

CK-6. Any essence frequency published as an audible value states the **band** and the integer `j` of the transposition `f 2^j`, and a set of values whose intervals are the point shares one `j`.

CK-7. Any surplus figure from the deployed functional is published as a **lower bound**, with "at least" or an inequality.

CK-8. Stevens' exponents are published with the **procedure**: method (estimation or production), stimulus range, instruction. An exponent without a procedure is not a measurement [Poulton, 1979].

CK-9. Weber fractions are never asserted for a modality unless measured in-house or cited. Parametric tables over `c` are the permitted substitute and are labelled parametric.

CK-10. Distortion is reported as `Delta = |ln r|` in a stated register, **never as the raw ratio `r` alone**, which is asymmetric between over- and under-framing.

CK-11. The moment equation is never published without its badge, nor without the note that `D` and `P` must share units.

CK-12. "Maximum moment `= ln N`" is published with both links of its derivation chain — the range result and the chosen normalisation — every time.

CK-13. Precision after conversion never exceeds precision before it. Report to the source's **significant figures**, not to the target register's natural resolution.

CK-14. Any table crossing registers is **computed**, not transcribed, and is reproducible from the constants of Section 4.1.

CK-15. Where a conversion depends on the essence exponent `s = 2`, the dependence is stated and the sensitivity table of Section 4.3 is available.

CK-16. No conversion between a ratio-scaled and an interval-scaled quantity without demoting the result and saying so. Specifically: **Fechner sensations may be subtracted but not divided.**

CK-17. Every formula entering a specification carries its full seven-gate validation table in print, including gates it fails (Appendix A).

CK-18. Failed and unattempted gates print as **FAIL** or **NOT YET ATTEMPTED** — never omitted, softened, or deferred to "future work" without naming the specific test.

CK-19. No intervention derived from these conversions removes a person's ability to decline it. With special force for anything delivered as tone: **audible, disclosed, refusable, with no subliminal content of any kind.**

CK-20. Any claim that two registers are "the same thing" is prohibited. They are interconvertible measures of quantities sharing a logarithmic structure. **That is the claim, and it is enough.**

18.10.3 10.3 Requirements on an essence set (ES)

ES-1. An essence set is published with its **domain and boundary** stated.

ES-2. Categories are **exhaustive and disjoint** over that domain (ES-R1), and the check is reported.

ES-3. The **ordering source** is stated and classified as (a) intrinsic magnitude, (b) generative sequence, or (c) measured rank with reliability. Type (c) reports its reliability statistic.

ES-4. The ordering is **established independently of the sonification** (ES-R2). Any set whose ordering was chosen or adjusted for its sound is disqualified.

ES-5. The **direction** of the index, ascending from ground, is stated and justified.

ES-6. Assignment is reproducible (ES-R3): the rule is stated in enough detail that a second analyst reproduces the index, and inter-rater agreement is reported where the assignment

involved judgement.

ES-7. `N`, the class count `ceil(N/2)`, and the ceiling `ln N` are published together.

ES-8. The **full index table** is published: category, index `n`, factorisation `2^a m`, class `m`, raw `f = k n^2`, class cents.

ES-9. Class collisions under 30 cents are disclosed, with the pair identified and the gap in cents.

ES-10. The **band and the transposition rule** are published, and whether a shared or per-index `j` was used.

ES-11. Every published frequency carries: *this is an essence frequency, not a physical resonance.*

ES-12. `k` is published as a **chosen** reference constant, with the note that it cancels from every interval.

ES-13. The **scale promotion** of Section 3.5 is badged wherever intervals are given a quantitative interpretation: the ordering is data, the spacing is the model.

ES-14. Consonance indices are published with their definitions and their CHOSEN status. Where two defensible indices disagree in ranking, both are published and neither is adjudicated.

ES-15. No essence set is used to rank, score, select, or exclude a person. The index is a position in a category ordering, not a measure of worth.

ES-16. Anything delivered as tone is **audible, disclosed and refusable**, with no subliminal content of any kind.

ES-17. Where a subset of a large set must be sonified, the **odd indices** are the default choice, being the class representatives and, among fully-distinct choices, the least dissonant (Section 7.7). A different subset requires a stated reason.

ES-18. Every formula in the construction carries its full seven-gate validation table in print, including gates it fails or cannot yet attempt.

18.11 11 Failure modes

Twenty-eight named failure modes, numbered FM-1 to FM-28 and grouped by subject. Each gives what it damages, its signature, and its fix. *This catalogue supersedes the source material's three separately numbered lists; the numbering here is sequential and the cross-references in this paper follow it.*

18.11.1 11.1 Faults of the built space

FM-1 — THE HIDDEN TONE. *Damages:* consent, and with it the entire ethical standing of the work. *Description.* A tone, a message, or a modulation is placed below the threshold of audibility, masked under a louder signal, or embedded in a carrier. *Signature.* Any signal path a person in the room cannot hear and was not told about; any spectrum-analyser trace showing content not on the posted disclosure. *Fix.* SA-1, SA-2, SA-3. **There is no partial fix and no acceptable dose. Remove it, or make it audible and disclosed.**

FM-2 — THE RESONANCE CLAIM, BUILT. *Damages:* everything, and it is easiest to commit here because the room really does resonate. *Description.* "The room resonates at the essence frequency of category *X*." The room resonates at 39.157484 Hz because it is 4.3798 m wide. The category does not resonate at anything. *Signature.* A category, a discipline, a material or a person as the grammatical subject of "resonates". *Fix.* SA-15, and rewrite: "the width was chosen so that the axial mode falls at the essence frequency of index 9."

FM-3 — THE UNBUILDABLE ROOM. *Damages:* the project. *Description.* A class triple is chosen for harmonic reasons and produces dimensions of, say, `0.74 x 3.60 x 10.00` m — a ceiling height of 74 centimetres and an aspect ratio of 13.4 : 1. That is exactly what PC11 : PC5

: PC3 gives if the raw class ratios are used with no octave offset, scaled so the middle axis is 3.60 m. **The ratio `1 : 121/25 : 121/9` is harmonically legitimate and architecturally impossible.** *Signature.* Any dimension below about 2.4 m or above about 5 m for a room-scale build; an aspect ratio beyond about 1 : 3. *Fix.* Search the class triples *and* the octave offsets, as Section 9.3 does, before committing. If no combination is buildable, **the honest report is that this category scheme does not produce a room**, and the set is used for cadence or tuned elements instead.

FM-4 — THE MODAL BLIND SPOT. *Damages:* the acoustic outcome, badly. *Description.* Axial modes are placed by essence and the tangential and oblique modes are never computed. Two of them land 0.5 Hz apart and the room throbs. *Signature.* A room-mode analysis containing only `(p,0,0)`, `(0,q,0)`, `(0,0,r)` entries. *Fix.* SA-9. Compute the full set to a stated truncation order and report the gaps — **and report the truncation order, because the mode count below a cutoff is not converged at `p,q,r <= 4`.**

FM-5 — THE ROUNDED CADENCE, UNDISCLOSED. *Damages:* the reproducibility of the whole schedule. *Description.* An essence-derived 9.9179-day cadence is rounded to "every second Tuesday", 14 days, and the schedule is still described as essence-derived. It is not: 14 days is 1.4116 times the derived value, a departure of **596.8 cents**. *Signature.* A published cadence at a round calendar interval with an essence derivation attached. *Fix.* SA-12. State the derived value, the rounding, and the size of the departure. **A rounded cadence is a perfectly good cadence; it is just not the derived one.**

FM-6 — PROPORTION OVER INTELLIGIBILITY. *Damages:* speech, turn-taking, and therefore the room's contribution to collective performance [Woolley et al., 2010]. *Description.* An essence-derived proportion is preserved at the cost of an `RT60` that lands at 1.2 s in a deliberation room, because absorbing enough to reach 0.5 s would require covering a surface the designer wanted left hard for "proportional integrity". *Signature.* A measured `RT60` above 0.8 s in a room intended for group discussion, with a design rationale referring to proportion. *Fix.* SA-10. **`RT60` wins. Every time.** The loudest speaker wins a reverberant room by physics, and no proportional system compensates for that [Curzi, 2026e].

FM-7 — THE BAND STRADDLING SCHROEDER. *Damages:* the coherence of the whole specification. *Description.* A folded band is chosen that spans `f_s`, so half the targets are modal and half statistical, and the treatment strategies for the two halves are incompatible. *Signature.* A folded set spanning, say, 100 to 300 Hz in a room whose `f_s` is 147 Hz. *Fix.* SA-8. Compute `f_s` first, then choose the band, then fold.

FM-8 — THE UNDISCLOSED LOUDSPEAKER. *Damages:* consent, indirectly but seriously. *Description.* The tuning is delivered by a ceiling speaker nobody knows about, at a level low enough that most occupants do not consciously notice it. Nothing is technically subliminal — it is above threshold — but nothing is disclosed either. *Signature.* An occupant who cannot say what is sounding in the room they work in. *Fix.* SA-2 and SA-13. **The disclosure requirement is not satisfied by audibility alone. A person must be able to know, not merely able in principle to notice.**

FM-9 — THE PHANTOM SIX. *Damages:* the whole composition. *Description.* A twelve-category scheme is realised as twelve tuned tubes. Six of them are octave duplicates. The room contains twelve objects and six sounds, and the extra six are presented as distinct voices. *Signature.* Two tubes whose lengths stand in a ratio of exactly 2 or 4. *Fix.* SA-7. Build six, label each with the categories it carries.

FM-10 — THE UNBEATEN BEAT. *Damages:* the occupants' experience, and the credibility of the tuning. *Description.* PC5 and PC7 are sounded together, beat at 7.73 Hz, and the room is described as "harmonious". Occupants describe it as "buzzing" and nobody connects the two reports. *Signature.* Any published set with a folded pair under 20 Hz apart and no beat rate reported. *Fix.* SA-14. Report the beat, then either separate the voices in time, transpose one by an octave, or accept the flutter and say so in the disclosure.

18.11.2 11.2 Faults of register crossing

FM-11 — THE UNSTATED BASE. *Signature:* a surplus, sensation or pitch figure published as a bare number; readers assume bits where nats were meant. *Damage:* a silent factor of 1.442695 or 0.693147 through every derived quantity; in headroom calculations this is the difference between a positive and a negative margin. *Detection:* audit any figure whose ratio to a companion figure sits near 1.4427 or 0.6931. *Fix:* CK-1.

FM-12 — THE FREE LUNCH CONVERSION. *Signature:* a modest surplus gain displayed in hertz, where it looks like a transformation. “We moved from 2 Hz to 20 Hz” is `N_eff` from 2.03 to 6.43 — **1.15 nats**, real but a third of what the hertz figure implies. *Damage:* over-claiming, then loss of credibility when the figure is recomputed. *Detection:* recompute in nats. If the nat figure is unimpressive, the hertz figure was theatre. *Fix:* nats or bits in the argument; hertz only in the display.

FM-13 — THE PHYSICAL RESONANCE SLIP. *Signature:* “the system resonates at”, “tuned to the frequency of”, “vibrates at”, applied to an essence frequency. *Damage:* **the framework is correctly reclassified as pseudoscience and the genuine results are discarded with the error.** *Detection:* search for “resonat”, “vibrat”, “frequency of the”; every hit must concern an actual physical system or carry the disclaimer. *Fix:* CK-5, without exception and without weariness.

FM-14 — THE BORROWED EXPONENT. *Signature:* a Stevens exponent measured by one procedure, imported into a specification using a different range, instruction, or modality subtype. *Damage:* the key is wrong by an unknown amount, and because the error is in an exponent it compounds with the range. *Detection:* ask what procedure produced it; “the literature” means borrowed. *Fix:* CK-8 [Teghtsoonian, 1971].

FM-15 — THE LINEAR PROMISE. *Signature:* a commitment to “twice the brightness” or “twice the loudness”, costed as though the physical quantity doubles. *Damage:* the real requirement is `2^(1/a)` — for brightness, 8.17 times. Budgets built on the linear assumption are short by a factor of four. *Detection:* any specification whose perceptual target and physical budget are the same multiple. *Fix:* **never promise a linear improvement in a quantity the recipient perceives logarithmically.**

FM-16 — THE UNBOUNDED MOMENT. *Signature:* a claim that experience can be arbitrarily enriched by intensity, novelty or attention, without reference to the perceiver’s category count. *Damage:* effort spent past the point where `ln N` binds, with no explanation available for the vanishing returns. *Detection:* compute `F_int / ln N`; above about 0.9 the ceiling binds and geometry offers nothing. *Fix:* raise `N` and accept that the gain is logarithmic. Distinguish from the *raw* `M`, which is unbounded as `P -> 0` and whose divergence is pathology.

FM-17 — THE CENTS ILLUSION. *Signature:* a surplus estimated to two significant figures, reported as 4747.67 cents. *Damage:* six figures of apparent precision on two figures of information; readers treat the difference between 4747 and 4750 cents as meaningful, when it is the fourth decimal of `u`. *Detection:* compare significant figures in source and conversion. *Fix:* CK-13. Convert, then round to the source’s precision.

FM-18 — THE MISSING ZERO. *Signature:* division of two quantities lacking a true zero — most often ordinal ratings treated as `D` and `P`. *Damage:* the ratio is arbitrary, its logarithm is arbitrary, and every downstream conversion is arbitrary while looking rigorous. *Detection:* ask what zero would mean for each term and whether the instrument can produce it [Stevens, 1946, Michell, 1997]. *Fix:* build a ratio scale, or demote the formula to a heuristic ordering **in print**.

FM-19 — THE STATUS UPGRADE. *Signature:* a postulate stated in nats in one section, cited in octaves in the next, treated as established by the third. *Damage:* a design decision acquires the authority of a theorem. *Detection:* trace any load-bearing constant to its first appearance and check the badge there. *Fix:* CK-3. **The badge travels with the number, not with the sentence.**

18.11.3 11.3 Faults of the essence set

FM-20 — THE TUNED ORDERING. *Signature:* an essence set whose index assignment was revised after the first listening. *Damage:* ES-R2 is void; the frequencies encode the analyst's preference and nothing else, and every downstream interval is an artefact. *Detection:* ask for the date and provenance of the ordering relative to the first sonification. *Fix:* none available after the fact. Re-derive from an external source and discard the tuned version. **This is the essence-set form of specification search and it is disqualifying** [Simmons et al., 2011].

FM-21 — THE ARBITRARY ORDINAL. *Signature:* categories indexed alphabetically, by order of discovery, or by the order they appeared in a spreadsheet. *Damage:* the lattice is arbitrary; a different arbitrary ordering gives different frequencies with equal claim to correctness. **This is the scale-type objection of Section 3.5 in operational form: an index with no intrinsic magnitude behind it is ordinal at best, and a square law on an ordinal index is not a licensed operation** [Michell, 1997]. *Detection:* apply a second plausible ordering and compare; if the intervals change materially, the ordering was doing no work. *Fix:* find an intrinsic magnitude or a generative sequence, or decline to sonify.

FM-22 — THE OVERLAPPING CATEGORY. *Signature:* an entity in the domain belonging to two categories. *Damage:* ES-R1 fails; the entity has two indices, two frequencies, and a spurious interval between itself and itself. *Detection:* attempt to classify twenty randomly drawn cases; any double assignment is a hit. *Fix:* split or merge categories until the partition is clean, then recompute `N` and every index.

FM-23 — THE CLASS COLLISION READ AS MEANING. *Signature:* two categories whose tones nearly coincide, interpreted as evidence that the categories are related. *Damage:* classes 3 and 17 are 6.00 cents apart because `9/8` and `289/256` are nearly equal. **That is a fact about integers, not about any domain. Reading it as a domain finding is numerology.** *Detection:* check whether the collision is predicted by the table of Section 7.4 for any set of that size; if it is, it is structural. *Fix:* disclose all structural collisions in advance (ES-9), so that none can later be mistaken for a result.

FM-24 — THE OVERGROWN SET. *Signature:* an essence set with thirty or forty categories. *Damage:* the top of the lattice is congested with adjacent intervals under 150 cents, collisions multiply, the class count grows linearly while the audible span does not, and the ceiling gain from the extra categories is logarithmic and negligible. *Detection:* compute the adjacent-interval table; any adjacent pair under about 100 cents indicates the set has outgrown the lattice. *Fix:* aggregate to a coarser, defensible partition and rebuild the index from the same ordering source.

FM-25 — THE CONSONANCE CHASE. *Signature:* a set curated toward consonant intervals, or a subset chosen because it "sounds harmonious". *Damage:* consonance is redundancy in this lattice (Section 7.7). The most consonant six-set collapses to two pitch classes. **A beautiful-sounding essence set is very often a collapsed one, worth `ln 2` where it should be worth `ln 6`.** *Detection:* count distinct classes in the chosen subset; fewer than `ceil(size/2)` means collapse. *Fix:* ES-17. Take the odd indices and understand that the dissonance is the sound of the set actually carrying information.

FM-26 — THE SCALE PROMOTION, UNBADGED. *Signature:* intervals from an ordinal-indexed set interpreted as measured magnitudes of relation. *Damage:* an unearned upgrade from rank data to a ratio-scale claim; the formula looks like a measurement and is a model. *Detection:* ask what would change if the spacing postulate were `n^1.5` instead of `n^2`. If the answer is "every interval" and the text does not say so, the badge is missing. *Fix:* ES-13, and the sensitivity table of Section 4.3.

FM-27 — THE LOST TRANSPOSITION. *Signature:* a published audible frequency with no `j` and no band. *Damage:* the raw essence frequency cannot be recovered, so the value cannot be checked or compared with another set. *Detection:* attempt to recompute `n` from the published hertz; if `sqrt(f/k)` is not near an integer for any small power of two, `j` is missing. *Fix:* ES-10.

FM-28 — THE MIXED TRANSPOSITION. *Signature:* a set of values folded into one octave with per-index `j`, then compared by interval. *Damage:* all inter-index intervals are destroyed;

a 1.15-octave relationship reads as 0.15 octaves. *Detection:* check whether `j` varies across the compared values. *Fix:* recompute with a shared `j` and a band wide enough to hold the span.

18.12 12 Results: three systems worked end to end

Every number below is computed from the stated parameters under the stated model. **No dataset was collected. Nothing in this section is a measurement of any real institution, and the third case is a refusal rather than a result.**

18.12.1 12.1 A twelve-category deliberation room

A research institute organised into twelve houses commissions a deliberation room for its cross-house committee.

Step 1 — Declare the category set and the ordinal rule. The twelve categories, in the order the institute's own published enumeration gives them:

n	Category	Domain
1	Mathematics and Pattern	Formal structure, number, proof
2	Physics and Energy	Matter, force, measurement
3	Biology and Body	Life, organism, genetics
4	Psychology and Mind	Cognition, emotion, development
5	Consciousness and Field	Awareness, observation, qualia
6	Communication and Code	Value, exchange, accounting
7	Technology and Craft	Tools, systems, engineering
8	Spirituality and Practice	Contemplation, tradition, experience
9	Art and Expression	Aesthetics, creation, performance
10	Ecology and Earth	Ecosystem, soil, climate
11	Language and Story	Grammar, narrative, translation
12	Ethics and Governance	Law, sovereignty, distribution

Ordinal rule, as declared: the index is the category's position in that enumeration. **This is a weak ordinal and is reported as one.** The source of the partition is explicit that twelve "is not asserted as correct" and that the partition is "one idealised coding, not a uniquely privileged carving of the world". The enumeration order is not derived from any property of the categories. It is publishable, reproducible and stable — anyone with the same document gets the same integers — **but it is not intrinsic, and it is ordering source type (b) at best and arguably neither (a), (b) nor (c).** ES-3 requires this to be stated and it is stated here.

Step 2 — Permutation sensitivity (ES-4). Three plausible re-orderings:

```
swap 3 <-> 12   : both odd part 3  -> pitch-class displacement    0.00 cents
swap 5 <-> 7    : class 5 <-> 7    -> displacement  772.63 - 737.65 =  34.98 cents
swap 9 <-> 11   : class 9 <-> 11   -> displacement 1102.64 - 407.82 = 694.82 cents
```

Maximum displacement 694.82 cents — well over a 100-cent threshold. The ordering is load-bearing. Since the ordinal rule is weak, this is the honest finding and it travels with every number below: **a different but equally defensible enumeration of the twelve categories would produce a materially different tuning. The room is being built to *an* essence set, not to *the* essence set.**

Steps 3 to 5 — Frequencies, classes, folding. `f(n) = 0.483425732988414 n^2` with `k` **defined** and its hertz **postulated**; `N = 12` so `ceil(12/2) = 6` classes; band `[220, 440)` Hz with per-index `j` published per value (SA-6).

n	Category	`f(n)` (Hz)	j	folded (Hz)	nearest note (A4=440)	dev (cents)	odd part	class
1	Mathematics and Pattern	0.483426	+9	247.5140	B3	+4.0	1	PC1
2	Physics and Energy	1.933703	+7	247.5140	B3	+4.0	1	PC1
3	Biology and Body	4.350832	+6	278.4532	C#4	+7.9	3	PC3
4	Psychology and Mind	7.734812	+5	247.5140	B3	+4.0	1	PC1
5	Consciousness and Field	12.085643	+5	386.7406	G4	−23.4	5	PC5
6	Communication and Code	17.403326	+4	278.4532	C#4	+7.9	3	PC3
7	Technology and Craft	23.687861	+4	379.0058	F#4	+41.7	7	PC7
8	Spirituality and Practice	30.939247	+3	247.5140	B3	+4.0	1	PC1
9	Art and Expression	39.157484	+3	313.2599	D#4	+11.8	9	PC9
10	Ecology and Earth	48.342573	+3	386.7406	G4	−23.4	5	PC5
11	Language and Story	58.494514	+2	233.9781	A#3	+6.6	11	PC11
12	Ethics and Governance	69.613306	+2	278.4532	C#4	+7.9	3	PC3

The six pitch classes are the entire harmonic vocabulary of this room:

class	categories carrying it	`f(m) = k m^2` (Hz)	j	folded (Hz)	note	dev
PC1	Mathematics; Physics; Psychology; Spirituality	0.483426	+9	247.5140	B3	+4.0
PC3	Biology; Communication; Ethics	4.350832	+6	278.4532	C#4	+7.9
PC5	Consciousness; Ecology	12.085643	+5	386.7406	G4	−23.4
PC7	Technology	23.687861	+4	379.0058	F#4	+41.7
PC9	Art	39.157484	+3	313.2599	D#4	+11.8
PC11	Language	58.494514	+2	233.9781	A#3	+6.6

Twelve categories, six voices, and the distribution is lopsided. Four categories share PC1, three share PC3, two share PC5, and PC7, PC9 and PC11 are singletons. **This is a structural statement about the enumeration used: the categories at powers-of-two positions 1, 2, 4 and 8 are harmonically indistinguishable from one another.** It is not a statement about mathematics, physics, psychology or spirituality; **it is a statement about positions 1, 2, 4 and 8 in a list** (FM-23).

Sorted by pitch, with the intervals between adjacent classes:

#	class	folded Hz	note	step to next (cents)
1	PC11	233.9781	A#3 +7	97.4
2	PC1	247.5140	B3 +4	203.9
3	PC3	278.4532	C#4 +8	203.9
4	PC9	313.2599	D#4 +12	329.8
5	PC7	379.0058	F#4 +42	35.0
6	PC5	386.7406	G4 −23	330.0 (wrapping to 2x PC11)

PC11 has folded to a position *below* PC1, because `121/128 = 0.945` is less than one. Folding into a fixed band reorders. The class labels are still correct; the ordering is not the index ordering, and comparing folded values across systems is FM-28. Within one room this is simply the scale.

Step 6a — The room proportion. Exhaustive search over class triples and octave offsets against the published ratio heuristics gave PC7 : PC9 : PC11 against Volkmann as the best

match, Euclidean error 0.031. Anchoring the axial fundamentals at the raw essence frequencies:

```
height  Lx = c / (2 f(11)) = 343 / (2 * 58.494514) = 2.9319 m
width   Ly = c / (2 f(9))  = 343 / (2 * 39.157484) = 4.3798 m
length  Lz = c / (2 f(7))  = 343 / (2 * 23.687861) = 7.2400 m

ratio 1 : 1.4938 : 2.4694,  exactly 1 : 121/81 : 121/49
Volkmann heuristic 1 : 1.5 : 2.5     deviation -0.0062, -0.0306

V = 92.969 m^3

total surface S = 131.555 m^2
occupancy at 2.5 m^2/person = 12.7 people
```

Twelve categories; twelve-and-a-bit seats. The room is the size of its own committee, and that was not arranged — it fell out of `c/(2f)`. It is also a coincidence, and Section 13.2 says why nothing may be inferred from it.

A room 4.38 m wide and 7.24 m long is a poor fit for a round table, the aspect ratio being 1.65, and a good fit for a long oval or an elongated polygon. **At 7.24 m the far-end sightline is at the outer limit of the published social-distance zone [Hall, 1966] and past comfortable facial-expression reading.** The honest resolution is to seat the twelve within the middle 5.5 m of the length and use the end 1.7 m for circulation and the monochord. **The proportional system proposed the room; governance geometry disposes of how it is furnished.**

Step 6b — Acoustic specification (SA-8, SA-10).

```
deliberation-room target: RT60 = 0.5 to 0.6 s

RT60 = 0.5 s  ->  A = 0.161 * 92.969 / 0.5 = 29.94 m^2 sabins  ->  alpha_bar = 0.2276
RT60 = 0.6 s  ->  A = 0.161 * 92.969 / 0.6 = 24.95 m^2 sabins  ->  alpha_bar = 0.1896

Schroeder frequency at RT60 = 0.5 s:  f_s = 2000 * sqrt(0.5/92.969) = 146.7 Hz
```

Check SA-8: the folded set spans 233.98 to 386.74 Hz, entirely above `f_s = 146.7` Hz. The whole set is in the statistical region and Sabine governs for all of it. The band is coherent. Band priority: four of six classes in the 250 Hz octave band, two in the 500 Hz band, so **the treatment budget is weighted toward the 250 Hz band, where porous absorbers are losing efficiency** — meaning at least one tuned membrane or Helmholtz element, not carpet alone. Step 6d supplies it.

Step 6c — Cadence (SA-11). The committee is a cross-category body, so its cadence is taken from PC1, the class carried by the largest number of categories.

```
f(PC1) = 0.483426 Hz  ->  T = 2.068570 s
folded into [7, 14) days: p = 19, T * 2^19 = 12.5524 days

institute delta, stipulated: 0.05 per week
tau = 1/delta = 20 weeks
P = 12.5524 days = 1.7932 weeks
P/tau = 1.7932 / 20 = 0.0897
```

`P/tau = 0.090`, far below the 0.5 requirement of SA-11. Admissible without folding down. The forcing period is well inside the section's time constant, so the stock integrates smoothly rather than sawtoothing between meetings [Curzi, 2026a].

Second cadence, for a sub-committee taking PC7:

```
f(PC7) = 23.687861 Hz -> T = 0.042216 s -> p = 24 -> 8.1975 days
P/tau  = 8.1975/140 = 0.0586        (140 days = 20 weeks)
```

Beat between the two cadences: `12.5524 x 8.1975 / (12.5524 - 8.1975) = 23.63` days. The two bodies coincide about every 24 days, roughly monthly, and that coincidence is a scheduling fact produced by the periods with no coordinator required.

Rounding, disclosed (SA-12): in practice both cadences are rounded to the working calendar. 12.5524 days becomes a fixed twice-monthly slot, average 15.2 days, a departure of `1200 log2(15.2/12.5524) = 331` cents; 8.1975 days becomes a fixed weekly-plus-one slot of 8 days, a departure of 42 cents. **Those are the actual cadences. The derived values are the design intent and the rounding is declared. Anything else would be FM-5.**

Step 6d — Tuned physical elements (SA-13). *One six-string monochord*, mounted along one wall, steel strings `mu = 0.0012` kg/m at 400 N so `v = 577.35` m/s:

```
PC11  233.9781 Hz  ->  L = 1.2338 m
PC1   247.5140 Hz  ->  L = 1.1663 m
PC3   278.4532 Hz  ->  L = 1.0367 m
PC9   313.2599 Hz  ->  L = 0.9215 m
PC7   379.0058 Hz  ->  L = 0.7617 m
PC5   386.7406 Hz  ->  L = 0.7464 m
```

Overall instrument length about 1.40 m. **Each string carries an engraved label: its class, the categories it represents, its frequency to four figures, its essence index, and the sentence required by SA-15.**

One Helmholtz absorber tuned to PC11, neck radius 25 mm, neck length 100 mm, cavity 12.00 litres, resonating at 58.4945 Hz. **This sits within 0.005 Hz of the room's `(1,0,0)` axial mode at 58.494514 Hz, so it is a working modal trap for the height axis as well as a tuned element. It is the cheapest single item in the specification and the most acoustically useful.**

Beat report (SA-14): PC7 and PC5 differ by 7.7348 Hz and PC11 and PC1 by 13.5359 Hz. **Both are in the roughness zone. If all six strings are struck together the result flutters at about 8 Hz and again at about 13 Hz.** This is disclosed on the instrument's label. Occupants wanting a clean chord strike PC1, PC3 and PC9 — the `1 : 9/8 : 81/64` Pythagorean triad, all within 8 cents of twelve-tone equal temperament.

Step 7 — The disclosure notice (SA-1, SA-2, SA-3, SA-15). Posted at the entrance, reproduced here in full because it is part of the specification rather than an appendix to it:

```
THIS ROOM IS PROPORTIONALLY TUNED. NOTHING IN IT IS HIDDEN.

Dimensions:  2.9319 m high, 4.3798 m wide, 7.2400 m long.
These were chosen so the room's three axial acoustic modes fall at
58.4945 Hz, 39.1575 Hz and 23.6879 Hz. The ratio is exactly 1 : 121/81 : 121/49.

A six-string monochord on the north wall is tuned to
233.98, 247.51, 278.45, 313.26, 379.01 and 386.74 Hz.
It sounds only when someone plays it. Anyone may play it. Anyone may stop.
Struck together, strings 5 and 6 beat at about 8 Hz and strings 1 and 2 at
about 13 Hz. This is expected.

A 12-litre Helmholtz absorber behind the north panel is tuned to 58.49 Hz.
It is passive. It makes no sound of its own.

There is no loudspeaker in this room and no continuous tone of any kind.
There is no masked, hidden, subliminal, or below-threshold content of any kind
in this room. If you cannot hear it, it is not here.
```

```
Derivation: the twelve houses of the institute, indexed by their position in the
published enumeration, through f(n) = k n^2 with k = 0.483425732988414 Hz.
Twelve categories yield six distinct pitch classes.
The full derivation is in the room file and anyone may have a copy.

These are ESSENCE frequencies, not physical resonances. No claim is made that
any material, room, institution or person physically resonates at these values.
The room's acoustic modes are ordinary acoustics: a room 4.3798 m wide has a
mode at 39.16 Hz because sound travels at 343 m/s, and for no other reason.

The indexing of the twelve categories is not intrinsic. A different but equally
defensible ordering would give a different tuning. This is one essence set,
not the essence set.
```

Step 8 — What would falsify a claim about this room (SA-16). No claim is made that the tuning improves anything. Should one be made, the protocol is fixed in advance: measure turn-taking equality [Woolley et al., 2010] in the old room and the new one, with the minimal estimation model `Y_{t+1} = a Y_t + b F(U_t) − C_t + eps` fitted on the first eight committee cycles and frozen, reported on cycles 9 to 12 against all four required baselines — persistence, direct input, matched autoregressive, and **the shuffled-input control** [Curzi, 2026i].

The prediction that would matter, and the one hardest to get: turn-taking equality improves in the new room *and* the improvement survives the shuffled-input control. If it does not survive, the honest conclusion is that the room is a good room because its `RT60` is 0.5 s and its sightlines work, and that the essence tuning contributed a defensible way of choosing among many acceptable proportions and nothing further. **That would be a perfectly good result and this paper would report it as one** — and it is, in fact, what H2 predicts. Note also that such a test is unblindable by construction (Section 3.4), because the room's disclosure notice names the tuning.

18.12.2 12.2 A metropolitan transit review board, in four registers

A municipal transit authority convenes a review board on a proposed bus-priority corridor. The board has **`N = 8` declared professional categories**: traffic engineering, urban planning, transit operations, accessibility, municipal finance, local business representation, environmental assessment, and legal and regulatory.

Non-parallelism is stipulated at `u = 0.42` by a disagreement-rate procedure across 40 recorded recommendations. **This is an in-example figure produced by a stated procedure in a constructed case, not a measurement of any real board.** Storage parameters, likewise stipulated: `eta = 0.35`, `delta = 0.08` per quarter, `Q = 4.0`, `C = 0.30`.

Step 1 — Effective count and surplus.

```
N_eff = 1 + (N − 1) u = 1 + 7 ∗ 0.42 = 3.94
F     = ln 3.94       = 1.371181 nats
```

Eight declared categories are worth 3.94 genuinely different ones. More than half the board's declared variety is redundant, which is the ordinary finding and not a scandal. **`N_eff = 3.94` here is the affine effective count `1 + (N−1)u`, not a Hill number** (Section 4.6); a Hill number of order two on the same roster would in general return a different value and the two must not be compared.

Step 2 — The four registers.

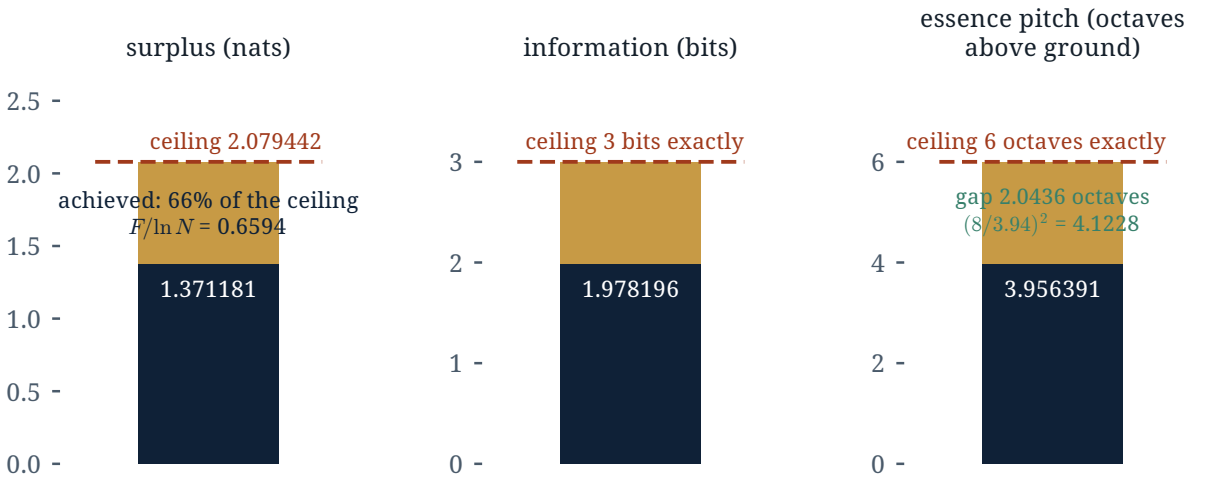

Figure 18.5: **One shortfall, said three ways: 66 per cent of the ceiling in nats and in bits is two full octaves below it in essence pitch.** With `N = 8` and `u = 0.42` the affine effective count is 3.94 — **not a Hill number** — giving 1.371181 nats, 1.978196 bits and 3.956391 octaves against a ceiling of `ln 8` = 2.079442 nats, 3 bits exactly and 6 octaves exactly. The pitch register amplifies what the surplus register compresses: `(8/3.94)^2` = 4.1228. Three panels because three units; never a dual axis. Model output from the stipulated parameters of Section 12.2, generated by `figs/src/CCP-018_fig05.py`.

register	value	reading
surplus	at least 1.371181 nats	lower bound on this board's per-session information
information	at least 1.978196 bits	just under two bits: the board resolves fewer than four states
essence pitch	3.956391 octaves above ground	
cents	4747.7 cents	reported as 4750 per CK-13, since `u` is stated to two figures
essence frequency	`f = k N_eff^2 = 7.504508` Hz	**essence frequency, not a physical resonance**
audible placement	120.07 Hz, band [110, 220) Hz, **j = 4**	

The bit figure is the one to put in front of the board. Two bits means this body, meeting as it currently meets, distinguishes fewer than four genuinely different states of the world per session.

Step 3 — The ceiling and the gap.

```
ceiling   ln N = ln 8 = 2.079442 nats = 3.000000 bits exactly = 6 octaves exactly
achieved  F/ln N = 1.371181 / 2.079442 = 0.6594
gap       ln N − F = 0.708261 nats = 2.0436 octaves = 2452 cents
```

The board is at **66 per cent of its own ceiling.** The ceiling frequency is `k (8)^2 = 30.939247` Hz, and the ratio of ceiling to achieved frequency is `(8/3.94)^2 = 4.1228` — **the board is two full octaves below its own maximum**, the same fact as "34 per cent of the ceiling unused", said in the register that makes it audible.

Step 4 — The storage arithmetic [Curzi, 2026a].

```
headroom      h  = eta*ln N - delta*Q - C
                 = 0.35 * 2.079442 - 0.08 * 4.0 - 0.30
                 = 0.727805 - 0.320000 - 0.300000
                 = +0.107805        h > 0: growth is available in principle

actual step      = eta*F - delta*Q - C
                 = 0.35 * 1.371181 - 0.320000 - 0.300000
                 = 0.479913 - 0.620000
                 = -0.140087        Q is DECLINING
```

Here is the diagnostic the conversion keys make visible: positive headroom, negative actual step. The ceiling permits growth; the geometry does not deliver it. In this constructed case the authority loses adopted structure at 0.14 nat-equivalents per quarter while believing itself functional, because nothing in its minutes records a quantity that would show the decline.

Step 5 — What is required. A non-decreasing step requires

```
S >= (delta*Q + C) / eta = (0.320 + 0.300) / 0.35 = 1.771429 nats
Feasible?  1.771429 <= ln 8 = 2.079442      YES, with 0.308 nats to spare
```

That feasibility test is the admissibility ceiling in its general form, and it is worth naming because of what it does not contain. The threshold rate a system must sustain is `c/eta` and it is admissible if and only if `c/eta <= ln N`; the same quantity re-expressed as a minimum sustaining frequency, `f_min = k e^(2 c/eta)`, **contains neither `delta` nor `N`** — retention loss sets the rate of arrival but not the threshold, and the category count enters only through the ceiling [Curzi, 2026]. Here `c/eta = 0.857143` in the cost-only reading and `1.771429` including the decay charge, both below `ln 8`, so the board is admissible on both readings.

Solving back for the geometry:

```
N_eff required = e^1.771429 = 5.879246
u    required  = (5.879246 - 1) / 7 = 0.697035
```

`u` must rise from 0.42 to 0.70 — a climb of `2 (1.771429 - 1.371181)/ln 2 = 1.154871` octaves, or 1385.85 cents, reported as 1390 per CK-13, with the essence frequency rising from 7.504508 Hz to 16.709870 Hz, a factor of 2.2266.

Step 6 — Specification and prediction. The binding constraint is `u`, not `N`. Adding a ninth category raises the ceiling from `ln 8 = 2.0794` to `ln 9 = 2.1972` nats — **0.1178 nats, one third of a bit, for the cost of an entire additional seat** — while doing nothing about the redundancy among the eight already present. **That is the same lever, computed and declined, that the corpus's intervention procedure reaches by a different route**: a ceiling gain of `eta(ln 6 - ln 5) = +0.1914` nats set against five added communication paths costing `+0.0714`, a 34 per cent haircut on the headline benefit [Curzi, 2026j]. The remedies that act on `u` rather than `N` are rotation across lineages, a standing adversarial role, a member from an unrelated trade, and an explicit prohibition on the pre-meeting alignment call that drives `u` toward zero before the session begins. **What that costs is priced by the marginal identity: the law values the two sources of non-parallelism identically, `df/du_cross = df/du_div = (N-1)/(1 + (N-1)u)`, while their productivity in the design variables differs sharply** [Curzi, 2026d].

Predicted outcome, stated so it can fail: if `u` rises to 0.70 or above and `eta`, `delta`, `C` hold, the quarterly step turns non-negative within two quarters and the stock stabilises near `Q_inf = (eta F - C)/delta = (0.35 x 1.771429 - 0.300)/0.08 = 4.000000` — **exactly its current level, because `S` was solved to make the step zero. The intervention stops the decline; it does not build.** Building requires raising `eta` or cutting `C`, which is a separate decision.

Falsification: if `u` measures above 0.70 for two consecutive quarters and the stock still declines, then either `eta` is below 0.35, or `C` is above 0.30, or the linear storage model is wrong for

this body. All three are checkable; the third is the one that would matter. **And a warning that outranks all three: the endogenous social effect in a body whose members both influence and constitute its output is not identified from observation** [Manski, 1993], so a fit that recovers `eta` has not measured it (Section 3.4).

Step 7 — What the sonification is for. If this board's trajectory is sonified, both values take **the same** transposition, `j = 4`: 120.07 Hz now, 267.36 Hz at the target, band `[110, 440)` Hz. The tone rises by 1.1549 octaves and the change is immediately audible where a table of nats is not.

The shared `j` is not a detail. Placing each value in a narrow band with its own `j` — 120.07 Hz at `j = 4` and 133.68 Hz at `j = 3` — preserves each pitch class but destroys the interval between them, collapsing 1.15 octaves to 0.15 (FM-28). Octave transposition preserves pitch class exactly and preserves intervals only when the transposition is shared. **Publish the band and the `j`, and use one `j` across any set of values whose intervals are the point** (CK-6).

Sonification is a display, and displays are for perception. It is not evidence. Nothing about the transit authority vibrates. The tone is an essence frequency computed from a stipulated geometry by a postulated square law with a chosen reference constant, and every one of those four qualifications belongs in the caption. The board should hear it, understand exactly what it is, and be free to ignore it.

18.12.3 12.3 A proxemic-zone lattice, and a refusal

The admissible case. Hall's *The Hidden Dimension* divides interpersonal distance into four zones — intimate, personal, social, public — and subdivides each into a close and a far phase, giving **eight categories ordered by physical distance** [Hall, 1966]. Checking the requirements of Section 8.1:

- **ES-R1 (exhaustive, disjoint):** the zones tile the distance axis from zero upward without gaps or overlaps. **PASS**, subject to the boundary being "interpersonal distance in a face-to-face encounter", which is stated.
- **ES-R2 (ordering from outside):** the ordering is by **measured distance**, an intrinsic physical magnitude, published in 1966 with no relation to any sonification. This is ordering source type (a), the strongest. **PASS.**
- **ES-R3 (reproducible assignment):** given a measured separation, the zone assignment is mechanical. **PASS.** Hall's zone *boundaries* are nominal and culturally variable — Hall said so — but the *ordering* is not in question, and only the ordering is used.

Direction: index 1 is the ground, assigned to the nearest zone. `N = 8`; class count `ceil(8/2) = 4`; ceiling `ln 8 = 2.079442` nats = **3.000000 bits exactly** = 6 octaves exactly.

n	category	f = k n^2 Hz	class m	class ratio	class cents	j	f*2^j Hz
1	intimate close	0.483426	1	1/1	0.000	8	123.7570
2	intimate far	1.933703	1	1/1	0.000	6	123.7570
3	personal close	4.350832	3	9/8	203.910	5	139.2266
4	personal far	7.734812	1	1/1	0.000	4	123.7570
5	social close	12.085643	5	25/16	772.627	4	193.3703
6	social far	17.403326	3	9/8	203.910	3	139.2266
7	public close	23.687861	7	49/32	737.652	3	189.5029
8	public far	30.939247	1	1/1	0.000	2	123.7570

Band `[110, 220)` Hz, per-index `j`, rule: the unique integer `j` placing `f 2^j` in the band. **Every value in the last column is an essence frequency, not a physical resonance. No claim is made that any distance, person, or encounter vibrates at any of these values.**

Four of the eight zones share one pitch class. Indices 1, 2, 4 and 8 all have odd part 1 — intimate close, intimate far, personal far, and public far are octave-identical in this lattice, all landing on **123.7570 Hz** in the chosen band. The distinct classes are `{1, 3, 5, 7}`, exactly the

four predicted by Theorem 7.1 and exactly the odd indices predicted as class representatives by Section 7.7.

This is a genuine structural finding about the lattice and it is emphatically not a finding about proxemics. Nothing about intimate distance and public distance is claimed to be similar. **The collapse is caused by the indices being powers of two, which is caused by where those four zones happened to fall in Hall's ordering. Had Hall subdivided into three phases per zone rather than two, giving twelve categories, the class structure would be entirely different — and Hall's choice was about ethnography, not about arithmetic.** That sentence is the whole lesson: **the lattice's structure is a fact about the index, the index's meaning is a fact about the domain, and the two must never be run together.**

Collision check (ES-9). The four realised classes sit at 0.000, 203.910, 737.652 and 772.627 cents.

```
class 1 (   0.000)  ->  class 3 ( 203.910)      203.910 cents
class 3 ( 203.910)  ->  class 7 ( 737.652)      533.742 cents
class 7 ( 737.652)  ->  class 5 ( 772.627)       34.976 cents  <-- COLLISION, disclosed
class 5 ( 772.627)  ->  class 1 (1200.000)      427.373 cents
```

Classes 7 and 5 — public close and social close — are 34.976 cents apart and will beat rather than form an interval if sounded together. Disclosed in advance, precisely so that nobody can later report it as a finding about the relationship between social and public distance. **It is `49/32` against `25/16`, and it is arithmetic.**

The full pairwise interval table, all 28 pairs:

pair	interval (cents)	essence ratio	HD_ess	pair	interval	ratio	HD_ess
1–2	2400.00	4/1	2.0000	3–5	1768.72	25/9	7.8138
1–3	3803.91	9/1	3.1699	3–6	2400.00	36/9	2.0000
1–4	4800.00	16/1	4.0000	3–7	2933.74	49/9	8.7846
1–5	5572.63	25/1	4.6439	3–8	3396.09	64/9	9.1699
1–6	6203.91	36/1	5.1699	4–5	772.63	25/16	8.6439
1–7	6737.65	49/1	5.6147	4–6	1403.91	36/16	5.1699
1–8	7200.00	64/1	6.0000	4–7	1937.65	49/16	9.6147
2–3	1403.91	9/4	5.1699	4–8	2400.00	64/16	2.0000
2–4	2400.00	16/4	2.0000	5–6	631.28	36/25	9.8138
2–5	3172.63	25/4	6.6439	5–7	1165.02	49/25	10.2586
2–6	3803.91	36/4	3.1699	5–8	1627.37	64/25	10.6439
2–7	4337.65	49/4	7.6147	6–7	533.74	49/36	10.7846
2–8	4800.00	64/4	4.0000	6–8	996.09	64/36	7.1699
3–4	996.09	16/9	7.1699	7–8	462.35	64/49	11.6147

The four most consonant nontrivial pairs are 1-2, 2-4, 3-6 and 4-8, all at `HD_ess = 2.0000` — and all four are index ratios of `2:1`, hence pitch-class collisions. **The most consonant pairs are exactly the redundant pairs, as Section 7.7 requires. The lattice is behaving.**

The refusal. Consider building an essence set from this framework's own six storage-law parameters — `delta`, `eta`, `N`, `u`, `C`, `Q`. It fails at Step 2 and it fails hard.

- **ES-R1:** the six are not categories of a common domain at all. `N` is a count, `u` is a geometric quantity in `[0,1]`, `Q` is a stock, `C` is a flow. They do not partition anything. **FAIL.**
- **ES-R2:** no intrinsic magnitude orders them. They could be ordered by the sequence in which the storage law is written, by alphabet, or by importance — three different orderings with no external arbiter, each giving a completely different lattice. **FAIL.**
- **ES-R3:** two analysts would not agree. **FAIL.**

Therefore the six parameters get no frequencies. They can be tabulated, reasoned about, measured, and used — everything the framework actually does with them — but they cannot

be sonified, because there is no defensible ordinal and the law would convert an arbitrary choice into a confident-looking set of hertz values.

That is the point of the requirements, and it is why they were stated before the arithmetic rather than after. Most category sets do not qualify. The instrument is narrow, and a narrow instrument used honestly is worth more than a wide one used loosely.

18.13 13 Discussion

18.13.1 13.1 What follows

A category scheme can generate a design target, and the derivation can be published. That is the whole positive claim and it is a real one. It replaces "pick a proportion that looks right" with "pick the proportion your own category scheme generates, and be able to state where it came from". The output is exact — `1 : 121/81 : 121/49`, a ratio of squares of integers, checkable by anyone — and it is therefore arguable in a way that a designer's taste is not. **Reproducibility is the contribution; efficacy is not claimed.**

The size of that contribution is bounded above and cannot be stated precisely, and the corpus has a template for reporting exactly that shape of claim. In a structural case elsewhere in this corpus the honest gain from an intervention is shown to lie strictly between zero and a computable ceiling — an off-ledger-to-represented ratio of `36.15/63.85 = 56.62` per cent, a base multiple of 1.5662 times — **with the realised gain bounded by that ceiling and not statable precisely** [Curzi, 2026]. The same form applies here. The upper bound on what essence tuning can contribute to a room is the spread of acceptable proportions it selects within, which the heuristic table of Section 9.3 makes explicit; the lower bound is zero; and no number between them is available, because no room was built and no comparison was run.

The four registers are one register up to a change of base, and the constants are exact. That is useful in a specific and limited way: a body's surplus stated as "1.37 nats" means nothing to most readers, "just under two bits" means something to an engineer, and a rising tone means something to everyone in the room. **The pitch register is a display register.** Its amplification of small surplus differences by a factor of `e^2` per nat is exactly what makes it good for display and bad for argument.

The forced ceiling is the sharpest consequence. `0 <= M <= ln N` says that the richest moment available to a perceiver is bounded by the logarithm of the number of kinds of thing that perceiver can distinguish, and the bound is logarithmic, so it is nearly immovable: doubling `N` buys exactly one bit wherever one starts. **That is a ceiling on the perceiver rather than on the world**, and it recovers the law of requisite variety inside first-person experience [Ashby, 1956]. It follows from the range result plus a chosen normalisation, and both links must always be published.

And the class-count theorem is a hard constraint on any application. Twelve categories give six voices. Twenty-four give twelve. The half that vanishes is not an artefact of the band or of the instrument; it is the odd-part rule, and no design decision recovers it. **Design to `ceil(N/2)`.**

18.13.2 13.2 What does not follow

Nothing about efficacy. The room described in Section 12.1 is not evidence that essence tuning does anything, and the coincidence that a twelve-category set generated a room seating twelve-and-a-bit people is a coincidence. It arose from `c/(2f)` with a particular `c` and a particular `k`, and one arithmetic step in a different direction would have produced an unbuildable room, as FM-3 shows for PC11 : PC5 : PC3. **Coincidences of this kind are the standard raw material of numerological reasoning and this paper declines to use them as evidence.** The literature on golden-ratio claims is instructive precisely because it documents how easily an

impressive-looking coincidence survives a hundred years of repetition without ever having been checked [Markowsky, 1992, Fischler, 1981].

Nothing about the domain from a collision. Classes 3 and 17 are 6.00 cents apart because `9/8` and `289/256` are nearly equal. Classes 5 and 7 are 34.976 cents apart because `49/32` and `25/16` are nearly equal. Indices 1, 2, 4 and 8 collapse because they are powers of two. **All three are facts about integers. Reading any of them as a finding about proxemics, or disciplines, or anything else, is FM-23.**

Nothing physical from an essence frequency. The room resonates; the category does not. That distinction is repeated in this paper more often than is elegant, and the repetition is deliberate: **it is the single sentence whose loss would reclassify the whole framework correctly as pseudoscience.**

Nothing about the ordering from the result. The instrument cannot check its own input. If the ordering was chosen because it sounded good, every interval is an artefact and no downstream computation detects it. The only defence is procedural — declare the ordering first, from a source outside the music — and it is the same defence preregistration provides in an experimental setting [Nosek et al., 2018, Simmons et al., 2011].

No thermodynamic or physical conclusion from any logarithm here. The entropy-like object in this paper is **Shannon entropy**, a dimensionless information measure quoted in nats or bits [Shannon, 1948], not thermodynamic entropy, which carries energy per temperature. They are different objects and nothing identifies the framework's surplus with either.

18.13.3 13.3 Relation to the surrounding literature

The consonance literature does not support the indices used here, and this paper says so. Tenney's harmonic distance [Tenney, 2015] and Euler's gradus suavitatis [Euler, 1739] are **defined functions on rationals**, chosen for their arithmetic properties. What is actually measured about consonance points elsewhere: roughness is a function of critical bandwidth [Plomp and Levelt, 1965], sensory and harmonic consonance are distinct phenomena [Terhardt, 1974], dyad consonance has been measured directly [Kameoka and Kuriyagawa, 1969], and — most damagingly for any argument resting on `9/8` — **consonance depends on the spectrum of the sound, so no ratio is a universal constant** [Sethares, 2005]. This paper uses the defined indices for their structural results (Theorem 7.2 and the consonance-redundancy identity) and makes no claim that they predict what a listener hears. The one perceptual claim it does make, H3, rests on roughness within a critical band and is cited to the measured literature.

Octave equivalence is grounded for pitch and only for pitch. It is formalised as the helical structure of pitch [Shepard, 1982] and measured as a genuine singularity in frequency-ratio discrimination [Demany et al., 2013] — and it is also weaker and more training-dependent than usually assumed [Hoeschele et al., 2012], and less cross-culturally general than scale-universality claims suppose [Burns, 1999]. **Carrying it over to a quantity that is not a pitch has no support at all**, and the framework's own bibliographic audit records that. The folding operation is well defined; its interpretation is not supported and is badged category 3 throughout.

The room acoustics are standard and are used as such. Sabine's relation [Sabine, 1922], the Schroeder boundary [Schroeder, 1965], the modal formula and the room-ratio heuristics [Beranek, 2004, Rossing et al., 2002] are established engineering, and nothing in this paper modifies or extends them. **If the essence law were withdrawn entirely, every acoustic number in Sections 9.2, 9.3 and 9.5 would stand unchanged.** That is the cleanest available statement of how much the framework contributes: the choice of which numbers to compute, and nothing else.

The psychophysics is cited to the sources and to their critics. Weber's fraction [Weber, 1834], Fechner's integration [Fechner, 1860] and Stevens' power law [Stevens, 1957] are the three pillars of the sensation register; the regression effect [Poulton, 1968, 1979], range effects [Teghtsoonian, 1971] and the dispute over whether magnitude estimation yields a ratio scale

at all [Luce, 2002, Narens, 1996] are cited alongside them. **The exponents are constants of a procedure, not constants of nature.**

18.14 14 Verification

The results of this paper compound from nine postulates. Each is atomic, checkable on its own, and carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped.** The reader who wants a single one-minute audit should perform the three checks of Section 14.4.

The status vocabulary is the corpus's own and is applied here without relaxation. The framework's reference apparatus sorts its content into a three-drawer honesty classification — **four items of established mathematics, seven of established psychology, and exactly three declared postulates, with every protocol stated to run on the first two and to steer by the third** [Curzi, 2026]. This paper adds two postulates to that ledger, P5 and P6 below, and both are drawn on by every dimensioned result it reports.

18.14.1 14.1 Dimensional audit

This is the load-bearing section of the paper. The whole argument converts between quantities that are dimensionless — nats, bits, octaves, cents — and a quantity that is not: frequency, `[T^-1]`, in hertz. **The audit's job is to state exactly where a dimensionless index acquires hertz, and by what authority.**

Symbol	Dimension	Unit	Status
`n` essence index	`[1]`	none	**DEFINED** dimensionless ordinal. Not a magnitude; see Section 3.5
`k`	`[T^-1]` **as used**	Hz	**The number is DEFINED** and exact; **the hertz is POSTULATED**
`f(n) = k n^2`	`[T^-1]`	Hz	**DERIVED**, and inherits `k`'s postulated hertz entirely
`u`	`[1]`	none	**DEFINED** dimensionless: `u = 1 - (x.y)^2`, unit vectors
`N`, `N_eff`	`[1]`	none	**DEFINED** dimensionless counts; `N_eff` is the affine one
`F`, `S`	`[1]`	nats	**DERIVED** dimensionless: a logarithm of a count
bits, octaves, cents	`[1]`	none	**DERIVED** dimensionless log-ratio measures
`1/ln2`, `2/ln2`, `2400/ln2`	`[1]`	none	**DEFINED**, exact, dimensionless
`c` speed of sound	`[L T^-1]`	m/s	**MEASURED**: 343 m/s at 20 C in dry air

Symbol	Dimension	Unit	Status
L, Lx, Ly, Lz	[L]	m	**DERIVED** from c/(2f)
V	[L^3]	m3	**DERIVED**
S_surf	[L^2]	m2	**DERIVED**
A absorption	[L^2]	m2 sabins	**DESIGN VARIABLE**; a sabin is dimensionally an area
RT60	[T]	s	**DERIVED**; see the balance note below
f_s Schroeder	[T^-1]	Hz	**DERIVED**; see the balance note below
T = 1/f period	[T]	s	**DERIVED**
P forcing period	[T]	days or weeks	**DESIGN VARIABLE**
delta	[1]	per period	**STIPULATED** dimensionless fraction per step
tau = 1/delta	[T]	periods	**DERIVED**
eta	[Q] per nat per step	stock units per nat per period	**STIPULATED**; not dimensionless
Q, C	[Q], [Q] per step	proxy units	**STIPULATED**; no natural unit exists
dF	[1]	nats	**DERIVED**
cycles required	[1]	count	**DERIVED**, 1/(8 pi dF)
a Stevens exponent	[1]	none	**MEASURED**, procedure-bound
c Weber fraction	[1]	none	**PARAMETRIC** here; no value asserted
HD, G	[1]	none	**DEFINED** functions on rationals; not measurements

Does f(n) = k n^2 balance? Only if k carries [T^-1]. The index n is dimensionless, so n^2 is dimensionless, so **every hertz in this paper enters through k and through nothing else.** The number (9/8)^2/phi^2 = 0.483425732988414 is a pure ratio of pure numbers and has no dimension whatever. **Writing it as 0.483425732988414 Hz is a separate act, it has no external precedent of any kind, and it is a POSTULATE** (P6 below). Every frequency, room dimension, cavity volume and string length in this paper stands on that one step. **If P6 is withdrawn, f(n) becomes a dimensionless index, L = c/(2f) becomes dimensionally ill-formed, and the room does not exist.** The intervals, the pitch classes, the class-count theorem and the collision structure all survive, because k cancels from every one of them.

Does L = c/(2f) balance? [L T^-1]/[T^-1] = [L]. Yes, given P6.

Does RT60 = 0.161 V/A balance? [L^3]/[L^2] = [L], so **the constant 0.161 is not dimensionless: it carries [T L^-1], seconds per metre.** It is 24 ln 10 / c = 55.262/343 = 0.16111 s/m, and it is therefore temperature-dependent through c. **A paper that quotes 0.161 as though it were a pure number has not audited its own equation**; the value is specific to c = 343 m/s.

Does f_s = 2000 sqrt(RT60/V) balance? sqrt([T]/[L^3]) = [T^{1/2}][L^{-3/2}], so for f_s to be [T^-1] **the 2000 must carry [T^{-1/2}][L^{3/2}]**, that is m^(3/2) s^(-1/2). It is an SI-specific constant and is not dimensionless either [Schroeder, 1965].

Are the conversion factors dimensionless? Yes, all of them, and that is the point. 1/ln 2, 2/ln 2 and 2400/ln 2 are ratios of logarithms of pure numbers. **The conversion chain nats to bits to octaves to cents never leaves the dimensionless world. The chain acquires hertz exactly**

once, at `k`, and never again.

Where the framework is silent. The essence index has **no operational unit and no magnitude**; it is an ordinal position and the audit records it as one rather than inventing a unit for it. Stored order `Q` has no natural unit either: it is counted in whatever a declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. **Comfort itself, the underlying construct of the corpus, has no operational unit at all** and is treated as a dimensionless magnitude by stipulation, not by measurement.

18.14.2 14.2 The postulates

P1 — `phi^2 = phi + 1`. *Status:* **CITED** — the defining property of the division in extreme and mean ratio [Euclid, 1956], with the general identity `phi^m = F(m) phi + F(m−1)` in Vajda [1989].

P2 — `(9/8)^2 = 1.265625`. *Status:* **ARITHMETIC.** `81/64 = 1.265625` exactly.

P3 — `log_b(x) = ln(x)/ln(b)`. *Status:* **CITED** — the change-of-base identity, and the reason information measures in different bases differ by a constant [Cover and Thomas, 2006, Shannon, 1948].

P4 — A cent is one twelve-hundredth of an octave. *Status:* **DEFINITION**, introduced by Ellis and universal since [von Helmholtz, 1885]. It carries no empirical weight.

P5 — `f(n) = k n^2`, with `n` the ordinal index. *Status:* **POSTULATED** — asserted by this framework, no external support, and not currently falsifiable (H6). The exponent is **defined by the model, not estimated** [Clauset et al., 2009].

P6 — `k` carries units of hertz. *Status:* **POSTULATED** — and this is a separate and much stronger claim than computing `k`. No physical, psychoacoustic or musicological literature combines a tuning ratio with an inverse square of the golden section to obtain a ground frequency [Markowsky, 1992]. **Every dimensioned result in this paper consumes P6 and no dimensionless result does.**

P7 — For a rigid rectangular enclosure the axial mode along `L` is `c/(2L)`, and reverberation obeys `RT60 = 24 ln 10 V/(cA)`. *Status:* **CITED** — Rossing et al. [2002], Sabine [1922], with the Schroeder boundary in Schroeder [1965]. This is real acoustics with a stated domain of validity.

P8 — `0 <= F <= ln N`. *Status:* **CITED** — the range result of the surplus functional [Curzi, 2026], following from `f(u) = ln(1 + (N−1)u)` on `u` in `[0,1]`.

P9 — The storage law is first order with time constant `tau = 1/delta`, and `delta = 0` is a pathology rather than an ideal. *Status:* **CITED** [Curzi, 2026a]. Consumed only by SA-11 and Section 9.4.

Two postulates that could be dropped were dropped. The normalisation of the moment onto `[0, ln N]` is consumed only by R4 and is named there rather than carried through the whole chain. The identification of the effective count with a cross-disciplinary index is consumed only by Section 4.6 and is verified there arithmetically rather than assumed.

18.14.3 14.3 The compounding chain

Read the status column. R1a, R1c, R1d, R3, R6a, R6b, CC-R1, R5a, R5b and L9 are **ARITHMETIC** and can be redone by hand. R2a to R2d and CRa are arithmetic **on top of cited physics**. R4 rests on a **cited range result plus a chosen normalisation**, and both links are named every time it is quoted. **R1b, and therefore every dimensioned result in the paper — the room, the cadence, the cavity volumes, the string lengths, the audible placements — consumes P6, which is POSTULATED with no external support of any kind.**

This chain is not a proof that anything in the world behaves this way, and the paper says so here rather than leaving a reader to notice. A chain whose dimensionless part is arithmetic and whose dimensioned part rests on one unsupported postulate delivers exact mathematics and delivers nothing whatever about categories, institutions or minds. **What it does deliver is a target-selection procedure whose every step is auditable.**

18.14.4 14.4 The three checks a reviewer can do in one minute

Check one — the constant. `(9/8)^2 = 81/64 = 1.265625.` `phi = (1 + sqrt 5)/2 = 1.618033988749895`, so `phi^2 = 2.618033988749895`, which is `phi + 1` as required. Dividing, `1.265625/2.618033988749895 = 0.483425732988414`. **Three divisions, no model.**

Check two — the factor of two. `f(2n)/f(n) = (2n)^2/n^2 = 4`, and `log2 4 = 2`. **One line, and it is the whole of the claim that one bit is two octaves.** Confirm at `N_eff = 3`: `f(6)/f(3) = 36/9 = 4`. At `N_eff = 12`: `f(24)/f(12) = 576/144 = 4`.

Check three — the room. `k (7)^2 = 0.483425732988414 x 49 = 23.687861` Hz; `343/(2 x 23.687861) = 7.239995` m. Repeat at `n = 9` and `n = 11` for 4.379750 m and 2.931899 m. Multiply: `V = 92.9687` m3. Then `0.161 x 92.9687/0.5 = 29.936` m2 sabins and `2000 sqrt(0.5/92.9687) = 146.67` Hz. **Five multiplications and two square roots, and the entire built result of the paper is established or refuted.**

18.14.5 14.5 Recomputation report: four printed values that did not reproduce

HC-4 requires every figure to be recomputed rather than transcribed. Four printed values in the source material did not reproduce, and they are listed here rather than corrected silently.

(i) `k` at seventeen significant figures. The exact value is `0.48342573298841433274...`, so the correctly rounded seventeen-figure value is **0.48342573298841433**. The corpus has printed **0.48342573298841435**, which is the IEEE-754 double-precision representation of the quotient rather than the correctly rounded exact value. **The fifteen- and sixteen-figure roundings, 0.483425732988414 and 0.4834257329884143, are both correct**, so the two precisions circulating in the corpus are not in conflict — they are the same number quoted at different precisions. Only the seventeenth figure is wrong, and it is wrong by one unit in the last place. This paper quotes fifteen figures.

(ii) `2400/ln 2`. The exact value is `3462.46809813351217766...`, so the correctly rounded seventeen-figure value is **3462.4680981335122**. The corpus has printed **3462.4680981335123**, again the double-precision representation. `1/ln 2` and `2/ln 2` are correct as printed at seventeen figures. This paper prints 3462.4680981335122.

(iii) The cadence-rounding departure in FM-5. Rounding a 9.9179-day derived cadence to 14 days is a ratio of 1.4116, and `1200 log2(1.4116) = 596.78` cents. **The source prints 590 cents.** No calculation returning 590 could be reconstructed; the corrected value is 596.8 cents and appears in FM-5 above.

(iv) The mode count below 150 Hz. The source prints **48 modes below 150 Hz** for the worked room. Enumerating `f(p,q,r)` over `p,q,r` from 0 to 4 returns 48; over 0 to 5 returns 53; and the count converges at **55**, which is the correct figure and is what Section 9.3 prints. **The published 48 is a truncation artefact of the source's own minimum recommended truncation order**, and SA-9 has been amended to require the truncation order to be stated.

Three smaller discrepancies are recorded for completeness. The steady state in the transit board case is printed in the source as `Q_inf = 3.9999`; **the exact value is 4.000000**, necessarily, because the required surplus was solved to make the quarterly step zero, so `eta S = delta Q + C` identically. The source describes the folded PC11 value as four octaves above `f(11)`; `233.9781/58.494514 = 4.000`, which is **two** octaves. And the source attributes the PC11 coincidence to indices 11 and 44 sharing an odd part; the index actually at work is 22, since `233.978055 = f(22)`, though the statement about 44 is independently true.

A fourth claim could not be reconstructed at all. The source states that the rendering-rate collapse at the `N = 16` to `N = 17` boundary is "a factor of exactly 8", and in the preceding parenthesis states it as 5.828. **Recomputation gives 5.8284 by both available routes** — the cents ratio `34.976/6.001` and the cycle-count ratio `22.957/3.939`, which are the same number `ln(50/49)/ln(289/288)` — and no calculation returning 8 could be found. Section 7.4 prints 5.828 and flags the inconsistency.

18.14.6 14.6 Limits, asymptotics, and the model's valid domain

`n -> 0`. `f = 0`. There is no zeroth essence and the law says so by returning silence. **`n = 1`.** `f = k`, the ground, and the unique meaningful invariant of the law (the algebraic fixed points

of `f(n) = n` sit at `n = 0` and `n = 1/k = 2.0685`, neither of which is meaningful, since index and frequency are not the same kind of quantity).

`n -> infinity`. `f` diverges quadratically and leaves the audible band quickly: at `j = 0` the last index inside 20 kHz is `n = 203`, since `k (203)^2 = 19921` Hz and `k (204)^2 = 20117` Hz. Under a shared transposition the bound is far tighter, `N <= 25` at `j = 6` (Section 8.3). **The working range is short and must be declared.**

`N = 1`. `ln N = 0`, one class, no interval exists at all. **A single category has zero available surplus, not a small amount**, and the ceiling and the achieved value collapse together. **`N = 2`.** Still one class: indices 1 and 2 are two octaves apart and harmonically identical. **A two-category set has a ceiling of one bit and a harmonic vocabulary of one voice**, which is worth stating because it is the smallest case where the ceiling and the vocabulary disagree.

`N -> infinity`. Classes grow as `N/2` — linearly — while the pitch span of the folded octave is fixed at 1200 cents and the raw span grows only as `2400 log2 N`. **The mean gap between classes therefore falls as `2400/N` and the minimum gap falls faster.** That asymptotic is the collision cliff of Section 7.4 seen from a distance: collisions are not an accident of the numbers 5, 7, 3 and 17, they are **forced**, and the only question is at which `N` each one arrives. **This limit is the strongest available argument for small essence sets and it is structural rather than aesthetic.**

`u -> 0`. `N_eff -> 1`, `F -> 0`, `f -> k`. Every category is a duplicate of every other and the roster has left the arithmetic; the pitch is the bottom of the instrument. **`u -> 1`.** `N_eff -> N`, `F -> ln N`, `f -> k N^2`, the ceiling is attained and no further gain is available from geometry.

`delta -> 0`. `tau = 1/delta -> infinity`, so the admissibility test `P <= tau/2` is satisfied by every cadence whatever. **That apparent permissiveness is a trap and it is a signature of the storage law's own pathology, not a licence:** at `delta = 0` the map is an isometry, no fixed point exists, and there is no equilibrium for a cadence to approach [Curzi, 2026a]. **SA-11 is valid only on `0 < delta <= 1` and is vacuous at `delta = 0`. `delta -> 1`.** `tau -> 1` period and then `tau_exact -> 0`, so no cadence is admissible; correctly so, because there is no stock left to build.

`RT60 -> 0`. `f_s -> 0`, so nominally the entire band is statistical — but an anechoic space has no diffuse field at all and Sabine's relation fails from the other side. **`A -> 0`.** `RT60 -> infinity`. Sabine's relation is known to overestimate reverberation at high mean absorption, where Eyring's form is preferred [Beranek, 2004, Rossing et al., 2002]; the worked room's `alpha_bar` runs 0.114 to 0.284, and the highest of those, at `RT60 = 0.4` s, is at the edge of the range in which Sabine is normally accepted. **The 0.5 to 0.6 s target used throughout sits at `alpha_bar = 0.19` to `0.23`, comfortably inside it.**

`dF -> 0`. Cycles required diverge as `1/(8 pi dF)`. **Resolving arbitrarily small surplus differences costs unbounded time**, which is the correct behaviour and is the reason the cliff at `N = 17` is expensive rather than merely narrow.

Stated domain. The results of this paper are valid for: `N` in `[2, 25]` for a rendered set under a shared transposition and `[2, 16]` if the 34.976-cent minimum gap is to be preserved; `u` in `[0,1]`; `delta` in `(0, 0.5]` for the cadence test; a rectangular enclosure with reasonably uniform absorption distribution and `alpha_bar` below about 0.3 for the Sabine arithmetic; and the audible band 20 Hz to 20 kHz for anything rendered. **Outside those ranges the arithmetic still returns numbers and they should not be interpreted.**

18.14.7 14.7 Invariance

The strongest invariance in this paper is exact and it is the reason the framework's weakest constant does not matter. Under `k -> lambda k` for any `lambda > 0`, every interval `f(m)/f(n) = m^2/n^2` is unchanged, every pitch class is unchanged, every consonance index is unchanged, and every room *ratio* is unchanged. **The chosen constant `k` — the one part of the law with no justification beyond preference — has no influence whatever on any relational result.** It sets where the instrument sits and not how it is tuned. **What would break it:** a law of the form `f = k n^2 + b` with `b` not zero, in which `k` would no longer cancel. The invariance holds for the pure power law and for no other form.

Pitch class is invariant under `n -> 2^a n` for integer `a`, and under nothing else. That is Theorem 7.1 restated as an invariance: the folding map's fixed-point set is the odd indices. **It holds only for integer transposition**; a fractional `j` destroys it immediately, which is why ES-10 requires `j` to be an integer and requires it to be published.

Intervals are invariant under a shared `j` and are not invariant under a per-index `j`. That is the precise statement of FM-28, and it is a genuine invariance question rather than a stylistic preference: a shared `j` is a similarity transformation on the whole set, a per-index `j` is not.

Room proportion is scale-free; room size is not. The ratio `1 : 121/81 : 121/49` is invariant under a uniform rescaling of all three axes and is a property of the class triple alone. **The absolute dimensions 7.2400 x 4.3798 x 2.9319 m are fixed only by the additional decision to anchor the axial fundamentals at the *raw* essence frequencies rather than at any transposition of them.** That decision is a choice, it consumes P6, and a different octave offset would give a room of the same shape and a different size — including, at some offsets, an unbuildable one (FM-3).

How many scales the claim has been exercised at: three, all constructed. One room, one eight-member board, one eight-zone published lattice. **Zero measured systems, zero independent replications, one author.** The invariance is a claim about form that has been exercised, not an invariance that has been established.

18.14.8 14.8 Analogy discipline and the precision of the numbers

Restated once more because it is this paper's central risk. Sabine's relation, the Schroeder boundary, the axial-mode formula, the tube, the Helmholtz resonator and the string are **category 1, genuine derivations**: the room is a physical resonator and satisfies the premises. The storage law as a first-order low-pass section and octave folding applied to a period are **category 2, a shared mathematical form**, and no physical authority transfers. **The mapping of a category index to a frequency, and every reading of meaning off the resulting pitch relations, is category 3 — an analogy with no formal warrant.** The classification is stated at first use in Sections 3.3, 9.2, 9.4 and 9.5 and is repeated here so that no reader can reach the conclusion without meeting it.

The formal coincidence between `f(n) = k n^2` and the eigenvalue spacing of a one-dimensional infinite square well, where `E_n` is proportional to `n^2`, is a genuine mathematical correspondence and is noted as such. **It is category 3 and it is not evidence of a physical mechanism**, and asserting the connection would be exactly the decorative analogy this framework's own honesty apparatus exists to prevent.

Precision. The numbers here are of four kinds and are quoted accordingly.

Defined and exact — `k = 0.483425732988414`, `1/ln 2`, `2/ln 2`, `2400/ln 2`, `(9/8)^2 = 1.265625`, `phi^2 = phi + 1`, every cents value of a rational interval, every `HD` and gradus. These may be recomputed to any further precision and the digits printed carry no uncertainty because there is no measurement behind them.

Derived from defined, given a cited physical relation — the room dimensions, `V`, `S`, `A`, `f_s`, the cavity volumes, the string lengths. **Their arithmetic is exact; their correspondence to a real room carries the construction tolerance of the build and the error band of Sabine's relation**, neither of which is a number this paper can supply because no room was built.

Illustrative model output — every number in Section 12 derived from a stipulated parameter: `u = 0.42`, `eta = 0.35`, `delta = 0.08`, `Q = 4.0`, `C = 0.30`, `delta = 0.05` per week. **These carry no measurement uncertainty because there was no measurement**, and six decimal places there record arithmetic rather than confidence. CK-13 requires the conversion to be rounded back to the source's precision, which is why `u = 0.42` at two figures yields 4750 cents and not 4747.67.

Measured — `c = 343` m/s at 20 C in dry air, and Stevens' exponents. **The exponents are constants of a procedure and are quoted nominally, without intervals, because the sources report them as method-dependent** [Poulton, 1979, Teghtsoonian, 1971]; that is a limitation of

the table and is stated as one rather than papered over with a spurious uncertainty.

No quantity in this paper is a fitted parameter, and no confidence interval appears anywhere in it, because nothing was fitted and nothing was measured by this work.

18.15 15 Limitations

No dataset was collected and no room was built. Every number in Section 12 is the output of stated parameters under the stated model, carried through so a reader can re-derive it. The three systems demonstrate that the procedure runs and that it reports its own refusals; **they are not evidence that any institution or any room behaves this way and must never be cited as such.**

The hertz is the weakest link and everything dimensioned hangs from it. `k` as a number is exact; `k` as a frequency is a postulate with no precedent in any literature (P6). Withdraw it and the room, the cadence in days, the cavity volumes and the string lengths all vanish, while the intervals, the classes and the class-count theorem survive untouched. **The paper's dimensionless results are much stronger than its dimensioned ones, and a reader should weight them accordingly.**

The square law is a postulate that is not currently falsifiable, and its exponent is defined rather than estimated. H6 states the condition under which it would become testable — a domain in which the relation between category types carries an independently measured magnitude — and no such domain is offered here. **The sensitivity table of Section 4.3 is what replaces a confidence interval, and it shows that every interval in the paper changes if the exponent changes**; the conversion key 2.885390 is exact given the postulate and is not a fact about the world. The distribution-fitting procedure that any estimated exponent would require [Clauset et al., 2009] is not run because no exponent was estimated; **that is a defence only so long as the paper never claims the exponent was found.**

The scale promotion is not licensed by the data and is conceded to be a stipulation. The index is ordinal; the frequency is ratio-scaled; the law manufactures the intervening structure by assertion (Section 3.5). Michell [1997] argues that psychology systematically assumes quantitative structure without testing for it, and **that is the strongest objection to this framework.** The available remedies — conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971] or a Rasch demonstration of specific objectivity [Rasch, 1960] — **have not been run for any construct here, and until one is, every quantitative reading of an essence interval is provisional.** The paper's own catalogue names the same objection operationally as FM-21 and FM-26.

The ordering is the whole method's input and this paper's central worked case has a weak one. The twelve-category enumeration of Section 12.1 has no intrinsic magnitude behind it. The permutation test returns a maximum displacement of 694.82 cents, which is **six times any reasonable threshold**, so the ordering is load-bearing and a different but equally defensible enumeration gives a materially different tuning. **The room in Section 12.1 is built to *an* essence set, not to *the* essence set, and no result derived from it is stable under a re-ordering.** Only the proxemic case of Section 12.3 has a type-(a) ordering source, and even there Hall's zone *boundaries* are nominal and culturally variable.

`N_eff = 1 + (N−1)u` is not a Hill number and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` of order one, and both are fully grounded [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]; `1 + (N−1)u` is a linear interpolation between 1 and `N` and is this framework's own construction, adopted by design axiom S3 [Curzi, 2026]. **A reviewer reaching for the Hill-number literature as support will find it does not apply.** The two quantities are used under one effective-count heading across this corpus, which is a real exposure; the concentration work that genuinely uses a Hill number of order two reports quantities on a different footing [Curzi, 2026] and the two must not be compared numerically.

The surplus functional's form is underdetermined by the evidence. Latané [1981]'s sublinear power law and Briscoe et al. [2006]'s `n log n` fit the qualitative facts as well as the log-

arithm. **Nothing assembled here discriminates between them.** The logarithm is chosen for its axiomatic characterisation, and one of the axioms is itself chosen. Where the logarithm *is* independently warranted — for a stock that compounds — the warrant is ergodic rather than perceptual [Peters and Gell-Mann, 2016], and **that is the warrant the argument should lean on** rather than on Fechner, whose perceptual story is contested and known to fail at the extremes of intensity.

The reflexive claim is not identified. The mechanism by which a room's acoustics act on a group runs through turn-taking, and a group whose members both influence and constitute its output is exactly the linear-in-means reflexive case whose endogenous effect is not recoverable from observational data [Manski, 1993], with influence and selection generically confounded in network data [Shalizi and Thomas, 2011]. **This paper adopts no remedy**, so the acoustic-exclusion mechanism it relies on is a **modelling position rather than an identified empirical result**. The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001], and it is not attempted here.

H2's test is unblindable by construction. The disclosure requirement of Section 3.6 means every occupant of a tuned room can read what the tuning is. Expectancy effects therefore cannot be removed from any comparison of a tuned against an untuned room [Rosenthal and Jacobson, 1968, Rosenthal and Fode, 1963], and the Hawthorne-type explanations that would otherwise be invoked are themselves weaker than commonly assumed [McCambridge et al., 2014]. **The framework's ethics and its evidential ambitions are in genuine tension here, and the ethics wins.** That is a permanent limit on what can ever be claimed for a disclosed tuning, and it is stated as one.

The shuffled-input control that the falsification protocol depends on is anti-conservative. It is recorded elsewhere in this corpus as measuring a false-positive rate against a nominal level that it exceeds, and as blind to repackaging and to a shared slow driver [Curzi, 2026i]. **A passed shuffle is therefore not on its own evidence that a tuned room did anything**, and SA-16's protocol inherits that weakness.

The consonance indices are chosen functions and disagree with the measured literature. Tenney distance and Euler gradus are defined on rationals [Tenney, 2015, Euler, 1739]; measured consonance depends on critical bandwidth and on spectrum [Plomp and Levelt, 1965, Sethares, 2005]. **The structural results of Section 7.6 and 7.7 are results about the defined indices and about nothing else**, and any claim that a listener will find the `HD_ess = 2.0000` pairs "most consonant" is an extrapolation the indices do not license.

Octave equivalence is carried outside its evidential domain. It is grounded for pitch [Shepard, 1982, Demany et al., 2013] and is weaker than assumed even there [Hoeschele et al., 2012]; **nothing supports applying it to a quantity that is not a pitch**, and folding an index into a band and reading meaning off the result is an unsupported interpretation of a well-defined operation.

No human-subjects research was conducted. H2, H3 and H4 all specify tests involving people, none has been run, and the constraints of Section 3.6 are constraints on prospective work rather than reports of practice.

Model comparison, effect sizes and replication. This paper fits nothing, so no information criterion applies to it; but it also therefore offers no out-of-sample evidence for anything, and the corpus's one applied fit reports held-out error against baselines and **no AIC or BIC**, so its parameter count was never paid for [Curzi, 2026i]. Nothing in Section 12 carries an interval, because nothing in Section 12 was measured. **Every system in this paper was constructed by one author and there is no independent replication of any parameter**, which the reproducibility literature is unambiguous about [Open Science Collaboration, 2015, Ioannidis, 2005]. And directional predictions are nearly costless in the social sciences [Meehl, 1967]; the point predictions with constants offered here are the right answer to that objection in form, **but none of them has yet been put at risk.**

Four printed values in the source material did not reproduce and one claim could not be reconstructed at all. They are listed in Section 14.5. Three are last-place floating-point artefacts, one is a truncation artefact in a mode count, one is a cents figure that is wrong

by seven cents, and one is a factor stated two different ways in adjacent sentences. **None changes a conclusion; all are printed because a reader who finds them first has reason to doubt everything else.**

Two recommendations in the source material are refused rather than carried. Subliminal embedding is refused on the ethical ground stated in Section 3.6, and the coil claimed as an amplifier is refused because no verified engineering basis exists for the claimed mechanism and no entry in this corpus's bibliography supports it. **Both refusals are recorded here so that a reader comparing this paper against its source can see that the omissions are deliberate.**

18.16 16 Conclusion

R1 — The conversion keys, exact. The four registers of this framework — surplus in nats, pitch in octaves, sensation, and the moment — are one register up to a change of logarithmic base, and the constants are exact and defined: **`1/ln 2 = 1.4426950408889634` bits per nat, `2/ln 2 = 2.8853900817779268` essence octaves per nat, `2400/ln 2 = 3462.4680981335122` cents per nat**, with the ground constant `k = (9/8)^2/phi^2 = 0.483425732988414`, **defined and exact as a number, and a POSTULATE the moment it is written in hertz.** A conversion carries the status of the quantity it converts and never upgrades it.

R2 — The room. Taking essence indices 7, 9 and 11 as axial-mode targets and `L = c/(2f)` with `c = 343` m/s gives a room of **7.2400 by 4.3798 by 2.9319 m**, exactly in the ratio `1 : 121/81 : 121/49`, with **`V = 92.969` m3**, floor area 31.709 m2, total surface 131.555 m2 and **occupancy 12.7** at 2.5 m2 per person. Its proportion matches the Volkmann heuristic at a Euclidean error of **0.031**, the best of five heuristics under an exhaustive search over class triples and octave offsets. **`RT60 = 0.5` s requires `A = 29.94` m2 sabins, a mean absorption of 0.2276**, and the **Schroeder frequency is 146.7 Hz**, below the entire folded set of **233.98 to 386.74 Hz**, so the whole set lies in the statistical region and Sabine governs for all of it. The room carries **55 modes below 150 Hz** — not the 48 previously printed, which is a truncation artefact — a mean gap of 4.02 Hz across the first twenty, a maximum gap of 15.47 Hz and a near-degeneracy at 0.51 Hz that will beat at half a hertz.

R3 — One bit is two octaves, not one. Doubling the effective count multiplies a square-law frequency by four, `f(2n)/f(n) = (2n)^2/n^2 = 4`, and four is two octaves. Verified at `N_eff = 1, 3, 12`, ratio 4.0 in every case. **The factor of two in `octaves = 2F/ln 2` is the exponent of the essence-law postulate and nothing else**, so the key is exact given the postulate and is not a fact about the world.

R4 — The forced ceiling. From the surplus range result plus the chosen normalisation, **`0 <= M <= ln N`**: the richest moment available to a perceiver is bounded by the logarithm of the number of kinds of thing that perceiver can distinguish. **A fully realised twelve-category system is `ln 12 = 2.484907` nats = `3.584963` bits = `7.169925` octaves.** Doubling `N` adds exactly one bit wherever one starts, so going from 2 categories to 1000 buys 6.21 nats — under nine bits. **The ceiling is on the perceiver, not on the world**, and both links of the derivation are published every time it is quoted.

R5 — The transport-board case. With `N = 8` and `u = 0.42`, the **affine** effective count is `N_eff = 3.94` — not a Hill number — and `F = ln 3.94 = 1.371181` nats = **1.978196 bits**, against a ceiling of `ln 8 = 2.079442` nats = **3 bits exactly = 6 octaves exactly**. The board sits at **66 per cent of its own ceiling**, and the ratio of ceiling to achieved essence frequency is `(8/3.94)^2 = 4.1228`, **two full octaves below its own maximum**. The diagnostic the registers make visible is positive headroom `h = +0.107805` against a negative actual step `−0.140087`: **the ceiling permits growth and the geometry does not deliver it.**

R6 — The disclosed collision. Eight proxemic zones ordered by distance give `ceil(8/2) = 4` pitch classes; **indices 1, 2, 4 and 8 collapse to one class at 123.7570 Hz** in `[110, 220)` Hz because their odd part is 1; and **classes 5 and 7, at `25/16` and `49/32`, sit 34.976 cents apart and will beat rather than form an interval.** The collision is disclosed in advance precisely so that it cannot later be reported as a finding about social and public distance. **It is arithmetic, and the same**

34.976-cent minimum gap holds unchanged for every set size from 7 to 16, collapsing to 6.001 cents the moment index 17 enters — a change of rendering-duration regime by a factor of 5.828.

CR — The counter-result the paper supplies against its own instrument. This framework's own six storage-law parameters — `delta`, `eta`, `N`, `u`, `C`, `Q` — **fail all three admissibility requirements**: they are not categories of a common domain, no intrinsic magnitude orders them, and two analysts would not agree. **They therefore get no frequencies at all.** With that refusal go two hard limits: **at most 25 essences fit the audible band under a shared transposition, and only at `j = 6`**, and **an essence frequency is never a physical resonance.** The instrument is narrow. **A narrow instrument used honestly is worth more than a wide one used loosely**, and this paper's principal claim is that the essence law generates targets — it does not generate effects, and nothing here has claimed that it does.

18.16.1 Declarations

Data and code availability

No external dataset was collected for this paper and no room was built. All numerical results are computed from the stated parameters under the models developed in the text, and every table can be re-derived from the equations and the constants of Section 4.1. The three systems worked in Section 12 are constructed examples with declared parameters, not field observations; the proxemic ordering of Section 12.3 is taken from a published source [Hall, 1966] and only its ordering, not its boundary values, is used. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the relations of Sections 4, 7 and 9.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, recomputed every printed figure, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The three worked systems are constructed. Hypotheses H2, H3 and H4 specify tests involving human participants; **none has been run**, and each is stated as a prospective test with its falsification condition rather than as a report of a result.

The no-subliminals constraint of Section 3.6 is a design prohibition adopted by this framework and a constraint on prospective work. It is not a report of any study performed, and it is not an empirical claim that concealed signal is ineffective. Its content is that a method working by removing a person's ability to decline is outside this framework's scope regardless of whether it works, and that a message a listener cannot hear is a message the listener cannot decline. The associated requirements — audibility at every listening position, written disclosure before entry, a disclosed off switch, and publication of any structural derivation — are stated as specifications SA-1 to SA-3, SA-15, CK-19 and ES-16, and they bind any future

application of this material. **Two recommendations present in the source material this paper analyses — the embedding of subliminal content in a rendered track, and the presentation of an unverified device as an amplifier — are refused here and the refusals are recorded in Sections 3.6 and 15.**

Preregistration

This paper reports no preregistered test of its own; its results are derivations and recomputations. The preregistered protocol for testing a framework claim against a real system, together with the confirmatory application that **failed** its second falsification rule, is reported in Curzi [2026i], and any applied claim resting on this paper inherits that result. Section 12.1 Step 8 specifies in advance the protocol that would be required before any claim is made for a tuned room, including the four baselines and the shuffled-input control; **that protocol has not been run, and Section 15 records both that fact and the reasons the control is weaker than it looks.**

18.17 Appendix A Seven-gate formula audits

Specifications CK-17 and ES-18 require every formula entering a specification to carry a full seven-gate audit in print, **including the gates it fails**. The gates are: **G1 dimensions**, **G2 scale type**, **G3 limiting cases**, **G4 fixed points**, **G5 identifiability**, **G6 falsification**, **G7 reproducibility**. Nine formulas enter the specifications of Section 10 and all nine are audited below. Four gates fail outright and three are recorded as not yet attempted.

18.17.1 A.1 The register conversion identity

```
x_target = x_source (ln b_source / ln b_target)
```

Gate	Test	Result
G1 dimensions	Both sides are dimensionless logarithms of a ratio; the multiplier is a ratio of logarithms of pure numbers. Units agree.	**PASS**
G2 scale type	All four registers are ratio-scaled *in the argument* and interval-scaled *in the logarithm*: a difference of two pitch values is meaningful, an absolute value requires a stated reference. The conversion is a positive linear map, permissible on interval and ratio scales alike.	**PASS, reference required in print**
G3 limiting cases	`x -> 0` gives 0 in every register — unison, zero surplus, ground essence. `x -> infinity` diverges in every register at the same rate. No register saturates or wraps.	**PASS**

Gate	Test	Result
G4 fixed points	`x = 0` is the unique fixed point: zero surplus is zero bits is zero octaves is zero cents. **The ground is shared by all four registers**, which is what makes them comparable.	**PASS**
G5 identifiability	The multiplier is fixed by the two bases; no free parameters to recover.	**N/A — no free parameters**
G6 falsification	Not empirically falsifiable: an identity of logarithms, arithmetically checkable and checked (Sections 4.4, 4.6). The framework claim riding on it — that the essence exponent is 2 — **is** falsifiable in principle and is flagged in Section 4.3 and H6.	**N/A (identity); dependent postulate flagged**
G7 reproducibility	Any correct implementation returns the same constants. Verified in double precision and cross-checked in 45-digit decimal arithmetic, which is how the two last-place discrepancies of Section 14.5 were found.	**PASS**

18.17.2 A.2 Fechner's law

```
S = k_F ln(I / I_0)
```

Gate	Test	Result
G1 dimensions	`I/I_0` is dimensionless by construction, so the logarithm is admissible. `S` carries the units of `k_F`, the scale constant of the chosen sensation unit.	**PASS if `I_0` declared; FAIL if the reference is omitted**

Gate	Test	Result
G2 scale type	`I` is ratio-scaled with a true zero. `S`, built by counting just-noticeable differences, is at best **interval-scaled**: JND counting gives equal-appearing increments, not verified equal ratios. This is the classic objection to Fechner and it is a real one. Ratio-scale sensation requires magnitude estimation, not JND integration.	**PARTIAL — `S` is interval; do not divide two Fechner sensations (CK-16)**
G3 limiting cases	`I -> I_0` gives `S -> 0`. `I -> 0` gives `S -> -infinity`: the divergence is the absolute threshold, below which the law is known to fail. `I -> infinity` gives unbounded `S`, failing at every modality's damage ceiling. **Both divergences name real phenomena and mark the law's known boundaries.**	**PASS, both boundaries named**
G4 fixed points	`I = I_0` is the unique invariant: the scale has no content until a reference is chosen, and the reference is a decision.	**PASS**
G5 identifiability	`k_F` and `I_0` trade off — rescaling `I_0` shifts `S` by an absorbable constant. **Identifiable only up to that offset**, so a fit must fix `I_0` by an independent operational definition.	**CONDITIONAL — fix `I_0` externally or the fit is degenerate**
G6 falsification	Falsified in a modality if the measured Weber fraction varies systematically with `I` across the working range. It has been so falsified at the extremes: dead as a universal law, standing as a middle-range description [Krueger, 1989].	**PASS — and has partially failed, honestly**
G7 reproducibility	Weber fractions recover across subjects and laboratories within modality-specific bounds — among the most reproducible findings in psychology.	**PASS**

18.17.3 A.3 The moment equation in log form

`ln M = ln D − ln P + ln E` — **POSTULATE, this framework's own formula**

Gate	Test	Result
G1 dimensions	`D` and `P` **must share units** so that `r = D/P` is dimensionless; `M` inherits `E`'s units. `ln D − ln P` is well formed if and only if `D` and `P` share both units and reference.	**CONDITIONAL — shared units are a requirement, not a result**
G2 scale type	Division requires **ratio scale with a true zero** for `D` and `P`. **This is the crux.** With only ordinal data the formula is a heuristic ordering, not an equation, and must be demoted in print [Michell, 1997, Stevens, 1946].	**UNRESOLVED PENDING MEASUREMENT**
G3 limiting cases	`P -> 0`: `M -> infinity` — a frame with no intake. `D -> 0`: `M -> 0` — sensation is not experience. `E -> 0`: `M -> 0`. **All three divergences name real, observable phenomena.**	**PASS — every divergence is nameable**
G4 fixed points	`D = P` gives `M = E`. **Frame matches intake and the moment equals the environment: veridical contact, stated as an equation.**	**PASS — fixed point is interpretable**
G5 identifiability	**FAILS as written.** `(D, P, E)` and `(cD, cP, E)` predict identical `M` for any `c > 0`; only `r` and `rE` are identified. The formula is testable in `r` and `M`, not in `D` and `P` separately, unless an independent operationalisation pins one scale.	**FAIL — identified only up to a common scaling of `D` and `P`**
G6 falsification	Template: preregister an operationalisation of `r` and `M`; fit; freeze; report held-out; beat persistence, direct-input, matched autoregressive and **shuffled-input** baselines [Curzi, 2026i, Nosek et al., 2018]. Killed if held-out `M` is not predicted better than the shuffled-input control.	**DEFINED, NOT YET RUN**
G7 reproducibility	Same operationalisation, different people, different laboratories: do `r` and the scale of `M` recover? **Not yet attempted. This gate decides whether the formula is science, and it is the one most often skipped** [Open Science Collaboration, 2015].	**NOT YET ATTEMPTED**

Two gates fail or stall and both are printed as failures. The identifiability failure is fixable and it says exactly what to do next: pin the scale of `P` by an independent measurement.

18.17.4 A.4 The maximum moment

`M_max = ln N`, the moment expressed in the surplus register

Gate	Test	Result
G1 dimensions	Both sides in nats; `N` a dimensionless count. Consistent.	**PASS**
G2 scale type	`N` is a **count** — ratio-scaled with a true zero — **provided "distinguishable category" has an operational definition.** Without one, `N` is not measured and the bound is not usable. The gate transfers to the operationalisation of the category set, which is Section 8.	**CONDITIONAL — requires a defensible category set**
G3 limiting cases	`N = 1`: `ln 1 = 0`. A perceiver with one category has no moment available — correct and severe. `N -> infinity`: the bound diverges logarithmically, arbitrarily slowly. No finite perceiver approaches it.	**PASS**
G4 fixed points	Attained if and only if `u = 1`, the framings mutually orthogonal [Curzi, 2026]. **The invariant is orthogonality and it is unreachable in practice** — a ceiling, not a target.	**PASS**
G5 identifiability	`N` and `u` are separately recoverable if category membership and pairwise non-parallelism are separately measurable; confounded if `u` is estimated by a procedure that already assumes the category count. **Estimate `u` by error decorrelation, not by labels.**	**PASS with a named confound**
G6 falsification	The bound is a theorem given the axioms plus the normalisation, so not falsifiable *as arithmetic*. The **normalisation** is: if a magnitude-estimation moment scale exceeded `ln N` for a subject whose `N` was independently established, the normalisation is wrong. A runnable experiment.	**NORMALISATION FALSIFIABLE; TEST SPECIFIED**

Gate	Test	Result
G7 reproducibility	Requires `N` to recover across instruments for the same person — specific objectivity, with Rasch separability as the standard [Rasch, 1960]. Not yet attempted.	**NOT YET ATTEMPTED**

18.17.5 A.5 Stevens' power law

`psi = k_S I^a`, equivalently `log psi = log k_S + a log I`

Gate	Test	Result
G1 dimensions	`I` must be a ratio to a stated reference before exponentiation; `I^a` of a dimensioned quantity is ill formed. `k_S` carries the units of `psi`.	**PASS if reference declared; a common silent failure otherwise**
G2 scale type	`I` ratio-scaled with a true zero. `psi` **ratio-scaled** — the point of magnitude estimation, which asks subjects for ratios directly and validates them by cross-modality matching. Multiplication and division of `psi` are permissible. **The claim is contested** [Luce, 2002, Narens, 1996].	**PASS as claimed; the gate Fechner fails and Stevens claims to pass, disputed**
G3 limiting cases	`I -> 0` gives `psi -> 0` for all `a > 0`: no stimulus, no sensation. `I -> infinity` diverges; real modalities terminate at damage or saturation, so an upper working range must be declared. At `a = 1` the law degenerates to proportionality, as observed for visual length.	**PASS, upper bound declared per modality**
G4 fixed points	`I = I_ref` gives `psi = k_S`. In log-log coordinates the invariant is the intercept: the anchor stimulus. **The anchor is chosen by the experimenter, which is exactly why instruction affects the exponent.**	**PASS, dependency named**
G5 identifiability	`a` is the log-log slope and `k_S` the intercept; separately recoverable from two or more levels spanning a decade. Cross-modality matching independently recovers the ratios of exponents, over-identifying the system.	**PASS — over-identified, which is strong**
G6 falsification	Killed in a modality if log-log plots are reliably curved over the declared range, or if the matching slope departs from the predicted `a_j/a_i` beyond measurement error. Both tests have run for decades.	**PASS — a live falsification test**

Gate	Test	Result
G7 reproducibility	Exponents recover across laboratories **within a fixed procedure** and fail to recover across procedures [Poulton, 1979, Teghtsoonian, 1971]. Honest verdict: constants of a specified method, not of a modality. **Report the procedure or the number is not a measurement.**	**CONDITIONAL PASS — procedure-bound**

18.17.6 A.6 The essence law

`f(n) = k n^2` — **POSTULATE about essence structure**

Gate	Test	Result
G1 dimensions	`n` is a dimensionless index; `k` carries hertz; `f` is in hertz. Both sides agree **only because `k` was given hertz**, which is postulate P6 and carries no external support. `k` must be published with its units or the equation is incomplete.	**PASS given P6; P6 itself is POSTULATED**
G2 scale type	**The crux.** `n` is ORDINAL. `f` is RATIO-scaled. The law promotes an ordinal to a ratio scale by postulating the spacing. Permissible as a model, impermissible as an inference from data [Michell, 1997, Stevens, 1946]. **Must be badged in print wherever intervals are interpreted.**	**PROMOTION BY POSTULATE — badged, not passed**
G3 limiting cases	`n = 0` gives `f = 0`: there is no zeroth essence, and the law says so by returning silence. `n = 1` gives `f = k`, the ground. `n -> infinity` diverges quadratically, leaving the audible band quickly — at `n = 24`, `f` is already 278 Hz and at `n = 203` it is 19.9 kHz. Transposition is the required remedy.	**PASS, with a declared working range**
G4 fixed points	`f(n) = n` has solutions at `n = 0` and `n = 1/k = 2.0685`, neither meaningful, since index and frequency are not the same kind of quantity. **The meaningful invariant is `f(1) = k`**, and the deeper one is that `k` cancels from every ratio (Section 14.7).	**PASS — invariant is the ground, not a self-map**
G5 identifiability	`k` and the exponent are separately recoverable from any two published values: two points determine both slope and intercept in log-log coordinates. **The exponent was recovered this way from the source document and matched a pure square to 14 significant figures.**	**PASS — and was actually performed**

Gate	Test	Result
G6 falsification	As arithmetic, not falsifiable. As a claim about category structure, falsifiable only once the relation between category types has an independent operationalisation with a measurable magnitude. **No such operationalisation exists and the honest statement is that the postulate is not yet testable** (H6).	**NOT CURRENTLY FALSIFIABLE — stated plainly**
G7 reproducibility	The arithmetic reproduces exactly. **The INDEX does not reproduce automatically** — it depends on the ordering, and the ordering is where reproducibility must be established, by ES-R3 inter-rater agreement.	**CONDITIONAL — the gate transfers to the ordering**

18.17.7 A.7 The interval law

`f(m)/f(n) = m^2/n^2`

Gate	Test	Result
G1 dimensions	A ratio of two frequencies: dimensionless. `k` cancels identically, so the result carries no dependence on the chosen reference **and no dependence on P6**.	**PASS — and it is the one result that does not consume P6**
G2 scale type	The ratio is well formed on a ratio scale, which `f` is by construction. **But the ratio-scale status of `f` was itself manufactured by the postulate (Section 3.5), so the interval inherits that status and not a stronger one.**	**PASS given the postulate, badged**
G3 limiting cases	`m = n` gives 1: unison. `n -> 0` diverges, and there is no zeroth essence, so the divergence is outside the domain. `m/n -> infinity` gives an unbounded interval, correctly: distant indices are distant pitches.	**PASS**
G4 fixed points	The ratio equals 1 if and only if `m = n`; it equals a whole number of octaves if and only if `m/n` is a power of two. **The invariant of the folding operation is the odd part**, which is CC-R2.	**PASS — fixed point is the class**

Gate	Test	Result
G5 identifiability	The interval determines `m/n` uniquely, by taking the square root. It does not determine `m` and `n` separately — `6:4` and `3:2` give the same interval. **The lattice is identifiable up to the reduced index ratio and no further**, which is exactly why consonance depends on the reduced ratio alone.	**PASS with a named degeneracy that turns out to be structural**
G6 falsification	Follows the essence law: falsifiable only when the underlying spacing postulate becomes testable. The interval law adds no new empirical content beyond it.	**INHERITS THE ESSENCE LAW'S STATUS**
G7 reproducibility	Exact arithmetic, reproducible anywhere. Verified independently in Section 7.1 against five recorded examples — all five agree.	**PASS**

18.17.8 A.8 Pitch-class folding by odd part

`class(n) = odd part of n`; the number of classes over `1..N` is `ceil(N/2)`

Gate	Test	Result
G1 dimensions	Both index and odd part are dimensionless integers; the class count is a dimensionless count. Consistent.	**PASS**
G2 scale type	The odd part is a NOMINAL label — a class identifier, not a magnitude. **Do not do arithmetic on class numbers.** The class's octave position in cents is interval-scaled and may be subtracted. The count `ceil(N/2)` is a ratio-scaled count. **Three different scale types in one construction, and they must not be mixed.**	**PASS with an explicit three-way scale warning**

Gate	Test	Result
G3 limiting cases	`N = 1`: one class, the ground. `N = 2`: still one class — indices 1 and 2 are two octaves apart and harmonically identical. `N -> infinity`: classes grow as `N/2` while the pitch span grows only logarithmically, which is why collisions appear and why they are forced rather than accidental.	**PASS — and the limiting behaviour explains the collisions**
G4 fixed points	The odd indices are the fixed points of the folding map: `class(m) = m` if and only if `m` is odd. **The class representatives are exactly the odd indices**, which Section 7.7 recovers independently by minimising dissonance.	**PASS — fixed-point set is interpretable and useful**
G5 identifiability	The class does not identify the index: `{3, 6, 12, 24}` all map to class 3. Recovering `n` from its class requires the octave count `a`, so the pair `(a, m)` is a bijection with `n`. **Publish `(a, m)`, not `m` alone, if the index must be recoverable.**	**PASS given `(a, m)`; FAILS given `m` alone**
G6 falsification	A theorem of arithmetic (Theorem 7.1), proved and verified by enumeration for `N = 1..24`, all 24 agreeing. Not empirically falsifiable; arithmetically checkable and checked.	**N/A (theorem) — verification reported**
G7 reproducibility	Exact and machine-independent. As with the essence law, reproducibility of the *index* transfers to the ordering (ES-R3).	**PASS for the arithmetic; conditional on ES-R3 for the input**

18.17.9 A.9 Octave transposition

`f_audible = f 2^j`, `j` an integer

Gate	Test	Result
G1 dimensions	Hertz times a dimensionless power of two gives hertz. Consistent.	**PASS**
G2 scale type	`f` is ratio-scaled; multiplication by a positive constant is permissible and preserves all ratios. `j` is an integer count of octaves.	**PASS**

Gate	Test	Result
G3 limiting cases	`j = 0` is the identity. Large positive `j` leaves the audible band above and large negative `j` below. Both are outside the working range, which is why the band must be declared.	**PASS with declared band**
G4 fixed points	The pitch class is invariant under the operation for every `j`. **That invariance is the entire justification for the method — and it holds only for integer `j`.**	**PASS**
G5 identifiability	`f` is recoverable from `f_audible` only if `j` is published. Without `j` the raw essence frequency is unrecoverable and the value cannot be checked. **This is why CK-6 and ES-10 exist.**	**PASS if `j` published; FAIL otherwise**
G6 falsification	An exact operation, not an empirical claim. Checkable and checked in Section 8.3. **The *interpretation* — that octave equivalence carries meaning for a non-pitch quantity — is a separate claim and is unsupported** [Shepard, 1982, Hoeschele et al., 2012].	**N/A (definition); the interpretation is badged category 3**
G7 reproducibility	Exact given `f`, the band, and the rule for choosing `j`. **The rule must be published, not just the `j`** — "the lowest `j` placing `f` in `[110, 220)`" is a rule; "`j = 4`" is a value.	**PASS if the rule is published**

Chapter 19

The Moment Equation and the Calibration Ratio: A Fixed Point at Contact, a Self-Imposed Demotion to Ordinal Scale, and the Price of Stored Error

Abstract. The moment equation $M = (D/P)\,E$ is put through this corpus's own validity protocol and **fails** its scale-type gate. The expression contains a division and a multiplication, so frame D, intake P and environment E must each sit on a ratio scale with a true zero; where only ordinal data exist the equation is demoted to a heuristic ordering and may not be printed as a fraction or computed. That demotion is the headline result, and it is Michell's remedy applied once. What survives is exact: four limiting cases, unit elasticity of magnitude one in every term, a ceiling $0 \le M \le \ln N$ inherited from the surplus bound, and a fixed point at $D = P$, equivalently $r = 1$, at which $M = E$ for every E. Distortion is $\ln r$, and the postulated correction map $\ln r_{t+1} = (1-a)\ln r_t$ is a first-order linear recurrence: attracting for $0 < a < 2$, neutral at $a = 0$, divergent at $a \ge 2$; from 0.8122 nats, six cycles at gain 2.3 reach 3.9203. In a constructed seeded audit with 25 per cent off-model items, $r = 50/29 = 1.724138$ and the confabulated fraction $1 - 1/r = 0.4200$ is exactly the false-discovery rate, with 63 per cent of the steady state stored error; a constructed fourteen-year inspector series runs $r = 0.353,\ 1.048,\ 1.900$, off-model detection falling to 13 per cent against a novice's 33. Several printed figures in both are shown not to reconcile. Contact is not an unqualified goal: at $r = 1$ in a saturating environment headroom is zero by exact cancellation.

Keywords: moment equation; calibration ratio; scale demotion; seeded audit; off-model items; veridical throughput; stored error; correction gain

Series: B. Engineering the Surplus **Paper:** CCP-019

19.1 1 Introduction

A framework that models how a group or an institution accumulates durable capability takes its input from the environment. The dynamical core of this corpus, the storage law `Q_{t+1} = (1-delta)Q_t + eta S_t - C_t`, integrates whatever arrives and does not inspect it [Curzi,

2026a]. That is a deliberate simplification, and it has a consequence the framework must answer for: a room is not the same room to two people standing in it, and the quantity the storage law integrates is not the room but the observer's reading of it. Something stands between the environment and the input.

This paper names that thing, gives it an equation, and then submits the equation to the corpus's own validity protocol — where **it fails.** The proposed relation is

```
M = (D / P) . E
```

with `D` the frame the observer brings, `P` the intake the observer takes, `E` what is available at that place and time, and `M` the moment as lived, which is the quantity the storage law integrates. The expression contains one division and one multiplication. Under the standard result that permissible arithmetic is fixed by scale type [Stevens, 1946], division and multiplication require all three inputs on a ratio scale with a true zero and a defensible unit. **No instrument places `D` and `P` on a common ratio scale with a shared true zero. The equation is therefore demoted to a heuristic ordering and may not be printed as a fraction, computed, or used to generate a number.** That demotion is the paper's headline result, it is a negative one, and it is reported here rather than in a footnote because a validation protocol that never demotes anything is decorative.

The demotion is precisely the remedy Michell [1997] prescribes: psychology routinely assumes that its attributes have quantitative structure and measures them without testing whether they do. The corpus applied that remedy once, to its own keystone formula. The honest position — argued in Section 15 and conceded there rather than defended — is that the remedy should be applied consistently rather than once, and that the conjoint-measurement test which would settle the question [Luce and Tukey, 1964, Krantz et al., 1971] has not been run for any quantity in this corpus.

What survives the demotion is exact and is not small. Four limiting cases, each naming a recognised condition. Unit elasticity of magnitude exactly one in every term, so no input's error is amplified relative to another's. A ceiling `0 <= M <= ln N` inherited from the surplus bound [Curzi, 2026], which converts the one divergence in the formula from an infinity into a saturation. And a fixed point at `D = P`, equivalently `r = 1`, at which the moment equals the environment for every environment. **All four need only ordinal information about `D` and `P`, and none of them is touched by the demotion. What is demoted is magnitude, not structure.**

Four contributions are new in this paper relative to the surrounding literature rather than relative to the framework. First, the demotion rule itself, stated as a rule and applied to the corpus's own equation before it is applied to anyone else's. Second, the identification of the observer's whole contribution with one dimensionless composite `r = D/P`, together with the exact statement of what that costs: `(D, P, E)` and `(kD, kP, E)` are observationally identical, so only the ratio is recoverable. Third, the correction map `ln r_{t+1} = (1−a) ln r_t` and its stability band, which is a first-order linear recurrence and inherits the whole standard theory of such recurrences [Elaydi, 2005, Åström and Murray, 2008] — a **shared mathematical form, not a derivation from physical premises.** Fourth, veridical throughput `V = E min(r,1)` and its complement the confabulated fraction `1 − 1/r`, which separate what an observer stored from what the environment supplied, and which show that the fixed point is not merely where the reading is undistorted but where the earned content of the reading is largest.

There is also a counter-result, and the paper states it against its own interest. **Contact is not an unqualified goal.** At `r = 1` in a maximally rich environment the input to the storage law sits at its ceiling, the store settles at its maximum, and the headroom gauge reads exactly zero by cancellation. A perfectly calibrated observer maximises fidelity and has no room left to build. Worse, an observer optimising raw stored order is driven *away* from `r = 1` altogether, because the raw track keeps climbing in `r` while the veridical track is flat above the fixed point — and the correction bill only ever catches up when the correction-load coefficient exceeds the decay rate.

Two worked audits carry the numbers. A seeded code-review packet with 25 per cent off-model items returns `r = 1.724138`, a false-discovery rate of 0.4200 that is exactly `1 − 1/r`, and

a steady state of which 63 per cent is stored error; correction at gain 0.35 takes the reviewer to `r = 1.032`, cuts false discovery by 92.6 per cent and raises true defects found from 29 of 40 to 31 of 40, while the metric the organisation actually watches — on-model detection — falls from 93 to 90 per cent. A fourteen-year building inspector series returns `r = 0.353` with a negative steady state at week two, `r = 1.048` at minimum loss in month nine, and `r = 1.900` at year fourteen, with on-model detection at its career maximum and off-model detection below a nine-day novice's. **Both are constructed examples, not collected datasets**, and Section 12.3 prints the numbers in them that do not reconcile.

The framework's static half — the surplus functional `F(u) = ln(1 + (N−1)u)` with its affine effective count `N_eff = 1 + (N−1)u` — is presupposed rather than re-derived [Curzi, 2026]. The founding reflexive law, written as the fixed point `T(x) = W(x, M(x))` of a composition of seeing and responding, is presupposed from Curzi [2026] and is the reason Section 3.7 must confront the reflection problem before anything else in this paper is interpreted empirically. The contraction theorem the correction map leans on — a contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass — is stated exactly in Curzi [2026].

Sections 2 and 3 state the hypotheses and the framework, including the scale-type gate and the identification problem. Section 4 develops the four limits, the composite ratio and the ceiling. Section 5 develops the fixed point and its dynamics. Sections 6 to 8 take the calibration ratio on its own: its measure, its diagnosis, its composition, its drift, and the cases in which `r = 1` is the wrong target. Section 9 reports the seven validation gates and their verdicts. Sections 10 and 11 collect the specifications and the named failure modes. Section 12 reports the two worked audits and the arithmetic in the source that does not reproduce. Sections 13 to 16 discuss what follows, verify the chain, state the limitations, and conclude.

19.2 2 Hypotheses

The limiting cases, the fixed point, the elasticities and the stability band are theorems about an equation and cannot be falsified by observation; they are labelled as derivations where they appear and they are re-derived in Section 14. What can be falsified is the claim that the equation describes a real observer. The hypotheses below separate the two, and each names the observation that would defeat it.

H1 is the one this paper tests, and it failed. It is reported here in the same plain language a success would have been given.

> **H1 — The moment equation is a quantitative law.** Frame, intake and environment admit measurement on a common ratio scale with a shared true zero and a defensible unit, so that `M = (D/P).E` may be printed as a fraction and computed. **Predicted:** an operationalisation of `D` and `P` linked across item sets, on which a reported `r` is invariant to an admissible change of items, and on which the statement "this observer's distortion is twice that one's" has a referent. **Falsified by:** the absence of any such instrument; or a demonstration that the magnitude — not merely the value — of `r` moves when the item set is exchanged for an equivalent one. **Result: FAILED.** No instrument links `D` and `P` across item sets. Counting recorded items supplies a zero and a unit *within* one item set and supplies no linkage *between* two, so the ratio moves when the items move. The magnitude of `D/P`, the distortion `Delta = |ln r|` as a number, and the quantitative form of the join from the moment to the store are withdrawn as measured quantities [Curzi, 2026t]. Section 3.5 states the demotion; Section 12.4 audits every operation in this paper that the demotion does not license; Section 15 concedes what the failure costs.
>
> **H2 — The fixed point is the unique maximum of veridical throughput.** The part of the moment the environment actually supplied, `V = E min(r,1)`, is maximised at `r = 1` and only there. **Predicted:** in a seeded audit containing off-model items, an

observer's true-item detection rises with `r` up to `r = 1` and is flat above it, while the false-discovery rate rises monotonically above it, tracking `1 − 1/r`. **Falsified by:** an audit in which both off-model detection and false-discovery rate improve as `|ln r|` grows; or one in which true detection continues to rise above `r = 1`, which would mean the assertion record is adding real conditions the intake record never held.

H3 — Correction converges only inside a stability band. A deliberate correction regime acting on a fraction `a` of the observed discrepancy per cycle converges to contact if and only if `0 < a < 2`. **Predicted:** geometric convergence with half-life `ln 2 / (−ln|1−a|)` cycles; monotone approach for `a < 1`; alternating sign with decreasing magnitude for `1 < a < 2`; a standing offset at `a = 0`; alternating sign with **growing** magnitude at `a >= 2`. **Falsified by:** a documented correction regime whose measured effective gain exceeds 2 and which nonetheless converges; or one inside the band that diverges in the absence of an external forcing term.

H4 — Off-model content is necessary for detecting over-framing. An audit built only from items inside the observer's standing model cannot separate an over-framed observer from a calibrated one. **Predicted:** sensitivity to over-framing rises with the off-model share of the seeded item set, and is zero at an off-model share of zero; an all-on-model audit returns its highest scores for the most over-framed observer. **Falsified by:** an audit with no off-model content that nonetheless separates the two states, or a measured off-model detection rate that does not fall as `r` rises.

H5 — Detection asymmetry grows with tenure in a stable frame. An observer working a fixed model in a moving environment gains on-model detection and loses off-model detection. **Predicted:** on-model hit rate rising and off-model hit rate falling with tenure, false-discovery rate rising, and time per case falling, at constant measured environment. **Falsified by:** a cohort in which off-model detection is flat or rising with tenure while the environment is independently shown to be unchanged. This hypothesis is adjacent to the myopia-of-learning result [Levinthal and March, 1993] and to the exploration/exploitation trade [March, 1991], both of which predict the same direction from a different mechanism; a confirmatory observation therefore does **not** discriminate this framework from theirs, which is the demand Durlauf [2005] makes of any formal social model.

H6 — Stored error is real and its bill arrives late. The gap between order stored on the moment as lived and order stored on the veridical part grows with `r`, and it is paid as correction cost on a lag. **Predicted:** rework, dispute and repair costs rising with a lag of several time constants behind a rise in `r`, with no change in the environment; and, where the correction-load coefficient `kappa` exceeds the decay rate `delta`, raw stored order eventually falling in `r` rather than rising. **Falsified by:** an over-framed body whose correction costs are stationary over a horizon of several `1/delta`.

Two claims in this paper are not hypotheses and are labelled accordingly. The demotion rule of Section 3.5 is a **consequence of a definition** — of what scale type licenses which operation — and not an empirical claim; what is empirical is the premise that no linking instrument exists, which is stated as postulate P3 in Section 14.2. The band table of Section 6.3 is a **convention of this framework**, chosen for round numbers in nats, and is not a measured set of thresholds; it must never be reported as one. The identification of the observer's whole contribution with a single non-negative scalar `r` is a **design choice**, adopted for tractability and for the fixed-point guarantee, and Section 3.6 states what it costs.

19.3 3 Framework: the equation, the scale-type gate, and what identification is available

19.3.1 3.1 What is presupposed

Three results from elsewhere in the corpus are used and not re-derived.

The surplus functional and its ceiling. `F(u) = ln(1 + (N−1)u)`, uniquely characterised by angle-only dependence, zero at parallel, an affine effective count and a normalisation, with `N_eff = 1 + (N−1)u` and `0 <= F(u) <= ln N` [Curzi, 2026]. The ceiling is the result this paper's own ceiling inherits from. **`N_eff = 1 + (N−1)u` is a linear interpolation between 1 and `N` and is not a Hill number**; `1/HHI` and `exp(H)` are the Hill numbers of order two and one and are fully grounded [Hill, 1973, Jost, 2006], and neither of them is the quantity used here. Every effective count in this paper is the affine one, and the ceiling `ln N` uses the **raw category count `N`**, not `N_eff`, because `F(u) <= ln N` is attained only at `u = 1` where the two coincide.

The storage law and its steady state. `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` is a first-order linear difference equation whose update map is a contraction for any `delta > 0`, with steady state `Q_inf = (eta S − C)/delta`, and for which `delta = 0` is a pathology rather than an ideal: no contraction, no unique fixed point, and an error-persistence column of all ones, so no mistake ever decays out of the stock [Curzi, 2026a]. This paper substitutes `M` for `S` and inherits everything.

The contraction theorem. A contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass [Curzi, 2026, Banach, 1922].

The reflexive law. The corpus's founding formal claim is the loop `T(x) = W(x, M(x))`, with the self-fulfilling prophecy identified as a fixed point of that composition of seeing and responding [Curzi, 2026]. It is presupposed, and Section 3.7 states what it costs.

19.3.2 3.2 The statement, badged

> **THE MOMENT EQUATION** *(postulate; this work; no external support).* For an observer in contact with an environment, the moment as lived is the environment scaled by the ratio of the frame the observer brings to the intake the observer takes:

```
M = (D / P) . E

D = perspective  : the structure the observer imposes —— model, expectation,
                   prior, doctrine, training, the shape the observer is
                   prepared to find
P = perception   : the structure the observer takes in —— intake, evidence
                   actually registered, the raw admission of what is there
E = environment  : what is actually available to be had at this place and time
M = moment       : the situation as it is lived; the input the observer's own
                   storage law will integrate
```

This is a postulate and not a theorem. **The corpus's own coverage audit records that no external literature was found for either this relation or the calibration ratio derived from it**; the nearest relatives are signal-detection theory, for which this bibliography holds no entry, and convergent/discriminant construct validation [Campbell and Fiske, 1959, Cronbach and Meehl, 1955], neither of which states this relation. Nothing established elsewhere in the corpus depends on it. It is offered as the load-bearing hypothesis of the internal instrument, with the badge on, and Section 9.2 names exactly what would kill it.

19.3.3 3.3 Why a ratio and not a difference

The first structural decision is that `D` and `P` are combined by division rather than by subtraction, and it is not free.

Four quantities in this framework are logarithmic: surplus `F = ln N_eff`, pitch `p = log2 f`, sensation `S = k ln(I/I_0)`, and the moment. Taking logarithms,

```
ln M = ln D − ln P + ln E
```

A ratio in the world is a difference in the lens. If `D` and `P` were combined additively the moment would not compose with surplus, with pitch or with sensation, and none of the framework's conversion keys would apply to it. By dividing, the moment joins the register the other three occupy, and every operation available there — the log-ratio distortion measure of Section 6, additive composition along a chain, the log-space contraction — becomes available here.

There is a second reason and it is empirical rather than architectural. Weber's law states that the just-noticeable difference is a constant *ratio* and not a constant difference [Weber, 1834], and Fechner's integration of it yields `S = k ln(I/I_0)` [Fechner, 1860, 1966]; the corpus states that integration exactly, as the Lens Theorem, and verifies it numerically to an absolute error of `1.02e−08` against `ln 100` [Curzi, 2026n]. If the instrument being modelled reports ratios, a model of it built out of ratios is the natural choice.

Two cautions belong with that argument and are stated here rather than in Limitations. First, the psychophysical warrant is contested: the power law and the logarithmic law were disputed for a century [Stevens, 1957, Krueger, 1989], and the fitted exponent depends on the experimenter's chosen stimulus range [Teghtsoonian, 1971]. Second, and more usefully, the logarithm does not need the perceptual story at all. Peters and Gell-Mann [2016] derives a logarithmic evaluation function from multiplicative dynamics with **no psychological assumption whatever**, which is a stronger warrant for the framework's logarithms than Fechner is, because it does not require the perceptual account to be true. Where this paper needs a logarithm — in the distortion measure of Section 6.2, whose whole content is that a multiplicative error should be reported additively — it is the multiplicative argument that carries it, and Fechner is a corroborating parallel and not the load path.

19.3.4 3.4 Dimensions and the commensurability requirement

For `M = (D/P).E` to be well formed, `[D] = [P]`. Their ratio is then dimensionless and

```
[M] = [E]
```

The moment inherits the units of the environment. `M` and `E` are the same kind of thing on the same scale, and the observer's contribution is a pure dimensionless multiplier on it. A moment is not a different species of object from the environment that produced it; it is that environment, scaled.

This constrains what `D` and `P` may be. They must be commensurable: the same quantity, measured the same way, once for the frame and once for the intake. **Years of training over number of things noticed is not a ratio and must not be written as a fraction.** The operational requirement is specification SP-1 in Section 10: `D` and `P` must both be *recorded items per unit of environment present*, or both *precision in the same units*, or both *bits of asserted structure per bit of available structure*. Anything else fails the dimensional gate.

For the units of `E` and therefore of `M` this framework adopts **nats of usable structure**, so that `M` substitutes directly for `S_t` in the storage law and inherits the ceiling `0 <= M <= ln N` of Section 4.6. The nat here is the unit of **Shannon entropy** — a dimensionless information measure over a distribution on `N` categories [Shannon, 1948, Cover and Thomas, 2006] — and **not** thermodynamic entropy, which carries `[energy][temperature]^−1`. The two are different objects and this framework identifies the moment with neither. Other unit choices are possible and must be declared.

19.3.5 3.5 The scale-type gate, and the demotion

This is the gate the formula fails, and the failure is the paper's principal result.

Permissible arithmetic is fixed by scale type [Stevens, 1946], and the condition is a condition on the transformations that leave the measurement structure invariant [Narens, 1996, Luce, 2002]:

Operation	Minimum scale required
Classification, identity	Nominal
Ranking, ordering, median, rank correlation	Ordinal
Addition, subtraction, arithmetic mean, standard deviation	Interval
Multiplication, division, ratio, geometric mean, logarithm	**Ratio, with a true zero**

`M = (D/P).E` contains one division and one multiplication. **Therefore `D`, `P` and `E` must each be measured on a ratio scale with a meaningful zero, or the expression is not an equation.** If the best available data on `D` is a five-point self-report of how strongly the observer expected what they found, the ratio `D/P` has no referent: a 4 is not twice a 2 on a summated rating item [Likert, 1932], because such an item carries neither a true zero nor a defensible unit. An interval scale can be built without asking respondents to use numbers at all [Thurstone, 1927], but an interval scale is still one gate short of what division requires.

> **DEMOTION RULE (R1).** Where only ordinal data exist for `D` or `P`, the moment equation shall be written and read as a **heuristic ordering** — *more frame relative to intake produces a larger and more model-shaped moment* — and shall **not** be printed as a fraction, computed, or used to generate a number. The demoted form remains useful. It is not the equation.

The rule is not hypothetical. It fires on this framework's own formula. The corpus's validation protocol, applied in full, returns DEMOTE on the scale-type gate for `M = (D/P).E` as the equation stands: `D` and `P` are not instrumented on a common ratio scale with a shared true zero, so the magnitude of `D/P`, the distortion as a number, and the quantitative moment-to-storage join are withdrawn as measured quantities [Curzi, 2026t]. That withdrawal is one entry in a standing register of the corpus's own demotions and inversions [Curzi, 2026], and the same verdict is recorded again where the corpus's personal formulary demotes five of its own nine entries on scale type, withdrawing `D/P` magnitude and the quantitative moment-to-storage join while retaining the limiting cases, the `D = P` fixed point and the over/under-framed ordering [Curzi, 2026q].

> **WHAT IS NOT REPORTABLE AS A MEASURED QUANTITY.** The *magnitude* of `D/P`; the distortion `Delta = |ln r|` as a number; and the quantitative form of the join from the moment to the store. **Every figure of that kind printed anywhere in this paper is an illustrative construction demonstrating the structure of the formula**, and is labelled as such at each occurrence and again in the audit of Section 12.4.
>
> **WHAT SURVIVES INTACT.** The four limiting cases (Section 4); the fixed point `D = P` and its uniqueness (Section 5.1); and the three-way ordering over-framed / calibrated / under-framed (Section 7.1). **All three need only ordinal information, and none is touched by the demotion. What is demoted is magnitude, not structure.**

The route out is procedural and it is costed. Given a badged additivity postulate, if `D` and `P` are measured as person-measures on one common linked scale under a Rasch model [Rasch, 1960, Andrich, 1988], then `Delta = |ln(D/P)| = |theta_D − theta_P|` is genuinely ratio-scaled, because the separability of the Rasch model supplies the true zero that division requires and

fixes the unit up to choice. The measurement cost is the honest part: **approximately 123 items per term to establish a half-logit distortion at 95 per cent, and about 31 items for a full logit** [Curzi, 2026t]. A twelve-item pair of scales cannot resolve anything below roughly 1.6 logits, and a practitioner reporting `r = 1.2` from one is reporting noise.

A second route out exists and is weaker than it looks. Magnitude estimation is claimed to yield genuine ratio-scale measurement of subjective quantity from human respondents [Stevens, 1957, 1975], which would supply the true zero directly. **But the method's own literature contains every failure mode it is exposed to** [Poulton, 1968, 1979], the exponent it recovers depends on the range the experimenter chose [Teghtsoonian, 1971], and self-report instruments in general are exposed to question wording and to focusing effects [Schwarz, 1999, Kahneman et al., 2006]. This paper therefore names magnitude estimation as an available route and does **not** treat it as a settled one.

Read the demotion as the protocol working. A validation gate that demotes its author's own keystone formula, names the exact quantity it kills, prices the study that would restore it, and leaves the structural content standing is doing the job it was written to do. The alternative — printing `r = 1.33` and hoping nobody asks what the unit is — is the practice the protocol exists to replace. The corpus has done this elsewhere and against its own interest: a chapter that refuses a fabricated data point, rejects its most attractive reading at 1,365 to 1, and badges a 25 per cent figure as an artefact of a chosen synthetic ratio rather than a constant [Curzi, 2026] is the same discipline applied in another domain, and it bounds what this paper may claim from constructed examples.

19.3.6 3.6 Michell's objection, met head on

The strongest single objection to this framework is not that the moment equation lacks support. It is Michell [1997]'s: that psychology systematically fails to test whether its attributes are quantitative at all before measuring them, and that the resulting enterprise is pathological science rather than measurement [Michell, 1999]. The corpus's founding move — treating comfort as a measurable quantity — is exactly the move Michell indicts.

This paper concedes the objection and does not answer it. Three things are true at once and all three are stated.

First, **the demotion of Section 3.5 is Michell's remedy applied once.** The framework declined to compute a ratio it could not license, named the quantity it withdrew, and priced the instrument that would restore it. That is the correct response and it is worth more than a confident number.

Second, **applying the remedy once is not applying it.** The same test that demotes `D/P` also bears on `u`, on `Q`, on `E` and on comfort itself, none of which has been subjected to it. A framework that demotes its keystone formula on scale type and then takes arithmetic means of everything else has not adopted a standard; it has made an exception. Section 12.4 therefore audits **every** operation in this paper against the gate, including the ones that survive.

Third, **the test that would settle the question has not been run.** Conjoint measurement is the formal procedure for deciding whether an attribute has additive quantitative structure at all [Luce and Tukey, 1964, Krantz et al., 1971], and it has not been applied to `D`, to `P`, to `E`, to `M`, or to any other quantity in this corpus. Until it is, the quantitative treatment of every one of them is a **stipulation and not a finding**, and the Rasch route of Section 3.5 is a proposal rather than a result. Reporting a coefficient of internal consistency in place of that test would not close the gap [Cronbach, 1951, Sijtsma, 2009].

19.3.7 3.7 Identification: three objections, none of them answered

Three identification objections bear on this paper. All three are stated here, in Method, and none is answered.

The reflection problem. The corpus's founding law is the reflexive loop `T(x) = W(x, M(x))` [Curzi, 2026]: the group influences the member and the members constitute the group. That is a linear-in-means reflexive specification, and Manski [1993] proves that the endogenous social effect in such a specification is **not identified from observational data**. It cannot be separated from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] show the same confounding for network data: influence and selection are generically confounded in observational settings.

This paper's own structure walks into it from the other side. The moment equation assumes `E` is exogenous — that the environment would have been the same had the observer concluded otherwise — and failure mode FM-10 in Section 11 excludes the cases where it is not: the negotiator, the forecaster whose forecast moves the market, the clinician whose diagnosis becomes the treatment. **That exclusion is not a solution to the identification problem. It is a confession that the framework has none**, and it removes from scope precisely the class of situations in which the corpus's founding reflexive law is operating.

Which remedy this paper adopts: none. The available options are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]; the last is the most realistic route here and the seeded audit's fixed, externally adjudicated item set is a step toward it rather than a substitute for it. Because no remedy is adopted, **every applied reading of `r` in this paper is a modelling position and not an identified empirical result**, and it is stated as one in Section 15. That reflexivity is a real phenomenon rather than a formal curiosity is not in doubt: MacKenzie and Millo [2003] documents a reflexive fixed point in the field, with dates and price data, in which a pricing model that did not fit the market when published came to fit it after traders adopted it. Soros [2013] is the closest existing named doctrine to the corpus's reflexive law and supplies the concept without an equation.

The observer as its own instrument. This paper's specific version of the problem is sharper than the general one. The quantity being estimated — the frame the observer brings — is the same quantity doing the estimating, which is why Section 7.3 concludes that calibration cannot be self-assessed. The supporting result is that people cannot reliably report the processes producing their own judgements [Nisbett and Wilson, 1977]; the framework's response is to make every estimator external (SP-8). But the external estimator is not free of the problem either, because prior expectation measurably shapes what is perceived and reported through identified channels [Rosenthal and Fode, 1963, Rosenthal and Jacobson, 1968], and the adjudicators who build the seeded item set are themselves observers with frames. **The framework's honest position is that the audit relocates the problem to a party whose frame is at least declared, and does not remove it.** The size of the expectancy effect is itself contested and is smaller than its popular reading [Jussim and Harber, 2005]; and the act of measuring an observer changes the observer being measured [McCambridge et al., 2014], which is a direct threat to any claim that a re-audit measures the same person.

The Lucas critique applied to this framework's own parameters. Lucas [1976] is the corpus's own reflexivity turned on the corpus: parameters estimated in a population that does not know the law cannot be assumed stable in a population that has read it, and classifications of people interact with the people classified [Hacking, 1995]. This paper asserts in Section 8.4 that a throughput metric drives `r` upward across a whole population, and prescribes changing the metric — and then treats the correction gain `a` and the drift rate `w` as constants over the correction horizon. **Both cannot hold without qualification.**

The position taken here is the narrow one, and it is a real restriction rather than a disclaimer. `a` and `w` are treated as stable **only over one declared audit cycle, and only while `r` and its components are not themselves reported targets.** The moment the off-model detection rate enters a quarterly report — which is exactly what Section 12.2 prescribes — it becomes a measure that is a target, and a measure that becomes a target ceases to be a good measure [Goodhart, 1975, Campbell, 1979]. The worked example in Section 12.1 shows this happening on schedule and does not conceal it. Where `r` is reported upward, the framework's own reflexivity applies to it and the constancy assumption fails. Prescriptive frameworks are not

neutral about what they make true [Ferraro et al., 2005], and a framework that tells an organisation its inspectors are two-thirds confabulating should expect that statement to change the inspectors.

19.3.8 3.8 Standing honesty clauses

1. **The moment equation is a postulate, not a theorem.** It is not derived from the corpus's established results and none of them depends on it.
2. **The correspondence with predictive processing (Section 5.7) is a correspondence between formalisms and nothing more.** It is badged in Section 14.7 as an analogy in the strict sense: a suggestive correspondence with no formal warrant, legitimate as motivation and never as evidence. **This bibliography contains no entry for the predictive-processing literature**, so the correspondence is stated here without external support and must not be read as borrowing that programme's authority.
3. **`M` is the moment as lived, not the moment as true.** The formula does not compute what is really there; it computes what the observer ends up with. Section 5.6 makes the difference quantitative.
4. **The ceiling `M <= ln N` is a consequence of a theorem plus a convention**, not a free-standing discovery: the bound `0 <= F <= ln N` is the surplus law's range result [Curzi, 2026] and the mapping of `M` into that register is a normalisation choice of this framework.
5. **No claim is made that `D`, `P` or `E` correspond to anything neural.** They are parameters of a descriptive model of behaviour.
6. **Every worked number in this paper is illustrative model output.** No dataset was collected. Section 12.3 prints the numbers in the source material that do not reconcile, rather than correcting them silently.

19.4 4 The composite parameter, the four limits, and the ceiling

Before the limits, the equation reads like a circuit. `E` is the source and has whatever it has: a room with three exits, a manuscript with eleven errors, a patient with a set of signs, a market with a set of prices. `E` does not depend on the observer, and that commitment is what makes this a relation about contact rather than about opinion; were `E` observer-dependent the expression would be circular and would predict nothing. `P` is the aperture — how much of `E` is admitted, which cannot exceed what is there and is usually well under it. `D` is the gain applied to whatever came through. `M` is what leaves the stage and is integrated by the storage law: the thing remembered, the thing that becomes character, the thing an institution writes down.

The four limiting cases are what happens when one element goes to an extreme, and each is a condition clinicians, editors, auditors and inspectors already recognise without an equation. **The claim is that one line predicts all four, and that the four are not four pathologies but one parameter at four values.**

19.4.1 4.1 The composite parameter

The equation has four symbols and three degrees of freedom, because `D` and `P` enter only through their ratio. Define

```
r = D / P          the CALIBRATION RATIO      (dimensionless)
M = r . E
```

Everything `D` and `P` do to the moment they do through `r`. **A tenfold increase in both is a tenfold increase in nothing.** The practical consequence is immediate: an intervention raising frame and intake together changes what the observer can handle, not how distorted the observer is.

This is also the identification limit, and it is exact. `(D, P, E)` and `(kD, kP, E)` are observationally identical for every `k > 0` — a one-parameter unidentified family. `r` is recoverable; the split of `r` into `D` and `P` is not recoverable from `M` alone; `E` requires an independent instrument. Any claim about the absolute magnitude of a person's frame or intake therefore needs a second instrument and must carry a note that it is not identified by the moment measurement (SP-4). The signed distortion is `ln r`, the unsigned distortion `|ln r|`, and both are developed in Section 6.

19.4.2 4.2 Limit 1: `P -> 0`, the frame with no intake

```
P -> 0,  D and E fixed  =>  M -> infinity
```

Computed, with `D = 1` and `E = 1`:

`P` (intake)	`M`
1.0	1.000
0.5	2.000
0.25	4.000
0.1	10.000
0.05	20.000
0.01	100.000
0.001	1 000.000
0.000001	1 000 000.000

This is the only divergence in the formula, and the limiting-case gate requires that a divergence name a real phenomenon or the formula is wrong. It does, under several names. **Dogma**: the doctrine is complete, no observation is admitted that could revise it, every event reads as confirmation, and the moment is enormous and entirely manufactured. **Apophenia**: structure perceived in noise, the intake carrying no signal and the frame supplying all of it. **Hallucination**, in the technical sense of a percept without a corresponding stimulus — the formula explains nothing about hallucination and makes no clinical claim; it says only that a percept with a frame and no intake has the term structure `D/0`. **The over-fitted institution**, whose model is elaborate and whose measurement is degraded, so that everything which happens is already in the plan; the organisational literature reaches the same place from sensemaking [Weick, 1995, 1993] and from the erosion of local variety under a legible scheme [Scott, 1998].

Note the direction, because it is counterintuitive and it is the formula's sharpest prediction. **Reducing intake does not reduce the moment. It inflates it.** The person who has stopped looking does not experience less; they experience *more*, and more confidently, and with less friction. A shrinking `P` feels like clarity. That is why the condition is stable, why it is pleasant and why it does not self-correct: the internal signal that would say *look harder* — the sense that the situation is thin — is exactly the signal that vanishes as `P` falls. **The subjective symptom of `P -> 0` is not confusion. It is certainty.**

There is an honest limit to what the formula can say here. **A divergence to infinity is a modelling artefact**; no real observer's moment is unbounded. Section 4.6 supplies the ceiling, and with it in place the correct statement is that as `P -> 0` the moment saturates at the observer's full repertoire — the observer sees the maximum their categories permit, all of it supplied by themselves. Saturation at maximum internal structure with zero external content is a better description of dogma than divergence to infinity, and it is what the bounded model predicts.

19.4.3 4.3 Limit 2: `D -> 0`, the intake with no frame

```
D -> 0,  P and E fixed  =>  M -> 0
```

`D` (frame)	`M` (with `P = 1`, `E = 1`)
1.0	1.000000
0.5	0.500000
0.1	0.100000
0.01	0.010000
0.001	0.001000
0	0.000000

The moment collapses. Everything is arriving; nothing is being made of it. **This limit carries the framework's second thesis, stated as flatly as it can be: sensation is not experience.** An observer can be saturated with intake — every detail registered, nothing missed — and have no moment at all, because a moment requires something to be made of what arrived, and `D` is the term that makes it.

The named conditions are **flooding** (the novice in their second week: they see everything, they can rank nothing); **overwhelm**, which is not too much input in an absolute sense but too much input relative to the structure available to organise it — a distinction that matters enormously for intervention, because reducing the load treats the first and supplying a frame treats the second, and the second is far more common; **the flattened moment**, described phenomenologically as things being present but not mattering, for which the formula offers a structure — full `P`, near-zero `D`, therefore near-zero `M` — and makes no clinical claim whatever; and **the data-rich, decision-poor organisation**, everything logged and nothing concluded.

The asymmetry between the two limits is worth staring at. **Losing intake makes the world feel bigger; losing frame makes it feel like nothing.** Neither feels like an error from inside. One feels like insight and the other like exhaustion.

19.4.4 4.4 Limit 3: `E -> 0`, the environment with nothing in it

```
E -> 0,  r fixed  =>  M -> 0
```

With `r = 3` fixed:

`E`	`M`
10	30.00
1	3.00
0.1	0.30
0.01	0.03
0	0.00

This limit looks trivial and is not. **No calibration ratio, however good, manufactures a moment out of an environment that has nothing in it.** The best-tuned observer in an empty room gets an empty moment; `r = 1` multiplied by zero is zero. That is the framework's answer to the doctrine that attitude is sufficient: it is not sufficient, it is a multiplier, and a multiplier on zero is zero. The engineering of `E` — the room, the table, the sightlines, the acoustics, the cadence — is not replaced by anything in this paper. **This paper is a multiplier on that work, and the equation encodes exactly that relationship.**

The reverse reading is the more useful one operationally. If `M` is small and `r` has been established near 1, the problem is `E` and no amount of internal work will fix it. **A calibrated observer in a poor environment is not a psychological case; they are a correct instrument reporting a true reading, and the intervention is in the room.** More observers are in this condition than in either distortion condition, and mislabelling it as a perception problem is among the most common and most damaging available errors (SP-10, FM-6).

19.4.5 4.5 Limit 4: the ratio limits

```
r -> infinity  =>  M / E -> infinity     over-framed without bound
r -> 0         =>  M / E -> 0            under-framed without bound
r = 1          =>  M = E                 the fixed point
```

r	M/E	signed distortion ln r	Condition
0.01	0.01	−4.6052	Extreme under-framing
0.10	0.10	−2.3026	Extreme under-framing
0.25	0.25	−1.3863	Severe under-framing
0.50	0.50	−0.6931	Severe under-framing
0.80	0.80	−0.2231	Mild under-framing
0.90	0.90	−0.1054	Mild under-framing
1.00	**1.00**	**0.0000**	**Calibrated — contact**
1.10	1.10	+0.0953	Calibrated (band edge)
1.25	1.25	+0.2231	Mild over-framing
1.50	1.50	+0.4055	Marked over-framing
2.00	2.00	+0.6931	Severe over-framing
4.00	4.00	+1.3863	Severe over-framing
10.00	10.00	+2.3026	Extreme over-framing
100.00	100.00	+4.6052	Extreme over-framing

Read the third column, not the first. **The log-ratio is symmetric — `r = 2` and `r = 0.5` are the same distance from contact, 0.6931 nats, in opposite directions — and the raw ratio is not.** On the raw scale over-framing appears to have unlimited room and under-framing appears squeezed into `(0,1)`. That is an artefact of the coordinate, and Section 6.2 removes it. **Under the demotion of Section 3.5 the entries in the last two columns are illustrative arithmetic on the model and not measurements**; what the table establishes is the ordering and the symmetry, both of which survive.

19.4.6 4.6 The ceiling `0 <= M <= ln N`, and which effective count it uses

Left as written, `M = (D/P).E` is unbounded, and Section 4.2 has already flagged that a divergence to infinity is an artefact. The bound comes from the register. For the moment to serve as `S_t` in the storage law it is normalised into the surplus band; the surplus law's ceiling is a theorem, `0 <= F(u) <= ln N` [Curzi, 2026], and the normalisation is a convention. Together:

```
0 <= M <= ln N        [THEOREM (surplus range) + CONVENTION (normalisation)]
N = the number of categories the observer can distinguish
```

`N` here is the raw count of distinguishable categories. The affine effective count `N_eff = 1 + (N−1)u` is the quantity that appears *inside* the surplus functional and reaches `N` only at `u = 1`, which is where the ceiling is attained; **it is not a Hill number** and no external literature contains it, whereas `1/HHI` and `exp(H)` are the Hill numbers of order two and one and are fully grounded [Hill, 1973, Jost, 2006]. A reviewer reaching for the Hill-number literature as support for `N_eff` will find that it does not apply. **The ceiling of this paper uses the raw `N`; every other effective count in this paper is the affine one; and neither is a measured quantity here.**

The richest possible moment is the logarithm of how many kinds of thing the observer can tell apart. The framework reads this as Ashby's law of requisite variety — only variety absorbs variety [Ashby, 1958, 1956] — in first-person form. **That reading is an analogy and is badged as one in Section 14.7:** Ashby's theorem is a statement about a regulator, a disturbance set and

a goal set, and this paper does not show that an observer's categories satisfy those premises. The bound itself does not depend on the reading; it follows from putting the moment into the surplus register at all.

Computed:

`N` (distinguishable categories)	`ln N` (max moment, nats)	in octaves at `2F/ln 2`
2	0.693147	2.0000
3	1.098612	3.1699
5	1.609438	4.6439
7	1.945910	5.6147
10	2.302585	6.6439
12	2.484907	7.1699
20	2.995732	8.6439
50	3.912023	11.2877
100	4.605170	13.2877
1 000	6.907755	19.9316
10 000	9.210340	26.5754

A note on the third column, because the source is silent on it and a reviewer will not be. The conversion used is `2F/ln 2 = 2.885390 F`, which is **twice** the direct change of logarithmic base `F/ln 2 = 1.442695 F`. The factor of two is not a typographical accident and it is not free: it comes from the exponent 2 in the corpus's essence bridge `f_min = k e^{2c/eta}` [Curzi, 2026], where a unit change in the argument moves the logarithm of the frequency by two — the same elasticity that makes `d ln f_min / d(c/eta) = 2` and turns a 0.1 error in `c/eta` into a 22.14 per cent error in `f_min` [Curzi, 2026]. **The source material of this paper does not say so.** Read as a plain change of base, the column is wrong by a factor of two; read as a conversion into the essence register it is correct and its warrant lies outside this paper. The defined constant in that bridge, `k = (9/8)^2 / phi^2 = 0.483425732988414`, is **exact by definition** and its fifteen figures are legitimate for that reason alone; attaching `Hz` to it is a separate and much stronger claim [Curzi, 2026]. Nothing in the present paper depends on `phi`, and the golden-section literature's own scepticism about attributions of `phi` [Markowsky, 1992] is recorded here because that constant is quoted at that precision.

Finally, the brutal fact of the logarithm, restated at this scope. **Doubling the repertoire adds `ln 2 = 0.693147` nats to the maximum moment, wherever one starts.** `ln 100 − ln 50 = 0.693147` and `ln 4 − ln 2 = 0.693147`, identically. Going from fifty distinguishable kinds of thing to a hundred buys precisely as much ceiling as going from two to four, at forty-eight times the cost. **A distortion problem cannot be solved by learning more categories.** Raising `N` raises a ceiling the observer is almost certainly not touching; at `r = 2.1` the observer is manufacturing half their moment, and added vocabulary gives them more material to manufacture it from. Fix `r` first: it is the multiplier, and `N` is only the roof.

19.5 5 The fixed point at contact and its dynamics

19.5.1 5.1 `D = P`: the fixed point

```
D = P    =>    r = 1    =>    M = E        for every E
```

When the frame the observer brings equals the intake the observer takes, the moment equals the environment. That is veridical perception stated as an equation, and it is the paper's second result. It requires care, because it is easy to read past.

It is an identity, not an approximation. At `D = P` the observer's contribution to the moment is exactly the multiplicative identity — not small, not negligible, exactly one. The observer

is still fully present: `D` is not zero, `P` is not zero, both are working at whatever magnitude the situation demands, and the product of their activity is the environment, unmodified.

It holds for every `E`. That is what makes it a fixed point of a relation rather than a coincidence at one value. There is no environment for which calibration fails to deliver contact, and none in which the calibrated observer must trade fidelity for scale. The condition is scale-free in `E`, and for the same structural reason the storage law is scale-free in its stock: only the dimensionless part of the model carries the observer's contribution. Section 14.6 states that invariance formally and says what would break it.

It is not the absence of a frame. This is the common misreading and it inverts the formula. `D = 0` is not contact; `D = 0` is Limit 2 and gives `M = 0`. **Undistorted contact is not the state of having no expectations. It is the state of bringing exactly as much structure as was taken in.** A tradition prescribing that perception be emptied of concept is describing `D -> 0`, and by this formula it is describing not clarity but the abolition of the moment. Clarity does not require less frame; it requires *matched* frame.

It is not passivity and it is not agreement. An observer at `r = 1` in an environment containing a hostile fact perceives a hostile fact at full magnitude. Contact is not comfort. The fixed point makes no promise about what the moment contains; it promises only that the moment contains what the environment does.

It is not certainty. At `r = 1` the observer asserts exactly what they took in, which in a half-legible environment is a half-legible reading. **Calibration means confidence tracks intake, which in a murky room means being appropriately unsure.** The observer at `r = 1` in fog reports fog; the observer at `r = 4` in fog reports a building.

19.5.2 5.2 Why it is a fixed point and not merely an equality

An equality is a coincidence at a value; a fixed point is the invariant of a map. The moment equation as written is a static relation, so a dynamics is required, and the dynamics is the observer's own correction behaviour. Postulate the simplest correction available: after each contact, compare what was asserted with what came back, and move the frame toward the intake by a fraction of the discrepancy. In log coordinates, with correction gain `a`:

```
ln r_{t+1} = (1 − a) . ln r_t              THE CORRECTION MAP  [POSTULATE]
fixed point:  ln r* = 0,  i.e. r* = 1,  i.e. D = P
```

This is a first-order linear recurrence in log space and nothing more exotic. It is the same object as the storage law with input and cost set to zero: a leaky integrator relaxing to its fixed point, with pole `(1−a)`. The whole standard theory of such recurrences applies without modification — the fixed point, the stability condition, the geometric transient [Elaydi, 2005, Kelley and Peterson, 2001] — and the control-theoretic reading of `a` as a loop gain with a stability margin is standard [Åström and Murray, 2008]. Its statistical twin is exponential smoothing with smoothing constant `a` [Holt, 1957, Brown and Meyer, 1961], and the first-order discrete section it describes is the one every signals text develops [Oppenheim et al., 1996]. **This is a shared mathematical form, not a derivation from physical premises**, and Section 14.7 says so in the terms the rigour standard requires: a leaky integrator is a leaky integrator whether it holds charge or a frame, and no physical result's authority transfers to an observer.

By the contraction theorem [Curzi, 2026, Banach, 1922] the map has a unique fixed point and iteration converges to it geometrically whenever `|1−a| < 1`, that is, whenever

```
0 < a < 2                    the stability condition for calibration
```

Trajectories from an initial distortion `ln r = +0.8122`:

gain `a`	pole `abs(1-a)`	steps to `abs(ln r) < 0.10`	first six values of `ln r`
0.10	0.90	20	+0.7310 +0.6579 +0.5921 +0.5329 +0.4796 +0.4316
0.20	0.80	10	+0.6498 +0.5198 +0.4158 +0.3327 +0.2661 +0.2129
0.35	0.65	5	+0.5279 +0.3432 +0.2231 +0.1450 +0.0942 +0.0613
0.50	0.50	4	+0.4061 +0.2031 +0.1015 +0.0508 +0.0254 +0.0127
0.75	0.25	2	+0.2031 +0.0508 +0.0127 +0.0032 +0.0008 +0.0002
1.00	0.00	1	0 0 0 0 0 0 (deadbeat)
1.30	0.30	2	−0.2437 +0.0731 −0.0219 +0.0066 −0.0020 +0.0006
1.80	0.80	10	−0.6498 +0.5198 −0.4158 +0.3327 −0.2661 +0.2129
2.00	1.00	never	−0.8122 +0.8122 −0.8122 +0.8122 −0.8122 +0.8122
2.30	1.30	never	−1.0559 +1.3726 −1.7844 +2.3197 −3.0157 +3.9204

The source of this paper describes `+0.8122` as "the value measured in the worked example" of the seeded review audit. It is not. That audit returns `ln r = +0.544727` (Section 12.1). The trajectories in the table are arithmetically correct from a start of `+0.8122` — Section 14.4 redoes the divergent row line by line — but the attribution is wrong, and it is printed here rather than corrected silently. `+0.8122` corresponds to `r = 2.2529`, which is not a value this paper computes anywhere.

Three readings follow, all of which Section 8.1 turns into procedure.

1. **Under-correction converges, slowly.** The observer who adjusts a little each time arrives: twenty encounters at `a = 0.10`, five at `a = 0.35`.
2. **Over-correction past `a = 1` oscillates** — the observer overshoots to the far side of contact each cycle — **and still converges while `a < 2`.** Oscillating correction is inefficient, not fatal.
3. **At `a >= 2` calibration diverges.** The observer who reverses their whole position at every contradiction, then reverses again, gets further from contact with each iteration. At `a = 2.30` the trajectory runs 1.06, 1.37, 1.78, 2.32, 3.02, 3.92 — a distortion of 3.92 nats, `r` near 50, a factor of fifty from contact reached in six cycles from a start of 0.81. **This is a mechanism and not a metaphor, and it is the same stability condition an engineer applies to a feedback loop** [Åström and Murray, 2008].

The fixed point is therefore an attractor and not a static ideal, and its basin is the set of correction gains strictly between 0 and 2. With no correction at all, `a = 0`, it is neutrally stable:

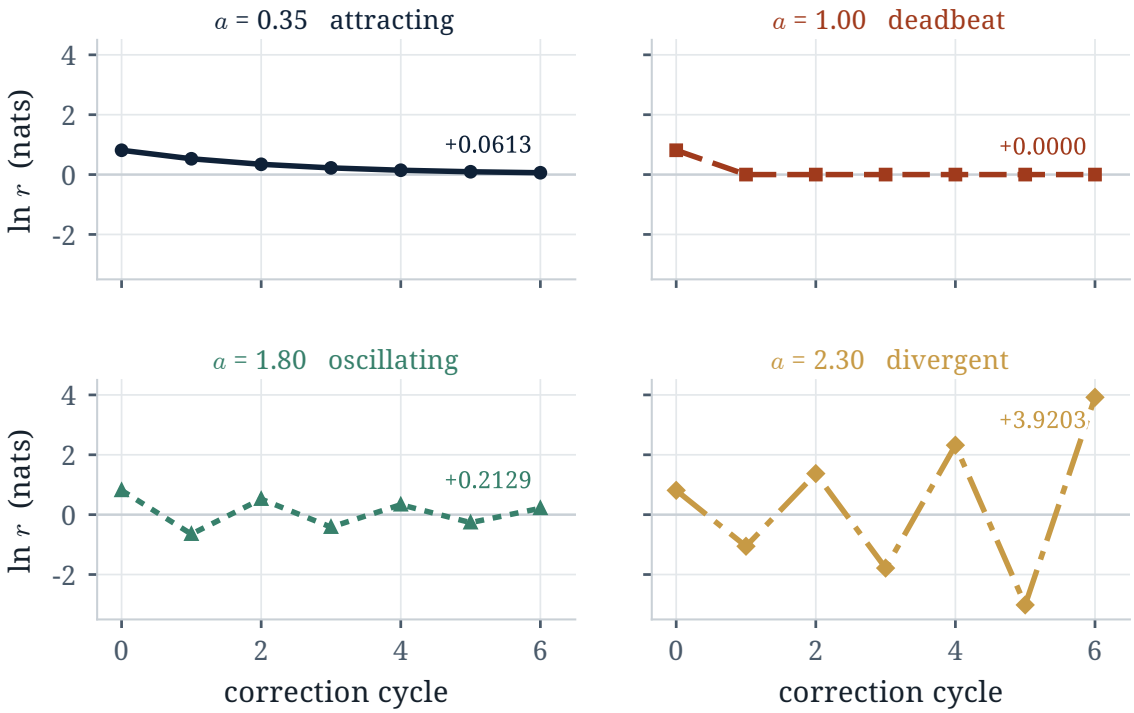

Figure 19.1: **The stability band is a property of the gain, not of the observer.** Trajectories of the signed distortion `ln r` under the correction map `ln r_{t+1} = (1−a) ln r_t` from a start of +0.8122, at the four gains that bracket the band: 0.35 converges monotonically inside five cycles, 1.00 is deadbeat and reaches zero in one, 1.80 oscillates and still converges, and 2.30 alternates with growing amplitude and reaches 3.9203 nats by the sixth cycle — `r` near 50, a factor of fifty from contact. Every plotted value is an entry of the trajectory table in Section 5.2. Illustrative model output from a stipulated start and stipulated gains; generated by `figs/src/CCP-019_fig01.py`.

whatever distortion the observer has, they keep. That is the default. **Contact is maintained, not attained.**

Under the demotion of Section 3.5 the *numbers* in that table are illustrative arithmetic on the model. **What survives the demotion is the trichotomy** — attracting, neutral, divergent — which depends only on the sign and rank of `ln r` and on the value of a design parameter the analyst chooses rather than measures.

19.5.3 5.3 The fixed point across scopes

The framework reads the same row at two scopes:

Term	Internal reading (psychology)	External reading (sociology)
`D/P`	frame-to-intake ratio	**doctrine-to-data ratio**
`M`	the moment as lived	the situation as the group constructs it

An institution at `D = P` asserts exactly what its instruments measured: it does not manufacture and it does not drown.

`r = 1` reads correctly at both scopes without modification, which a merely metaphorical correspondence would not do. That is offered as the framework's evidence that psychology

and sociology are one subject at two scopes, and it is worth exactly what a structural observation is worth — **it is not an identified empirical result**, for the reason Section 3.7 gives, and the group-scope reading in particular is the one the reflection problem bites hardest [Manski, 1993].

19.5.4 5.4 Sensitivity: unit elasticity in all three terms

Differentiating the log form,

```
ln M = ln D − ln P + ln E
dM/M = dD/D − dP/P + dE/E
```

Every elasticity is exactly +1 or −1. Verified numerically at `D = P = E = 1`: `+1.000000` with respect to `D`, `−0.999999` with respect to `P` (finite-difference error), `+1.000000` with respect to `E`.

A one per cent error anywhere produces a one per cent error in the moment. There is no term that may be treated sloppily and no term whose error is amplified. That is a genuine virtue of the multiplicative form: a formula with a squared term or an exponent would have a sensitive parameter and a forgiving one and would require measurement effort to be allocated unevenly. It is also what makes the framework's *other* elasticity results notable by contrast — the essence bridge has elasticity 2 and is correspondingly brittle [Curzi, 2026].

The asymmetry that does exist is between numerator and denominator at large deviations, because a ratio is not symmetric in its arguments:

perturbation	effect on `M`
`D` up 1%	factor 1.0100 (+1.00%)
`D` up 10%	factor 1.1000 (+10.00%)
`D` up 50%	factor 1.5000 (+50.00%)
`P` up 10%	factor 0.9091 (−9.09%)
`P` down 10%	factor 1.1111 (+11.11%)
`P` up 50%	factor 0.6667 (−33.33%)
`P` down 50%	factor 2.0000 (+100.00%)

Halving intake doubles the moment; halving frame halves it. The two errors are not equally available or equally seductive, and the table shows why: the pathological direction is the one with the larger reward.

19.5.5 5.5 The join: the moment becomes character

The moment equation is the input stage and not the end of the pipeline. Substituting the moment for the surplus input in the storage law,

```
THE SELF-STORAGE LAW      Q_{t+1} = (1 − delta) Q_t + eta M_t − C_t
```

That is the architecture: perspective and perception produce the moment; the moment becomes character. All the storage law's properties are inherited [Curzi, 2026a]. The consequence for calibration is unpleasant.

Take an observer with `eta = 0.35`, `delta = 0.08`, `C = 0.20`, in an environment worth `E = 1.0` nat. The steady state `Q_inf = (eta M − C)/delta` gives:

condition	r	M = rE	Q_inf
Under-framed	0.352941	0.3529	−**0.9559**
Calibrated	1.047619	1.0476	+2.0833
Over-framed	1.900000	1.9000	**+5.8125**

The over-framed observer stores nearly three times as much as the calibrated one. The storage law integrates the moment as lived and does not inspect it; there is no term in `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` that asks whether `M` was earned. That is not a defect in the storage law. It is the storage law telling the truth about a real phenomenon: **dogma accumulates faster than knowledge, and by exactly the same mechanism.** The confident, model-driven, low-intake observer builds a large, stable, internally consistent structure very efficiently.

The under-framed observer by contrast has a **negative** steady state — `eta M < C`, the regime the storage law's steady-state theorem explicitly refuses to hide [Curzi, 2026a]. The flooded novice is not slowly building; they are running down. The model says the flooded state is unsustainable and must be exited, and that is correct.

All three rows are illustrative model output from stipulated parameters. They carry no uncertainty because nothing was measured, and they inherit the demotion of Section 3.5 through `M`, so their magnitudes are not findings.

19.5.6 5.6 Veridical throughput: separating what was stored from what was earned

If the storage law cannot distinguish earned structure from manufactured structure, the analyst must, and the equation supplies the instrument.

> **VERIDICAL THROUGHPUT** *(definition).* The part of the moment the environment actually supplied is

```
V = min(M, E) = E . min(r, 1)
confabulated fraction   = (M − V)/M = 1 − 1/r     for r > 1
missed fraction         = (E − M)/E = 1 − r       for r < 1
```

r	M/E	V/E	confabulated fraction	missed fraction
0.10	0.1000	0.1000	—	0.9000
0.25	0.2500	0.2500	—	0.7500
0.50	0.5000	0.5000	—	0.5000
0.75	0.7500	0.7500	—	0.2500
1.00	**1.0000**	**1.0000**	**—**	**—**
1.33	1.3300	1.0000	0.2481	—
2.00	2.0000	1.0000	0.5000	—
4.00	4.0000	1.0000	0.7500	—
10.00	10.0000	1.0000	0.9000	—

`V` is maximised exactly at the fixed point and only there. Over-framing does not increase what the environment gave; it adds material that came from the observer and is stored as though it came from outside. Under-framing loses what was there. **That is the strongest of the four senses in which `D = P` is the formula's centre: the fixed point is not merely where the moment is undistorted, it is where the earned content of the moment is largest.** This is hypothesis H2, and it is a claim about an audit's shape that a real audit could refute.

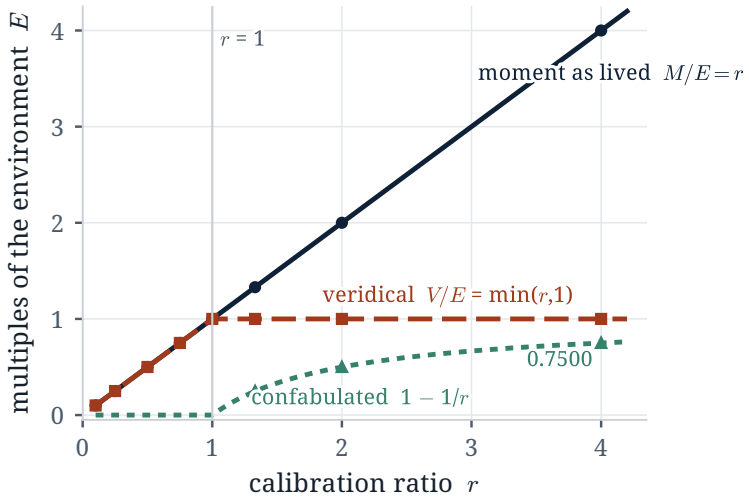

Figure 19.2: **Veridical throughput is single-peaked at contact and the confabulated fraction is its price.** The moment as lived `M/E = r` climbs without limit while the part the environment actually supplied, `V/E = min(r,1)`, is flat above the fixed point; the confabulated fraction `1 − 1/r` accounts for the whole of the difference, reaching 0.2481 at `r = 1.33`, 0.5000 at `r = 2.00` and 0.7500 at `r = 4.00`. Every marked value is a row of the veridical-throughput table in Section 5.6; that table's `r = 10.00` row lies outside the plotted range. Illustrative arithmetic on the model, not a measurement; generated by `figs/src/CCP-019_fig02.py`.

Running both quantities through the storage law separates stored structure from stored error:

condition	`Q_inf` on `M` (as lived)	`Q_inf` on `V` (veridical)	stored error
Under-framed, `r = 0.353`	−0.9559	−0.9559	0.0000
Calibrated, `r = 1.048`	+2.0833	+1.8750	+0.2083
Over-framed, `r = 1.900`	+5.8125	+1.8750	**+3.9375**

The over-framed observer's structure is **68 per cent stored error at steady state** (3.9375 of 5.8125, which is 67.7 per cent, rounded to two figures because the number is illustrative model output and not a measurement). It will be defended as vigorously as the earned third, because from inside there is no difference: **stored error and stored knowledge occupy the same variable.**

The one mechanism that eventually distinguishes them is cost. Structure that does not match the environment generates correction events, contradictions, failures and repairs, and those are `C`. **Over-framing shows up in the books not as bad `Q` but as rising `C`, on a lag.** That lag is why the condition is stable for years and why the diagnostic instruments of Section 7 must be run deliberately rather than waited for. It is hypothesis H6, and Section 8.5 gives the exact condition under which the bill ever catches up.

19.5.7 5.7 What the fixed point costs, and the predictive-processing correspondence

A fixed point that is free is a fixed point nobody needs a procedure for. This one is not free, and the cost has two distinct shapes.

The effort cost. Maintaining `D = P` requires every increase in intake to be matched by an increase in frame and every decrease likewise. Both are effortful — `P` costs attention, `D` costs the construction and maintenance of usable structure — so **calibration is a continuous matching problem under a load budget, and the load appears in the storage law as `C`.** This yields the framework's least comfortable prediction: **distortion is cheap and contact is expensive, in both directions.** Dropping `P` while holding `D` is the cheapest available move: it costs less attention and produces a larger, more confident moment. That is the economics of dogma in one sentence. Dropping `D` while holding `P` is also cheap: nothing then has to be concluded. Both are downhill; only the match is uphill. The engineering response is to **build the circumstance that holds the state** rather than to require a person to hold it by effort, which is what the specifications of Section 10 are for.

The structural cost, which is the counter-result of this paper. At `r = 1` in an environment that saturates the observer's repertoire, the input to the storage law sits at its ceiling, `S = ln N`. Substituting into the steady state and reading the headroom gauge:

```
S     = ln N                        (contact at the fixed point, in a saturating environment)
Q_inf = (eta ln N − C) / delta
h     = eta ln N − delta Q_inf − C
      = eta ln N − (eta ln N − C) − C
      = 0        exactly, by cancellation
```

A perfectly calibrated observer converges to exactly zero headroom. Not approximately, and not through mismanagement: perfect contact drives the input to its maximum, the maximum input drives the store to its maximum, and the maximum store consumes the whole budget in maintenance. The cancellation is exact and both `delta` and `C` drop out of it.

> **A condition the source does not state, and it matters.** The cancellation requires `E = ln N`, not merely `r = 1`. `r = 1` gives `M = E`; it does not give `E = ln N`. The zero-headroom result therefore holds for a calibrated observer **in an environment that saturates their repertoire**, and for no other. In an environment worth `E < ln N` a calibrated observer has headroom `h = eta E − delta Q_inf − C`, which by the same substitution is again zero at the steady state of *that* input — the cancellation is a property of any steady state under constant drive, not of the ceiling. **What the ceiling adds is that a calibrated observer in a rich environment has no room even in principle.** The source presents the two as one step; they are two, and only the second needs the ceiling.
>
> **CORRECTION, and it applies wherever this paper speaks of calibration as a goal: `r = 1` is NOT an unqualified target.** Calibration maximises fidelity and veridical throughput. It does not maximise room to build, and at equilibrium it leaves none. An observer wanting headroom at a settled state must either shed `Q` deliberately or accept `r != 1` as a **declared policy** (Section 8.4). The framework states the trade rather than pretending it away. That headroom is the corpus's name for organisational slack is not incidental: slack is what a system spends when the environment moves [Cyert and March, 1963], and an observer with none is an observer who cannot absorb a surprise.

The predictive-processing correspondence, badged. Predictive-processing accounts in cognitive science model perception as the weighting of top-down predictions against bottom-up sensory evidence, with weights set by the precisions — the inverse variances — assigned to each. In the simplest Gaussian case, with prior mean `mu` at precision `pi_D` and observation `y` at precision `pi_P`, the posterior mean is the precision-weighted average

```
mu_post = (pi_D . mu + pi_P . y) / (pi_D + pi_P)
```

Writing `lambda = pi_D / pi_P` and `w = lambda/(1 + lambda)` for the weight on the prior gives `mu_post = w mu + (1−w) y` and the identity

```
logit(w) = ln( w / (1 − w) ) = ln lambda
```

lambda	w	1 − w	logit(w) = ln lambda
0.01	0.009901	0.990099	−4.605170
0.10	0.090909	0.909091	−2.302585
0.25	0.200000	0.800000	−1.386294
0.50	0.333333	0.666667	−0.693147
1.00	**0.500000**	**0.500000**	**0.000000**
2.00	0.666667	0.333333	+0.693147
4.00	0.800000	0.200000	+1.386294
10.00	0.909091	0.090909	+2.302585
100.00	0.990099	0.009901	+4.605170

The signed distortion `ln r` is the logit of the weight a precision-weighted average assigns to the prior, when `r` is read as the precision ratio. Both formalisms place their invariant at the ratio one and measure departure from it in log units. A worked instance, with a prior expectation of 100 and an observation of 60:

lambda	w	posterior	distance from the evidence
0.1	0.0909	63.636	+3.636
0.5	0.3333	73.333	+13.333
1.0	0.5000	80.000	+20.000
2.0	0.6667	86.667	+26.667
10.0	0.9091	96.364	+36.364

Three caveats, and they are not decoration.

First, **predictive processing is an active and contested research programme, not settled fact**, and — as Section 3.8 records — **this bibliography contains no entry for it at all.** The correspondence is therefore stated here with no external support whatever, and it must not be read as borrowing that programme's authority for anything.

Second, **structural similarity is not identity, and the two objects differ in a way that matters.** The Bayesian weight `w` is bounded in `[0,1]`: a precision-weighted average cannot land outside the interval between prior and evidence. The moment equation's `r` is unbounded above, so `M` can exceed `E` up to the `ln N` ceiling. **The Bayesian model interpolates; the moment equation scales.** The logit identity maps one onto the other cleanly at the level of the log-ratio parameter and does not make them the same model. An observer whose posterior sits between prior and evidence is not manufacturing content; an observer at `r = 4` is.

Third, **the direction of inference runs one way and it is the weak way.** That two independently constructed formalisms place their invariant at the same point is interesting. It is not evidence that either is correct, and this paper does not use it as such. **Section 14.7 classifies it as an analogy in the strict sense** — a suggestive correspondence with no formal warrant — because the premises under which a precision-weighted average is the right model of an observer have not been shown to hold.

19.6 6 The calibration ratio: its measure and its aggregation

The observer's entire contribution to the moment passes through one dimensionless number. This section takes that number on its own, gives distortion a measure, and audits the operations the framework performs on it.

19.6.1 6.1 Definitions

THE CALIBRATION RATIO *(definition).* `r = D / P`, dimensionless, `r > 0`. `r = 1` is contact: the fixed point of Section 5.1, at which `M = E`.

THE DISTORTION MEASURE *(definition).* The signed distortion is `ln r`, in nats, with range `(-inf, +inf)` and zero at contact. The distortion is `Delta = |ln r|`, in nats, with range `[0, +inf)` and zero at contact.

Both are stated as definitions rather than as postulates, because they define quantities rather than assert facts. **What is postulated is that these quantities are worth measuring and that they behave as this paper says; that claim is falsifiable and Section 9.2 says how.** What is *demoted* is their magnitude, and Section 6.3 states what follows.

19.6.2 6.2 Why the measure is a logarithm

Three independent arguments force the logarithm, and a reader who rejects one still has two.

Symmetry. On the raw ratio scale over-framing has infinite room and under-framing is crushed into `(0,1)`. That is a coordinate artefact and it corrupts every summary statistic computed on it. Under the logarithm:

r	ln r	1/r	ln(1/r)
2	+0.693147	0.5000	−0.693147
3	+1.098612	0.3333	−1.098612
4	+1.386294	0.2500	−1.386294
10	+2.302585	0.1000	−2.302585

`ln(1/r) = -ln r` identically. **Seeing twice as much as is there and seeing half as much as is there are the same magnitude of error in opposite directions, and only the log coordinate says so.** On the raw scale `r = 2` sits 1.00 above contact and `r = 0.5` sits 0.50 below it: the same fault priced at half.

Composition. Lenses compose multiplicatively and logarithms turn that into addition:

```
r_total = r_1 . r_2 . ... . r_n
ln r_total = ln r_1 + ln r_2 + ... + ln r_n
```

Distortion budgets are additive in log units and only in log units. Section 8.2 builds a pipeline budget on this and it is not constructible any other way.

Register. Surplus, pitch, sensation and the moment are all logarithmic in this framework, and every conversion between them is linear in log space with exact constants. Reporting distortion in nats puts it in the same register as `F = ln N_eff` and as `S = k ln(I/I_0)` [Curzi, 2026n].

Which of the three the argument actually needs. The symmetry and composition arguments are properties of the logarithm as a function of a multiplicative quantity; they require nothing about perception and nothing about psychophysics. The register argument is the one that leans on Fechner [Fechner, 1860], and it is the weakest of the three, because the psychophysical literature has never settled the logarithmic-against-power dispute [Stevens, 1957, Krueger, 1989] and the fitted exponent depends on the experimenter's range [Teghtsoonian, 1971]. **The stronger warrant for a logarithm, where one is needed, is that a logarithmic evaluation follows from multiplicative dynamics with no psychological assumption at all** [Peters and Gell-Mann, 2016]. This paper's use of the logarithm is the multiplicative one: `r` composes by multiplication along a chain, so its natural additive coordinate is its logarithm. Fechner corroborates and does not carry the load.

19.6.3 6.3 The band table, and what the demotion does to it

Distortion is a continuum and applied work needs bands.

> **The bands below are a CONVENTION of this framework**, chosen for round numbers in nats and for correspondence with recognisable states. **They are not measured constants and must not be reported as if they were.**

Band	`Delta = abs(ln r)` (nats)	over-framed `r`	under-framed `r`	Reading
CALIBRATED	0.00 – 0.10	1.000 – 1.105	0.905 – 1.000	Contact. Within ±10.5 per cent of the environment.
MILD	0.10 – 0.35	1.105 – 1.419	0.705 – 0.905	Detectable, tolerable, worth trending.
MARKED	0.35 – 0.69	1.419 – 1.994	0.502 – 0.705	The moment is meaningfully not the environment. Correct.
SEVERE	0.69 – 1.61	1.994 – 5.003	0.200 – 0.502	Factor of two to five. Decisions from this reading are unsafe.
EXTREME	1.61 and above	5.003 and above	0.200 and below	Factor of five or more. The observer is not in contact.

The band edges are `ln 2 = 0.693147` at the marked/severe boundary and `ln 5 = 1.609438` at the severe/extreme boundary.

The scale-type audit of this table, which the framework owes and which is stated here rather than left to a reviewer. Three claims are being made and they do not all survive.

- **Banding itself is licensed.** Cutting an ordered variable at declared thresholds requires only that the variable be ordinal, and `Delta` is ordinal by Section 3.5. An observer whose distortion falls between two audits has moved toward contact, and that is a finding.
- **The claim that the severe band is "exactly wrong by a factor between two and five" is NOT licensed.** It reads the magnitude of `r`, which the demotion withdrew.
- **The claim that the two directions "occupy the same band width" is NOT licensed either.** Equality of differences on `ln r` requires an interval scale, and `ln r` inherits only an ordinal one. **The symmetry is a property of the logarithm as a function, and it becomes a property of the measurement exactly when `Delta` becomes a Rasch logit difference and not before** [Rasch, 1960, Curzi, 2026t].

The corpus's `f_min` result is the same defeat in another domain and is worth reading beside this one: relabelling an ordinal triple (1.0, 2.0, 3.0) as (0.5, 2.0, 5.0) leaves the ordering unchanged and moves one computed frequency by a factor of 54.6 [Curzi, 2026]. **An ordering that survives relabelling and a magnitude that does not are exactly what an ordinal scale is.**

19.6.4 6.4 Aggregation: the arithmetic mean of `r` is not licensed, and neither is the mean of `ln r`

An observer measured on several occasions produces several values of `r`. The summary statistic matters enormously and the obvious one is wrong.

occasions	arithmetic mean `r`	geometric mean `r`	mean `ln r`	**mean `abs(ln r)`**
{0.5, 2.0}	1.250000	1.000000	0.000000	**0.693147**
{0.4, 0.8, 1.5, 2.5}	1.300000	1.046635	+0.045580	**0.615298**
{1.2, 1.25, 1.15, 1.3}	1.225000	1.223723	+0.201898	**0.201898**

Read row one. An observer who over-framed by a factor of two on one occasion and under-framed by a factor of two on another has an arithmetic mean `r` of 1.25, reporting mild over-framing that never occurred; a geometric mean of exactly 1.000, reporting perfect calibration that also never occurred; and a mean distortion of 0.693 nats, which is severe. **Only the third statistic describes what happened.**

By Jensen's inequality the arithmetic mean of `r` is at least the geometric mean, with equality only when every `r` is identical, so **the arithmetic mean of a calibration ratio always reports over-framing that may not be there.** Row three is the degenerate case where all three agree: a steady, one-directional bias.

The framework's rule, and then the correction the scale type forces on it.

> **AGGREGATION RULE.** Report mean `|ln r|` as the distortion of an observer across occasions. Report mean `ln r` as the bias — the direction they lean. Report the geometric mean of `r` only as a back-transform of the second. **Never report the arithmetic mean of `r`.**

That rule is right about the arithmetic mean and it is **not far enough**. The reason the arithmetic mean is wrong is that `r` is a ratio, and the licensed central tendency of a ratio-scale quantity under multiplicative composition is the geometric mean — which is the arithmetic mean in log coordinates, and which is why the log-scaled psychophysical register recommends it [Fechner, 1860] and why a multiplicative-dynamics argument recommends it independently of any perceptual story [Peters and Gell-Mann, 2016]. **But an arithmetic mean of `ln r` requires `ln r` on an interval scale, and Section 3.5 withdrew that.** Strictly, therefore:

- **Not licensed pending instrumentation:** the arithmetic mean of `r` (twice over — wrong statistic *and* wrong scale); the geometric mean of `r`; the mean of `ln r`; the mean of `|ln r|`; and every percentage change computed from any of them.
- **Licensed now, on ordinal data:** the **median** of `ln r` across occasions; the **sign** of that median, which is the bias; the **rank order** of observers by `|ln r|`; and the **direction of movement** of one observer between two audits on a common item set.
- **Licensed the moment the Rasch instrument of Section 3.5 exists:** all of the above, because `Delta` is then a logit difference on a linked scale [Rasch, 1960, Andrich, 1988].

This paper continues to print means and percentage changes, because they are the arithmetic of the model and a reader must be able to redo them. **Every one of them is badged in the audit of Section 12.4 as not licensed as a measurement**, and the conclusions drawn from them in Section 13 are stated at the ordinal strength the data support. The pair (median `ln r`, rank on `|ln r|`) is the whole honest summary: a direction and a position. An observer with bias `+0.20` and distortion 0.20 leans one way consistently; an observer with bias 0.00 and distortion 0.69 is unstable in both directions and is the harder case, because they pass any audit that averages.

19.7 7 Diagnosis: two states, a differential, and five estimators

19.7.1 7.1 The two states

```
r > 1     OVER-FRAMED      M > E     projection, prejudice, seeing the expected
r = 1     CALIBRATED       M = E     contact
r < 1     UNDER-FRAMED     M < E     flooding, overwhelm, cannot make it mean anything
```

Neither state feels like an error from inside, and the two feel like opposite things. Over-framing feels like clarity, competence, speed and confidence. Under-framing feels like exhaustion, fog and inadequacy. **The pleasant one is the dangerous one**, and that asymmetry organises everything below: over-framing has to be hunted, under-framing announces itself.

Over-framed: the cardinal features.

Feature	What is observed
High on-model detection	Finds what the model predicts, reliably and fast.
Low off-model detection	Misses what the model does not contain, almost completely.
High false-discovery rate	Asserts things that are not there, in the model's shape.
Falling time per case	Speed increases as intake falls, and is rewarded.
Falling surprise rate	Being contradicted becomes rare. Read as mastery.
High confidence	Subjectively: clarity.
Low revision rate	Positions do not change on new information.

Four subtypes differ in what to do about them. **The doctrinal**: the frame is institutional and enforced, deviation carries a career cost, the individual's `r` is a property of the organisation, and individual correction will fail. **The expertise decay**: the frame was earned, was once accurate, and has outlived the environment that validated it — the commonest and most sympathetic form, in which competence correctly acquired becomes distortion by the passage of time in the environment rather than by any error of the observer. This is the mechanism the organisational literature reaches independently, as the myopia of learning [Levinthal and March, 1993] and as the homogenising effect of fast learning on a slow environment [March, 1991]; it is also the mechanism by which an anomaly is progressively normalised into the standing model [Vaughan, 1996]. **The prejudicial**: the frame is a category applied to persons in advance of evidence about them. Structurally identical to the others; the ethical weight is different and this paper does not pretend the arithmetic settles the ethics. What the arithmetic does say is that the mechanism is `P` falling rather than `D` being wicked, and that the correction is intake. **The apophenic**: the intake carries no signal — noise, sparse data, a genuinely ambiguous situation — and the frame supplies all the structure; distinguished by the environment, since a thin `E` makes any `D` produce a large `r`, and **the correction here is often to withhold assertion rather than to change the frame.**

Under-framed: the cardinal features.

Feature	What is observed
High or adequate intake	Notices a great deal. The notes are long.
Low assertion rate	The output is thin relative to the notes.
Rising time per case	Everything takes longer, and the extra time buys little.

Feature	What is observed
High surprise rate	Frequently caught out; the world keeps being unexpected.
Low confidence, high revision	Positions change on weak evidence.
Missed material	Not because it was not seen — because it was not concluded from.
Subjective report	Overwhelm; the material cannot be made to mean anything.

Four subtypes again. **The novice**: the frame has not been built yet; time and structure fix it. This is the benign case and the one everyone assumes they are looking at. **The overloaded**: the frame exists and is adequate but the intake rate exceeds the rate at which it can be applied — distinguished from the novice by performance on a smaller sample, and if the assertions come on a third of the material this is a load problem and the correction is on `P` or on the schedule, not on `D`. **The deframed**: the observer has been instructed to drop their assumptions and come to it fresh, so `D` has been reduced by advice — an **iatrogenic** case in which the intervention caused the condition (FM-5, FM-17). **The fragmented**: the frame exists but is not retrievable under the conditions of use — distributed across notes nobody consults, held by a person not in the room, or dependent on a system that is down. `D` is high in principle and zero in practice, and the correction is availability, not training.

19.7.2 7.2 The differential diagnosis

Observation	Over-framed	Under-framed	Poor environment	Overloaded
`r` from seeded audit	> 1.105	< 0.905	about 1	< 0.905
Intake `P`	Low	High	Normal	High
Assertion `D`	High	Low	Normal	Low
False discovery rate	High	Low	Low	Low
Off-model hit rate	Very low	Moderate	Normal	Low
Time per case	Falling	Rising	Normal	Rising
Surprise rate	Low	High	Normal	High
Performance on a **reduced sample**	Unchanged	Unchanged	Unchanged	**Improves markedly**
Independent measurement of `E`	Rich	Rich	**Thin**	Rich
Primary correction	Raise `P`, cap `D`	Raise `D`	Rebuild `E`	Cut load

Two rows are the ones nobody runs and both are cheap. **The reduced-sample test separates the overloaded from the under-framed in a single session**, and the two need opposite treatments: the overloaded observer given training gets worse, because training adds to the load. **The independent measurement of `E` separates every internal diagnosis from the case where the instrument is fine and the room is empty** (SP-10), and it is the first thing to check because it is the only diagnosis whose correction lies outside the person.

Note the row that carries the threshold: the differential quotes `r` cut points of 1.105 and 0.905, which are the band edges of Section 6.3. **Those are convention, not measurement**, and using them as decision thresholds imports the convention into the diagnosis. The licensed reading of that row is *higher than a declared cut* and not *greater than 1.105 as a magnitude*.

19.7.3 7.3 Why an observer cannot detect their own `r`

The states are not introspectively distinguishable from their causes, and the reason is structural rather than psychological.

At `r > 1` the internal report is: the situation is clear, I know what this is, this is going quickly. Every one of those reports is *also* what contact feels like. There is no experience attached to the assertions that were not there, because the observer does not experience them as manufactured — **`M` is the moment as lived, and a manufactured moment is lived exactly as a found one is.** The only internal signal that would discriminate is surprise, and surprise is precisely the quantity that falls as `P` falls. At `r < 1` the internal report is: I am not good enough at this — indistinguishable from the report a calibrated observer would make in a genuinely hard environment, and indistinguishable from the report of an overloaded one.

Therefore calibration cannot be self-assessed, and this framework does not accept self-assessment as evidence for it (SP-8). That is not a comment on honesty; it is a consequence of the fact that the quantity being estimated is the thing doing the estimating. The supporting result outside the framework is that people cannot reliably report the processes producing their own judgements [Nisbett and Wilson, 1977], and self-report instruments are additionally exposed to wording and framing effects [Schwarz, 1999, Kahneman et al., 2006]. The instruments below are therefore all external — and Section 3.7 records that being external relocates the problem rather than removing it.

19.7.4 7.4 Estimating `r` with ground truth: the seeded audit

```
E      : a set of conditions planted or adjudicated in advance, independent of the observer
P_hat  : (real conditions appearing in the observer's intake record) / (conditions present)
D_hat  : (total items in the observer's assertion record)           / (conditions present)
r      = D_hat / P_hat
```

Requirements: at least 20 per cent off-model items (SP-9), an intake record distinct from the assertion record (SP-18), and ground truth from a source that is not the observer (SP-3). **Cost: one packet, one session, two counts.** This is not an expensive instrument. It is a rarely used one.

19.7.5 7.5 Estimating `r` without ground truth: five behavioural estimators

Ground truth is not always available. Five estimators that do not require it follow. **All five are proposed by this framework, none is validated, and each is badged.**

> **E1 — THE ASSERTION-TO-NOTICE RATIO** *(estimator, unvalidated).* `r_hat = (items asserted) / (items noticed)`. Because `D_hat` and `P_hat` divide by the same `E`, the ratio is the two raw counts and **the environment cancels**. The cheapest estimator available, requiring only that intake and assertion be separately recorded. *Biased by:* whether a note and an assertion are really the same unit — SP-1 must be argued explicitly for the particular records used. *Blind to:* the case where both counts are low because the environment is thin.
>
> **E2 — THE SURPRISE RATE** *(estimator, unvalidated).* Occasions on which the observer's expectation was contradicted, over occasions. Falls with `r` in the over-framed direction and rises in the under-framed one. **Its value is as a trend and not**

as a level: a falling surprise rate in a stable environment is the earliest available indicator of drift toward over-framing, and it is available from ordinary records. *Biased by:* changes in the environment, which move it for reasons that have nothing to do with the observer.

E3 — THE REVISION RATE *(estimator, unvalidated).* Positions changed after new evidence, over occasions of new evidence. Near zero at high `r`; high and unstable at low `r`. **Combined with E2 it separates the directions**: low surprise with low revision is over-framing; high surprise with high revision is under-framing; high surprise with low revision is an observer being contradicted and not updating, which is over-framing under pressure and is the worst of the four combinations.

E4 — TIME TO COMMIT *(estimator, unvalidated).* Time from first contact to first firm assertion. Short and falling at high `r`; long and rising at low `r`. *Biased by:* incentives on speed, which are usually present and usually push `r` up. **In any organisation that measures throughput, expect a systematic push toward over-framing.**

E5 — THE OFF-MODEL RATIO *(estimator, unvalidated).* Assertions outside the standing model, over assertions in total. Requires only a written model to compare against. A ratio near zero over many occasions is evidence of over-framing **or** of an environment that genuinely contains nothing off-model, and the two must be distinguished by a seeded item or by rotation.

Use at least two, from different rows (SP-16). E1 and E5 together are the cheapest useful pair: one gives magnitude — subject to the demotion — and the other gives the over-framing direction, and both come out of records that already exist. **None of the five has been validated against a criterion, which is exactly the convergent and discriminant demonstration a construct of this kind owes** [Campbell and Fiske, 1959, Cronbach and Meehl, 1955], and none has been run.

19.8 8 Correction, composition, drift, and the operating point

19.8.1 8.1 The correction map as procedure, and choosing the gain

The correction map of Section 5.2 is a first-order recursion in log space and is used here as procedure:

```
ln r_{t+1} = (1 − a) . ln r_t              [POSTULATE −− the correction map]
a  = correction gain: the fraction of the observed discrepancy acted on per cycle
fixed point ln r* = 0
stability: converges iff |1 − a| < 1, i.e. 0 < a < 2
```

Distortion half-lives, computed as `ln 2 / (−ln|1−a|)`:

gain `a`	pole `abs(1−a)`	half-life (cycles)	cycles to one tenth
0.05	0.95	13.513	44.891
0.10	0.90	6.579	21.854
0.20	0.80	3.106	10.319
0.35	0.65	1.609	5.345
0.50	0.50	1.000	3.322
0.65	0.35	0.660	2.193
0.80	0.20	0.431	1.431

That is the same half-life formula the storage law gives for the decay of stored order under `delta`, with `|1−a|` in the role of `(1−delta)` [Curzi, 2026a]. It is the same circuit. Calibration is a leaky integrator whose leak is the correction procedure, and the correction procedure is the only leak it has: **with no correction, distortion does not decay. There is no natural forgetting of a bad frame.**

That is the practical heart of the material, and it inverts the storage law's problem. Stored order decays without maintenance and must be defended; distortion **persists** without maintenance, because the storage law integrates it as readily as anything else. **An observer does not drift back into calibration. They are corrected into it or they stay where they are.** The corpus reaches the same structure in a very different domain, where the exposure quantity turns out to be not the event but the time value sits uncorrected between events — a five-second hop being `1.585e−07` of a year against `0.0822` for value rested thirty days, a ratio of about 518,400 [Curzi, 2026]. **The dwell of an uncorrected frame is the exposure, and the audit interval is the dwell.**

Choosing the gain. The gain is a design parameter and the table is its specification, in the same sense that a filter gain is chosen rather than measured [Kalman, 1960, Åström and Murray, 2008].

- `a` **below about 0.10** is under-correction. It converges — twenty-two cycles to reduce distortion tenfold — but slowly enough that the environment may change first.
- `a` **between 0.20 and 0.50** is the working band: half-lives of three cycles down to one.
- `a` **near 1.00** is deadbeat correction, one step to zero in theory. In practice it means discarding the entire existing frame in one move, and the cost appears immediately in the storage law's admissibility condition `C_t <= (1−delta)Q_t + eta M_t`. **Deadbeat correction of a large `Q` violates admissibility and produces the collapse it was meant to prevent** (SP-23).
- `a` **between 1 and 2** oscillates and converges. Wasteful but safe.
- `a` **at or above 2** diverges (FM-8, FM-22). From `Delta = 0.8122`, six cycles at `a = 2.3` reach `Delta = 3.9203` — a factor of fifty from contact, arrived at by correcting hard every single time.

The design rule is one line: never move more than the evidence, and never move twice on the same evidence. Both halves are needed. The first bounds `a` below 2 on a single step; the second stops the same discrepancy being counted repeatedly, which is the mechanism by which a well-intentioned corrector reaches an effective gain above 2 without ever deciding to.

Correcting over-framing (`r > 1`) has two levers, and the specification requires both to be considered, because the same `Delta` can be reached from either end.

Lever A — lower `D`; make assertion cost something.

Procedure	Mechanism	Effect on `r`
Citation requirement	Every assertion must name the intake-record entry that generated it. An assertion with no intake behind it cannot be filed.	Direct cut to the numerator; in the audit of Section 12.1 this removed 20 of 21 unfounded items.
Assertion cap	A hard limit on items per case, forcing prioritisation.	Cuts `D`; risks cutting true findings too. Use with a measured audit, not alone.
Explicit alternative	Require one written alternative reading of the same evidence before committing.	Reduces the frame's monopoly on the intake.

Procedure	Mechanism	Effect on `r`
Falsifier statement	Require, per assertion, the observation that would show it wrong.	Converts unfalsifiable frame-output into a testable claim [Popper, 1959, Platt, 1964]; several will not survive the writing.

Lever B — raise `P`; buy intake back.

Procedure	Mechanism	Effect on `r`
The off-model pass	A separately timed pass whose only question is what is here that the model does not cover, with its own note field.	Raises the denominator and attacks the low off-model hit rate directly. Highest-value single procedure.
Rotation	Move the observer across contexts so the standing model stops matching.	Raises `P` by making the frame visibly insufficient; also raises non-parallelism across the body [Curzi, 2026].
Fresh eyes	A second observer of a different lineage, reporting independently before comparison.	Reveals the off-model material the first observer's frame filtered. Requires independent record before discussion, or the second observer inherits the first one's frame.
Slowing the case	Restore time removed by throughput incentives.	Raises `P`; unpopular; often the only thing that works when E4 shows an incentive-driven `r`.
Seeded items in live work	Plant known off-model conditions in real caseloads at low rate.	Maintains intake by making it consequential. Requires consent and governance (SP-28).

Lever B is usually the better one and is almost never the one chosen. Lowering `D` is visible, fast and satisfying; raising `P` costs time, which is the resource the organisation is already short of. But cutting `D` alone moves `r` toward 1 while leaving the observer's contact with the environment exactly where it was, and the veridical throughput `V = E min(r,1)` does not improve at all until `P` improves. **Cutting `D` fixes the ratio; raising `P` fixes the reading.**

Correcting under-framing (`r < 1`) also has two levers, and the second is usually dismissed.

Lever C — raise `D`; supply structure. Worked exemplars, which build the pattern library faster than instruction; a written taxonomy, which is literally raising `N` and raises the ceiling as well as the frame; a checklist **with a decision rule**, because a checklist that says only what to look at raises `P` and not `D` and will make under-framing worse (FM-18); apprenticeship, which is expensive, slow, and the most reliable; and forced commitment — a written conclusion before leaving the case, even a provisional one, which converts intake into assertion by fiat and generates the error signal correction needs.

Lever D — lower `P`. For the overloaded observer, whose frame is adequate and whose intake exceeds their capacity to apply it, the correction is to reduce the intake: smaller batches, fewer simultaneous cases, a filter upstream, a longer interval. **Turning down the input is a correction, not a retreat**, and the reduced-sample test is what licenses it (SP-20). The engineering

statement is that `r` is a ratio and a ratio can be corrected from either term; an organisation that only ever responds to under-performance with training is only ever pulling one lever, and it is pulling the expensive one.

19.8.2 8.2 Composition, the compensating-distortion trap, and the distortion budget

Distortion composes along a chain of observers: `r_total = r_1 . r_2 . ... . r_n`, so `ln r_total = sum_i ln r_i`. The consequence that matters:

chain	net `r`	net `Delta`	total `Delta` injected
2.5 then 0.4	1.0000	0.000000	**1.832581**
0.5 then 2.0	1.0000	0.000000	**1.386294**
1.6 then 0.625	1.0000	0.000000	**0.940007**

A severely over-framed observer feeding a severely under-framed one produces a perfectly calibrated output and a completely broken system. The net distortion is zero; the total distortion present is 1.83 nats; the end-to-end measurement certifies contact. This is not a curiosity. It is the standard structure of a hierarchy in which an enthusiastic analyst reports to a sceptical manager, and it is *stable*, because the end-to-end numbers look good and each party's correction of the other maintains the balance. It fails the moment either party is replaced, and it fails without warning, because the failure is a change in a quantity nobody was measuring.

> **DECOMPOSITION RULE.** Distortion shall be measured per stage and not end to end. Report both `|ln r_total|` (net) and `sum_i |ln r_i|` (injected). **A system in which the injected distortion materially exceeds the net distortion is a compensating system and shall be recorded as fragile** (SP-24).

The distortion budget, along a four-stage reporting pipeline:

Stage	`r`	`ln r`	cumulative `r`	cumulative `ln r`	injected `Delta` so far
Field intake	0.85	−0.162519	0.850000	−0.162519	0.162519
Write-up	1.15	+0.139762	0.977500	−0.022757	0.302281
Supervisor review	1.35	+0.300105	1.319625	+0.277348	0.602385
Client summary	1.60	+0.470004	2.111400	+0.747351	1.072389

End-to-end `r = 2.111`, net distortion 0.747 nats, total injected 1.072 nats. Two readings. **No single stage is worse than mild-to-marked and the end product is severely over-framed**, because distortion accumulates additively in log units and each stage's contribution is small enough to survive its own review. And the pipeline briefly passes through near-calibration at stage two, cumulative `ln r = −0.0228`, so **a measurement taken at the write-up would certify the pipeline as calibrated. Where the measurement is taken decides what is found, and a single measurement point in a multi-stage pipeline is not a measurement of the pipeline** (FM-15).

A budget is set as any engineering error budget is set: allocate a total, divide it across stages, measure per stage, and require the sum to stay under the total. A defensible starting allocation for four stages with a target of a mildly distorted reading at the client is a total budget of 0.35 nats, which is 0.0875 nats per stage — **every stage inside about ±9 per cent.**

That is demanding, and stating it as a number is the point: most pipelines have never been told what their per-stage tolerance is and consequently do not have one.

The scale-type audit of this subsection, which the framework owes. Adding `ln r` across stages requires `ln r` on an interval scale, and Section 3.5 withdrew that. **Chain addition is therefore a structural argument and not an arithmetic one until the Rasch instrument exists.** What survives the demotion is the *structure*: that compensating stages exist, that a net figure conceals them, and that per-stage measurement is required to see them. Those follow from the sign pattern alone. The numbers 1.832581 and 1.072389 are illustrative arithmetic on the model.

19.8.3 8.3 Drift: why calibration is a maintenance item

The correction map as written has no source term, so left alone `ln r` sits where it is. But `E` moves — the building stock changes, the codebase changes, the population changes — and a frame that matched the old environment does not match the new one. **In a moving environment, holding a frame constant is drift**, and drift is a forcing function on the correction loop:

```
ln r_{t+1} = (1 - a) . ln r_t + w_t          [POSTULATE -- the driven correction map]
w_t = distortion injected per cycle by environmental change, in nats
```

This is the driven first-order system, a leaky integrator with a source, and it has the standard steady state [Elaydi, 2005, Oppenheim et al., 1996]. Setting `ln r_{t+1} = ln r_t = ln r_inf` with constant `w`:

```
ln r_inf = w / a                    THE RESIDUAL DISTORTION
```

Residual distortion is the drift rate divided by the correction gain. It is not zero and it cannot be made zero. A maintained observer in a moving environment does not sit at contact; they sit at a fixed offset from it, and the size of the offset is set by two numbers, only one of which they control.

drift `w` (nats/cycle)	gain `a` = 0.05	0.10	0.20	0.35	0.50
0.02	0.400 MARKED	0.200 MILD	**0.100 CAL.**	0.057 CAL.	0.040 CAL.
0.05	1.000 SEVERE	0.500 MARKED	0.250 MILD	0.143 MILD	**0.100 MILD**
0.10	2.000 SEVERE	1.000 SEVERE	0.500 MARKED	0.286 MILD	0.200 MILD
0.20	4.000 SEVERE	2.000 SEVERE	1.000 SEVERE	0.571 MARKED	0.400 MARKED

Holding the residual inside the calibrated band requires `a >= w / 0.10`:

drift `w` per cycle	minimum gain required
0.02	0.20 — achievable
0.05	0.50 — achievable, at the top of the working band
0.10	1.00 — deadbeat, forbidden by SP-23 at any material `Q`
0.20	2.00 — at the stability limit; **not achievable at all**

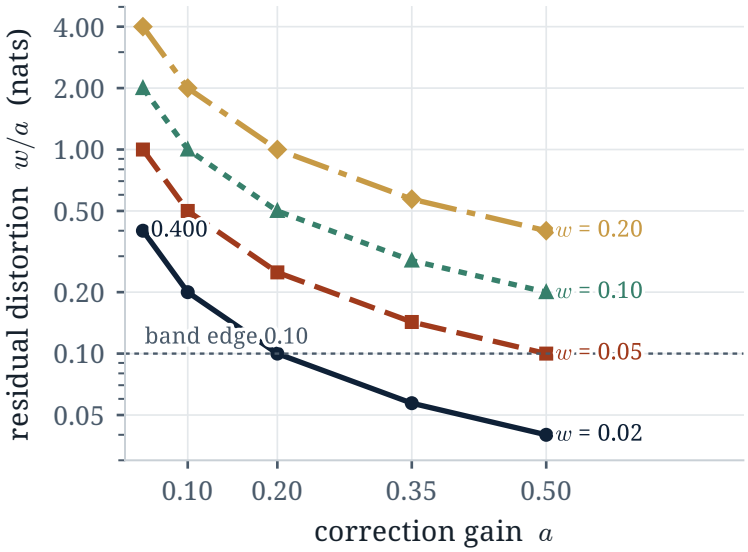

Figure 19.3: **No admissible gain holds calibration against a fast environment.** Residual distortion `ln r_inf = w/a` at the four drift rates of Section 8.3, against correction gain. Only `w = 0.02` reaches the 0.10-nat calibrated band inside the working gain range; `w = 0.10` requires deadbeat correction, which the admissibility condition forbids at any material stored order, and `w = 0.20` requires a gain of 2.00, which is the stability limit itself. Every plotted value is an entry of the residual-distortion table in Section 8.3. Illustrative arithmetic on the model; the drift rates are stipulated, not measured; generated by `figs/src/CCP-019_fig03.py`.

If the environment injects more than about a tenth of a nat of distortion per correction cycle, no achievable gain holds calibration, and the only remaining lever is to shorten the cycle. That is why the audit cadence is a specification item rather than a preference. **A drift problem cannot be corrected out of by correcting harder**: past `a` of about 0.5 the increments buy little, and past `a = 1` they are forbidden by the admissibility condition. It is corrected out of by correcting **more often**.

The drift rate `w` is a property of a domain and must be estimated locally — by re-auditing a *frozen* frame against a fresh environment and reading the distortion that accumulated between the two dates. What follows from the table is the cadence rule.

> **CADENCE RULE.** The audit interval shall be short enough that the distortion injected between audits is below the tolerance band width. With `w_year` the annual drift and `B` the band width in nats, the interval in years satisfies `T <= B / w_year` **and** the gain satisfies `a >= w_year . T / B`. Both, not either (SP-27).

If the band is 0.10 nats and the domain moves 0.10 nats a year, the requirement is an annual cycle at gain 0.5 or better, or a quarterly cycle at gain 0.13. **Most organisations in fast-moving domains run frames last validated at a cadence set by convenience, and the residual distortion that implies has never been computed.** It takes four numbers and one line of arithmetic: `w`, `a`, `B` and the interval.

Scale-type audit. `w/a` is a ratio of two quantities neither of which is instrumented, and it is not licensed as a magnitude. **What survives is the two monotonicities** — more drift gives more residual, more gain gives less — **and the qualitative conclusion that a sufficiently fast environment cannot be held by any admissible gain**, which follows from the stability bound `a < 2` and the band width alone, both of which are declared rather than measured.

19.8.4 8.4 When `r` should not be 1: the operating point as policy

Calibration is not always the objective, because the moment is not always the product. The moment equation says `r = 1` maximises fidelity and veridical throughput. It does not say `r = 1` minimises loss, and where the costs of the two error types differ, the loss-minimising operating point is not the fidelity-maximising one.

Take the three operating points of the inspector series of Section 12.2 and price them under three cost structures:

Operating point	`r`	misses	false alarms	cost at 1:1	cost at 10:1 (miss:alarm)	cost at 1:3 (miss:alarm)
Novice	0.353	41	3	44	413	50
Trained	1.048	10	4	**14**	**104**	**22**
Veteran	1.900	20	27	47	227	101

The calibrated point wins under all three, which is the comfortable case. It does not always. **Where a miss is catastrophic and a false alarm is cheap, a deliberate `r > 1` is a rational policy**: screening, triage, safety interlocks and early-warning systems are all built to over-assert on purpose, and their false-discovery rates are a design choice rather than a fault. Conversely, **where assertion is expensive and irreversible — a public accusation, a permanent record, a decision that cannot be unwound — a deliberate `r < 1` is rational**: withhold conclusion, keep taking intake, decline to make it mean something yet. **This bibliography contains no signal-detection-theory entry**, so that statement is carried here by the paper's own cost arithmetic and by nothing borrowed; Section 15 records it as an uncited claim.

> **Calibration is a property of the instrument. The operating point is a policy.** An observer may be perfectly calibrated and still choose to assert above or below their intake because the loss function says so. **What is never legitimate is an operating point that was not chosen — a policy-level `r` that is an uncorrected instrument error, defended after the fact as prudence or as decisiveness** (SP-26, FM-20).

The test is whether the observer can state the loss function. A screener who says the office runs hot because a miss costs a hundred times a false alarm has a policy. A reviewer who says they have a good eye for these has an uncorrected `r`, and the two are indistinguishable from outside until asked.

Two structural reasons follow, and both correct any reading that treats `r = 1` as a simple goal. The first is the zero-headroom result of Section 5.7, with the condition stated there. The second is sharper and is developed next.

19.8.5 8.5 The two-track ledger and the knife edge at `kappa = delta`

Section 5.5 established that over-framing *increases* stored order, because the storage law integrates the moment as lived and never asks whether it was earned. Turn that into a two-track ledger: raw `Q` against veridical `Q^V`, with stored error

```
Z_{t+1} = (1 − delta) Z_t + eta (M_t − V_t)
correction load   C_t = c_0 + kappa Z_t
```

Because `V = E min(r,1)` is flat above the fixed point while `M = rE` keeps climbing, the veridical track stops improving at `r = 1` and the raw track does not. Computed at `eta = 0.35`, `delta = 0.08`, `c_0 = 0.20`, `kappa = 0.02`, `E = 1.0`:

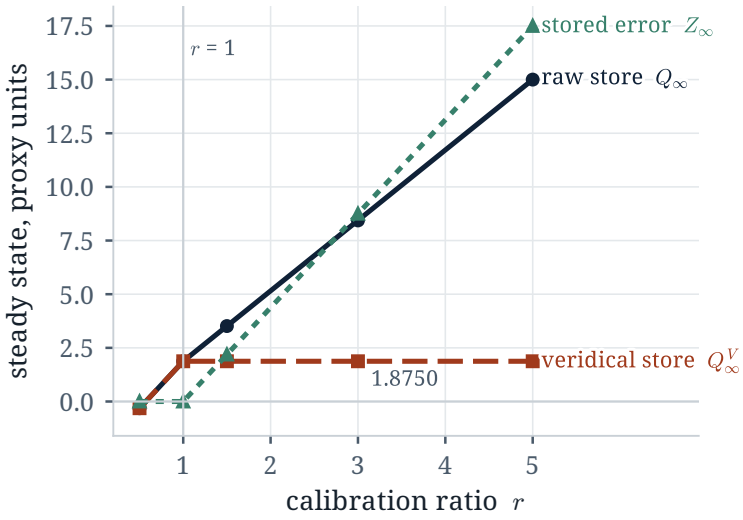

Figure 19.4: **The ledger points away from contact.** Raw stored order at steady state rises without bound in the calibration ratio — from 1.8750 at `r = 1` to 15.0000 at `r = 5` — while the veridical track is flat at 1.8750 above the fixed point and the stored-error stock climbs from zero to 17.5000. At the stipulated parameters the correction-load coefficient `kappa = 0.02` is below the decay rate `delta = 0.08`, which is the condition under which the correction bill never catches up. Every plotted value is an entry of the two-track table in Section 8.5. Illustrative construction with stipulated parameters, not a measurement; generated by `figs/src/CCP-019_fig04.py`.

r	M	V	Z_inf	Q_inf (raw track)	Q_inf^V (veridical track)
0.50	0.5000	0.5000	0.0000	−0.3125	−0.3125
1.00	1.0000	1.0000	0.0000	**1.8750**	**1.8750**
1.50	1.5000	1.0000	2.1875	3.5156	1.8750
3.00	3.0000	1.0000	8.7500	8.4375	1.8750
5.00	5.0000	1.0000	17.5000	15.0000	1.8750

Illustrative construction: the veridical column is flat above the fixed point by construction, and every magnitude in the table inherits the demotion of Section 3.5. The structure is the finding, not the numbers.

Dogma banks faster than knowledge, and the bill arrives on a lag as correction load. Differentiating for `r > 1` gives the exact condition under which the bill ever catches up:

```
dQ_inf/dM = eta (1 − kappa/delta) / delta        ->    negative iff  kappa > delta
```

The knife edge is exactly `kappa = delta`. Where correction load accrues more slowly than stored order decays, raw `Q` rises without bound in `r`, and every incentive attached to raw `Q` is an incentive to over-frame. That is not a moral claim about the observer; it is the arithmetic of what they are being paid in. **Measure `Q^V`, or measure `Z` alongside `Q`, or the ledger being optimised points away from contact.** At the stated parameters `kappa = 0.02 < delta = 0.08`, so the worked case is on the wrong side of the knife edge and the raw track rises in `r` throughout.

19.8.6 8.6 Why the two directions are policed unequally

> **This subsection is the author's reading and is badged as such: it is an observation about which quantities are easy to count, not a derived result and not a measured one.**

Institutions detect and punish under-framing readily and detect over-framing almost never, and the reason is visible in the signature panels. **The under-framed observer is slow, uncertain and produces thin output, and every one of those is directly measurable by instruments organisations already run.** The over-framed observer is fast, confident and produces abundant output, and detecting them requires an instrument — off-model seeded items — that almost nobody runs.

The arithmetic of Section 12.2 supports the asymmetry rather than the intuition: the over-framed veteran produces a worse total error count than the untrained novice, in a fifth of the time, while being the office's most productive inspector by the office's own metric. **The state that gets caught is the one that costs least; the state that costs most is the one that gets promoted.** That is a claim about which quantities happen to be easy to count, and it is correctable by counting a different one — which is the whole reason SP-17 exists and the requirement to defend when someone proposes to simplify the audit. It is also the mechanism by which a measure that becomes a target ceases to be a measure [Goodhart, 1975, Campbell, 1979].

19.9 9 The validation protocol applied: seven gates, one demotion, two unrun

The framework's formula validation protocol runs seven gates on any proposed relation [Curzi, 2026t]. They are labelled G1 to G7 here. **One gate is demoted and two are unrun, and this paper does not pretend otherwise.**

19.9.1 9.1 The gate table

Gates on the moment equation `M = (D/P).E`.

Gate	Test applied	Finding	Verdict
G1 DIMENSIONS	Units of each term; both sides agree; ratios dimensionless.	Requires `[D]=[P]`; then `r` is dimensionless and `[M]=[E]`. Any `D`, `P` pair not measured in identical units is inadmissible.	**PASS**, conditional on SP-1
G2 SCALE TYPE	Division requires a ratio scale with a true zero.	No instrument puts `D` and `P` on a common ratio scale, so the magnitude of `D/P`, the number `Delta`, and the quantitative join to the store are **not reportable as measured quantities**. The limiting cases, the fixed point and the three-way ordering survive on ordinal information. Route out: Rasch logit difference on a linked scale, at about 123 items per term for a half-logit. Section 3.5.	**DEMOTE** — structure stands, magnitude does not

Gate	Test applied	Finding	Verdict
G3 LIMITING CASES	Each term to 0 and to infinity; every divergence must name a real phenomenon.	Four cases, Sections 4.2 to 4.5. `P–>0` diverges and names dogma, apophenia, the over-fitted institution; `D–>0` and `E–>0` give 0. No unexplained divergence.	**PASS**
G4 FIXED POINTS	Solve for the invariant; state its meaning.	`D = P` gives `r = 1` and `M = E` for every `E`. Under the correction map it is unique and attracting for `0 < a < 2`.	**PASS**
G5 IDENTIFIABILITY	Recoverable from obtainable data? Do distinct parameter sets predict identically?	`r` is recoverable; `D`, `P`, `E` are not separately recoverable from `M`. `(D,P,E)` and `(kD,kP,E)` are observationally identical. The reflexive case is not identified at all [Manski, 1993].	**OPEN**
G6 FALSIFICATION	Preregister, freeze, held out, four baselines including a shuffled-input control.	Protocol in Section 9.2. Killing result: a frozen `r` that fails to beat the shuffled control has no content.	**NOT RUN**
G7 REPRODUCIBILITY	Different people, different sites: do the parameters recover?	Procedure-portable in principle. Whether `r` is a trait-like parameter or a property of the item set is **unknown and decisive**.	**NOT RUN**

Gates on the calibration ratio `r` and the distortion `Delta`, where they differ. G1 inherits and fails with SP-1 if that is violated. **G2 returns DEMOTE for both**: the count-based estimator supplies a zero and a unit *within* one item set but not the cross-set linkage that would make the magnitude of `r` a measurement rather than a tally, and rating-scale estimators supply neither. G3 passes: `r` cannot be negative, because `D` and `P` are counts or precisions and both are non-negative; `r –> 0` gives total under-framing and `r –> infinity` saturates at `ln N`. G4 passes, with `Delta` acting as a Lyapunov function for the correction map — it decreases monotonically under any gain in `(0,1)`, which is what proves the correction converges. **G5 is the strong gate for `r`**: under the assertion-to-notice estimator `r = (items asserted)/(items noticed)`, two counts, and ground truth is needed only to distinguish a low `r` from a poor environment. G5 for `Delta` carries a warning: **`Delta` discards the sign and is therefore not sufficient on its own to choose a correction**, since the two directions have opposite treatments (SP-19). G6 for `Delta` adds one specific test and it is the highest-value single test available: **does `Delta` predict downstream correction cost?** The framework claims high `Delta` raises `C` on a lag; a `Delta` that does not predict rework, dispute or repair cost is measuring nothing that matters. G7 inherits and is unrun.

19.9.2 9.2 G6 in full: what would kill this formula

Preregistration. Fix the operationalisation of `D`, `P` and `E`, the population, the item set, the number of occasions, and the analysis, in writing, before data collection [Nosek et al., 2018]. The reason is not ceremony: without a rule declared in advance, the number of defensible analysis paths is large enough that a result of the required shape is nearly always obtainable [Simmons et al., 2011, Gelman and Loken, 2013], and the base rate of published findings that do not replicate is what it is [Ioannidis, 2005, Open Science Collaboration, 2015].

Fit and freeze. Estimate `r` for each observer on a training block. Freeze every parameter.

Held-out prediction. Predict, on a held-out block, a quantity the formula constrains and that is not the quantity used to fit: the false-discovery rate, the off-model detection rate, and the ratio of asserted to noticed items.

Four baselines, all of which must be beaten. (i) *Persistence* — the next block equals the last. (ii) *Direct input* — prediction from environment richness alone, ignoring the observer. (iii) *Matched autoregressive* — an autoregressive model on the observer's own past output **with the same number of free parameters**, so that the parameter count is paid for. (iv) *Shuffled-input control* — the same model fitted to observer/environment pairings randomly permuted. **The fourth is the one most often omitted and it is the decisive one.** If the formula predicts as well on shuffled pairs as on true pairs, `r` carries no information about the observer and the formula has no content.

The killing result, stated in advance: if a frozen `r` fails to beat the shuffled-input control on held-out prediction, the moment equation is dead as a quantitative model and must be demoted to the heuristic ordering of Section 3.5. **A framework that cannot fail cannot be trusted, and this is exactly how this one fails.**

What this protocol is worth is known, because the corpus has already run it once on a different law and reported the failure. The confirmatory application of the same protocol to the storage law landed its fit strictly inside the admissible box and agreed with independent measurement within 4.8 per cent on decay and 16.8 per cent on conversion, and then **beat a matched autoregression by 2.8 per cent on held-out error against a preregistered requirement of 10 per cent**, so the verdict was *parameters corroborated, predictive advantage not demonstrated* [Curzi, 2026i]. That is the standard this paper's G6 would be held to, and it is a standard the corpus has already failed once in public.

G7 in full. The reproducibility gate requires the same operationalisation run by different investigators on different populations, asking whether `r` recovers as a property of the observer or turns out to be a property of the item set. **If `r` for the same observer swings by more than the calibrated band width, 0.10 nats, across equivalent item sets, `r` is not a parameter of the person and the framework's psychological reading collapses even if its item-specific reading survives.** The separability property of the Rasch model is the standard this gate should be held to [Rasch, 1960, Andrich, 1988], and the ceiling on individual-level prediction from rich longitudinal data is a reason to expect the gate to be hard rather than easy [Hofman et al., 2017, Salganik et al., 2020].

19.10 10 Specifications

The specifications below are numbered SP-1 to SP-28 and are stated in the imperative form a procedure requires. SP-1 to SP-13 govern the moment equation; SP-14 to SP-28 govern the calibration ratio, and two of them restate earlier requirements because those are the ones most often dropped.

SP-1 — Commensurability. `D` and `P` shall be measured in identical units, by procedures differing only in which of the two they measure. A ratio of two quantities that are not the same kind of quantity shall not be written as a fraction.

SP-2 — Ratio scale or demotion. Before any numerical use of `M = (D/P).E`, the analyst shall state the scale type of each term. Where any term is ordinal, the formula shall be printed in its demoted heuristic form and no number shall be computed from it.

SP-3 — `E` measured independently. `E` shall be measured by an instrument that does not depend on the observer whose moment is being modelled — a seeded item list, an independent panel, a ground-truth record. An `E` inferred from the observer's own report makes the equation circular and its outputs void.

SP-4 — Report `r`, not `D` and `P`. Because only the ratio is identified, reports shall give `r` and `ln r`. Separate values of `D` and `P` shall be reported only where a second independent instrument fixes the scale, and shall carry a note that they are not identified by the moment measurement alone.

SP-5 — Report veridical throughput alongside the moment. Any report of `M` shall be accompanied by `V = E min(r,1)` and by the confabulated or missed fraction. **Reporting a large moment without its veridical throughput is the single most misleading use available for this instrument.**

SP-6 — Distortion in log units. Distortion shall be reported as `ln r` (signed) and `|ln r|` (magnitude), never as a raw ratio or a percentage.

SP-7 — Correction gain within the stability band. Any deliberate correction procedure shall target a gain `0 < a < 2`, and shall be inspected for `a >= 2` behaviour — alternating overshoot of increasing amplitude — at least once per quarter for any observer or body under correction. A correction regime producing alternating extreme positions shall be stopped, not tuned.

SP-8 — No calibration claim without a seeded audit. A claim that an observer, panel or institution is calibrated shall rest on a measurement against known items. Self-assessed calibration shall be recorded as absent.

SP-9 — Off-model items mandatory. Every seeded audit shall include items outside the frame under test, at a stated proportion of at least 20 per cent of seeded items. **An audit containing only on-model items cannot detect over-framing and shall not be used to certify calibration.**

SP-10 — Environment checked before the observer. Where `M` is low, `E` shall be measured before any intervention on the observer. A calibrated observer reporting a poor environment is a correct instrument and shall not be treated as a perception problem.

SP-11 — The ceiling declared. Any use of the normalised moment shall state the assumed `N` and therefore the ceiling `ln N`, and shall state that the normalisation is a convention while the bound `0 <= F <= ln N` is a theorem [Curzi, 2026].

SP-12 — Reflexive environments excluded. Where the observer's assertion materially changes `E`, the analyst shall record the situation as out of scope and shall not report an `r` for it. **This is an exclusion and not a remedy; Section 3.7 says why.**

SP-13 — Decline path. No calibration procedure shall be administered to a person who has not agreed to it, and a refusal shall be recorded as a refusal and not as a result.

SP-14 — Report in log units, signed and unsigned. A raw ratio or a percentage shall not be used as a distortion measure, because it is not symmetric between the two directions and does not compose additively.

SP-15 — Never the arithmetic mean of `r`. Aggregation across occasions shall use mean `|ln r|` for distortion and mean `ln r` for bias. **Section 6.4 tightens this: pending instrumentation, the licensed summaries are the median of `ln r` and the rank order on `|ln r|`.**

SP-16 — Two estimators minimum. Any `r` used for a decision shall rest on at least two estimators drawn from different rows of Section 7.5, or on one seeded audit. A single behavioural estimator shall be recorded as an indication and not as a measurement.

SP-17 — Off-model content at 20 per cent minimum. Restated from SP-9 because it is the requirement most often dropped: every calibration audit shall contain at least 20 per cent off-model items. An audit without them cannot detect over-framing.

SP-18 — Separate intake and assertion records. Any observer whose calibration is to be measured shall keep an intake record distinct from the assertion record. **Where the two are the same document, `r` is 1 by construction and cannot be measured.** This is a records-design requirement and must be in place before the audit.

SP-19 — Direction before correction. The sign of `ln r` shall be established before any correction is applied. `Delta` alone is not sufficient to choose a procedure, and the two directions have opposite treatments.

SP-20 — The reduced-sample test before any training prescription. Where `r` is below the under-framed cut, the reduced-sample test shall be run before training is prescribed. **An overloaded observer given training gets worse**, because training adds to the load that is already the binding constraint.

SP-21 — The environment measured first. Restated from SP-10: where performance is poor, `E` shall be measured independently before any correction is applied to the observer.

SP-22 — Gain inside the stability band. Correction regimes shall target `0 < a < 2` and shall be reviewed for divergent behaviour — alternating sign with growing magnitude — at least quarterly. A regime showing that signature shall be stopped rather than tuned.

SP-23 — No deadbeat correction of a large `Q`. Where stored order is large, correction gain shall not be set at or near 1. Verify against the admissibility condition `C_t <= (1−delta)Q_t + eta M_t` before setting the gain.

SP-24 — Per-stage measurement in pipelines. Distortion in a multi-stage process shall be measured per stage. Reports shall give both net `|ln r_total|` and injected `sum_i |ln r_i|`. A system whose injected distortion materially exceeds its net distortion shall be recorded as fragile and shall not be certified on its end-to-end figure alone.

SP-25 — Declare the budget. Any process with a calibration requirement shall state its total distortion budget in nats and its per-stage allocation, before measurement.

SP-26 — Operating point declared as policy. Any deliberate departure from `r = 1` shall be recorded in writing with the loss function that justifies it. An undeclared departure shall be treated as instrument error and not as policy.

SP-27 — Audit cadence tied to environmental drift. The audit interval shall be shorter than the time in which the environment is expected to move by the width of the tolerance band. The estimate of that rate shall be written down and revised.

SP-28 — Consent and decline. Calibration measurement is measurement of a person. Participation shall be voluntary, refusal shall be recorded as refusal rather than as a result, and results shall not be used for a purpose not disclosed before the audit.

19.11 11 Failure modes

Twenty-two named failure modes follow, FM-1 to FM-10 on the moment equation and FM-11 to FM-22 on the calibration ratio. Each states its description, what it damages, its diagnostic signature, and its fix. **FM-22 is FM-8 at organisational scope and is listed separately because its detection route differs, not because the mechanism does.**

FM-1 — The incommensurable fraction. `D` and `P` measured in different units — years of experience over items noticed, confidence rating over minutes spent — and divided anyway. *Damages:* every downstream number; the output has units nobody can name. *Signature:* ask what `r = 1` would mean physically; if the answer is not a sentence about the same quantity appearing twice, G1 has failed. *Fix:* SP-1; rebuild both measurements from one procedure.

FM-2 — The Likert fraction. `D` and `P` from five-point self-report scales, divided. *Damages:* G2; the number has the form of a ratio and none of the content. *Signature:* the instrument has no true zero — ask what a score of 0 would be and whether a 4 is genuinely twice a 2 [Likert, 1932]. *Fix:* SP-2; demote in print, or build a ratio scale by magnitude estimation or by counting.

FM-3 — Certainty read as calibration. High confidence and low confusion taken as evidence of good contact. *Damages:* detection of `P -> 0`; the condition is misdiagnosed as competence. *Signature:* **falling surprise rate combined with a rising false-discovery rate** — the observer is being contradicted less and being wrong more; also time per case falling while off-model detection falls. *Fix:* SP-8 and SP-9. There is no soft version: confidence is the symptom of the disease, so it cannot be the test.

FM-4 — The empty aperture mistaken for discipline. An observer with a strong frame reads their own low intake as focus and the organisation rewards it as decisiveness. *Damages:* `P`, therefore `r`, therefore `V`. *Signature:* off-model hit rate near zero with on-model hit rate near one — in Section 12.2, on-model detection at its career maximum against off-model detection below a novice's. *Fix:* rebuild intake specifically for off-model material — mandated fresh-eyes passes, rotation across contexts, and an explicit *what is here that is not on the list* step

with its own time allocation.

FM-5 — Frame removal prescribed as clarity. An under-performing observer is advised to drop their assumptions, come to it fresh, stop overthinking; `D` is driven toward zero. *Damages:* `D`, therefore `M`; drives the observer into Limit 2. *Signature:* intake high, output thin, time per case rising, the observer describing the work as overwhelming rather than as wrong. *Fix:* the opposite of the advice given — supply structure: checklists with decision rules, worked exemplars, a taxonomy, an apprenticeship. **The instruction to have no expectations is a prescription for `M = 0`.**

FM-6 — The environment blamed on the observer. `M` is low; the observer is sent to training. *Damages:* wastes the intervention budget, leaves `E` unimproved, damages the observer's standing, and usually raises `C`. *Signature:* a seeded audit returns a calibrated `r`; the instrument is fine. *Fix:* SP-10; measure `E`.

FM-7 — Stored error defended as experience. A long-tenured observer or institution has accumulated large `Q` at high `r`; the structure is coherent, confident, and substantially manufactured, and challenges to it are read as challenges to competence. *Damages:* `Q` as stored error, and `C` on a long lag. *Signature:* compute `Q_inf` on `M` and on `V` separately; a gap of more than about a third of `Q_inf` is the signature. Cross-check the trend in `C`: **rising rework, rising dispute, rising correction cost with no change in the environment is the lagging indicator of a high-`r` history.** *Fix:* shedding stored order to regain headroom is legitimate and underused; combine with a correction regime at gain in `(0,1)`. **Do not attempt deadbeat correction on a large `Q`**: the cost is paid in one period and usually exceeds what the admissibility condition allows.

FM-8 — The divergent corrector. An observer or body responds to each contradiction by reversing position entirely, then reverses again. Effective gain at or above 2. *Damages:* `r`, with increasing amplitude — from `|ln r| = 0.8122`, six iterations at `a = 2.3` reach 3.9203, a factor of fifty from contact. *Signature:* alternating sign of `ln r` with growing magnitude across successive audits; rhetorically, *we were completely wrong about that* appearing at a regular cadence, each time about the previous correction. *Fix:* SP-7; reduce the gain. **Never move more than the evidence, and never move twice on the same evidence.**

FM-9 — The unmeasured environment. `E` is estimated from the observer's own account and `r` is computed from it. *Damages:* circularity — `r` comes out near 1 by construction and the audit certifies calibration that was assumed. *Signature:* ask where the ground truth came from; if the answer is the observer, the number is void. *Fix:* SP-3; seed the items.

FM-10 — The reflexive case forced into the formula. `r` is computed for a negotiator, a forecaster whose forecast moves the market, or a clinician whose diagnosis becomes the treatment. `E` is not exogenous. *Damages:* everything; the formula's central assumption is violated. *Signature:* ask whether the environment would have been the same had the observer concluded otherwise; if not, out of scope. *Fix:* SP-12; record as out of scope and do not report an `r`. **This is the exclusion Section 3.7 identifies as a confession rather than a remedy: the excluded class is exactly where the corpus's own reflexive law operates** [Curzi, 2026, Manski, 1993], and it is the class in which a reflexive fixed point has actually been documented in the field [MacKenzie and Millo, 2003].

FM-11 — Confidence audited as calibration. Certainty, fluency and speed taken as evidence of contact. *Damages:* detection of over-framing entirely. *Signature:* falling surprise rate with rising false-discovery rate, and no seeded audit on file. *Fix:* SP-8, SP-17.

FM-12 — The model-shaped audit. The calibration audit is built from the same checklist the observer works from; every seeded item is on-model. *Damages:* the audit itself, which will certify an over-framed observer as excellent with high apparent sensitivity. *Signature:* compare the seeded item list against the standing model; if the overlap is total, the audit is a mirror. *Fix:* SP-17; off-model items at 20 per cent minimum, generated by someone who does not work from that model.

FM-13 — The arithmetic mean of ratios. An observer's `r` values across occasions are averaged arithmetically and reported as their calibration. *Damages:* the measurement; by Jensen's inequality the figure is biased toward over-framing, and an observer who swings

both ways is reported as a mild over-framer with no indication of instability. *Signature:* any report containing a mean `r`. *Fix:* SP-15, as tightened in Section 6.4.

FM-14 — Compensating distortion. Two stages with opposite distortions netting to `r` near 1; end-to-end measurement certifies the system. *Damages:* robustness; the system fails without warning on any personnel change. *Signature:* per-stage `r` values spread widely around a net near 1, with injected distortion much larger than net. *Fix:* SP-24. Correct each stage independently, and **expect the end-to-end figure to get worse before it gets better** — correcting the over-framed stage first reveals the under-framed stage that was hiding behind it, so a system in compensation for years will look like it is deteriorating during the repair. Say this in advance or the repair will be reversed.

FM-15 — The single measurement point. A multi-stage pipeline measured at one stage and the result reported as the pipeline's calibration. *Damages:* everything downstream of the measurement point. *Signature:* ask where the measurement was taken; in the budget of Section 8.2 a measurement at the write-up returns `ln r = −0.0228` for a pipeline delivering `r = 2.11`. *Fix:* SP-24.

FM-16 — Training prescribed for overload. An observer with `r < 1` is sent to training; their frame was already adequate and the intake rate was the constraint, so training adds load. *Damages:* `r` falls further, `C` rises, and the observer is now also being told the problem is their competence. *Signature:* the reduced-sample test — if performance improves markedly on a third of the material, this is load. *Fix:* SP-20, then Lever D.

FM-17 — The deframing prescription. An under-framed observer is advised to have fewer expectations. `D` is reduced further. *Damages:* `D`, therefore `M`. **Iatrogenic.** *Signature:* advice on file targeting the numerator when `r` is already below 1. *Fix:* Lever C — supply structure: exemplars, a taxonomy, a checklist **with a decision rule**, a forced written conclusion per case.

FM-18 — The checklist that raises `P`. An under-framed observer is given a checklist of things to look at containing no rule for what any observation implies. *Damages:* raises intake without raising assertion; `r` falls; the observer notices more and concludes no more. *Signature:* the checklist's items are all nouns and no item has a *therefore*. *Fix:* add the decision rule to each item. **A list of what to look at is an intake instrument; a list of what things mean is a frame instrument; only the second treats under-framing.**

FM-19 — Throughput incentive read as skill. Time per case is measured and rewarded, `r` rises across the whole body over years, and the organisation reads it as growing expertise. *Damages:* `P` organisation-wide, therefore `r`, therefore `V`. *Signature:* time-to-commit falling across the whole population simultaneously, off-model detection falling in step, and no change in the environment. **A population-wide movement in `r` is an organisational signal and not a personnel one.** *Fix:* individual correction will not hold against a standing incentive; change what is measured, or accept the operating point and declare it under SP-26. This is a measure that has become a target [Goodhart, 1975, Campbell, 1979].

FM-20 — Uncorrected `r` defended as judgement. A persistent departure from `r = 1` is described after the fact as professional judgement, prudence or decisiveness; no loss function was ever stated. *Damages:* correction is blocked and the state is now protected by an account of itself. *Signature:* ask for the loss function. A policy has one, in numbers, from before; an uncorrected instrument produces one on request, in words, afterwards. *Fix:* SP-26. **A stated policy is auditable; a retrospective justification is not, and the difference between them is the whole of the governance available here.**

FM-21 — Calibration assumed to persist. An observer certified as calibrated years ago is treated as calibrated now; the environment has moved. *Damages:* `r`, silently and progressively. *Signature:* date of last audit relative to the estimated environmental drift rate. *Fix:* SP-27. **There is no decay term on distortion: nothing returns an observer to contact except correction, so calibration is a maintenance item with a schedule, like any other.**

FM-22 — The divergent corrector at organisational scope. Effective gain at or above 2 in a body rather than a person: position reverses fully at each contradiction, then reverses again. *Damages:* `r`, with growing amplitude. *Signature:* alternating sign of `ln r` across successive audits with increasing magnitude. *Fix:* SP-22; reduce the gain, and check specifically for the

same discrepancy being acted on more than once, which is the usual mechanism by which a modest per-event gain compounds past 2.

19.12 12 Results

Both audits below are constructed examples with declared parameters. No dataset was collected, no observer was measured, and no organisation was studied. They demonstrate that the procedure runs and that it reports its own failures; they are not evidence that any reviewer or inspector behaves this way and must never be cited as such. The corpus has refused a fabricated data point elsewhere and badged a headline percentage as an artefact of a chosen synthetic ratio rather than a constant [Curzi, 2026], and the same discipline bounds what may be claimed here: where the corpus reports a 56.62 per cent widening from a constructed input set, it badges the figure as a **ceiling on constructed inputs and not a promise**, distinguishes visibility from pledgeability, and presents the result as an architecture rather than a system [Curzi, 2026]. **The two audits below are constructed inputs in exactly that sense.**

19.12.1 12.1 A seeded-defect review audit

A software group runs code review. One reviewer is respected, fast, and finds a great deal. The group wants to know whether that reviewer's output is contact or manufacture.

Step 1 — Build E. A real, already-shipped module is seeded with 40 known defects by two people who will not participate in the review, adjudicated in advance so that E is fixed before any reviewer sees it. Of the 40, **30 are on-model** — null checks, off-by-one, resource leaks, the categories the team's review guide lists — and **10 are off-model**: a licence incompatibility, a timezone assumption, a comment contradicting the code, an error message leaking a path, and six others outside the guide. Off-model items are 25 per cent of the total, satisfying SP-9. **Without them the audit cannot detect over-framing and would have certified the reviewer as excellent.**

Step 2 — Define D and P commensurably (SP-1). Both are *recorded items per condition present*:

```
P_hat = (real conditions appearing in the working notes) / (conditions present)
D_hat = (total items in the submitted review)            / (conditions present)
```

The working notes are the intake record — everything written down while reading, including what was later dropped. The submitted review is the assertion record. **The two records are the same kind of object, items the reviewer wrote, which is what makes the fraction dimensionally legal.**

The caveat G1 forces into print: this treats a note and a review comment as the same unit of recorded item. **That is an assumption.** It is defensible because both are discrete written assertions about the module, and it is checkable, since two independent counters should agree on the count to within a few per cent — but it is an assumption and it is the weakest joint in the measurement. It is also, precisely, the point at which the scale-type demotion bites: counting supplies a zero and a unit inside this item set and supplies no link to any other.

Step 3 — Run the audit, baseline.

```
conditions present                    40   (30 on-model, 10 off-model)
real conditions touched in the notes  29
items in the submitted review         50   (29 real, 21 not real)

P_hat = 29 / 40 = 0.725000
D_hat = 50 / 40 = 1.250000
r     = 1.250000 / 0.725000 = 1.724138
ln r  = +0.544727 nats
```

The reviewer is over-framed by a factor of about 1.7; the moment lived while reviewing is about 1.7 times the module. By the band table that is marked over-framing, one band below severe. **Under the demotion, the reportable findings here are the sign and the band, not the figure 1.724138.**

There is an identity worth noting, because it makes the estimator far cheaper than it looks. Since `r = (calls/present)/(noticed/present) = calls/noticed`, and since in this audit every real condition that reached the notes also reached the review,

```
r = 50/29 = 1.724138
confabulated fraction = 1 − 1/r = 1 − 29/50 = 0.4200 = false discovery rate exactly
```

When everything noticed is asserted, the confabulated fraction of the moment is exactly the false-discovery rate. `r` is then computable from two counts and needs no ground-truth adjudication at all — though ground truth is still required to measure `P` against `E` and therefore to distinguish this case from an under-framed one. The equality `1 − 1/1.724138 = 0.4200` is arithmetic and is redone in Section 14.4.

Step 4 — The secondary indicators.

```
on-model hit rate     28/30 = 0.9333
off-model hit rate     1/10 = 0.1000
false discovery rate  21/50 = 0.4200
intake (P_hat)              0.7250
```

The signature of FM-4 is present in the open: 93 per cent detection of what the guide predicts, 10 per cent detection of what it does not. **The reviewer is not reading the module. The reviewer is checking the module against the guide, and the guide is also supplying 21 findings that are not there.** These four figures reconcile exactly: `28 + 1 = 29` real items in a 50-item review, so `50 − 29 = 21` are false.

Step 5 — Veridical throughput and stored error. With `E` normalised to 1.0 nat and the group's stipulated personal parameters `eta = 0.35`, `delta = 0.08`, `C = 0.20`:

```
M = r . E = 1.7241 nats
V = E . min(r,1) = 1.0000 nats
confabulated fraction = 0.4200

Q_inf on M (as lived)   = (0.35 . 1.7241 − 0.20)/0.08 = +5.043
Q_inf on V (veridical)  = (0.35 . 1.0000 − 0.20)/0.08 = +1.875
stored error            = +3.168
```

The reviewer's accumulated review expertise, at steady state, is about 63 per cent stored error — 3.168 of 5.043, which is 62.8 per cent, rounded to two figures because it is illustrative model output and not a measurement. **This is not a statement about a person. It is a statement about what a guide-driven review process does to anyone who runs it long enough without an off-model channel**, and this reviewer is the group's best precisely because they run the process hardest.

Step 6 — Design the correction. The distortion is `ln r = +0.5447` and the specification requires both levers to be tried, because `r` can be moved from either end. *Lower `D`:* cap review comments; require that each submitted comment cite the line in the working notes that generated it, so that an assertion with no intake behind it cannot be filed. This attacks the 21 unfounded items directly. *Raise `P`:* add a mandated fifteen-minute off-guide pass with its own note field, asking only what is in this module that the guide does not cover; rotate a second reviewer from a different subsystem weekly, which also raises non-parallelism across reviewers [Curzi, 2026]. Target gain `a = 0.35`, well inside the stability band, giving five review cycles to the calibrated band.

Step 7 — Re-audit after six cycles. Fresh packet, same design, 40 seeded conditions, 30 on-model and 10 off-model.

```
real conditions touched in the notes   31
items in the submitted review          32   (31 real, 1 not real)

P_hat = 31/40 = 0.775000
D_hat = 32/40 = 0.800000
r     = 1.032258
ln r  = +0.031749 nats        CALIBRATED
```

Metric	Baseline	After six cycles	Change
`r`	1.7241	1.0323	−40.1%
`abs(ln r)` (nats)	0.5447	0.0317	**17.2-fold reduction**
Intake `P_hat`	0.7250	0.7750	+6.9%
On-model hit rate	0.9333	0.9000	−3.6%
Off-model hit rate	0.1000	0.4000	**4.0-fold**
False discovery rate	0.4200	0.0312	−92.6%
True defects found	29/40 = 0.725	31/40 = 0.775	+6.9%
Confabulated fraction	0.4200	0.0312	−92.6%
`Q_inf` stored error	+3.168	+0.141	−95.5%

The rows reconcile: after correction, on-model 0.900 gives 27 of 30 and off-model 0.400 gives 4 of 10, so 31 real items in a 32-item review and 1 false, and the false-discovery rate is `1/32 = 0.03125`.

Read the on-model row honestly: it went down. The reviewer now finds 90 per cent of guide-listed defects instead of 93. If the group measures reviewer quality by guide-listed defect detection — and most groups do — **this intervention registers as a small regression by the metric being watched**, while total true defects found rose, false alarms fell by 93 per cent, and detection of the defects nobody was looking for quadrupled.

That is Goodhart's law arriving on schedule [Goodhart, 1975, Campbell, 1979]. **The measure that made the reviewer look excellent was the measure that was making the reviewer over-framed, because it counted only the items the frame already contained.** The audit that found it works solely because 25 per cent of its items were outside the frame. SP-9 exists for this reason, and it is the requirement to fight for when someone proposes to simplify the audit — which is hypothesis H4.

Step 8 — What would falsify this. The group preregisters for the next quarter: the frozen `r = 1.03` predicts a held-out false-discovery rate below 0.10 and an off-model hit rate above 0.30, and does so better than (i) persistence from the baseline audit, (ii) a model using packet difficulty alone, (iii) an autoregressive model on past comment counts with the same parameter count, and (iv) the same model fitted to reviewer/packet pairings randomly shuffled across the team. **If the shuffled control predicts as well, `r` is a property of the packet and not of the reviewer, the instrument is measuring nothing about the reviewer, and this estimator fails G7 for this application.** The group commits in writing to publish that result internally if it occurs. **That commitment, and not the arithmetic, is what would make the audit an instrument rather than an opinion** [Nosek et al., 2018].

19.12.2 12.2 A building inspector, measured three times across fourteen years

A municipal inspection office wants to know what happens to an inspector's calibration over a career. It runs one audit design at three career points, with inspectors who volunteered under SP-28.

The audit. A vacant municipal building is prepared with **50 conditions**, adjudicated in advance by two structural engineers and a code officer who take no part in the inspections. **35**

are on-model: conditions named in the office's standing inspection schedule — egress width, handrail height, panel labelling. **15 are off-model**: a roof drain discharging onto a fire-escape landing, a mislabelled shut-off, an added partition that changed the occupancy classification, a masonry repair executed in a mortar harder than the surrounding brick, and eleven others. Off-model content is 30 per cent, above the SP-17 minimum. **The office's first instinct was to build the audit from the inspection schedule, which would have made every item on-model and guaranteed the result the office expected.** The 30 per cent is the whole reason this audit finds anything. Each inspector carries a field notebook (intake) and a filed report (assertion), so SP-18 is satisfied by existing practice.

Point 1 — Week 2. A new inspector, nine days out of orientation.

```
conditions present                        50   (35 on-model, 15 off-model)
real conditions appearing in the notebook 34
items in the filed report                 12   (9 real, 3 not real)
time on site                              232 minutes

P_hat = 34/50 = 0.680000
D_hat = 12/50 = 0.240000
r     = 0.352941        ln r = -1.041454      Delta = 1.0415 nats     SEVERE UNDER-FRAMING
```

The notebook contains 34 of the 50 real conditions — this inspector's intake is not the problem, and it is better than the veteran's will be. The report contains twelve items. Real conditions were written down in the notebook and never became findings. Nearly four hours on site. The recorded subjective report was that a lot of things were seen that the inspector was not sure counted, which is Limit 2 in plain language: intake without frame, the moment collapsing to about a third of the environment. Veridical throughput `V/E = min(r,1) = 0.3529`, so **about 65 per cent of the building was missed, and most of it was missed after being seen.**

Point 2 — Month 9. The same inspector, after training and supervised fieldwork.

```
real conditions appearing in the notebook 42
items in the filed report                 44   (40 real, 4 not real)
time on site                              118 minutes

P_hat = 42/50 = 0.840000
D_hat = 44/50 = 0.880000
r     = 1.047619        ln r = +0.046520      Delta = 0.0465 nats     CALIBRATED
```

Both terms rose. **This is the composite-parameter effect of Section 4.1: `D` and `P` went up together, which changed what the inspector could handle without changing how distorted they were — except that the frame rose slightly faster, which moved `r` from 0.353 to 1.048.** Off-model detection 60 per cent, false discovery 9 per cent, true conditions found 40 of 50, half the time on site. **The correction raised `D`, which was the correct lever because the diagnosis was under-framing with adequate intake**; had the diagnosis been overload, the same intervention would have made things worse (FM-16).

Point 3 — Year 14. The same inspector, now the office's most productive.

```
real conditions appearing in the notebook 30
items in the filed report                 57   (30 real, 27 not real)
time on site                              41 minutes

P_hat = 30/50 = 0.600000
D_hat = 57/50 = 1.140000
r     = 1.900000        ln r = +0.641854      Delta = 0.6419 nats     MARKED, edge of SEVERE
```

The intake has fallen below where it was in week two. Thirty of fifty conditions reach the notebook, against thirty-four in the first week. The report has fifty-seven items, of which twenty-seven are not there.

Metric	Week 2	Month 9	Year 14
`r`	0.353	1.048	1.900
`ln r`	−1.0415	+0.0465	+0.6419
Band	Severe under	**Calibrated**	Marked over
Intake `P_hat`	0.680	0.840	**0.600**
On-model hit rate	0.400	0.886	**0.943**
Off-model hit rate	0.333	0.600	**0.133**
False discovery rate	0.250	0.091	**0.474**
Minutes on site	232	118	**41**
True conditions found	19/50	40/50	35/50
Veridical throughput `V/E`	0.353	1.000	1.000
Confabulated fraction	—	—	**0.474**

Two rows carry the diagnosis. On-model detection is at its career maximum, about 94 per cent — and off-model detection has fallen to about 13 per cent, below the novice's 33 per cent. The inspector has become excellent at finding what the schedule contains and worse than a nine-day novice at finding what it does not. That is FM-4, and it is the expertise-decay subtype: a frame that was correct, earned honestly, and outlived the building stock it was built on — the myopia of learning with an equation attached [Levinthal and March, 1993, March, 1991].

> **This is the paper's most interesting empirical-shaped claim and it is NOT empirical.** The fourteen-year series is a constructed illustration with stipulated counts. The figures are rounded to two significant figures here because that is all an illustration supports; they carry no uncertainty because nothing was measured; and **three of the rows in the table above do not reconcile with the filed-item counts, as Section 12.3 sets out.**

Productivity, priced properly. The office's metric is inspections per day, and by that metric Year 14 is 5.7 times Week 2.

	true conditions found per hour	false alarms per hour
Week 2	2.328	0.776
Month 9	20.339	2.034
Year 14	**43.902**	**39.512**

The veteran finds real conditions about nineteen times faster than the novice and generates false alarms about fifty-one times faster. Under equal error costs the veteran's total error count on this building — 20 misses plus 27 false alarms, 47 — is worse than the novice's 44, achieved in a fifth of the time. The trained mid-career point, at 14, is a third of either. The cost table of Section 8.4 prices all three under three loss structures and the calibrated point wins under all three.

Storage consequence. With office-typical stipulated parameters `eta = 0.35`, `delta = 0.08`, `C = 0.20`, and `E` normalised to 1.0 nat:

Point	`M = rE`	`Q_inf` on `M`	`Q_inf` on `V`	stored error
Week 2	0.353	−**0.956**	−0.956	0.000

Point	`M = rE`	`Q_inf` on `M`	`Q_inf` on `V`	stored error
Month 9	1.048	+2.083	+1.875	+0.208
Year 14	1.900	**+5.813**	+1.875	**+3.938**

The novice's steady state is negative — `eta M < C`, the unsustainable regime the storage law declines to hide [Curzi, 2026a] — which is a correct model statement about an observer who cannot continue in that condition and must be moved out of it, in either direction, quickly. The veteran's steady state is the largest of the three and **about 68 per cent of it is stored error** (3.938 of 5.813, 67.7 per cent). Fourteen years of confident, fast, internally consistent structure, two thirds of which the building did not supply. It will be defended, and the defence will be sincere, because from inside there is no difference between the earned third and the manufactured two thirds.

The correction. Diagnosis: over-framed, expertise-decay subtype, driven by a throughput incentive — FM-19 is present at office level, with time-to-commit having fallen across the whole inspection staff. Because the driver is organisational, SP-26 applies first: the office must either change the throughput metric or declare the operating point as policy with a loss function. It changes the metric, adding off-model detection rate to the quarterly report. **That act is itself an intervention on the system being measured, and Section 3.7 records that the framework's own constancy assumptions do not survive it.**

Individual procedure, both levers. *Lever B (raise `P`), primary:* a mandated fifteen-minute off-schedule pass with its own notebook section, question fixed as what is in this building that the schedule does not cover; rotation onto two building types outside the inspector's usual stock, one per quarter. *Lever A (lower `D`), secondary:* every filed item must cite the notebook entry that generated it, and items with no notebook entry cannot be filed. Target gain `a = 0.35` — the working band, half-life 1.61 cycles, comfortably inside the stability condition and nowhere near deadbeat, which SP-23 forbids at this `Q`.

cycle	`ln r`	`r`	band
0	+0.6419	1.900	Marked
1	+0.4172	1.518	Marked
2	+0.2712	1.312	Mild
3	+0.1763	1.193	Mild
4	+0.1146	1.121	Mild
5	+0.0745	1.077	**Calibrated**
6	+0.0484	1.050	Calibrated

Five audit cycles to the calibrated band. At a quarterly cadence that is fifteen months, and the office should expect the inspector's headline productivity to fall by roughly half during it — time on site rising from 41 minutes toward something near the mid-career 118 — while true conditions found per inspection rises and false alarms collapse. **Say that in advance.** A correction that reduces the number people have been watching, in order to improve numbers nobody has been watching, is reversed in month four unless the trade was written down in month zero (SP-25).

Falsification. The office preregisters: the inspector's frozen post-correction `r` predicts a held-out false-discovery rate below 0.15 and an off-model hit rate above 0.40 on a fresh building, and beats persistence from the Year 14 audit, a model using building complexity alone, an autoregressive model on past filed-item counts, and **the same model fitted to inspector/building pairings shuffled at random across the office's staff.** If the shuffled control predicts as well, `r` is a property of the building and not of the inspector, the instrument measures nothing about the person, and the office has agreed in writing to publish that internally and stop using it.

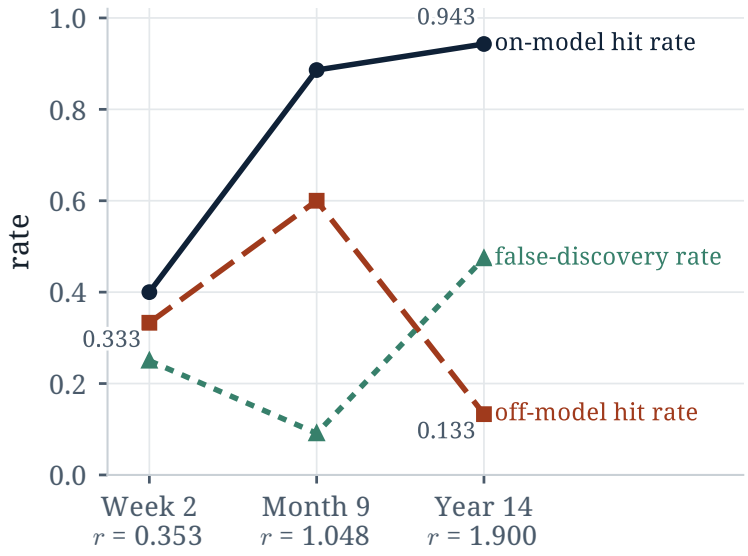

Figure 19.5: **On-model detection rises with tenure while off-model detection collapses below the novice's.** The three career points of the constructed inspector series: on-model hit rate climbs 0.400, 0.886, 0.943 while off-model hit rate goes 0.333, 0.600, 0.133 and the false-discovery rate goes 0.250, 0.091, 0.474. The calibration ratios at the three points are 0.353, 1.048 and 1.900. **The Week-2 and Year-14 hit rates do not reconcile with the filed-item counts of the same worked example, and Section 12.3 prints the discrepancy; the figure plots the source's rates unaltered.** Illustrative construction, not a measurement; generated by `figs/src/CCP-019_fig05.py`.

19.12.3 12.3 Numbers in the source material that do not reproduce

Five printed figures in the material this paper converts fail to reconcile. They are printed here rather than corrected silently, because a reader recomputing the worked examples will hit them.

(1) The starting distortion of the correction-map table is misattributed. The trajectory table of Section 5.2 begins at `ln r = +0.8122` and describes that as the value measured in the seeded review audit. **The seeded review audit returns `ln r = +0.544727`** (Section 12.1). The trajectories are arithmetically correct from `+0.8122`, and `+0.8122` corresponds to `r = 2.2529`, a value computed nowhere in this material. **The arithmetic stands; the attribution does not.** Everything downstream that quotes the divergent case — six cycles at gain 2.3 reaching 3.92 nats — is correct from the stated start and unattached to the audit.

(2) The Week-2 hit rates do not reconcile with the Week-2 filed-item count. The filed report holds 12 items of which 9 are real. The reported on-model hit rate 0.400 implies 14 of 35 and the off-model hit rate 0.333 implies 5 of 15, which is 19 true conditions found — **more true conditions than there are items in the report.** The signature panel's *true conditions found 19/50* carries the same figure. Against this, the per-hour table (`9 / (232/60) = 2.328` true per hour) and the cost table (41 misses out of 50) are both computed from **9**, and both reproduce exactly. **The internally consistent count is 9; the hit rates and the 19/50 row are the entries that fail.**

(3) The Year-14 hit rates do not reconcile with the Year-14 filed-item count. The filed report holds 57 items of which 30 are real. On-model 0.943 implies 33 of 35 and off-model 0.133 implies 2 of 15, which is 35 — again more than the 30 real items recorded, and again matching the panel's *true conditions found 35/50*. The per-hour table (`30 / (41/60) = 43.902`) and the cost table (20 misses) are computed from **30** and reproduce exactly. **If the 30-item count is held and the off-model rate of 2 of 15 is held, the on-model rate is 28 of 35 = 0.800, not 0.943.** In other words, **the headline figure "94 per cent on-model detection" is the number that fails,**

while “13 per cent off-model, below the novice’s 33 per cent” survives on either reading, since the novice’s off-model figure is not in doubt and 2 of 15 is below 5 of 15 whatever the on-model row says. **The paper reports the discrepancy rather than choosing a repair, because choosing one would silently invent a number.**

(4) The crossover claim on the cost table is wrong by a factor of about five. The material states that the office would have to value a miss at more than about six times a false alarm before the veteran’s operating point beats the novice’s. Solving directly with the tabled counts: the veteran (20 misses, 27 alarms) beats the novice (41 misses, 3 alarms) when `20m + 27a < 41m + 3a`, that is when `24a < 21m`, that is when `m/a > 24/21 = 1.142857`. **The crossover is at about 1.14, not about 6.** At a 1.2:1 weighting the veteran already wins, 51 against 52.2. The three tabled cost structures are each correct; only the crossover sentence is wrong.

(5) The claim that no cost structure lets either point beat the calibrated one is false as stated. It is true of the three structures tested. It is not true in general: the novice (41 misses, 3 alarms) beats the calibrated point (10 misses, 4 alarms) when `41m + 3a < 10m + 4a`, that is when `a/m > 31`. **At a false-alarm cost more than thirty-one times a miss, the novice’s operating point is cheaper.** That is an extreme weighting and it is not absurd — it is the regime in which assertion is public, irreversible and expensive, which Section 8.4 names explicitly as the case for a deliberate `r < 1`. The correct statement is *no cost structure among the three tested*.

A sixth item is a silence rather than an error and is recorded in Section 4.6: the octave column of the ceiling table converts at `2/ln 2 = 2.885390` rather than at the direct `1/ln 2 = 1.442695`, and the factor of two comes from the exponent in the corpus’s essence bridge [Curzi, 2026,?], which the source of this paper does not say.

A seventh is a logical gap rather than an arithmetic one and is recorded in Section 5.7: the zero-headroom cancellation requires `E = ln N` and not merely `r = 1`, and the source presents the two as one step.

19.12.4 12.4 The unlicensed-operation audit

The rigour standard requires that wherever a paper computes a mean, a difference or a ratio of something that is only ordinal, it says the operation is not licensed and either justifies it or downgrades the conclusion. **This paper computes many. Every one is listed.**

Operation, where it appears	Scale required	Scale available	Verdict and what is done
`D/P` and `M = (D/P).E`, throughout	Ratio, common true zero	Ordinal at best; counts linked within one item set only	**NOT LICENSED.** Conclusion downgraded to the heuristic ordering (R1); no magnitude reported as measured.
`ln r`, `Delta = abs(ln r)`, Sections 6.1 onward	Ratio on `r`	As above	**NOT LICENSED as magnitude.** Sign and rank order retained as findings.

Operation, where it appears	Scale required	Scale available	Verdict and what is done
Band cut points, Section 6.3	Ordinal	Ordinal	**LICENSED as banding.** The claims that the bands are equal in width and that severe means a factor of two to five are **NOT LICENSED** and are marked as such in Section 6.3.
Arithmetic mean of `r`, Section 6.4	Ratio, and wrong statistic besides	Ordinal	**NOT LICENSED twice over.** Prohibited by SP-15; shown only to demonstrate the bias.
Geometric mean of `r`, mean `ln r`, mean `abs(ln r)`, Section 6.4	Interval on `ln r`	Ordinal	**NOT LICENSED pending instrumentation.** Licensed substitute stated in Section 6.4: median of `ln r`, rank on `abs(ln r)`.
Chain addition `sum_i ln r_i`, Section 8.2	Interval on `ln r`	Ordinal	**NOT LICENSED as arithmetic.** Retained as a **structural** argument, exactly as the source itself states.
Residual distortion `w/a`, Section 8.3	Ratio on both	Neither instrumented	**NOT LICENSED as a magnitude.** The two monotonicities and the unreachability conclusion survive on the stability bound alone.
Percentage changes in the re-audit table, Section 12.1 — the `r` and `abs(ln r)` rows	Ratio	Ordinal	**NOT LICENSED.** Downgraded to *moved toward contact*.
Percentage changes in the same table — hit rates, false-discovery rate, defect counts	Ratio	**Counts with a true zero**	**LICENSED.** These are the rows the conclusions in Section 13 actually rest on.
Minutes on site, per-hour rates, Section 12.2	Ratio	**Duration, true zero**	**LICENSED.**
Miss and false-alarm counts and the cost tables, Sections 8.4 and 12.2	Ratio	**Counts with a true zero**; the loss weights are stipulated	**LICENSED**, conditional on the declared weights being a policy rather than a measurement.

Operation, where it appears	Scale required	Scale available	Verdict and what is done
`Q_inf` on `M` and on `V`, and the stored-error fractions 63 and 68 per cent	Ratio, via `M`	Inherits the demotion through `M`	**NOT LICENSED as magnitudes.** The *sign* of the gap, and the ordering of the three career points by it, survive.
Elasticities `dM/M = dD/D − dP/P + dE/E`, Section 5.4	None — property of the algebra	Not applicable	**LICENSED.** A statement about the model, not about data.
The ceiling `0 <= M <= ln N`, Section 4.6	Requires `M` in nats on the surplus scale	Normalisation is a convention	**LICENSED conditional on the declared convention** (SP-11); the bound itself is a theorem [Curzi, 2026].
`1 − 1/r = 0.4200` at `r = 50/29`, Section 12.1	None — arithmetic identity on two counts	Counts	**LICENSED.** This is the one magnitude in the paper that does not need the demoted scale, because it reduces to `1 − 29/50` on the raw counts.

Two conclusions follow from that table and both are stated against the framework's interest. First, **the licensed rows are the count rows.** Every conclusion in Section 13 that is stated at full strength rests on hit rates, defect counts, durations and error counts — quantities with genuine true zeros — and not on `r`. Second, **the equation's own outputs are the unlicensed ones.** The paper's most quotable magnitudes, 1.724138 and 1.900000 and 63 per cent and 68 per cent, are exactly the numbers the demotion withdraws. That is uncomfortable and it is the correct reading of the framework's own protocol.

19.13 13 Discussion

19.13.1 13.1 What follows

A validation protocol that demotes its author's own keystone formula is doing its job. The result reported here is negative — the moment equation fails the scale-type gate — and the value of the finding is not that the equation is bad but that the gate is real. The framework named the exact quantity it withdrew, left the structural content standing, and priced the instrument that would restore the magnitude at about 123 items per term [Curzi, 2026t]. That sequence — demote, delimit, cost, specify — is what makes the rest of the corpus's numbers worth reading, because a corpus that never demotes anything has not told the reader what its standard is.

The structural content that survives is not small. Four limiting cases predicted from one line, each naming a condition practitioners already recognise. A fixed point at `D = P` which holds for every environment, is not the absence of a frame, is not certainty, and is not comfort. Unit elasticity in every term, so no input's error is amplified. A ceiling inherited from a theorem. A stability band on correction that is the same band an engineer applies to a feedback loop. And a separation of what was stored from what was earned, which is what makes the

framework's least comfortable prediction statable at all: **stored error and stored knowledge occupy the same variable, and the only mechanism that eventually distinguishes them is cost, on a lag.**

The counter-result is the part the framework had least reason to publish. Contact is not an unqualified goal. At the fixed point in a saturating environment the headroom gauge reads exactly zero by cancellation, and an observer optimising raw stored order is driven away from `r = 1` unless the correction-load coefficient exceeds the decay rate. **Where `kappa < delta`, every incentive attached to raw stored order is an incentive to over-frame**, and that is arithmetic about a ledger rather than a claim about anyone's character.

The strongest practical consequence is a requirement on audit design. An audit built from the model under test is a mirror. Twenty-five per cent off-model content is what makes the seeded review audit find anything; thirty per cent is what makes the inspector audit find anything. **Both audits would have certified their subjects as excellent if the audit had been built from the standing guide**, which is the ordinary way audits are built.

19.13.2 13.2 What does not follow

- **It does not compute what is really there.** `E` is exogenous and must be measured by an instrument outside the observer (SP-3).
- **It does not tell anyone whether a moment is good.** It addresses whether the moment is faithful. Fidelity and value are different questions and the framework answers only the first.
- **It does not separate `D` from `P`.** `(D, P, E)` and `(kD, kP, E)` make identical predictions; only the ratio is identified, and any claim about the absolute magnitude of a person's frame or intake needs a second instrument.
- **It does not apply to environments that respond to the observer.** Where the assertion changes `E` the formula as written is inapplicable, and that is a substantial class of real situations — negotiation, diagnosis, forecasting — which the framework excludes rather than models [Manski, 1993].
- **It does not establish that any observer obeys the relation.** That is a postulate, gate G6 has not been run, and the corpus's one preregistered confirmatory test of a different law did not meet its declared margin [Curzi, 2026i].
- **It does not show that `r` is a property of a person.** Gate G7 is unrun and is the gate that decides whether the psychological reading survives at all.
- **The predictive-processing correspondence establishes nothing.** Two formalisms placing their invariant at the same point is interesting and is not evidence, and this bibliography holds no entry for the literature in question.

19.13.3 13.3 Relation to the surrounding literature

Where the framework converges with existing results, it does not discriminate against them. The prediction that on-model detection rises and off-model detection falls with tenure in a stable frame is the myopia of learning [Levinthal and March, 1993] and the homogenisation of a fast-learning organisation [March, 1991], reached from a different mechanism; the progressive absorption of an anomaly into the standing model is documented [Vaughan, 1996]; and the destruction of local variety by a legible scheme is the same movement at institutional scale [Scott, 1998]. **A confirmatory observation of H5 therefore does not distinguish this framework from any of them**, and the demand for a differential prediction — one the simpler accounts do not also make — is the correct demand to place on a formal social model [Durlauf, 2005]. The framework's candidate differential predictions are the quantitative ones: the exact `1 − 1/r` relation between over-framing and the false-discovery rate, and the knife edge at `kappa = delta`. **Both are exactly the predictions the scale-type demotion withdraws**, which is the honest summary of where the framework currently stands.

Where it is exposed, the exposure is measurement-theoretic and not empirical. Michell [1997] is the objection, conjoint measurement is the test [Luce and Tukey, 1964], and neither has been run. The framework's response is to demote rather than to argue, which is the right response and is not a substitute for the test.

Where the literature supplies something the framework needs, it is used and named. The logarithm is warranted by multiplicative dynamics rather than by psychophysics [Peters and Gell-Mann, 2016]. The stability band is standard control theory [Åström and Murray, 2008, Elaydi, 2005]. The reflexive fixed point is documented in the field with dates and prices [MacKenzie and Millo, 2003], which is the existence proof the corpus's reflexive law needs and does not itself supply. The Rasch route out is specified because separability is what supplies the true zero [Rasch, 1960, Andrich, 1988]. And the ceiling on individual-level prediction from very rich data [Hofman et al., 2017, Salganik et al., 2020] is the reason to expect gate G7 to be hard, and the reason not to promise that it will pass.

On the corpus's own terms, this paper is one entry in a register. The demotion recorded here appears in the corpus's standing register of its own demotions and inversions [Curzi, 2026], alongside a formulary that demotes five of its own nine entries on the same ground [Curzi, 2026q]. **A framework's credibility is not built by having no weaknesses. It is built by being the party that found them first**, and the register is the evidence that this is the practice rather than the slogan.

19.14 14 Verification

The results of this paper compound from seven postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped.**

19.14.1 14.1 Dimensional audit

`[E]` denotes the dimension of environmental structure, adopted here as **nats** — a dimensionless information measure — and `[T]` the dimension of time, whose unit is the correction cycle or audit interval.

Symbol	Dimension	Unit	Status
`D`	`[X]`	recorded items per condition present, or precision, as declared	**stipulated commensurable with** `P` (SP-1); the framework fixes no unit and says so
`P`	`[X]`	the same unit as `D`, necessarily	**stipulated**; identical to `D` by SP-1 or the fraction is malformed
`r = D/P`	`[1]`	none	**derived** dimensionless; the only quantity the moment measurement identifies
`ln r`, `Delta`	`[1]`	nats	**derived**; convertible to bits at `1/ln 2 = 1.442695`

Symbol	Dimension	Unit	Status
`E`	`[1]`	nats of usable structure	**stipulated** by the register convention; requires an independent instrument (SP-3)
`M = rE`	`[1]`	nats	**derived**: `[M] = [E]` exactly, since `r` is dimensionless
`N`	`[1]`	a count	**declared** (SP-11): the raw number of distinguishable categories
`ln N`	`[1]`	nats	**derived**; the ceiling on `M`
`V = E min(r,1)`	`[1]`	nats	**derived**; same dimension as `E`
`a`	`[1]`	per cycle, dimensionless fraction	**design parameter**, chosen and not measured
`w`	`[1]`	nats per cycle	**stipulated**; must be estimated locally, and the framework supplies no value
`eta`	`[Q]` per nat per step	proxy units per nat per cycle	**stipulated** here; measured in the storage law [Curzi, 2026a]
`delta`, `kappa`	`[1]`	per cycle	**stipulated** dimensionless fractions per step
`Q`, `Q^V`, `Z`	`[Q]`	declared order proxy	**derived** from the storage law; two systems' values are incomparable unless they declare the same proxy
`C`, `c_0`	`[Q]` per step	proxy units per cycle	**stipulated**
`h`	`[Q]` per step	proxy units per cycle	**derived** headroom

Does the equation balance? `M = (D/P).E` balances if and only if `[D] = [P]`, which makes `r` dimensionless and forces `[M] = [E]`. That is the whole of gate G1 and it is conditional on SP-1: **a ratio of two quantities that are not the same kind of quantity is not dimensionless, it is meaningless, and no amount of downstream arithmetic repairs it.** The self-storage law `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` balances if and only if `eta M` carries `[Q]` per step; since `M` is dimensionless in nats, **`eta` must carry `[Q]` per nat per step and is not dimensionless** [Curzi, 2026a].

Where the framework has no operational unit, it is said here. `D` and `P` have **no operational unit fixed by the framework**; SP-1 requires only that whatever unit is chosen be the same for both, and the two worked audits choose *recorded items per condition present*. `E` is denominated in nats by convention and not by measurement. `Q` is counted in whatever the declared order proxy counts. **Comfort itself, the underlying construct of the corpus, has no operational unit at all** and is treated as a dimensionless magnitude by stipulation, not by measurement;

Section 15 records that the quantitative structure required for that stipulation has not been tested.

19.14.2 14.2 The postulates

P1 — The moment equation is the model form: `M = (D/P).E`. *Status:* **POSTULATED** — this work's own proposal, with no external support; the corpus's coverage audit records that none was found. It carries no empirical weight on its own.

P2 — Permissible arithmetic is determined by scale type: multiplication and division require a ratio scale with a true zero. *Status:* **CITED** — Stevens [1946], with the invariance formulation in Narens [1996], Luce [2002].

P3 — No instrument currently places `D` and `P` on a common ratio scale with a shared true zero. *Status:* **POSTULATED** — this is an empirical claim about the state of instrumentation and is the only empirically loaded premise in the chain. It is corroborated by the corpus's own protocol run [Curzi, 2026t] and is consistent with Michell [1997]'s general finding, but it is not proved by either, and a counterexample would consist of exactly one working linked instrument.

P4 — Surplus is bounded: `0 <= F(u) <= ln N`, with `F(u) = ln(1 + (N−1)u)`. *Status:* **CITED** — the range result of the surplus functional [Curzi, 2026].

P5 — A first-order linear recurrence `x_{t+1} = c x_t` converges to 0 from any start if and only if `|c| < 1`, and the transient falls by `|c|` per step. *Status:* **CITED** — Elaydi [2005], Kelley and Peterson [2001]; the metric-space form supplying uniqueness and start-independence is Banach [1922], Curzi [2026].

P6 — `ln(xy) = ln x + ln y`, so a multiplicative composition is additive in logarithms. *Status:* **ARITHMETIC** — elementary, and it is the whole content of the composition argument of Section 6.2.

P7 — `E` is exogenous: the observer's assertion does not change what is available to be observed. *Status:* **POSTULATED** — a modelling restriction, enforced by SP-12 and violated by an important class of situations. Manski [1993] is the reason it cannot simply be assumed away in the class where it fails.

Two postulates carry all the empirical weight and both are POSTULATED: P3 and P7. Everything else is arithmetic, a definition, or an external citation. A reader who rejects P3 recovers the quantitative reading of the equation and gains an obligation to produce the instrument; a reader who rejects P7 loses the equation entirely in the reflexive class.

19.14.3 14.3 The compounding chain

```
P1              -> L1   M = rE with r = D/P; three degrees of freedom, not four;
                        (D,P,E) and (kD,kP,E) are observationally identical.   ARITHMETIC

P1 + P6         -> L2   ln M = ln D − ln P + ln E, so every elasticity is
                        exactly +1 or −1.                                      ARITHMETIC

P2 + P3         -> R1   the magnitude of D/P is not a measured quantity; on
                        ordinal data the equation is a heuristic ordering and
                        may not be printed as a fraction or computed.
                                                  CITED (stevens1946theory) + POSTULATED (P3)

L1              -> R2a  D = P  <=>  r = 1  =>  M = E for every E; the fixed
                        point is an identity, not an approximation.            ARITHMETIC

L1 + P4         -> R2b  0 <= M <= ln N under the register convention, so the
                        P -> 0 divergence saturates at ln N rather than
```

```
                        diverging.                  CITED (ccp:CCP-A02) + DEFINITION (normalisation)

P5              -> R3   ln r_{t+1} = (1-a) ln r_t converges iff |1-a| < 1,
                        i.e. 0 < a < 2; neutral at a = 0; divergent at a >= 2;
                        half-life ln 2 / (-ln|1-a|).       CITED (elaydi2005introduction)

R3              -> R3b  at a = 2.3 from ln r = 0.8122, six steps give
                        -1.0559, +1.3726, -1.7844, +2.3197, -3.0157, +3.9203.  ARITHMETIC

L1              -> R4a  V = E min(r,1); confabulated fraction 1 - 1/r for
                        r > 1; missed fraction 1 - r for r < 1; V is uniquely
                        maximised at r = 1.                                    DEFINITION

R4a             -> R4b  at r = 50/29 = 1.724138, 1 - 1/r = 1 - 29/50 = 0.4200
                        exactly, which is the audit's false-discovery rate
                        21/50.                                                 ARITHMETIC

R4b + ccp:CCP-007 -> R4c  with eta = 0.35, delta = 0.08, C = 0.20, E = 1:
                        Q_inf on M = 5.043, on V = 1.875, stored error 3.168,
                        62.8 per cent of the store.       ARITHMETIC on stipulated parameters

R4a             -> R5   re-audit at r = 32/31 . 40/40 = 1.032258: false
                        discovery 21/50 = 0.4200 -> 1/32 = 0.03125, a 92.6 per
                        cent reduction; true defects 29/40 -> 31/40.           ARITHMETIC

R4a             -> R6   inspector series r = 12/34 = 0.352941, 44/42 = 1.047619,
                        57/30 = 1.900000; stored error at year 14 is 3.9375 of
                        5.8125, 67.7 per cent.            ARITHMETIC on stipulated counts

R2a + ccp:CCP-007 -> CR1 at r = 1 AND E = ln N: h = eta ln N - delta Q_inf - C
                        = eta ln N - (eta ln N - C) - C = 0 exactly.            ARITHMETIC

L1 + ccp:CCP-007 -> CR2 with C_t = c_0 + kappa Z_t, dQ_inf/dM =
                        eta (1 - kappa/delta)/delta, which is negative iff
                        kappa > delta.                                         ARITHMETIC
```

Every line is checkable from its own stated inputs. R2a, R2b, R3, R3b, R4a to R4c, R5, R6, CR1 and CR2 are arithmetic or definitional consequences of one postulated model form (P1), one cited range result (P4), one cited stability condition (P5) and elementary algebra. **R1 — the paper's headline — is the only result carrying empirical weight, and it consumes one citation (P2) and one postulate with no external support (P3).**

What this chain does not establish. It does not establish that any observer obeys P1. That is the modelling postulate, gate G6 has not been run, and the one preregistered confirmatory test of a different law reported in this corpus did not meet its own declared margin [Curzi, 2026i]. **A chain whose steps are ARITHMETIC and CITED delivers the mathematics with certainty and delivers nothing whatever about observers.**

19.14.4 14.4 The verification instance, computed by hand

Check 1 — the false-discovery identity. The audit records 50 items filed, 29 of them real. Then `r = 50/29`. Compute `1/r = 29/50 = 0.58` exactly, so `1 - 1/r = 0.42` exactly. Independently, the false-discovery rate is `(50 - 29)/50 = 21/50 = 0.42`. **The two are the same number because they are the same fraction written twice**, and the decimal expansion `50/29 = 1.7241379...` rounds to the printed `1.724138`, from which `1 - 1/1.724138 = 0.420000023...`, agreeing to six

decimals. **ARITHMETIC**, and it is the one magnitude in the paper that does not need the demoted scale, because it reduces to a ratio of two counts with a true zero.

Check 2 — the divergent correction, six steps. With `a = 2.3` the pole is `1 - a = -1.3`. From `ln r_0 = 0.8122`:

```
step 1:  -1.3 x 0.8122     = -1.055860
step 2:  -1.3 x -1.055860  = +1.372618
step 3:  -1.3 x 1.372618   = -1.784403
step 4:  -1.3 x -1.784403  = +2.319724
step 5:  -1.3 x 2.319724   = -3.015641
step 6:  -1.3 x -3.015641  = +3.920333
```

which reproduces the printed row `-1.0559 +1.3726 -1.7844 +2.3197 -3.0157 +3.9204` to four decimals. `exp(3.9204) = 50.42`, which is the factor of fifty from contact. **ARITHMETIC.** Contrast the convergent case at `a = 0.35`, pole `0.65`: `0.65 x 0.8122 = 0.527930`, then 0.343155, 0.223050, 0.144982, 0.094238 — below 0.10 at the fifth step, which is the tabled entry. **The whole of the stability claim is visible in ten multiplications.**

Check 3 — the headroom cancellation. With `S = ln N`, `Q_inf = (eta ln N - C)/delta`, so `delta Q_inf = eta ln N - C` identically, and `h = eta ln N - delta Q_inf - C = eta ln N - (eta ln N - C) - C = 0`. **Both `delta` and `C` cancel and no parameter values are needed.** ARITHMETIC — and Section 5.7 records that the step requires `E = ln N` and not merely `r = 1`.

Check 4 — the knife edge. With `C = c_0 + kappa Z` and `Z_inf = eta(M - V)/delta`, at `r > 1` we have `V = E` fixed, so `dZ_inf/dM = eta/delta` and

```
Q_inf = (eta M - c_0 - kappa Z_inf)/delta
dQ_inf/dM = (eta - kappa . eta/delta)/delta = eta(1 - kappa/delta)/delta
```

which is negative exactly when `kappa > delta`. At the tabled values `eta = 0.35, delta = 0.08, kappa = 0.02`, the derivative is `0.35 x (1 - 0.25)/0.08 = 3.28125` per nat, positive, so raw stored order rises in `r` — and the tabled `Q_inf` values 1.8750, 3.5156, 8.4375, 15.0000 at `r = 1, 1.5, 3, 5` rise accordingly. **ARITHMETIC.**

Check 5 — the aggregation rows. For `{0.5, 2.0}`: arithmetic mean `1.25`; geometric mean `sqrt(0.5 x 2.0) = 1.000`; mean `ln r = (-0.693147 + 0.693147)/2 = 0`; mean `|ln r| = 0.693147`. For `{0.4, 0.8, 1.5, 2.5}`: the product is `1.2`, so the geometric mean is `1.2^{1/4} = 1.046635` and `ln` of that is `0.045580`; the four absolute logarithms are 0.916291, 0.223144, 0.405465 and 0.916291, averaging 0.615298. **ARITHMETIC**, and the point of the check is that the three statistics disagree by construction, not by accident.

19.14.5 14.5 Limits, asymptotics, and the model's valid domain

`P -> 0^+`. `M -> +infinity` in the unbounded form, and `M -> ln N` under the register convention. **The limit is not the pathology; the saturation is.** The bounded reading — the observer sees the maximum their categories permit, sourced entirely from themselves — is the better description and is what the bounded model predicts. **`P = 0` exactly is outside the model's domain**, because `D/0` is undefined and the bounded form is a repair applied after the fact rather than a property of the expression.

`D -> 0^+`. `M -> 0`. Everything arrives and nothing is made of it. **At `D = 0` exactly, `M = 0` and the equation is well formed**, unlike the `P` case; this asymmetry between numerator and denominator is real and is the same asymmetry that makes halving intake double the moment while halving frame merely halves it.

`E -> 0`. `M -> 0` for every finite `r`. A multiplier on zero is zero. `E = 0` is admissible and gives a true reading of an empty environment.

`r -> 0` and `r -> infinity`. Under-framing and over-framing without bound; the second saturates at `ln N` and the first does not need a bound because it is already at zero. `r < 0` is inadmissible: `D` and `P` are counts or precisions and both are non-negative.

`a -> 0^+`. The pole tends to 1, the half-life to infinity, and the residual distortion `w/a` to infinity. **At `a = 0` exactly the map is the identity: neutrally stable, no contraction, and whatever distortion the observer has, they keep.** That is the structural twin of the `delta = 0` pathology in the storage law [Curzi, 2026a], and it says the same thing: **without a leak there is no attractor.** It is also the default state of an unaudited observer.

`a -> 1`. Deadbeat: the pole is zero and the distortion is annihilated in one step. **The mathematics is fine and the application is not**, because it means discarding the whole existing frame in one period, and the cost violates the admissibility condition `C_t <= (1−delta)Q_t + eta M_t` at any material stored order (SP-23).

`a -> 2^−` and `a >= 2`. The pole tends to 1 in magnitude with alternating sign; convergence becomes arbitrarily slow, and at `a = 2` the map is `ln r_{t+1} = −ln r_t`, a period-two orbit that never converges and never diverges. **Above 2 it diverges geometrically.** `a >= 2` is outside the model's admissible design range.

`N -> 1`. `ln N = 0`, so the ceiling and the achievable moment collapse together and `M = 0` for every `r`. **A single category has zero available moment, not a small one.** **`N -> infinity`.** The ceiling grows without bound but only logarithmically, and the marginal gain `ln N − ln(N−1)` behaves as `1/N` and vanishes. **The limit is not a licence to raise `N`**; it is why Section 4.6 concludes that a distortion problem cannot be solved by learning more categories.

`w -> 0`. Residual distortion vanishes and the correction map is the undriven one; a static environment is the only one in which contact is attainable rather than merely approachable. **`w` large.** Beyond about `0.10` nats per cycle at the stated band width, no admissible gain holds calibration and only the cadence remains.

`kappa -> delta`. The knife edge: `dQ_inf/dM = 0` and raw stored order becomes indifferent to `r`. Below it the raw ledger rewards over-framing; above it the raw ledger penalises it. **The framework supplies no measured value of either parameter.**

Stated domain. The relation as used here is valid for `D >= 0`, `P > 0`, `E >= 0`, `N >= 2`, correction gain `a` in `(0, 1]` for applied use and `(0, 2)` for the mathematics, and an environment that does not respond to the observer's assertion. Outside that domain the expression still produces values and they should not be interpreted as statements about an observer.

19.14.6 14.6 Invariance

The scaling invariance, and why it is also the identification failure. The relation is invariant under `(D, P) -> (kD, kP)` for every `k > 0`, since `r` is unchanged and `M` depends on `D` and `P` only through `r`. **That is a genuine one-parameter invariance and it is exactly why the split is not identified**: the group of admissible transformations is larger than the data can distinguish. `E` is not in the group — rescaling `E` rescales `M` proportionally — so `r` is the unit-free quantity of the relation and `E`, `M` and `V` are the unit-carrying ones. **Two observers may be compared on `r` directly; they may not be compared on `M` unless they share a declared `E` instrument.**

The invariance in `E` at the fixed point. `M = E` holds at `r = 1` for every `E`, which is a scale-freedom claim and is stated as one: the fixed point is invariant under any rescaling of the environment. **What would break it:** an `r` that varies with `E` — which is precisely the apophenic case, where a thin `E` makes any `D` produce a large `r`, so **the invariance already fails in one of the framework's own named subtypes** and holds only where `D` and `P` are set independently of the richness of the environment. That is a real restriction and it is stated as one rather than assumed away.

The invariance of the distortion measure under change of logarithmic base. `ln r` in nats converts to bits at `1/ln 2 = 1.442695`, and the sign, the ordering and the fixed point at zero are all preserved. **The band table is not invariant**, because its cut points are declared in nats; a framework reporting in bits must restate them.

How many scales the claim has been exercised at: two, both constructed. One reviewer and one inspector, both synthetic, both by one author, with no independent replication of anything. The internal/external reading of Section 5.3 asserts the same fixed point at a third scope and exercises it at none.

19.14.7 14.7 Analogy discipline, and the precision of the numbers

The correction map is a shared mathematical form, not a derivation from physical premises. The map `ln r_{t+1} = (1−a) ln r_t` and the first-order discrete section are governed by the same difference equation, so every theorem about such recurrences applies to both [Elaydi, 2005, Oppenheim et al., 1996, Åström and Murray, 2008]. Nothing about charge, capacitance or current is claimed to hold of an observer, and **no physical result's authority transfers.** The same label attaches to the exponential-smoothing twin [Holt, 1957, Brown and Meyer, 1961] and to the fixed-gain filter reading [Kalman, 1960].

The contraction theorem is a derivation within the mathematics and a shared form in the application. The map genuinely is a contraction on the reals for `|1−a| < 1`, so Banach [1922] applies without qualification *to the map*. **That an observer's correction behaviour is described by the map is a postulate, not a derivation**, and the theorem's certainty does not transfer to the observer.

Ashby's law of requisite variety, applied to `M <= ln N`, is an analogy. Ashby's theorem concerns a regulator, a disturbance set and a goal set [Ashby, 1958, 1956], and this paper does not show that an observer's category repertoire satisfies those premises. **The bound does not depend on the reading**; it follows from the surplus law's range result and the normalisation convention [Curzi, 2026]. The reading is offered as motivation and is never used as evidence.

The predictive-processing correspondence is an analogy in the strict sense. A suggestive correspondence with no formal warrant, legitimate as motivation and never as evidence. The premises under which a precision-weighted average is the correct model of an observer have not been shown to hold; the two objects differ structurally, one interpolating and the other scaling; and **this bibliography contains no entry for the literature in question**, so the correspondence borrows no authority because there is none available to borrow.

Entropy, named. The `ln N` appearing throughout is **Shannon entropy** of a uniform distribution over `N` categories, a dimensionless information measure reported in nats [Shannon, 1948, Cover and Thomas, 2006]. It is **not** thermodynamic entropy, which carries `[energy][temperature]^−1`. The framework identifies the moment with neither.

Precision of the numbers. The numbers here are of three kinds and are quoted accordingly. *Defined or derived-from-defined* — `ln 2 = 0.693147`, `ln 5 = 1.609438`, the half-life formula, the geometric-mean rows, `1 − 29/50 = 0.42`, and the constant `k = (9/8)^2/phi^2 = 0.483425732988414` where it is mentioned in Section 4.6 — are exact to the precision printed and may be recomputed further. *Illustrative model output* — every entry in every trajectory table, every `Q_inf`, every `r` in both worked audits, the stored error fractions — is the output of stipulated parameters and **carries no measurement uncertainty because there was no measurement**; the decimals record the arithmetic and not the confidence, and the summary figures are rounded to two significant figures in the text for that reason. *Measured or fitted* quantities **do not appear anywhere in this paper**, because nothing in it was measured. Any application of this framework to real data must report fitted parameters with intervals, and Section 15 records that the corpus's one such report gives an interval on one parameter and none on several others.

19.15 15 Limitations

The paper's headline result is a failure of its own equation, and everything below follows from taking that seriously rather than from softening it.

The moment equation failed the scale-type gate and the failure is not repaired anywhere in this paper. `M = (D/P).E` contains a division and a multiplication, which require all three inputs on a ratio scale with a true zero [Stevens, 1946]; no instrument links `D` and `P` across item sets; the magnitude of `D/P`, the distortion as a number, and the quantitative join to the store are therefore withdrawn as measured quantities [Curzi, 2026t]. **Every quotable magnitude in this paper — 1.724138, 1.900000, 63 per cent, 68 per cent — is on the withdrawn side of that line**, and Section 12.4 lists every operation performed on them. What survives is the structure, and the structure is what the Conclusion states.

Michell's objection is conceded, not answered, and conjoint measurement has not been run. Michell [1997, 1999] argue that psychology systematically fails to test whether its attributes are quantitative before measuring them. **The demotion of Section 3.5 is that remedy applied once. Applying it once is not adopting it.** The same test bears on `u`, on `Q`, on `E` and on comfort itself, and none has been subjected to it. The formal procedure that would settle the question [Luce and Tukey, 1964, Krantz et al., 1971] has not been applied to any quantity in this corpus. **Until it is, every quantitative treatment in the corpus, including the ones this paper leaves standing, is a stipulation and not a finding.** A reliability coefficient would not close the gap [Cronbach, 1951, Sijtsma, 2009], and the construct validation this instrument owes — convergent and discriminant, across methods — has not been performed [Campbell and Fiske, 1959, Cronbach and Meehl, 1955].

Both worked audits are constructed, and one of them does not reconcile with itself. No dataset was collected. Every number in Section 12 is the output of stipulated counts and stipulated parameters. **Three rows of the inspector series — the Week-2 and Year-14 on-model and off-model hit rates and the true-conditions-found row — are mutually inconsistent with the filed-item counts of the same example**, as Section 12.3 sets out; the per-hour and cost tables reproduce from the filed-item counts and the hit rates do not. **The headline figure "94 per cent on-model detection" is the entry that fails**; "13 per cent off-model, below the novice's 33 per cent" survives on either reading. The paper prints the discrepancy and does not choose a repair, because choosing one would invent a number. Two further printed claims are wrong and are corrected in Section 12.3: the cost-crossover figure (about 1.14, not about 6) and the claim that no cost structure lets either non-central point beat the calibrated one (false above a false-alarm-to-miss weighting of 31).

The 94/13 result is the paper's most interesting empirical-shaped claim and it is not empirical. It is a constructed fourteen-year series with stipulated counts. It carries no uncertainty because nothing was measured, and no bare point estimate in this paper should be read as a measurement.

Gates G6 and G7 have not been run and G7 is the one that decides everything. No preregistered test of the moment equation exists. **Whether `r` is a property of an observer or a property of an item set is unknown**, and if `r` for one observer swings by more than the band width across equivalent item sets, the psychological reading collapses. The ceiling on individual-level prediction from very rich longitudinal data [Hofman et al., 2017, Salganik et al., 2020] is a reason to expect that gate to be hard. The corpus's one preregistered confirmatory test of a different law reported a 2.8 per cent held-out advantage over a matched autoregression against a declared 10 per cent margin and recorded the verdict as *predictive advantage not demonstrated* [Curzi, 2026i]; **that is the current evidential status of every applied claim resting on this paper, and it is weaker than the mathematics.**

The reflection problem is unanswered and no remedy is adopted. The corpus's founding law is a reflexive specification [Curzi, 2026] whose endogenous effect is not identified from observational data [Manski, 1993], with the same confounding of influence and selection in network settings [Shalizi and Thomas, 2011]. **This paper's response is an exclusion (SP-12, FM-10), not a solution**, and the excluded class is exactly where the reflexive law operates. The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001]; the seeded audit's externally adjudicated item set is a step toward it and not a substitute. **Every applied reading of `r` in this paper is therefore a modelling position and not an identified empirical result.**

The Lucas critique applies to this framework's own parameters and the position taken is narrow. The paper asserts that a throughput metric drives `r` upward across a population and prescribes changing the metric, then treats the gain and the drift rate as constant over the correction horizon. **Both cannot hold without qualification** [Lucas, 1976, Hacking, 1995]. The position adopted is that the parameters are stable only over one declared audit cycle and only while `r` and its components are not themselves reported targets; the moment off-model detection enters a quarterly report it becomes a target and ceases to be a good measure [Goodhart, 1975, Campbell, 1979]. **Where `r` is reported upward the constancy assumption fails**, and Section 12.1 shows Goodhart's law arriving on schedule inside the framework's own worked example. A framework that tells an organisation its inspectors are two-thirds confabulating should expect that statement to change the inspectors [Ferraro et al., 2005, McCambridge et al., 2014].

The observer cannot be separated from the instrument. Calibration cannot be self-assessed, for the structural reason of Section 7.3 and for the general reason that people cannot reliably report the processes producing their judgements [Nisbett and Wilson, 1977]. **But the external audit relocates the problem rather than removing it**: the adjudicators who build the seeded item set are observers with frames, and prior expectation measurably shapes what is perceived and reported [Rosenthal and Fode, 1963, Rosenthal and Jacobson, 1968] — an effect whose size is itself contested and smaller than its popular reading [Jussim and Harber, 2005].

The five behavioural estimators are unvalidated and none has been run. E1 to E5 are proposals. None has been compared against a criterion, none has a reported reliability, and SP-16's requirement of two from different rows is a design rule and not a demonstration.

The band table and the diagnostic cut points are conventions. 0.10, 0.35, 0.69 and 1.61 nats were chosen for round numbers and for correspondence with recognisable states. They are not measured thresholds, the differential diagnosis of Section 7.2 imports them as decision rules, and **a reader who changes them changes every band assignment in this paper.**

Parameters chosen rather than measured. In both worked audits, `eta`, `delta`, `C`, `c_0`, `kappa`, `E`, the correction gain `a` and every seeded count are stipulated. The drift rates in Section 8.3 are stipulated. The loss weights in Section 8.4 are stipulated. **The framework supplies no measured value for any parameter it uses.**

`N_eff = 1 + (N−1)u` is not a Hill number and no external literature contains it. `1/HHI` and `exp(H)` are the Hill numbers of order two and one and are grounded [Hill, 1973, Jost, 2006]; the affine interpolation is this framework's own construction. The ceiling in this paper uses the raw `N`, and a reviewer reaching for the Hill-number literature will find it does not apply to the effective count.

The functional form of the surplus the ceiling inherits from is underdetermined by the evidence. A sub-linear power law [Latané, 1981] and an `n log n` form [Briscoe et al., 2006] fit the qualitative facts as well as `ln(1 + (N−1)u)` does, and **nothing assembled here discriminates between them.** The logarithm is chosen for its axiomatic characterisation and is not established by measurement. The one genuine strengthening available is that a logarithmic evaluation follows from multiplicative dynamics with no psychological assumption [Peters and Gell-Mann, 2016], which is what this paper's own use of the logarithm rests on; the psychophysical warrant is weaker, contested [Stevens, 1957, Krueger, 1989], and range-dependent [Teghtsoonian, 1971].

Two claims in this paper are uncited because the bibliography contains nothing that supports them, and they are named here rather than given a citation that does not fit. First, **the claim that loss asymmetry between misses and false alarms moves the optimal operating point** (Section 8.4) is carried by this paper's own cost arithmetic; this bibliography holds no signal-detection-theory entry, and no citation is attached. Second, **the predictive-processing correspondence** (Section 5.7) is stated with no external support at all, because the bibliography holds no entry for that literature; it is badged as an analogy and must not be read as borrowing that programme's authority.

Where `r` is read as a similarity or distance between frame and intake, it cannot be assumed to behave metrically, since psychological similarity is asymmetric and violates the triangle in-

equality [Tversky, 1977]. The framework treats the two directions as symmetric under the logarithm, which is a property of the coordinate and not a demonstrated property of the psychology.

No scaling, power-law or heavy-tail claim is made in this paper, so the distribution fitting procedure any such claim would require [Clauset et al., 2009] does not apply. The one distributional statement made — that distortion decays geometrically under correction — is a property of a postulated linear map and has not been tested against data.

Unmet rigour checks, printed rather than left to a reviewer. *(i) Model comparison.* This paper fits nothing, so no information criterion applies to it; gate G6 requires a matched autoregression with the same parameter count, and that requirement is stated and unrun. *(ii) Effect sizes and intervals.* Nothing in Section 12 carries an interval because nothing in Section 12 was measured; that is honest for a constructed example and is not a substitute for the intervals a real application owes. *(iii) Scale type.* Handled at length above and audited in Section 12.4. *(iv) Independent replication.* Every worked system in this paper and in the corpus's applied papers was constructed or surveyed by one author; there is no independent replication of any parameter estimate, and the reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005]. *(v) Directional versus point prediction.* Meehl [1967] observes that directional predictions are nearly costless in the social sciences; this framework does make point predictions with constants, which is the right answer to that objection — **and the scale demotion has withdrawn exactly those points.** *(vi) Differential prediction.* H5 is predicted equally by two existing literatures [Levinthal and March, 1993, March, 1991], so confirming it would not discriminate [Durlauf, 2005]. *(vii) The field's own indictment.* The standard charge against physics-styled social modelling — sub-standard statistical procedure, universality claimed from limited data, models built on assumptions known to be false [Gallegati et al., 2006] — is a checklist this paper is exposed to on the second and third counts, and answers on the first only by having run no statistics at all. Cartwright [1999] offers the generous reading and the framework takes it: a law of this kind holds inside a specified stable arrangement or not at all, and Section 14.5 states the arrangement.

Nothing in this paper is a human-subjects finding. No participants were recruited, no interventions were run, and the consent and decline requirements of SP-13 and SP-28 are design constraints on prospective work rather than reports of past practice.

19.16 16 Conclusion

The moment equation `M = (D/P).E` is the corpus's own formula, and it fails the corpus's own scale-type gate. The expression contains a division and a multiplication, so frame, intake and environment must each be measured on a ratio scale with a true zero and a defensible unit [Stevens, 1946]. No instrument places `D` and `P` on a common ratio scale with a shared zero. **R1, the demotion rule: where only ordinal data exist for frame or intake, the moment equation is a heuristic ordering — more frame relative to intake produces a larger and more model-shaped moment — and may not be printed as a fraction, computed, or used to generate a number.** The magnitude of `D/P`, the distortion as a number, and the quantitative join from the moment to the store are withdrawn as measured quantities. That is the paper's headline result, it is negative, and it is the remedy Michell [1997] prescribes applied once — the honest position being that it should be applied consistently rather than once, and that the conjoint-measurement test which would settle the matter [Luce and Tukey, 1964] has not been run for any quantity in this corpus.

R2 — the fixed point. `D = P`, equivalently `r = 1`, gives `M = E` **for every `E`**: an identity and not an approximation, holding at both personal and institutional scope, and meaning matched frame rather than absent frame. Every elasticity of the relation is exactly `+1` or `−1`, so a one per cent error anywhere is a one per cent error in the moment and no term's error is amplified. The ceiling `0 <= M <= ln N` — with `N` the raw count of distinguishable categories, inherited from the surplus range result [Curzi, 2026] under a declared normalisation — makes the one

divergence in the formula finite: as `P -> 0` the moment **saturates at `ln N`** rather than diverging, which is a better description of dogma than an infinity is.

R3 — the correction map. `ln r_{t+1} = (1−a) ln r_t` is a first-order linear recurrence, **attracting for `0 < a < 2`, neutral at `a = 0`, oscillating but convergent for `1 < a < 2`, and divergent at `a >= 2`**, with distortion half-life `ln 2 / (−ln|1−a|)` cycles. From a distortion of 0.8122 nats, six cycles at gain 2.3 reach 3.9203 nats — `r` near 50, a factor of fifty from contact. **There is no decay term on distortion: an observer does not drift back into contact, and calibration is a maintenance item with a schedule.** In a moving environment the residual distortion is `w/a`, drift over gain, which is not zero and cannot be made zero; above about a tenth of a nat of drift per cycle no admissible gain holds calibration and only the cadence remains.

R4 — veridical throughput. `V = E min(r,1)` is the part of the moment the environment supplied, and it is uniquely maximised at the fixed point; the confabulated fraction is `1 − 1/r` for `r > 1`. In a seeded review audit with 25 per cent off-model items, 50 filed items of which 29 were real give `r = 50/29 = 1.724138` and a confabulated fraction `1 − 29/50 = 0.4200` **exactly equal to the false-discovery rate `21/50`** — the one magnitude in this paper that survives the demotion, because it reduces to a ratio of two counts. At stipulated `eta = 0.35`, `delta = 0.08`, `C = 0.20`, the reviewer's steady state is **about 63 per cent stored error**.

R5 — correction works, and the metric being watched gets worse. At gain 0.35 the same reviewer reaches `r = 1.032` after six cycles: false discovery falls 92.6 per cent, true defects found rise from 29 of 40 to 31 of 40, off-model detection quadruples — **and on-model detection falls from 93 to 90 per cent**, which is a small regression by the metric most organisations actually watch.

R6 — the inspector series. Across a constructed fourteen-year career the same inspector returns `r = 0.353` with a **negative** steady state at week two, `r = 1.048` at minimum loss in month nine, and `r = 1.900` at year fourteen with **about 68 per cent of the store being error**, on-model detection at its career maximum and **off-model detection about 13 per cent, below the nine-day novice's 33 per cent**. Three rows of that series do not reconcile with its own filed-item counts and the discrepancy is printed in Section 12.3 rather than repaired.

CR — the counter-result. Contact is not an unqualified goal. At `r = 1` in an environment that saturates the observer's repertoire, the input sits at its ceiling and the headroom gauge reads `h = eta ln N − (eta ln N − C) − C = 0` **exactly, by cancellation**: a perfectly calibrated observer maximises fidelity and has no room left to build. Worse, an observer optimising raw stored order is driven away from `r = 1` altogether, because `dQ_inf/dM = eta(1 − kappa/delta)/delta` is negative **only when the correction-load coefficient exceeds the decay rate**; below that knife edge the raw ledger rewards over-framing without bound. **Calibration is a property of the instrument; the operating point is a policy; and an undeclared departure from `r = 1` is instrument error and not judgement.**

All of this is arithmetic on a postulated relation. Whether any observer is described by `M = (D/P).E` is a separate question; it is a postulate rather than a result; the falsification and reproducibility gates have not been run; and **the equation's own scale-type demotion is this paper's headline finding and its principal negative result.**

19.16.1 Declarations

Data and code availability

No external dataset was collected for this paper, no observer was measured, and no organisation was studied. All numerical results are computed from the stated parameters and stipulated counts under the relations developed in the text, and every table can be re-derived from the equations and values printed beside it. **The seeded review audit of Section 12.1 and the fourteen-year inspector series of Section 12.2 are constructed examples with declared counts, not field observations**, and Section 12.3 records the numbers in the source material for those examples that do not reconcile. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the relations

of Sections 4 to 8.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. Both worked audits are constructed. The consent and decline requirements stated as SP-13 and SP-28 — that no calibration procedure is administered to a person who has not agreed to it, and that a refusal is recorded as a refusal and not as a result — are design constraints on prospective work and are not reports of any study performed. The framework is explicit that calibration measurement is measurement of a person and that results may not be used for a purpose not disclosed before the audit.

Preregistration

This paper reports no preregistered test of its own; its results are derivations, and its principal finding is a self-imposed demotion rather than an empirical outcome. The preregistration protocol that would test the moment equation — fit, freeze, held-out prediction, and four baselines including a shuffled-input control — is specified in Section 9.2 and **has not been run.** The corresponding protocol applied to a different law elsewhere in this corpus **failed its second falsification rule**, returning a 2.8 per cent held-out advantage over a matched autoregression against a declared margin of 10 per cent [Curzi, 2026i]. Any applied claim resting on this paper inherits that result.

19.17 Appendix A The demoted and the surviving, side by side

The table below is the operational summary of Section 3.5 and is provided so that a practitioner can tell at a glance which statements this framework licenses.

Statement	Status under the demotion
This observer is over-framed / calibrated / under-framed	**SURVIVES.** Needs only the sign of `ln r`.
This observer moved toward contact between two audits on a common item set	**SURVIVES.** Needs only rank order.
Observer A is further from contact than observer B on the same item set	**SURVIVES.** Ordinal comparison.
As intake falls with frame held, the moment inflates	**SURVIVES.** A limiting case.

Statement	Status under the demotion
With no frame the moment is zero, whatever the intake	**SURVIVES.** A limiting case.
With an empty environment the moment is zero, whatever the ratio	**SURVIVES.** A limiting case.
At `D = P` the moment equals the environment for every environment	**SURVIVES.** An identity in the model.
The moment is bounded above by `ln N`	**SURVIVES**, conditional on the declared normalisation (SP-11).
Correction converges for gain in `(0,2)` and diverges at or above 2	**SURVIVES.** A property of a chosen design parameter.
Veridical throughput is maximised at the fixed point	**SURVIVES.** A property of `min(r,1)`.
This observer's `r` is 1.72	**DEMOTED.** Magnitude withdrawn.
This observer's distortion is 0.54 nats	**DEMOTED.** Magnitude withdrawn.
This observer's distortion is twice that one's	**DEMOTED.** Requires a ratio scale.
This observer's distortion fell by 92.6 per cent	**DEMOTED** for `r` and `abs(ln r)`; **retained** for the false-discovery rate, which is a ratio of counts.
Sixty-three per cent of this observer's store is error	**DEMOTED.** Inherits through `M`.
The pipeline injected 1.07 nats in total	**DEMOTED as arithmetic**; retained as the structural claim that compensating stages exist and a net figure conceals them.
The confabulated fraction is `1 − 29/50 = 0.42`	**SURVIVES.** Reduces to two counts with a true zero.
This audit found 31 of 40 seeded defects, up from 29	**SURVIVES.** Counts.
Time on site fell from 232 to 41 minutes	**SURVIVES.** Duration, true zero.

19.18 Appendix B The route out, and what it costs

The instrument that would restore the magnitudes is specified rather than gestured at, and the specification is what makes the demotion a finding rather than a complaint.

The construction. Measure `D` and `P` as person-measures on **one common linked scale** under a Rasch model [Rasch, 1960, Andrich, 1988], given a badged additivity postulate. Rasch separability supplies the true zero that division requires and fixes the unit up to choice, and the distortion becomes a difference of logits on that scale, `Delta = |ln(D/P)| = |theta_D − theta_P|`, which is genuinely ratio-scaled.

The price, in items. About **123 items per term** to establish a half-logit distortion at 95 per cent, and about **31 items** for a full logit [Curzi, 2026t]. A twelve-item pair of scales resolves nothing below roughly 1.6 logits, so **a practitioner reporting `r = 1.2` from a twelve-item pair is reporting noise.**

What it does not buy. It does not answer Michell [1997], because the Rasch model assumes the additive structure it then exploits rather than testing for it; the test for additive conjoint structure is a separate procedure [Luce and Tukey, 1964, Krantz et al., 1971] and it has not been run. It does not identify the split of `r` into `D` and `P`, which is a separate and unrelated failure (Section 4.1). It does not address the reflection problem [Manski, 1993]. **And it does not make the framework empirical**, because gates G6 and G7 remain unrun whatever scale the terms are measured on.

What it does buy. Everything in the demoted column of Appendix A, and with it the framework's two candidate differential predictions — the exact `1 - 1/r` relation between overframing and false discovery, and the knife edge at `kappa = delta` — which are the only claims here that a simpler account of expertise decay does not also make [Levinthal and March, 1993, Durlauf, 2005].

Chapter 20

The Perceptual Lens: Fechner's Law as the Register of the Surplus Functional, with a Postulate Method and Its Held-Out Tests

Abstract. The Lens Theorem states that if percepts of multiplied intensities add, the transfer function must be logarithmic; the inference is Cauchy's functional equation and is verified numerically to an absolute error of 1.02×10^{-8}. The substantive result is that this corpus's surplus functional is a Fechner law: $f(u) = \ln(1 + (N-1)u)$ rewrites exactly as $\ln((u+u_0)/u_0)$ with $u_0 = 1/(N-1)$ an absolute threshold of difference, so concavity is a property of the register rather than a pessimistic assumption, and $f'(0)/f'(1) = N$ exactly. The storage law in world coordinates is correspondingly a geometric accumulator, $G_{t+1} = G_t^{1-\delta}\, N_{\text{eff}}^{\eta}\, e^{-C}$, agreeing with the additive form to fourteen significant figures. The design consequence is a prohibition: never promise a linear improvement in a logarithmic quantity. At a brightness exponent of 0.33 a promised twenty per cent delivers 6.201 per cent perceived, 31 per cent of the promise, and a real twenty per cent costs a 73.76 per cent load increase; a reading-room case closes a perceived zone gap from 26.09 to 9.06 per cent for 8.00 per cent more energy. A postulate method defines empirical content as $H_{\text{forbid}} = -\ln q$, and the worked postulate was refuted on one of four declared consequences at three times its pre-set tolerance and amended in public. Two corrections are carried throughout: the corpus's logarithm needs multiplicative dynamics rather than Fechner, and the paper's own ratio-invariance test — response ratios of 2.5100 and 2.5000 agreeing to 0.40 per cent — is the power law's invariant, favouring Stevens over Fechner by $\Delta\text{AIC} = 26.57$ at equal parameter count.

Keywords: Lens Theorem; Fechner's law; Stevens exponent; geometric accumulator; ratio invariance; magnitude estimation; postulate method; empirical content

Series: B. Engineering the Surplus **Paper:** CCP-020

20.1 1 Introduction

The Creature Comforts framework computes in logarithms. Its surplus functional is `F(u) = ln(1 + (N–1)u)`; its storage law accumulates that logarithm; its distortion measure is `|ln r|`; its ceiling is `ln N`. A framework that takes a logarithm everywhere owes an account of why,

and the account it has so far offered is psychophysical: perception reports ratios rather than differences, and a device that converts ratios into differences is a logarithm.

This paper supplies that account, states exactly how much of it the framework actually needs, and reports the test that cuts against it.

Three things are established. **First**, the Lens Theorem: if the map from a world quantity to its perceived magnitude is continuous and carries multiplication into addition, then that map is a logarithm and is the only such map up to one scale constant. That half is algebra — the continuous solution of Cauchy's logarithmic functional equation — and it is verified here numerically by a 200,000-rectangle midpoint sum against `ln 100`, absolute error `1.02e-08`. **Second**, the framework's own surplus functional is a Fechner law: setting `u_0 = 1/(N-1)`, `ln(1 + (N-1)u)` rewrites exactly as `ln((u + u_0)/u_0)`, which is Fechner's near-threshold form with non-parallelism as the stimulus and `u_0` as an absolute threshold of difference. The identity is exact to floating-point noise and is independently verified across `N = 2` to `100` at seven values of `u` to a maximum deviation of `8.9e-16` in Curzi [2026]. Its consequences are not decorative: concavity becomes a property of the register rather than a pessimistic assumption, the ratio of first to last marginal value is exactly `N`, and the storage law read in world coordinates is a weighted geometric accumulator. **Third**, a postulate method — the discipline by which an unobservable quantity is given a structure, its observable consequences derived, and the structure held to them — is stated with six admissibility conditions, an empirical-content measure, and a held-out testing procedure, and is then exercised on a worked postulate that **failed**.

Two corrections to the framework's own reading of this material are carried in the body, and they matter more than the confirmations.

The logarithm does not need Fechner. Peters and Gell-Mann [2016] derive a logarithmic form from the dynamics of a multiplicative process with no psychological premise at all: the time-average growth rate of such a process is logarithmic in the accumulating quantity, and nothing about observers is assumed. That is a **stronger** warrant for the corpus's logarithms than Fechner's, precisely because it does not require the perceptual story to be true, and it is not exposed to the century of measurement-theoretic objection that Fechner's is [Stevens, 1957, Poulton, 1979, Luce, 2002, Narens, 1996]. Section 3.3 states the division of labour explicitly and Sections 13 and 15 restate it: **where the framework needs only the functional form, Peters and Gell-Mann are sufficient and Fechner is optional colour; where the framework needs the perceptual claim — which it does, in exactly one place, the design consequences about promised versus perceived magnitude — Fechner and Stevens are load-bearing and their unresolved contest is a live cost.**

The functional form is underdetermined. Latané [1981] proposes a sub-linear power law in the number of sources; Briscoe et al. [2006] propose `n log n`; this framework proposes `ln(1 + (N-1)u)`. All three are increasing, concave in the relevant range, and consistent with the qualitative facts. Nothing assembled in this paper discriminates among them, and Section 3.5 says so with a figure. The one genuinely discriminating test the corpus possesses is the ratio-invariance test of Section 12.3 — and **it returns a power-law exponent, which is Stevens rather than Fechner.** Section 12.3 reports that plainly, and Section 13.2 draws the consequence: a ratio-invariance test that succeeds is evidence for a power law and against a Fechnerian logarithm on the same data. The corpus keeps its logarithm on axiomatic [Curzi, 2026] and dynamical [Peters and Gell-Mann, 2016] grounds, not psychophysical ones.

Sections 2 and 3 state the hypotheses and the framework. Section 4 develops the translation table between operations in the perceptual register and operations in the world. Sections 5 and 6 apply it to the framework's own two central equations, the storage law and the surplus functional. Section 7 draws the design consequences and prices them. Section 8 states the postulate method. Section 9 presents the psychophysical record on which the method's exemplar rests. Sections 10 and 11 collect the specifications and the named failure modes. Section 12 reports three worked cases, one of which refuted its own postulate. Sections 13 to 16 discuss, verify, limit and conclude.

20.2 2 Hypotheses

The Lens Theorem of Section 3.1 is a theorem about a functional equation and cannot be falsified by observation; it is labelled a derivation where it appears, and its **antecedent** — that perception is such a map — is the empirical claim. The hypotheses below separate the two. Each names the observation that would defeat it.

H1 — The register is ratio-based. Equal ratios of a physical stimulus produce equal increments of subjective magnitude, over the mid-range of a modality, rather than equal absolute differences producing equal increments. **Predicted:** a constant Weber fraction `c = dI/I` over the mid-range, so that the count of just-noticeable differences between two stimuli depends only on their ratio; and, equivalently, a straight line when a well-constructed magnitude scale is plotted against `ln I` or against `log psi` versus `log I`. **Falsified by:** a modality showing a constant *absolute* just-noticeable difference over its mid-range, or `c` varying systematically with `I` in the mid-range beyond measurement error. **Status of the evidence:** run, and passing in the middle of the range and failing at both ends in a characteristic and reproducible way [Weber, 1834, Stevens, 1975].

H2 — Subjective magnitude admits a ratio scale under a ratio instruction. Numbers emitted under an unbounded proportional-assignment instruction have the internal structure of ratio measurement, and numbers emitted under a bounded category instruction do not. **Predicted:** for equal physical ratios presented at different absolute levels, the response ratios agree within measurement error; and a bounded rating scale does not reproduce that invariance because its ceiling forbids it. **Falsified by:** response ratios that depend on absolute level; or a bounded rating scale that reproduces the invariance as well as the unbounded instruction does. **Not established even if it passes:** the conjoint-measurement conditions that would license the quantitative treatment in the first place [Luce and Tukey, 1964, Michell, 1997]. Section 15 records that they were not tested.

H3 — The surplus functional is the framework's Fechner law. The corpus's `F(u)` is not merely logarithmic in form but is the threshold form of Fechner's law with `u` as the stimulus. **Predicted:** `ln(1 + (N−1)u) = ln((u + u_0)/u_0)` identically on `u` in `[0,1]` for every `N >= 2`, with `u_0 = 1/(N−1)`; hence `N_eff(u_0) = 2` and `F(u_0) = ln 2` for every `N`, and `f'(0)/f'(1) = N` exactly. **Falsified by:** any `(N, u)` pair at which the two expressions differ by more than floating-point rounding. **This hypothesis is an algebraic identity and is therefore a derivation, not an empirical claim** — it is listed here because it is the paper's substantive result and a reader is entitled to see it stated in falsifiable form and then to check it.

H4 — The linear-promise prohibition. A commitment stated as a percentage change in a world quantity systematically overstates the perceived change delivered, in every compressive modality, by the modality's exponent. **Predicted:** at a brightness exponent of `0.33`, a delivered `+20%` illuminance yields `1.20^0.33 − 1 = +6.201%` perceived, which is `31.0%` of the promise; and delivering a genuine perceived `+20%` requires `1.20^(1/0.33) − 1 = +73.76%` of world quantity. **Falsified by:** post-occupancy magnitude estimation returning a perceived change matching the physical percentage rather than the exponent-converted one, in a modality whose exponent is below one and has been measured under the application's own conditions. **Depends on:** the perceptual claim, not merely the functional form. **This is the one hypothesis in the paper for which Fechner and Stevens are load-bearing and Peters and Gell-Mann are not substitutes**, because the quantity being predicted is what a person reports, not how a stock grows.

H5 — Empirical content is what a postulate forbids, and it is measurable comparatively. Over a fixed, published outcome list, the content of a postulate that admits a

fraction `q` of the listed outcomes is `H_forbid = −ln q` nats, and postulates ranked by this quantity are ranked in the order that repays a fixed testing budget. **Predicted:** `q = 1` buys zero nats; halving the admitted outcomes buys `ln 2 = 0.6931` nats; content adds under independent conjunction, `−ln(q_1 q_2) = H_1 + H_2`. **Falsified by:** a preregistered set of postulates with declared content scores, tested under a fixed budget, in which the high-content postulates do **not** produce more parameter revision per unit cost than the low-content ones. **Status:** the arithmetic is a **definition**; the claim that it helps is an untested hypothesis, and Section 8.6 badges it accordingly.

H6 — Held-out prediction with a shuffled-input control separates storage from shape. A model whose predictive advantage comes from the postulated storage mechanism loses that advantage when its input series is permuted; a model that has merely learned the series' shape does not. **Predicted:** with frozen parameters, held-out error under a shuffled input rises materially and the skill score against persistence goes negative. **Falsified by:** shuffled-input held-out error close to the unshuffled figure while the other baselines are beaten — the diagnostic signature of a model that is not using its inputs. **Precedent, and a caution:** the corpus's one preregistered confirmatory application of this protocol beat its shuffle at `p = 0.0005` and nonetheless **failed** its own second falsification rule, at a 2.8 per cent held-out advantage over a matched AR(1) against a declared 10 per cent margin [Curzi, 2026i].

Three further claims in this paper are **not** hypotheses and are labelled where they appear. The **Postulate Method** of Section 8.2 is a house formalisation of ordinary hypothetico-deductive practice [Popper, 1959, Platt, 1964]; no priority is claimed for it and it is not the kind of thing that is true or false. The **badge taxonomy** of Section 8.3 is a **definition**, a naming convention for evidential status, parallel to the four-drawer classification of Curzi [2026]. The **identification of the storage law's world-coordinate form with a geometric accumulator** (Section 5) is a **change of coordinates** — a shared mathematical form in the sense of Section 14.7, exactly equivalent to the additive form, and therefore evidence for nothing.

20.3 3 Framework: the lens, its two warrants, and what it does not settle

20.3.1 3.1 The Lens Theorem

The Lens Theorem [conditional theorem]. If the map from a world quantity `I > 0` to its perceived magnitude `S` is continuous and converts multiplication into addition, that is if

```
S(I_1 . I_2) = S(I_1) + S(I_2)      for all I_1, I_2 > 0
```

then that map is a logarithm, and it is the only such map up to a single positive scale constant:

```
S(I) = k ln I ,   k > 0
```

equivalently, with a reference intensity `I_0` at which the percept is zero,

```
S(I) = k ln(I / I_0) .
```

The inference is a theorem and it is not new. It is the continuous solution of Cauchy's logarithmic functional equation, and it is the statement that the logarithm is the unique continuous isomorphism from the multiplicative group of the positive reals onto the additive group

of the reals. No psychology enters the proof; it is an algebraic fact about two operations. The badge is therefore on the **antecedent** — the claim that perception is such a map — and not on the inference. Section 9 gives the record of the antecedent and Section 9.9 gives its limits.

The direction a designer needs is the inverse:

```
I = I_0 . e^{S/k}
```

A linear schedule of percepts requires an exponential schedule of world quantities. Equal experienced steps demand equal ratios, and equal ratios compound. Every design consequence in Section 7 is a worked instance of that one line.

20.3.2 3.2 Weber's law and Fechner's integration

Weber [1834] reported that the smallest detectable increase in a stimulus is a constant proportion of the stimulus already present:

```
dI / I = c ,     c the Weber fraction, constant over the mid-range of a modality
```

Weber's law is on the observable side of the wall: it concerns discrimination performance, settled by a forced choice and a tally, and asserts nothing about inner magnitude. Fechner [1860] took the step that makes it a lens by postulating that every just-noticeable difference is one equal unit of subjective magnitude, and integrating:

```
dS = k dI / I  =>  S = k ln I + const  =>  S = k ln(I / I_0)
```

Fechner's equal-JND postulate is a postulate, badged as such wherever it is used in this paper. It does not follow from Weber's law; it is an additional assumption; it has been disputed since it was made; and Fechner's law is what follows if it is granted. The standard English text for quotation is Fechner [1966]; Weber [1978] is the translation of Weber.

The integration step is verified numerically. With `k = 1` and `I_0 = 1`, integrating `1/I` from `I = 1` to `I = 100` by 200,000 midpoint rectangles:

```
midpoint Riemann sum = 4.605170176
ln(100)              = 4.605170186
absolute error       = 1.021e-08
```

The Weber fraction fixes how many perceptual steps a physical range contains, and the counts are small:

Weber fraction `c`	JNDs across a 2:1 range	JNDs across a 1000:1 range
0.02	35.00	348.83
0.05	14.21	141.58
0.10	7.27	72.48
0.20	3.80	37.89

A thousandfold range of world quantity contains 72 discriminable steps at a Weber fraction of 0.10, and a doubling contains seven. The world's dynamic range is large and the register's is small. That compression is what the register is for, and the observation that people cannot distinguish a three per cent improvement from nothing is a statement about working sense organs rather than about inattention.

20.3.3 3.3 The two warrants for the logarithm, and which one this framework needs

This is the section the rest of the paper's honesty depends on, and it is placed before any use of the logarithm rather than after.

Warrant 1 — psychological (Fechner). Sensation is logarithmic in intensity because equal just-noticeable differences are equal steps of sensation and just-noticeable differences are constant ratios of intensity [Weber, 1834, Fechner, 1860]. This warrant requires the perceptual story to be true. It is **contested**: Stevens [1957] produced a competing power law by a method Fechner had not considered, and no logarithmic sensation scale can produce the expansive exponents that method returns (Section 9.5); Poulton [1968] and Poulton [1979] catalogue the biases in the competing method; Luce [2002] and Narens [1996] ask axiomatically what must be true of a subject's judgements for either scale to exist at all; Krueger [1989] is the standing reconciliation attempt, with peer commentary, and the dispute is not closed.

Warrant 2 — dynamical (Peters and Gell-Mann). The time-average growth rate of a multiplicative process is logarithmic in the accumulating quantity [Peters and Gell-Mann, 2016]. **No psychological assumption is made anywhere in that derivation.** The companion statement — that the time average of a multiplicative process differs from its ensemble average, so that a parameter estimated across individuals does not describe what happens to any one of them over time — is Peters [2019], and it bears directly on this framework, whose stored quantity accumulates over time for one system.

Which warrant does the argument need? The answer differs by claim, and the paper states it claim by claim rather than once.

- **For the functional form of the surplus law and of the storage law, Warrant 2 is sufficient and Warrant 1 is optional.** `F(u) = ln(1 + (N−1)u)` is characterised in this corpus by four axioms about interaction geometry, with no reference to perception [Curzi, 2026]; the storage law's world-coordinate form (Section 5) is multiplicative, which is exactly the class of process for which Peters and Gell-Mann [2016] derive a logarithm. **Neither claim is exposed if Fechner is wrong.** The Fechner identity of Section 6 is then a structural convergence between two independent routes to one function, and Section 6.1 says explicitly that a convergence is not evidence that either route is correct.
- **For the design consequences about promised versus perceived magnitude, Warrant 1 is load-bearing and Warrant 2 is not a substitute.** Section 7.2 predicts what a person will report after an illuminance change. That prediction is about perception; a dynamical derivation of a logarithm says nothing about it; and the applicable constant is a measured Stevens exponent whose value, method-dependence and between-study variation are the live cost of using it (Sections 9.3 and 9.9). **The title of this paper claims more than most of its content requires, and that is said here rather than left for a reviewer to notice.**

The honest summary, restated in Section 13.1 and again in Section 15: **the corpus needs a logarithm; Peters and Gell-Mann supply one without needing observers; Fechner supplies one that does need them and is contested; the corpus's central formal claims rest on the first, and only its design advice rests on the second.**

20.3.4 3.4 Stevens' power law, and why it relocates the register rather than abolishing it

Stevens [1957] proposed

```
psi = k I^a                                  the power law
```

obtained by **magnitude estimation** — asking observers to assign numbers in proportion to their sensations. The competition with Fechner is real and unresolved. It does not remove the register, and the reason is one line of algebra:

```
psi = k I^a   =>   ln psi = ln k + a ln I
```

A power law is a straight line in log-log coordinates: it is the logarithmic register with a gain. Under Fechner the operative case is `log in, linear out`; under Stevens it is `log in, log out`, with the world-side ratio raised to `a`:

```
perceived ratio = (world ratio)^a ,      perceived change in nats = a ln(world ratio)
```

The exponent `a` is therefore a **measured conversion key** between the physical and perceptual registers, and holding both theories at once amounts to saying: the register is logarithmic, and `a` is its gain. Published exponents, presented as **nominal, modality- and method-dependent constants of a procedure and not constants of nature** [Stevens, 1975, Teghtsoonian, 1971]:

Modality	exponent `a`	character
Loudness (1 kHz, sound pressure)	0.67	compressive
Brightness	0.33	compressive
Visual length	1.00	linear
Taste (salt)	1.30	expansive
Heaviness (lifted)	1.45	expansive
Warmth on arm	1.60	expansive
Electric shock	3.50	strongly expansive

`a < 1` compressive, `a = 1` linear, `a > 1` expansive. **Most senses compress; pain expands.** Section 7.6 shows that the expansive modalities invert every design rule in Section 7, which is why an exponent must be looked up rather than assumed.

These are cited point estimates, not measurements made here, and they carry no interval. The literature is explicit that they shift with stimulus range [Teghtsoonian, 1971], with instruction and modulus [Poulton, 1979], and across observers, replicating in rank order and to within roughly ten to twenty per cent for well-studied modalities [Stevens, 1975]. Section 15 records that every design number in Section 7 inherits that variation, and Section 10 requires re-measurement before any exponent is used to calibrate rather than to orient.

20.3.5 3.5 The functional form is underdetermined, and this paper does not settle it

Three candidate laws relate an aggregate to a count of contributing sources, and all three are increasing and concave over the range in which this framework operates.

Candidate	Form	Source
Sub-linear power law	influence grows as `N^t` with `t < 1`	Latané [1981]
`n log n`	network value grows as `N ln N`, not `N^2`	Briscoe et al. [2006]
This framework	`F(u) = ln(1 + (N−1)u)`	Curzi [2026]

Nothing in this corpus discriminates among them on data, and the shape comparison this paper can perform is reported here with its arithmetic. Affinely matching each alternative to `ln N` at both endpoints of `N` in `[2, 50]` — two constraints, so no free parameter is left over except the power law's exponent — gives:

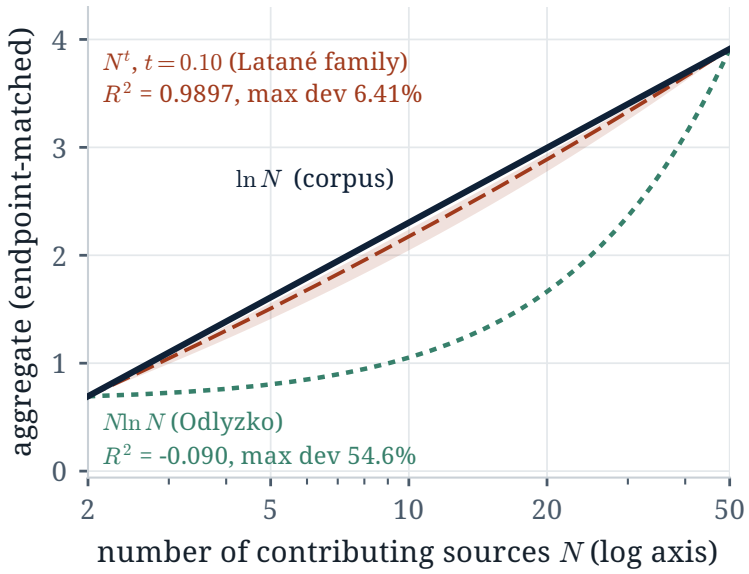

Figure 20.1: **A shape argument cannot separate the corpus's logarithm from a sub-linear power law, and can separate it from `n log n`.** Each alternative is affinely matched to `ln N` at both endpoints of `N` in `[2, 50]`. A power law with `t = 0.10` tracks `ln N` at `R^2` = 0.9897 with a maximum relative deviation of 6.41 per cent, and the band shows `t` from 0.05 to 0.20; the logarithm is the `t -> 0` member of that family, so no exponent value is invented here and none is published in the source. `N ln N` departs by 54.60 per cent and is a claim about a different quantity. Functional forms only, with two endpoint constraints and no fitted parameters; generated by `figs/src/CCP-020_fig01.py`.

alternative, endpoint-matched to `ln N` on `N` in `[2,50]`	`R^2` against `ln N`	max relative deviation
`N^t, t = 0.05`	0.9974	3.24%
`N^t, t = 0.10`	0.9897	6.41%
`N^t, t = 0.20`	0.9593	12.49%
`N ln N`	-0.090	54.60%

The sub-linear power family is not discriminated from the logarithm at small exponents, and it cannot be, because the logarithm *is* its limiting member: `(N^t - 1)/t -> ln N` as `t -> 0`, so the corpus's law sits on the boundary of the family Latané [1981] proposes and the source supplies the constraint `t < 1` rather than a value. **A shape argument cannot separate them and no shape argument in this corpus has tried.** `N ln N` does differ in shape over the same range — which is a genuine finding and a limited one, because Briscoe et al. [2006]'s quantity is the *total value of a network of `n` members* and the corpus's is a *per-ensemble surplus*, so the two are not measurements of the same thing and a shape comparison between them is suggestive at best. **What the table shows is the ceiling on what shape alone can settle: a range of a decade and a half separates `N ln N` from `ln N` and does not begin to separate `ln N` from `N^{0.05}`.**

The corpus adopts the logarithm because it is uniquely characterised by four stated axioms, one of which — that the effective count be affine in `u` — is a **design axiom, chosen and not derived** [Curzi, 2026], and because a multiplicative dynamics supplies a logarithm independently [Peters and Gell-Mann, 2016]. **It is not adopted because it fits better than the alternatives, and no comparison in this corpus has shown that it does.**

Two further cautions belong here. Briscoe et al. [2006]'s actual point is that a network-value functional form was adopted without evidence and then used to justify valuations; a

framework quoting them in support must not repeat the error they are describing. And where any claim of a power law or heavy tail is made anywhere in this corpus, the distribution-fitting procedure of Clauset et al. [2009] is binding — no such claim is made in this paper, and Section 3.4's exponents are cited point estimates from magnitude-estimation studies, not tail exponents estimated from a sample.

20.3.6 3.6 Which effective count, and the Hill-number caution

Two different effective counts appear in this corpus and they must not be conflated. `1/HHI` is the Hill number of order two and `exp(H)` is the Hill number of order one; both are fully grounded [Hill, 1973, Jost, 2006], and the concentration instrument that uses `1/HHI` — naive HHI `0.293430` giving 3.41 effective jurisdictions against a bloc-HHI of `1.000000` and an effective count of `1.00` — is Curzi [2026]. **`N_eff = 1 + (N−1)u` is not a Hill number of any order.** It is a linear interpolation between 1 and `N`, it is this framework's own construction under a declared design axiom, and no literature in ecology, economics, political science or information theory contains it. **Every occurrence of an effective count in this paper is `1 + (N−1)u` unless it says otherwise**, including the `N_eff` in the geometric accumulator of Section 5 and in result R3, and a reviewer reaching for the Hill-number literature as support for it will find that the literature does not apply.

20.3.7 3.7 Identification, reflexivity, and what this paper does not claim to have measured

The material in Section 8 concerns postulates an observer makes about their own interior, and Section 8.9 observes that such postulates behave like stored order — they decay, they convert experience into structure, they cost something to hold. Where that observation is extended to a group whose members both influence and constitute an aggregate, **the specification becomes reflexive and its endogenous effect is not identified from observational data.** Manski [1993] proves this for the linear-in-means case, and Shalizi and Thomas [2011] show that influence and selection are generically confounded in observational network data. **No amount of data, held out or otherwise, recovers the parameter.**

This paper adopts no remedy. The known options are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]; none is free, and none is exercised here. Every claim in Sections 8 and 12.2 about a structure inferred from a pattern of self-reports is therefore a **modelling position rather than an identified empirical result**, and Section 15 repeats it.

Two related points are stated once and not repeated. The existence proof that a description can become true by being used is MacKenzie and Millo [2003] — Black–Scholes prices did not fit the market when published, and after traders adopted the model the market came to fit the model, with dates and price data. Hacking [1995] is the general form: classifications of people interact with the people classified, so the referent moves. Against these, Jussim and Harber [2005] review thirty-five years of work after Rosenthal and Jacobson [1968] and find that classroom self-fulfilling prophecies are **real but small**, do not typically accumulate, and may dissipate; McCambridge et al. [2014] find the same for participation effects generally. **The reflexive mechanism exists and its measured effect sizes are much smaller than a framework built on it would like.** Merton [1948] named it; Lucas [1976] is the version that applies to this framework's own parameters, and Section 15 answers it narrowly rather than pretending it does not apply.

20.3.8 3.8 Standing honesty clauses

1. **The Lens Theorem's mathematics is a theorem; its applicability is an empirical claim.** The second is not to be presented with the confidence of the first.

2. **Fechner's equal-JND postulate is a postulate.** It does not follow from Weber's law.
3. **Stevens exponents are constants of a procedure.** Method, range, modulus and instruction are reported with any exponent, or the number is not usable.
4. **Percepts are interval-scaled, not ratio-scaled, under Fechner.** They may be subtracted and may not be divided. Under magnitude estimation both are licensed, and that is the methodological difference between the two accounts that matters most here.
5. **Nats of one modality are not nats of another.** Section 10, S9 is explicit, and this is the most likely way for the material in Section 7 to be misused.
6. **This paper concerns magnitude judgement.** It is not a theory of cognition, preference or value, and extending it to those requires separate evidence which is not offered.
7. **Nothing here is a claim about consciousness, physics or thermodynamics.** The entropy that appears anywhere near `ln N` is Shannon entropy [Shannon, 1948], a dimensionless information measure in nats, and not thermodynamic entropy.

20.4 4 The translation table: one operation, two registers

Every arithmetic operation performed on a perceived quantity has a counterpart on the world quantity that produces it. The table below is the paper's working instrument; the subsections that follow take the rows that carry weight for the framework.

```
LENS SIDE  = what the observer experiences,  S = k ln(I/I_0)
WORLD SIDE = what has to be built,           I
```

Operation in the perceptual register	Corresponding operation in the world
`S_a + S_b` — addition	**Multiplication.** `I_a . I_b / I_0`
`S_a - S_b` — subtraction	**Division.** The ratio `I_a / I_b`
`0` — the origin	**The reference `I_0`. Not absence.**
a negative percept	`I < I_0`: a reciprocal ratio, below reference
`c . S` — scalar multiplication	**Exponentiation.** `I^c`, relative to reference
`S / c` — scalar division	**The c-th root.** `I^(1/c)`
`2S` — doubling the percept	**Squaring the world quantity**
arithmetic mean of percepts	**Geometric mean** of world quantities
midpoint between two percepts	**Geometric midpoint**, `sqrt(I_a . I_b)`
linear interpolation	**Geometric interpolation**
arithmetic progression, equal steps	**Geometric progression, equal ratios**
sum over `n` terms	**Product over `n` terms**
`abs(S_a - S_b)` — distance	**`abs(ln(I_a/I_b))` — the log-ratio metric**
variance, normal distribution	**Log-variance, lognormal distribution**
`dS/dt` — a rate of change	**A proportional growth rate**, `(dI/dt)/I`
`dS/dx` — a derivative	**An elasticity**, `(dI/I)/(dx/x)`
a straight line, rising	**Exponential growth**
a straight line in log-log	**A power law**
a concave curve in world units	**A straight line, seen through the lens**
the integral of `S` over time	**The geometric (product) integral of `I`**
unbounded below, `S -> -infinity`	**`I -> 0`: the missing floor, Section 6.2**

20.4.1 4.1 Addition, and the octave constant

```
S(I_a) + S(I_b) = k ln(I_a/I_0) + k ln(I_b/I_0) = k ln( I_a I_b / I_0^2 )
```

Two percepts added correspond to two world quantities multiplied, with the reference divided out once. In the base-ten form people use when they say “orders of magnitude”, `+1` is `x10`, `+2` is `x100`, `+6` is `x1 000 000`. In nats:

step (nats)	world multiple
+0.250000	x1.284025
+0.500000	x1.648721
+0.693147	**x2.000000**
+1.000000	x2.718282
+2.000000	x7.389056
+3.000000	x20.085537
+4.605170	x100.000000

One octave — a halving or a doubling — is `ln 2 = 0.693147` nats, which is `0.301030` decades. That single constant is the conversion between the language of ratios and the language of steps, and it recurs across this corpus: as the boundary between marked and severe distortion in the calibration instrument [Curzi, 2026m], as the pitch octave, and as the surplus bought by doubling `N` [Curzi, 2026]. It is one constant doing one job in several places because there is one register.

20.4.2 4.2 The mean: an average of percepts is a geometric mean of quantities

```
mean of percepts:   (S_a + S_b)/2 = k ln( sqrt(I_a . I_b) / I_0 )
```

The world quantity corresponding to the average percept is the geometric mean.

between	arithmetic midpoint	**perceptual midpoint**
1 and 100	50.5000	**10.0000**
10 and 1 000	505.0000	**100.0000**
1 and 2	1.5000	**1.4142**
300 and 2 400 lux	1 350.0000	**848.5281**
20 Hz and 20 000 Hz	10 010.0000	**632.4555**

The quantity halfway between 1 and 100 in experience is 10, not 50.5. The frequency halfway between the bottom and the top of human hearing is 632 Hz, which is near the middle of a piano keyboard — an instrument labelled in octaves by people who have been working in this register for four centuries.

The corollary for rates:

```
+50% then −50%:      1.5 x 0.5 = 0.75              net −25.00%
arithmetic mean of the two changes:                 0.00%      WRONG
geometric mean factor: sqrt(0.75) = 0.866025       −13.40% per step   CORRECT
mean of the logs: (ln 1.5 + ln 0.5)/2 = −0.143841 nats -> exp = 0.866025
```

A four-period example: factors `1.10, 1.10, 0.80, 1.25` give a net of `1.210000`, a geometric mean of `1.048809` per period, and an arithmetic mean of factors of `1.062500`, which compounded over four periods predicts `1.2744` against the true `1.2100`. **The arithmetic mean of ratios always overstates, by Jensen’s inequality, and always in the same direction.** Section 6.4 shows that the same inequality, applied to a concave register rather than to a convex compounding, produces a penalty in the opposite direction and resolves a discrepancy in this corpus’s own reported figures.

20.4.3 4.3 The metric: distance is a log-ratio

```
perceptual distance between I_a and I_b  =  abs(ln I_a − ln I_b) = abs(ln(I_a/I_b))
```

a	b	difference	ratio	perceptual distance (nats)
1	2	1	2.0000	**0.693147**
50	100	50	2.0000	**0.693147**
1 000	2 000	1 000	2.0000	**0.693147**
1	1.1	0.1	1.1000	**0.095310**
100	110	10	1.1000	**0.095310**

Equal perceptual distance, with the underlying differences varying by a factor of a thousand. This is the row that makes an absolute-difference metric wrong for any perceived quantity, and it is why the corpus's distortion measure is `abs(ln r)` and not `abs(r − 1)` [Curzi, 2026m]. The same choice governs comparisons of very unequal magnitudes elsewhere in the corpus: a five-second settlement hop is `1.585e−07` of a year against `0.0822` for value rested thirty days, a ratio of about 518,400 to one, and that comparison is only readable as a ratio [Curzi, 2026].

20.4.4 4.4 The derivative: a slope in the lens is an elasticity in the world

```
d(ln psi) / d(ln I) = (I/psi) . (dpsi/dI) = elasticity
```

For a power law `psi = k I^a` this evaluates to exactly `a`. **The Stevens exponent is the elasticity of percept with respect to stimulus — the percentage change in experience per percentage change in the world — and it is constant across the range.** That is what "the log-log plot is a straight line" means, restated for use. The corpus's moment equation yields unit elasticities in all three of its terms by the same operation, `dM/M = dD/D − dP/P + dE/E` [Curzi, 2026m], which is a consistency check on the register rather than an independent result.

20.4.5 4.5 Zero in the lens is the reference in the world

`S = 0` at `I = I_0`, and `I_0` is not zero. **The origin of the perceptual coordinate is the reference level, not the absence of the stimulus.** Three consequences are practical:

- **A percept of zero means "at reference", not "nothing there".** Silence in a room is not zero sound; it is sound below threshold.
- **Percepts may be subtracted and may not be divided** under Fechner. "Twice as bright" is a claim about a ratio-scaled magnitude estimate, not about a Fechnerian percept, and the two are different objects.
- **The reference is a design variable.** It is set by adaptation and by context [Helson, 1948], including what the observer was exposed to immediately before. A designer who does not control the reference is not controlling the percept, and moving the reference is usually cheaper than moving the quantity — which is why a dim vestibule makes the reading room beyond it feel bright. Section 7.5 develops this and Section 7.7 states its ethical boundary.

The adaptation literature also supplies this corpus's strongest empirical ally and its strongest warning: comfort decays toward a set point [Brickman et al., 1978], with the revision that set points move and adaptation is incomplete [Diener et al., 2006].

20.4.6 4.6 Subtraction: the difference between two readings

Subtraction in the register is division in the world. The corpus's return difference, `Delta_R = abs(ln(M'/M))` for a quantity `M` sent and `M'` returned, is that row of the table and required no separate invention; it rests on a badged postulate of commensurability, and `Delta_R = 0` records a null exchange rather than a success [Curzi, 2026q].

sent `M`	returned `M'`	ratio	`Delta_R` (nats)
1.0	1.0	1.0000	**0.000000**
1.0	1.2	1.2000	0.182322
1.0	0.8	0.8000	0.223144
1.0	3.0	3.0000	1.098612
1.0	0.333333	0.3333	1.098612

A threefold amplification and a threefold attenuation carry the same 1.098612 nats, where an absolute-difference measure would have priced them at 2.0 and 0.667. And the first row is the one that is misread: **zero return difference means no information came back**, which is not the same as a good result.

20.4.7 4.7 Variance: symmetric in the lens is skewed in the world

If percepts are normally distributed, world quantities are **lognormally** distributed. With `ln I` normal about `mu = ln 300`:

sigma (nats)	median	mean	mode	mean/median
0.2	300.000	306.060	288.237	1.0202
0.5	300.000	339.945	233.640	1.1331
0.8	300.000	413.138	158.188	1.3771
1.2	300.000	616.330	71.078	**2.0544**

Mean, median and mode are three different numbers and the gap grows with the spread. At `sigma = 1.2` the mean is more than twice the median and nearly nine times the mode, so "the average" of a perceptually distributed quantity reports a value almost nobody experiences, and reports it high.

The symmetric interval is likewise asymmetric in the world. At `sigma = 0.5` about `mu = ln 300`:

```
−1 sd : 181.959      median : 300.000      +1 sd : 494.616
distance below the median : 118.041
distance above the median : 194.616
```

One standard deviation down is 118 units; one up is 195 units — same perceptual distance, different world distance, by a factor of 1.65. Any tolerance band on a perceived quantity written symmetrically in world units is asymmetric in experience. Written as a ratio — `x1.65` or `/1.65` rather than `±195` — it is symmetric in both. This is why the corpus's distortion bands are stated as `abs(ln r)` intervals and then back-translated: the band `0.35 <= abs(ln r) < 0.69` is `r` in `[1.419, 1.994)` **or** `r` in `(0.502, 0.705]`, two intervals of different width in `r` and identical width in the register [Curzi, 2026m].

20.4.8 4.8 Linear in the lens is exponential in reality

If the percept is to rise linearly in time, `S(t) = S_0 + ct`, then `I(t) = I_0 e^{(S_0 + ct)/k}`. Priced at a modest ten per cent per period, worth `ln 1.1 = 0.095310` nats:

period	world multiple	cumulative percept (nats)
0	1.0000	0.00000
3	1.3310	0.28593
6	1.7716	0.57186
9	2.3579	0.85779
12	**3.1384**	1.14372
24	**9.8497**	2.28744
48	**97.0172**	4.57489

Holding a barely noticeable rate of perceived improvement for forty-eight quarterly periods requires the world quantity to grow ninety-seven-fold, for a total advance of 4.57 nats — under two decades of world quantity, and that is the cheap reading. **Steady perceived improvement requires exponentially growing world quantity, indefinitely, and no physical or budgetary system supplies that.** Programmes of continuous perceived improvement therefore stall for a reason that is a fact about the register rather than about the programme, and the available responses are to move the reference (Section 7.5), to move to a modality with headroom, or to stop promising a rate the arithmetic forbids.

The source manuscript prints this last figure as 4.57488; `48 ln 1.1 = 4.5748886`, which rounds to 4.57489. The corrected value is used above and the discrepancy is recorded here rather than silently absorbed.

20.5 5 The storage law in world coordinates is a geometric accumulator

The last structural row of the table is the integral: a sum in the register is a product in the world. The corpus's central recursion is a sum, so it has a world-side reading.

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t                storage law, register coordinates
```

Exponentiate. Write `G_t = e^{Q_t}` for stored order in world coordinates and note that `S_t = ln N_eff,t`, so `e^{S_t} = N_eff,t` exactly, with `N_eff = 1 + (N−1)u` and **not** a Hill number (Section 3.6):

```
G_{t+1} = G_t^{(1−delta)} . (N_eff,t)^{eta} . e^{−C_t}   storage law, world coordinates
```

Verified against direct computation at `delta = 0.08`, `eta = 0.35`, `C = 0.20`, `N = 12`, `u = 0.5` — so `N_eff = 6.5` and `S = 1.871802` — from `Q_0 = 0`:

t	Q_t	G_t = e^{Q_t}	direct e^{Q_{t+1}}	product form	difference
0	0.00000	1.00000	1.57638	1.57638	0.00e+00
1	0.45513	1.57638	2.39612	2.39612	8.88e-16
2	0.87385	2.39612	3.52216	3.52216	4.44e-16
4	1.61348	5.02024	6.95549	6.95549	8.88e-16
8	2.76936	15.94848	20.14478	20.14478	0.00e+00

t	Q_t	G_t = e^{Q_t}	direct e^{Q_{t+1}}	product form	difference

Read against the translation table, the three terms are:

- **`G_t^{(1-delta)}` — decay is taking a root.** The leak does not subtract from the world quantity; it takes the `(1-delta)`-th power of it.
- **`(N_eff)^{eta}` — conversion is exponentiation.** Efficiency is the power to which the effective count is raised before being multiplied in, not a fraction of an amount added.
- **`e^{-C}` — cost is a divisor.** Dissipation divides the world quantity rather than subtracting from it.

The fixed point follows by setting `G_{t+1} = G_t`, giving `G^delta = (N_eff)^{eta} e^{-C}` and

```
G_inf = ( (N_eff)^{eta} . e^{-C} )^{1/delta}
```

which at the parameters above evaluates to **295.6376**, identical to `e^{Q_inf}` with `Q_inf = (eta S - C)/delta = 5.689135`; the two agree to fourteen significant figures (the residual is `2.3e-13` on a value of `295.6376`, a relative agreement of `7.7e-16`). The equivalent statement that the fixed point is positive if and only if the drive exceeds the cost — `Q_inf > 0` iff `eta F(u*) > c*` — is derived in Curzi [2026], and the invariance of the summed drive `b_i = eta_i F - c_i` under any transfer of cost among participants is Curzi [2026].

This is not a new theorem. It is the corpus's own steady-state result — the fixed point `Q* = (eta S - C)/delta`, which is the DC gain `1/delta` of a first-order discrete section applied to the net drive [Curzi, 2026a] — written in different coordinates, and it makes no new claim. What it demonstrates is that the framework has been working in the register throughout: the storage law looks like a linear accumulator because it is written in log coordinates, and the thing it accumulates is a count, which combines by multiplication. **The fourteen-figure agreement is a numerical identity check on a change of variables, not evidence for anything** (Section 14.7).

20.6 6 The surplus functional is a Fechner law

20.6.1 6.1 The identity

The corpus's surplus functional is `f(u) = ln(1 + (N-1)u)` [Curzi, 2026]. Set `u_0 = 1/(N-1)` and rewrite:

```
f(u) = ln(1 + (N-1)u)
     = ln( (N-1) . ( u + 1/(N-1) ) )
     = ln( (u + u_0) / u_0 )                    with u_0 = 1/(N-1)
```

Compare Fechner's law in the near-threshold form in which the reference is added rather than divided out, `S = k ln((I + I_0)/I_0)`, which is the standard correction applied as the stimulus approaches absolute threshold. **They are the same function. The surplus law is Fechner's law with non-parallelism `u` as the stimulus, `k = 1`, and an absolute threshold `u_0 = 1/(N-1)`.**

N	u_0 = 1/(N-1)	u	ln(1+(N-1)u)	ln((u+u_0)/u_0)	difference
2	1.00000000	0.50	0.405465108108	0.405465108108	0.00e+00
3	0.50000000	0.20	0.336472236621	0.336472236621	0.00e+00
5	0.25000000	1.00	1.609437912434	1.609437912434	0.00e+00
12	0.09090909	0.05	0.438254930931	0.438254930931	-1.11e-16

N	u_0 = 1/(N−1)	u	ln(1+(N−1)u)	ln((u+u_0)/u_0)	difference
50	0.02040816	0.50	3.238678452164	3.238678452164	-4.44e-16
1 000	0.00100100	1.00	6.907755278982	6.907755278982	0.00e+00

The residuals are floating-point noise; **the identity is exact.** The same identity is verified independently over `N = 2` to `100` at seven values of `u` to a maximum deviation of `8.9e−16`, with the further consequences that `N_eff(u_0) = 2` and `F(u_0) = ln 2` for every `N` [Curzi, 2026]. Both consequences are one line of arithmetic: `N_eff(u_0) = 1 + (N−1)/(N−1) = 2` and `F(u_0) = ln 2 = 0.693147`, for every `N` whatever.

What the identity licenses, stated exactly. The surplus law was derived from four axioms about interaction geometry with no reference to perception [Curzi, 2026]; Fechner's law was derived in 1860 from experiments on lifted weights [Fechner, 1860]. They are the same function. **That does not show that surplus is perceived, or that perception is surplus.** It shows that a system built to count difference with diminishing returns and a threshold takes one particular form, and that an axiomatic route and a psychophysical route arrive at it. The convergence is structural and real. **It is not evidence that either route is correct, and no more is claimed from it.** The corpus's own reference apparatus files the same restatement in its established-mathematics drawer while assigning the application to the postulate drawer [Curzi, 2026], and the four-drawer classification records the surplus form as proved *conditionally* on a chosen design axiom [Curzi, 2026].

20.6.2 6.2 The threshold, and why infinitely fine discrimination is a pathology

`u_0 = 1/(N−1)` is an absolute threshold of difference: the amount of non-parallelism below which a difference does not register as difference. It shrinks as `N` grows.

N	u_0	f(0.01)	ln N	f(0.01)/ln N
2	1.000e+00	0.009950	0.693147	0.0144
10	1.111e-01	0.086178	2.302585	0.0374
100	1.010e-02	0.688135	4.605170	0.1494
10 000	1.000e-04	4.615022	9.210340	0.5011
1 000 000	1.000e-06	9.210439	13.815511	0.6667

An observer with a larger repertoire has a lower threshold of detectable difference, and the same small non-parallelism `u = 0.01` that is nearly invisible at `N = 2` delivers half the available surplus at `N = 10 000`. That is a precise statement of what a larger repertoire buys, and it is requisite variety [Ashby, 1956] arriving from a threshold constant rather than from a ceiling.

It also explains why `N -> infinity` is not desirable. As `u_0 -> 0` any non-zero difference produces unbounded surplus while `f(0)` remains exactly zero, so the function approaches a step. **An observer with infinitely fine discrimination is not maximally perceptive but maximally unstable, because every difference becomes total.** The finite threshold is what keeps the register from having an infinite basement, and finite `N` is what supplies it. The point has an independent precedent: the number of categories reliably identified without a comparison stimulus is small and does not track discrimination acuity [Miller, 1956], and Section 9.2 records that the just-noticeable-difference count therefore overstates usable categories and must be reported as an upper bound.

20.6.3 6.3 Concavity is the register, not pessimism

`f` is strictly concave in `u`, unconditionally [Curzi, 2026]. That is usually read as bad news — diminishing returns, the fortieth member worth less than the second, effort meeting a wall. **The reading is a coordinate error.** Section 6.1 showed that `f` is a logarithm of `(u + u_0)`, and a logarithm is what a straight line looks like when plotted in the world's coordinates instead of the register's. Concavity is the shape of the register, not the shape of the returns.

The marginal surplus is `f'(u) = (N−1)/(1 + (N−1)u)`. At `N = 12`:

u	f(u)	f'(u)
0.00	0.000000	**11.000000**
0.05	0.438255	7.096774
0.10	0.741937	5.238095
0.20	1.163151	3.437500
0.40	1.686399	2.037037
0.60	2.028148	1.447368
0.80	2.282382	1.122449
1.00	2.484907	**0.916667**

`f'(0) = N − 1 = 11` is the function's sharp Lipschitz constant, the quantity that feeds the contraction condition `d(T(x),T(y)) <= k d(x,y)` with `0 <= k < 1` giving existence, uniqueness and geometric convergence from any start [Curzi, 2026]. `f'(1) = 11/12`. **The ratio of first to last marginal value is exactly `N`:**

```
f'(0)/f'(1) = (N−1) / ((N−1)/N) = N = 12        verified
```

Now change coordinates and ask what the world must do to deliver **equal perceived steps** of surplus, half a nat at a time, at `N = 12`:

target `F` (nats)	required `u`	`(u + u_0)`	ratio to previous
0.0000	0.000000	0.090909	—
0.5000	0.058975	0.149884	**1.648721**
1.0000	0.156207	0.247117	**1.648721**
1.5000	0.316517	0.407426	**1.648721**
2.0000	0.580823	0.671732	**1.648721**
2.5000	1.016590 — **impossible**, `u > 1`; the ceiling is `ln 12 = 2.484907`		

Every equal step of 0.5 nats multiplies `(u + u_0)` by exactly `e^{0.5} = 1.648721`. The diminishing returns are a perfectly constant ratio requirement seen from the wrong side.

> **Concavity is not a statement that effort stops paying. It is a statement that equal experience costs equal ratios, and equal ratios compound.** The fortieth member is not worth less because members get worse; the fortieth member is worth less because by then the request is for a sixty-five per cent increase in a quantity already near its ceiling.

And the last row matters more than the pattern: **the fifth equal step is impossible, not expensive.** `u` would have to exceed 1 and cannot. `f(1) = ln N = 2.484907` is a hard bound [Curzi, 2026]. The register compresses right up to a wall, and past the wall there are not diminishing returns but no returns.

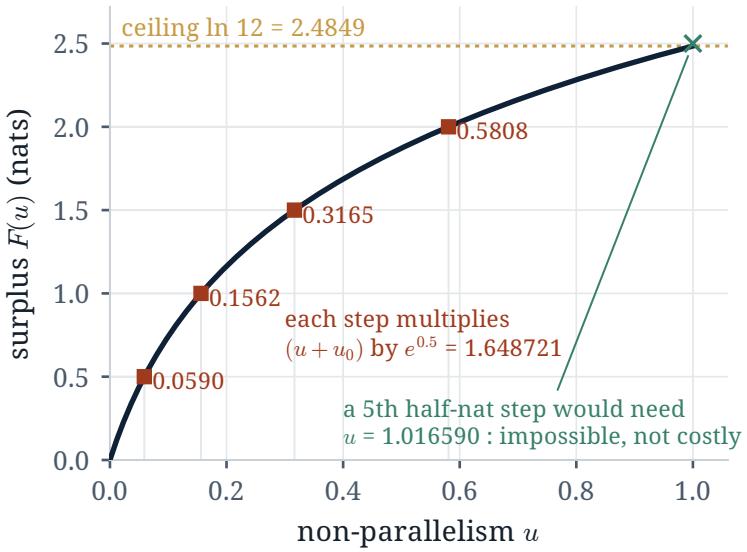

Figure 20.2: **Equal steps of experience are equal ratios of `(u + u_0)`, and the fourth step is the last one possible.** At `N = 12` the threshold is `u_0 = 1/11 = 0.090909` and each half-nat of surplus multiplies `(u + u_0)` by exactly `e^{0.5} = 1.648721`; the marginal value falls from `f'(0) = 11` to `f'(1) = 0.916667`, a ratio of exactly `N = 12`, and the fifth half-nat step would require `u = 1.016590`, which is impossible rather than expensive against the ceiling `ln 12 = 2.484907`. Derived from the surplus functional at the stated `N`; generated by `figs/src/CCP-020_fig02.py`.

20.6.4 6.4 Jensen's inequality on a concave register: the mean of percepts is not the percept of the mean

Because `f` is strictly concave, Jensen's inequality fixes a direction that this corpus's own reported figures depend on, and this paper is where the arithmetic belongs.

```
for a strictly concave f and a non-degenerate distribution of U:
    E[ f(U) ]  <  f( E[U] )
```

Averaging the percept is not the same as taking the percept of the average, and the first is always the smaller. The gap is a concavity penalty paid purely for variability in the underlying quantity, and it is not small at realistic dispersions.

The corpus's surveyed office [Curzi, 2026i] reports `N = 5` and a realised mean non-parallelism `U = 0.6019` with a realised surplus `F = 1.1498` nats. **Those two numbers are not consistent under `F = ln(1 + 4U)` and are not meant to be.** Taken as a percept of the mean,

```
f( 0.6019 ) = ln(1 + 4 x 0.6019) = ln(3.4076) = 1.226008 nats
```

whereas the reported `1.1498` nats is the **mean of `f` over the 278 operating weeks**. The two differ by `0.0762` nats, `6.2` per cent of the surplus, lost to the variability of the geometry alone and to nothing else.

> **Every occurrence of a realised surplus in this corpus must state which of the two it is.** A mean of percepts and a percept of a mean are different quantities on a concave register, they differ by a computable penalty, and reporting one under the other's name is the same error as reporting the arithmetic mean of a set of ratios (Section 4.2) with the sign reversed.

Two disclosures about the figures themselves. Curzi [2026i] prints `F(mean U) = 1.2262` and a gap of `0.0761` nats. From the printed `U = 0.6019` the value is `1.226008`, and the gap against the printed `1.1498` is `0.0762`; the printed `1.2262` corresponds to an unrounded mean `U` slightly above `0.6019`, and `1.2262 − 1.1498 = 0.0764`, so the three printed figures are not mutually consistent at the fourth decimal. The discrepancy is at the level of the rounding of `U` and does not affect the six-per-cent conclusion. It is recorded rather than corrected because the correction would require the unrounded series, which this paper does not have.

The same inequality, run the other way, is why an input delivered on several occasions can strictly dominate the same input delivered at once, and why an analyst who aggregates a variable geometry before applying `f` will read a concavity artefact as a discovery about time scale [Curzi, 2026i].

20.7 7 Design consequences, and what each one costs

Everything in this section depends on **Warrant 1** of Section 3.3 — the perceptual claim — and on a measured exponent. It is the part of the paper that Fechner and Stevens carry and that Peters and Gell-Mann [2016] cannot.

20.7.1 7.1 Budget in ratios

If equal experience is equal ratio, the unit of a design budget for a perceived quantity is a ratio and not a difference. Practically, allocate log units: a target of "the room should feel appreciably better" becomes a number — say 0.20 nats of perceived improvement — which can be divided across levers and checked by addition, because logs add. Section 12.1 does exactly this.

The constraint that makes it bite is economic. **Most world quantities cost money in proportion to the quantity and deliver experience in proportion to its logarithm; cost is linear, experience is logarithmic, so the cost of experience is exponential.** That is why the third refinement costs more than the first two together.

20.7.2 7.2 Never promise a linear improvement in a logarithmic quantity

Quantified. A designer promises "twenty per cent brighter" and delivers `+20%` illuminance:

```
delivered:  1.20 x illuminance
perceived:  1.20^0.33 = 1.06201   ->  +6.201%
the recipient receives 31.0% of what they heard
```

To deliver a perceived `+20%`:

Modality	a	world quantity required
Loudness (sound pressure)	0.67	x1.3127 (+31.27%)
Brightness	0.33	**x1.7376 (+73.76%)**
Visual length	1.00	x1.2000 (+20.00%)
Taste (salt)	1.30	x1.1506 (+15.06%)
Heaviness (lifted)	1.45	x1.1340 (+13.40%)
Warmth on arm	1.60	x1.1207 (+12.07%)
Electric shock	3.50	x1.0535 (+5.35%)

A promise of "twenty per cent brighter" is a promise to raise the lighting load by 73.76 per cent. The promise was made in per cent, the delivery is in per cent, the two per cents are

different quantities, and nobody in the conversation noticed. The correction is a rule rather than a calculation:

> **State the promise in the recipient's units and convert to the builder's before agreeing to it. A commitment expressed as a percentage of a world quantity is not a commitment about experience and must not be sold as one.**

The exponent is the uncertain part of every row above. These are cited point estimates with known between-study variation [Stevens, 1975, Teghtsoonian, 1971, Poulton, 1979]; they carry no interval here because none is available from the sources as reproduced, and Section 10 requires re-measurement under an application's own conditions before any of them calibrates anything.

20.7.3 7.3 Doubling the percept, by modality

`psi = k I^a` doubles when the world quantity is multiplied by `2^{1/a}`:

Modality	`a`	world multiple to **double** the percept	percept of a x2 world	percept of a +10% world
Loudness (1 kHz, sound pressure)	0.67	**2.8138**	x1.5911	+6.59%
Brightness	0.33	**8.1698**	x1.2570	+3.20%
Visual length	1.00	2.0000	x2.0000	+10.00%
Taste (salt)	1.30	1.7044	x2.4623	+13.19%
Heaviness (lifted)	1.45	1.6129	x2.7321	+14.82%
Warmth on arm	1.60	1.5422	x3.0314	+16.47%
Electric shock	3.50	**1.2190**	x11.3137	+39.60%

Two anchors. **Doubling apparent brightness takes 8.17 times the luminance. Doubling apparent loudness takes 2.81 times the sound pressure, which is 8.99 dB** — the familiar rule of about ten decibels per doubling of loudness, recovered from the exponent rather than asserted, and cross-checked against the independent loudness-matching convention in Section 9.4 [Stevens, 1956]. And the last row inverts everything: **doubling the sensation of an electric shock takes only twenty-two per cent more current.** In the expansive modalities a small world change is a large experience, which is why heat, weight and pain are dangerous to design near and why margins there are set in world units.

20.7.4 7.4 Geometric ladders

Anything intended to deliver equal steps of experience must be a geometric progression. A five-rung ladder from 40 000 to 100 000 with equal perceived steps has common ratio `(100000/40000)^{1/4} = 1.257433`, that is `+25.74%` per rung:

rung	value	`ln`
0	40 000.00	10.596635
1	50 297.34	10.825707
2	63 245.55	11.054780
3	79 527.07	11.283853
4	100 000.00	11.512925

Each `ln` step is `0.229073`, identical. The linear ladder over the same range, in equal steps of 15 000:

rung	value	ratio to previous	`ln` step
0	40 000.00	—	—
1	55 000.00	1.375000 (+37.50%)	0.318454
2	70 000.00	1.272727 (+27.27%)	0.241162
3	85 000.00	1.214286 (+21.43%)	0.194156
4	100 000.00	1.176471 (+17.65%)	0.162519

The linear ladder's perceived steps shrink monotonically: the last step is barely half the first. An equal-increment ladder is experienced as a decelerating one, and the person on the top rung feels the least rewarded.

Whether money is perceived logarithmically is a contested empirical question and this paper does not settle it. The arithmetic demonstrates what a geometric ladder does to *any* logarithmically perceived quantity; the construction applies without argument to quantities known to be logarithmic — light, sound, and the surplus law of Section 6 — and its application to compensation is an extension requiring separate measurement.

20.7.5 7.5 Reporting: geometric means, log axes, ratios

Three reporting rules, each a corollary of a table row.

1. **Central tendency of a perceived quantity is the geometric mean** (Section 4.2). The arithmetic mean is reported only where the quantity is genuinely additive in the world and nobody is experiencing it.
2. **Plot on a log axis.** A log axis is the register. A quantity plotted linearly and perceived logarithmically produces a chart whose visual impression contradicts the experience it describes.
3. **Report ratios, not differences.** "From 200 to 300 lux" is `+50%` and `0.405465` nats of world ratio; "an increase of 100 lux" has no perceptual content until the starting point is known.

20.7.6 7.6 The reference is cheaper than the quantity, and where the register does not apply

From Section 4.5: the percept is `k ln(I/I_0)` and `I_0` is set by adaptation and context [Helson, 1948]. **Moving the reference by a factor of two has exactly the same perceptual effect as moving the quantity by a factor of two, and is usually far cheaper.** A designer who only ever moves `I` is working with one of two available terms.

Six boundaries limit everything above.

- **Expansive modalities invert the advice.** At `a > 1` the world compresses rather than the percept and a small world increment is a large experience; every rule about needing large ratios reverses. **The exponent must be looked up. Compression is not the default.**
- **Small counts are not logarithmic.** Numerosity for very small sets is direct and near-linear.
- **Visual length is essentially linear** at `a` near 1.00. For spatial extent, differences behave like differences, and this section's corrections are unnecessary and would be wrong. This is precisely why bar charts work and area encodings do not.
- **The register describes magnitude judgement, not value, preference or decision.** Extending it is a separate empirical claim and is not made here.
- **Outside the working range the Weber fraction is not constant.** Near threshold and near saturation the law degrades in a documented way.

- **The constants are individual.** The form recovers across people; `c`, `k` and `a` vary. Where precision matters, measure the person.

20.7.7 7.7 The ethical boundary

A register argument can be used to give someone more experience for the same resources, or to give them the same experience for fewer resources while telling them it is more. The arithmetic is identical and the two uses are not. The operative test is disclosure and decline: a reference-shifting technique the recipient would object to on being told of it is not endorsed here, and its efficiency does not change that. The vestibule that makes a reading room feel bright is disclosed by walking through it; a brightness claim computed in world units and sold in perceptual ones is not.

Disclosure is a test, not an immunity. The corpus's own strongest available test case records that disclosure did **not** confer immunity, that a stated component count overstated diversification by a factor of 4.61, and that a levy presented as a costless accounting correction in fact reallocated burden [Curzi, 2026]. A designer relying on disclosure to license a reference-shifting technique should read that record first.

20.8 8 The postulate method

20.8.1 8.1 What is established in this section, and what is not

Nothing in this section is a theorem. Postulation is a discipline of practice rather than a mathematical object. What is offered is: a statement of the **Postulate Method**, badged as a house formalisation of standard hypothetico-deductive practice [Popper, 1959, Platt, 1964]; six **admissibility conditions** separating a legitimate postulate from an unfalsifiable one; one genuine derivation — Fechner's integration of Weber's law — as the exemplar, because it is the historical case in which the method worked on exactly this problem; two quantitative instruments, an **empirical-content measure** and a **held-out skill score**; and the **badge convention**. Everything asserted here is asserted about the practice of inquiry, not about minds. The claims about minds are in Section 9 and they arrive with data.

20.8.2 8.2 The method, stated

> **The Postulate Method [house formalisation].** Let `X` be a quantity that cannot be observed.
>
> **Step 1 — POSTULATE.** Assert a structure for `X`: what kind of thing it is, what operations it supports, how it relates to observable quantities. State the assertion in the open, badged, in the sentence in which it is first used.
>
> **Step 2 — DERIVE.** From the postulate plus already-accepted results, derive statements about observables. The derivation must be valid. **A derived statement counts only if the negation of the postulate would not also produce it.**
>
> **Step 3 — FORBID.** Extract the set of observations the postulate rules out, and write them down before looking. This is the postulate's content and the only part of it that can be tested.
>
> **Step 4 — TEST.** Observe. If a forbidden observation occurs, the postulate is dead as stated. If none occurs, the postulate has survived, which is not the same as being true.
>
> **Step 5 — DECLARE.** Publish the surviving postulate with its badge still on. Survival does not promote a postulate to a theorem, and nothing does.

Step 2's second sentence is where most work in the human sciences fails. **A derivation that both a postulate and its negation produce is not evidence for the postulate.** If "I am a morning person" predicts that some mornings go well and its negation predicts the same, then mornings going well is data about mornings.

The method is not original and no priority is claimed for it. It is the falsificationist requirement [Popper, 1959] sharpened by the demand that competing hypotheses be discriminated rather than merely tested [Platt, 1964], with the protective-belt problem named as Lakatos [1970] named it, and with Meehl [1967]'s observation in view that directional predictions are almost costless in the social sciences — which is why this framework's specifications require point predictions with constants.

20.8.3 8.3 The badge taxonomy

The badges are a closed, small, non-overlapping set, because from here on almost every claim is one of these things and the reader is entitled to know which. This is a **definition**, not a finding; the corpus's four-drawer evidential classification — PROVED, POSTULATED, BORROWED, UNTESTED — is the same instrument at corpus scope [Curzi, 2026].

Badge	Meaning	Test that applies	Can it be wrong?
PROVEN	A theorem: follows from stated axioms by valid deduction	Check the proof	Only if the proof is invalid
DESIGN AXIOM	Chosen, not derived; fixes a modelling convention	None; it is a decision	It can be *unwise*, not false
POSTULATE	An assertion about the world that generates forbidden observations	Steps 3 and 4	**Yes, and how is stated**
HEURISTIC	A rule of thumb that orders or triages; not an equation	Does it improve triage?	It can be useless
INTERPRETIVE CORRESPONDENCE	Two formalisms have the same shape; no theorem connects them	None available	Not the kind of thing that is true or false
METAPHOR	A figure of speech carried deliberately	None	No; it carries no claim

Four rules govern use. **(i)** The badge appears in the same sentence as the first statement of the thing — not in a footnote and not "as discussed earlier". **(ii)** A badge never upgrades through use: a postulate repeated for two hundred pages is still a postulate, and the commonest corruption in this literature is an assumption made once, then referenced, then referenced by the reference, until the fourth-generation citation reads as a finding. **(iii)** A postulate that cannot state what would kill it is not a postulate; it is at best a heuristic and must be demoted in print, visibly. **(iv)** Interpretive correspondences and metaphors carry no evidential weight whatever; they may be productive and they may not be cited as support.

The badge is not a hedge. It is a specification of what kind of test the reader is entitled to demand: PROVEN licenses a demand for a proof, POSTULATE for the forbiddance list, DESIGN AXIOM for a justification and a counter-proposal.

20.8.4 8.4 Six admissibility conditions

A postulate is admissible in this framework if and only if it satisfies all six. They are labelled CC-P1 to CC-P6 to keep them distinct from the verification postulates P1 to P7 of Section 14.2.

```
CC-P1  OPENNESS      Stated explicitly, in the open, badged, before it is used.
CC-P2  ASYMMETRY     Generates at least one observable statement that its own negation
                     does not generate.
CC-P3  REACHABILITY  The forbidden observations are reachable with instruments the reader
                     has, at a cost the reader can pay.
CC-P4  LETHALITY     A specific, named, pre-recorded result kills it, written before looking.
CC-P5  MINIMALITY    It does not smuggle. Every clause does work; a clause that forbids
                     nothing is deleted, not carried.
CC-P6  STABILITY     Its parameters recover across scopes and observers, or the postulate
                     states plainly that it is indexed to one observer and claims nothing
                     wider.
```

CC-P1 to CC-P4 are the standard falsificationist demands, sharpened [Popper, 1959]. CC-P5 and CC-P6 are the two that most work in the human sciences fails.

CC-P5 is a defence against the protective belt. Lakatos [1970] described how a research programme protects its core by accreting auxiliary hypotheses, each added to absorb a disconfirmation; each addition is locally reasonable and the aggregate is a postulate that forbids nothing. **A postulate should get smaller as it survives, not larger.**

CC-P6 is reproducibility demanded in advance. A postulate about one observer's inner structure that holds only for that observer is admissible — single-subject work is real work — **but it must say so and must not be quoted as a claim about people.** The formal version of this gate is specific objectivity: a comparison of two objects must not depend on which instrument was used, and the corpus's treatment shows what it takes to earn it — given a badged postulate, Rasch person measures make a difference of person measures genuinely ratio-scaled, with separation supplying the true zero that division requires [Curzi, 2026t, Rasch, 1960].

20.8.5 8.5 The exemplar: how Fechner did it

The reason to believe the method works on inner states is a case rather than an argument. In 1860 Fechner [1860] executed Steps 1 to 5 on the least tractable quantity available and the result is still in use.

He began with something measured: Weber [1834]'s finding that the smallest detectable change in a stimulus is a constant proportion of it. A weight of 100 g needs about the same fractional increment to feel heavier as a weight of 1000 g; the increment in grams is ten times larger and the ratio is the same. **That is a finding about behaviour — what people can and cannot discriminate — and nothing about inner magnitude is asserted by it.**

Fechner wanted the quantity on the other side of the wall and could not reach it, so he postulated a bridge:

> **Fechner's postulate [POSTULATE, 1860].** All just-noticeable differences are subjectively equal. The step in sensation produced by one just-noticeable difference is the same size wherever on the scale it is taken.

It is audacious because it asserts an equality between inner quantities nobody can inspect, and modest because it asserts exactly one thing and hands the consequences to arithmetic:

```
postulate:   dS = k' x (one JND)          all JNDs equal in sensation units
Weber:       one JND = c I                in stimulus units
therefore:   dS = k dI / I                k absorbs k' and c
integrate:   S = k ln I + const
```

```
set S = 0 at absolute threshold I_0:
            S = k ln( I / I_0 )          FECHNER'S LAW
```

The ladder arithmetic is checkable. With a Weber fraction `c = 0.05`, the stimulus after `n` just-noticeable steps is `I_n = I_0 (1+c)^n`, and inverting recovers the count exactly:

n	I_n	ln(I_n/I_0) / ln(1+c)
0	1.0000	0.0000
10	1.6289	10.0000
50	11.4674	50.0000
100	131.5013	100.0000
200	17 292.5808	200.0000
283	992 136.9785	283.0000

Sensation measured in just-noticeable-difference units is exactly the log of the stimulus ratio divided by `ln(1+c)`, and the constant is `k = 1/ln(1.05) = 20.495934` JND per nat. **This is where the unit of `k` is fixed and it is the answer to the dimensional question of Section 14.1.**

Now the step that makes this an exemplar rather than an anecdote. **Fechner's postulate is not tested by looking at it; it is tested by consequences that live entirely on the observable side of the wall.** The law forbids equal stimulus *differences* producing equal report differences across the range; it forbids a modality with a constant Weber fraction from showing a linear relation between stimulus and any well-constructed sensation scale; it forbids the count of just-noticeable differences between two stimuli from depending on the path taken between them; and it predicts, quantitatively, the number of discriminable steps across a modality's dynamic range. Every one of those is testable with nineteenth-century equipment.

Some of them turned out to be wrong, which is the point. Section 9.5 documents how Stevens [1957] killed Fechner's law as a general account and replaced it with a power law, using a method Fechner had not considered. **The postulate died the death a legitimate postulate is supposed to die: by its own consequences, at the hands of a better instrument.** A working postulate is not one that survives forever; it is one that fails informatively.

20.8.6 8.6 Empirical content: measuring what a postulate forbids

Popper [1959]'s central point was that the content of a theory grows with the class of what it forbids, and that a theory compatible with everything says nothing. That can be given a number.

> **The content measure [HEURISTIC — this framework's own construction].** Let a postulate admit a fraction `q` of the outcomes enumerated as possible before it was adopted, `0 < q <= 1`. Define
>
> ```
> H_forbid = −ln q      nats
> ```
>
> `q = 1`, forbidding nothing, gives zero content. Halving the admitted outcomes adds `ln 2` nats.

The formula is this framework's own and no external source states it. Popper [1959], Lakatos [1970], Platt [1964] and Meehl [1967] support the underlying idea that content is what a theory forbids and that bold conjectures are worth more per test; **none of them states this formula**, and it is badged POSTULATED in the verification chain of Section 14.3.

q (fraction of outcomes still admitted)	nats	bits
1.000	0.0000	0.0000
0.900	0.1054	0.1520
0.500	0.6931	1.0000
0.250	1.3863	2.0000
0.100	2.3026	3.3219
0.050	2.9957	4.3219
0.010	4.6052	6.6439
0.001	6.9078	9.9658

The table is used comparatively, never absolutely. Two postulates about the same question, over the same enumerated outcome set, can be ranked by content, **and the higher-content postulate is the one to test first.** A postulate at `q = 0.9` costs a full experiment and, if it survives, has bought `0.1054` nats; a postulate at `q = 0.05` costs the same experiment and buys `2.9957` nats, twenty-eight times the return for the same expenditure. That ratio is the practical argument for preferring bold postulates, and it is arithmetic rather than temperament.

Four limits are stated with the instrument. **(i)** `q` is a fraction *of something*, so the outcome set must be enumerated and fixed in advance; chosen after the fact, the number is meaningless. **(ii)** `q` presupposes a defensible measure over outcomes, which is almost never available — hence HEURISTIC and not equation. **(iii)** Two analysts enumerating outcomes differently assign different `q` to the same postulate, so the measure is identifiable only relative to a published outcome list: publish the list or do not publish the number. **(iv)** Content adds under independent conjunction, `−ln(q_1 q_2) = H_1 + H_2`, which is the property that makes a log measure the right shape and the reason to prefer it over `1 − q`. **Whether the heuristic helps is itself an untested empirical question** (H5), and the test is stated in Section 15.

20.8.7 8.7 Introspective report is data, not verdict

The sharpest form of the objection to any of this is not that inner states are unobservable but that the reports substituted for them are unreliable. Nisbett and Wilson [1977] made the case directly: people confidently report the causes of their own judgements and those reports are frequently constructions assembled after the fact rather than readouts of process. The framework accepts the result. **It changes what a report is for.**

```
WRONG USE   The subject reports "the second one was twice as loud", and the analyst records
            that the second one was twice as loud in their experience. This treats the report
            as a verdict about an inner quantity.

RIGHT USE   The subject emits the number 2 under a specified procedure. The analyst records
            the number as behaviour, then asks whether numbers emitted under that procedure
            have the structure the postulate predicts: consistency under repetition,
            transitivity, agreement across observers, the right functional form against a
            physical variable, and invariance when the procedure's irrelevant details change.
```

The right use never requires the report to be accurate about anything. It requires the *pattern* of reports to have properties that would be unlikely if the postulated structure were absent — which is how a thermometer is validated, nobody having asked whether mercury knows the temperature. Nisbett and Wilson [1977]'s finding constrains *causal* reports about one's own processing specifically; it constrains magnitude reports far less, and Section 9 shows how well those pass the structural tests. **Two further constraints on any self-report instrument are real and are not answered here:** question wording, scale range and order effects [Schwarz, 1999], and the focusing illusion that contaminates any rating of a named component of well-being [Kahneman et al., 2006].

20.8.8 8.8 The freeze, and the held-out skill score

The move that separates a test from a story is the **freeze**, and it is more necessary at single-observer scope than at institutional scope, because the person fitting the model and the person being measured are the same and there is no reviewer.

```
1. Split the record in two by TIME, never at random. Early half = training.
2. Fit the parameters on the training half only.
3. WRITE THE PARAMETERS DOWN. They are frozen. No refitting.
4. Predict the held-out half with the frozen parameters.
5. Compare against four baselines. Report all five numbers, including the embarrassing ones.
```

The four required baselines are **persistence** (tomorrow equals today), **direct input** (output is a rescaling of input, no storage), a **matched autoregression** (the same free-parameter count, no theory in it), and the **shuffled-input control** (the same frozen model with the input series randomly permuted). The fourth is usually omitted and is the decisive one: **if the model predicts the held-out data just as well with its inputs shuffled, it is not using the inputs.** The full protocol, its preregistration form and its confirmatory application are Curzi [2026i], whose own application **failed** its second falsification rule at a 2.8 per cent held-out advantage over a matched AR(1) against a declared 10 per cent margin. This is preregistration used as designed [Nosek et al., 2018], against the researcher degrees of freedom that make anything presentable as significant [Simmons et al., 2011] and the forking paths that catch an honest author [Gelman and Loken, 2013].

The comparison statistic is the ordinary forecasting skill score:

```
SS = 1 − RMSE_model / RMSE_baseline
```

`SS = 0` means the model matched the baseline, `SS > 0` that it beat it, `SS < 0` that the baseline beat it, unbounded below, which correctly expresses that a model can be arbitrarily worse than doing nothing. One `SS` is reported per baseline and **the headline number is the smallest of them.** An `SS` approaching 1 is treated as **a red flag for leakage rather than as success**, and a baseline whose own error is zero leaves nothing to explain and makes the statistic undefined. Three limits attach. RMSE requires at least an interval scale on the outcome, so an ordinal one-to-five rating does not license it and the honest substitutes are rank-based — the same demotion rule the corpus applies to its own moment equation, which contains a division and a multiplication and is therefore demoted to a heuristic ordering when its inputs are ordinal [Curzi, 2026m]. Identifiability fails the instant any refitting occurs after the split, and the only defence is the written frozen parameter list. And against the shuffled control `SS = 0` reads in the opposite direction from every other row: it means the model was never using its inputs.

20.8.9 8.9 Postulates behave like stored order

A postulate is a load-bearing member in this framework, and postulates behave like the stored order the framework already models: they decay without maintenance, they convert experience into structure at some rate, they cost something to maintain, and they occupy headroom, since a mind full of unexamined postulates has no capacity for a new one. The amendment ledger of Section 11.2 is a decay-reduction device and the freeze is a conversion-raising one.

This is an identical model form at a different scope, and identical structure at three scopes is a statement about the chosen model, not a claim of kinship or of cross-scope aggregation [Curzi, 2026]. It is badged accordingly, and Section 3.7 records that where the scope includes a group whose members constitute the aggregate, the specification is not identified from observational data [Manski, 1993].

20.9 9 The register perception uses: three laws, and their limits

Section 8's method is only as good as its best case, and this is the best case. The claim to be established is narrow and consequential:

> **Subjective magnitude has been measured — not ranked, not rated, not scored, but measured on a scale that supports ratios, from reports given by ordinary participants under a procedure taking about twenty minutes, and the measurements replicate.**

If that claim is false, the framework's treatment of inner quantities is metaphor. If it is true, the question about the inside is not *whether* it can be measured but how well, at what cost, and with what error bars — which is an engineering question. **The claim is defensible and it is not proved**; Section 9.9 gives the limits, which are severe, and Section 15 records that the measurement-theoretic conditions that would settle it were never tested.

20.9.1 9.1 Three laws, one register

```
WEBER    1834    dI / I = c              the JND is a constant RATIO
FECHNER  1860    S = k ln(I / I_0)       sensation is LOGARITHMIC in intensity
STEVENS  1957    psi = k I^a             sensation is a POWER FUNCTION of intensity
and, taking logarithms of the third:
                 log psi = log k + a log I        LINEAR in log–log
```

Three statements, and the third did not abolish the register but relocated it. Weber's law is about ratios; Fechner's law is a logarithm outright; Stevens' law is a straight line *in log-log coordinates*, which is to say that equal ratios of stimulus produce equal ratios of sensation. **All three say that perception operates on ratios and not on differences. They disagree about what the ratio does when it arrives.** That is the register claim on which the Lens Theorem's antecedent rests, and it survives the Fechner-to-Stevens transition intact: the transition replaced *log in, linear out* with *log in, log out*.

Two properties make Weber's law a strong result rather than an observation. It concerns discrimination performance, which is behaviour, settled by a forced choice and a tally with no inner quantity invoked. And it holds across modality after modality over the middle of each range and fails at both ends in a characteristic and reproducible way — near absolute threshold `c` rises, near saturation it rises again. A law that fails at the edges in the same way everywhere has a mechanism behind it.

Three cautions attach to Weber's law and are stated once. `I` must be ratio-scaled with a true zero, so the law is **not statable** for a stimulus dimension lacking one — for pitch, for hue, for position, the analogous statement must be constructed differently. As `I -> 0` the law predicts infinitely fine discrimination, which is false and known to be false; absolute threshold intervenes and the standard repair is `dI/(I + I_r) = c` with `I_r` a small resting term. And a just-noticeable difference is conventionally the 75 per-cent-correct point in a two-alternative task, so **the convention must be stated with the number**, since a `c` defined at 75 per cent and one defined at 84 per cent are different numbers for the same observer.

20.9.2 9.2 The discriminable-step count, and why it is an upper bound

If sensation is counted in just-noticeable differences, a modality's dynamic range contains a finite, computable number of discriminable steps:

> **The discriminable-step count [derived from Weber].** For a modality with Weber fraction `c` over a dynamic range `R = I_max / I_min`, `N_jnd = ln R / ln(1 + c)`.

c	R = 10	R = 100	R = 10^4	R = 10^6	ln N_jnd at R = 10^6
0.01	231.4	462.8	925.6	1388.4	7.2359
0.02	116.3	232.6	465.1	697.7	6.5477
0.05	47.2	94.4	188.8	283.2	5.6460
0.10	24.2	48.3	96.6	145.0	4.9764
0.20	12.6	25.3	50.5	75.8	4.3278
0.33	8.1	16.1	32.3	48.4	3.8804

The last column connects the psychophysics to the framework. `N_jnd` is a count of distinguishable categories along one perceptual dimension, so `ln N_jnd` is the surplus ceiling for that dimension [Curzi, 2026]. A modality with a Weber fraction of 0.05 and six decades of range affords at most 5.646 nats; a modality with `c = 0.33` affords 3.880. **The maximum surplus available along a perceptual dimension is fixed by that dimension's discrimination acuity and its dynamic range, both measurable with a forced-choice task.** That is requisite variety [Ashby, 1956] arriving with a number.

The formula overstates usable categories and must be reported as an upper bound. Absolute-identification experiments — counting the categories reliably distinguished without a comparison stimulus present — recover far fewer than the just-noticeable-difference count predicts, because identification without a comparison is much harder than discrimination with one [Miller, 1956]. The gate is real and frequently failed, and Section 11.3's failure mode FM26 is named for it.

A moment is not built from one dimension. If an observer attends to `m` perceptual dimensions whose discriminations are independent, the joint category count multiplies and the ceiling adds, `ln N_total = sum_i ln N_jnd(i)` — **and the independence condition does all the work.** Independence across perceptual channels is the `u = 1` condition transposed to one observer's own channels and is not generally satisfied: loudness and brightness in a room co-vary with how many people are in it. The honest form is the framework's own, `N_eff = 1 + (m−1)u` with `u` the mean non-parallelism between channels, and **at this scope it is a postulate about model form rather than a derived result** [Curzi, 2026]. Two perceptual channels that always move together are one channel.

20.9.3 9.3 What an exponent costs

The design question is how much more of the physical thing must be supplied for a recipient to notice a doubling.

modality	a	log-ratio required (nats)	in decades
Electric shock	3.50	0.1980	0.0860
Warmth on arm	1.60	0.4332	0.1881
Heaviness (lifted)	1.45	0.4780	0.2076
Taste (salt)	1.30	0.5332	0.2316
Visual length	1.00	0.6931	0.3010
Loudness (1 kHz, SPL)	0.67	1.0345	0.4493
Brightness	0.33	2.1004	0.9122

computed as `ln 2 / a` nats, a perceived doubling costing `ln 2 = 0.693147` nats of response log-magnitude which the exponent converts into stimulus log-units. **To double perceived brightness requires 0.912 decades — a factor of 8.17 — of luminance; to double perceived shock requires 0.086 decades, a factor of 1.22.** Measured in the log units where the comparison is proper, 2.1004 nats against 0.1980, a ratio of 10.6. A budget that treats "make it brighter"

and “make it hurt less” as comparable engineering requests will be wrong by most of an order of magnitude.

Compressive modalities are the ones that must handle enormous physical ranges — sound pressure across the audible range spans six orders of magnitude, luminance across a day more than ten — and a compressive exponent packs that range into a manageable perceptual span at the cost of resolution. **Expansive modalities are the ones that must trigger action:** warmth at `a = 1.6` triples in felt magnitude when the stimulus doubles, and shock at `a = 3.5` multiplies by 11.31 when the stimulus doubles and by 3162 when it goes up a factor of ten. **A system that must produce withdrawal before damage cannot afford compression, and the numbers show it has none.** The functional reading is an interpretation; the numbers are the data.

20.9.4 9.4 The loudness cross-check, and the factor-of-two trap

The loudness exponent is quoted as 0.67 and is the row most often misused, because 0.67 is an exponent on **sound pressure** and intensity goes as pressure squared:

```
pressure ratio for perceived doubling       = 2.8138
intensity ratio  = 2.8138^2                 = 7.9177
in decibels      = 10 log10(7.9177)         = 8.986 dB
implied intensity-domain exponent = 0.67/2  = 0.335
```

Compare the independent convention from acoustics. The sone scale defines a doubling of loudness and the standard rule of thumb is that a 10 dB increase doubles perceived loudness [Stevens, 1956]; that rule implies an intensity-domain exponent of `ln 2 / ln 10 = 0.3010` and hence a pressure-domain exponent of `0.6021`.

```
from Stevens' 0.67 (pressure)   ->  perceived doubling at  8.99 dB
from the sone convention        ->  perceived doubling at 10.00 dB
discrepancy                                                1.01 dB
```

Two methods developed for different purposes — one from magnitude estimation, one from loudness-matching standards — agree on the location of a perceived doubling to within about one decibel. That is the kind of convergence that makes a measurement claim credible, and it is offered here precisely because it is not exact: the one-decibel gap is the method dependence of Section 9.9 appearing in the third significant figure, exactly where the honesty clauses say to expect it.

20.9.5 9.5 Why the dispute lasted a century, and the two-decade problem

A logarithm and a compressive power function look alike over a limited range, and the resemblance is computable. Fitting a logarithmic law by least squares to a power function with `a = 0.33` over 200 log-spaced points:

```
over I in [1, 100]   (two decades)
    best fit:  S = 0.6306 + 0.7475 ln I
    R^2      = 0.963165
    maximum relative deviation = 36.94 %

over I in [1, 10000] (four decades)
    R^2      = 0.872523
    maximum relative deviation = 314.06 %
```

Over two decades a logarithm captures 96.3 per cent of the variance of a power function. With nineteenth-century instrumentation, observer variability of ten to twenty per cent, and

stimulus ranges rarely exceeding two decades, the two were not distinguishable. Over four decades the maximum relative deviation goes from 37 per cent to 314 per cent.

Stevens did not win by argument; he won by extending the range and by asking a question whose answer discriminated the hypotheses — which is Platt [1964]'s prescription exactly, and the general rule is worth extracting: *when two models fit equally well, the remedy is not more data in the same range but data in a range where they disagree.* The second and decisive blow was qualitative. **A logarithmic law cannot produce an expansive relation at all**, because `ln` is concave everywhere, so no logarithmic sensation scale can grow faster than its stimulus. Heaviness at 1.45, warmth at 1.6 and shock at 3.5 are not near-misses for Fechner's law; they lie outside its range of possible outputs. One expansive modality measured reliably kills the law as a general account, and several were [Stevens, 1975]. Krueger [1989] is the standing attempt at reconciliation, with peer commentary, and the framework cites it rather than adjudicating the dispute on its own authority.

This section is also the standing warning against this paper's own headline fit. An `R^2` of 0.999932 over two decades (Section 12.3) does not by itself exclude a logarithmic law, for the reason computed above, and Section 12.3 therefore rests its conclusion on the residual pattern, the ratio-invariance test and an explicit model comparison rather than on the fit statistic.

20.9.6 9.6 Running a magnitude estimation

The procedure, in the form that survives the criticisms of Section 9.9 best. It is the instrument this framework borrows, so it is specified rather than described.

```
1. FIX THE CONTINUUM. One dimension, varied alone, everything else held constant.
2. CHOOSE THE STIMULUS SET. At least 7 levels, GEOMETRICALLY spaced, spanning at least
   1.5 decades. Linear spacing wastes most of the points at the top.
3. RANDOMISE ORDER, fresh per observer. Sequential dependencies are real.
4. INSTRUCT IN RATIOS, not in categories:
     "Assign any positive number to the first stimulus. For each one after, assign a
      number in PROPORTION to how strong it seems. If one seems half as strong, use half
      the number. Do not restrict yourself to whole numbers or to any range."
   The ratio instruction and the removal of range restriction are both load-bearing. An
   instruction mentioning a scale from 1 to 10 destroys the ratio property and yields
   ordinal data.
5. FREE MODULUS, or a modulus in the MIDDLE of the range. A modulus at an extreme biases
   the exponent.
6. REPLICATE each level at least twice per observer, separated in the sequence.
7. AGGREGATE BY GEOMETRIC MEAN, never the arithmetic mean.
8. FIT IN LOG-LOG. Report slope, intercept, R^2, the residual pattern, the stimulus range,
   the modulus policy, and the exact instruction text.
9. TEST THE RATIO PROPERTY DIRECTLY: pick stimulus pairs with equal physical ratios at
   different absolute levels; the response ratios must match.
```

Step 9 deserves the emphasis. The ratio-scale claim is not established by the fit; it is established by the invariance. A power function fitted to numerals would still fit. What a merely ordinal response would not do is produce the *same* response ratio for the same stimulus ratio at different absolute levels. **That test is cheap and it is skipped almost universally**, and Section 12.3 runs it and reports what it does and does not establish.

The scale-type stakes are exactly the ones the measurement literature sets. A one-to-seven rating item is not magnitude estimation and yields ordinal data [Likert, 1932, Stevens, 1946]; an interval scale can be built from paired comparisons without asking anyone to use numbers [Thurstone, 1927]; and what must be true before a quantity can be said to exist at all is Krantz et al. [1971].

20.9.7 9.7 Cross-modality matching

The strongest internal-consistency argument removes numbers altogether. Instead of asking an observer to say a number, ask them to **adjust one modality to match another** — squeeze a handgrip until the force feels as strong as the tone sounds loud. If modality 1 has exponent `a_1` and modality 2 has `a_2` against their respective physical continua, matching 1 to 2 should produce a relation whose log-log slope is `a_1/a_2`:

match	to	predicted matching exponent `a_1/a_2`
heaviness	loudness	2.1642
warmth	brightness	4.8485
shock	length	3.5000
salt	loudness	1.9403

These are risky predictions in the sense of Section 8.2: derived from measurements made with one procedure and tested with a completely different one involving no numbers at all. Nothing in the matching task lets an observer consult the exponents. Stevens [1975] reports that matching exponents came out close to the predicted ratios across many modality pairs, and this is the strongest available evidence that magnitude estimation measures something rather than recording a habit of number use.

It is evidence of consistency rather than of correctness. A systematic bias present in both tasks would produce the same agreement, and the measurement-theoretic literature has pressed exactly this point [Luce, 2002, Narens, 1996]. The correct summary is that the numbers cohere across procedures sharing no method, which is much more than a rating scale can claim and less than a physical measurement can claim.

20.9.8 9.8 The exponent as a conversion key

```
perceptual log-magnitude:   ln psi = ln k + a ln I
therefore:                  d(ln psi) = a d(ln I)
ONE NAT of stimulus log-ratio  ->  a NATS of perceptual log-ratio.
```

The exponent is a linear map between two logarithmic registers, which is what a conversion key is. Worked: a tenfold increase in luminance is `ln 10 = 2.302585` nats of stimulus log-ratio; at `a = 0.33` that is `0.759853` nats of perceptual log-ratio, which is `0.759853 / ln 2 = 1.096` bits. A tenfold increase in shock intensity is the same 2.302585 nats of stimulus and `8.059` nats of perceptual log-ratio, which is `11.63` bits. **The same physical decade lands as 1.1 bits in one register and 11.6 bits in another.** The conversion is exact given the exponent; the exponent is the uncertain part.

Two conversions differ by a factor of two, and which one is meant has to be stated every time. The corpus's tabulated keys give `2.885390` for nats to octaves and `3462.4681` for nats to cents, alongside `1.442695` for nats to bits, and the first two are exactly twice what a reader arriving from acoustics would compute. **The factor of two is derived rather than mistaken, and this paper adopts the corpus's reading while insisting on the label that makes it unambiguous.**

The two quantities are these.

- **A doubling of the quantity itself.** One octave is one doubling, so it is `ln 2 = 0.693147` nats and the key is `1/ln 2 = 1.442695` — numerically identical to the nats-to-bits key, because an octave and a bit are both one doubling — with `1200/ln 2 = 1731.234` cents per nat. This is the conversion used in Section 4.1 and everywhere in this paper that an octave means a doubling of a stimulus, a stock or a percept.
- **An octave of *essence pitch* per nat of *surplus*.** The corpus's essence law is square in its index, `f(n) = k n^2`, so the cross-disciplinary frequency is `f = k N_eff^2 = k e^{2F}` and

`log_2(f/k) = 2F / ln 2`. **Doubling the effective count therefore multiplies the frequency by four, which is two octaves and not one** [Curzi, 2026l]. The key is `2/ln 2 = 2.885390` essence octaves per nat and `2400/ln 2 = 3462.468098` cents per nat, and both are *exact given the square-law postulate* [Curzi, 2026k].

The two figures are internally consistent with each other (`3462.4681 / 2.885390 = 1200` exactly) because they are the same conversion expressed in two units, and the corpus derives the doubling explicitly rather than acquiring it by accident [Curzi, 2026l,?]. **What is a real defect is the label**: the tabulated key reads "nats to octaves" without the word *essence*, and read generically it is off by a factor of two. That is the exact shape of the failure mode named in Section 11.3 as FM22, the pressure-versus-intensity confusion, and the repair is a word rather than a number. **This paper writes "essence octaves" wherever the square-law conversion is meant and "octaves" only for a plain doubling**, and the exponent `s` in `f(n) = k n^s` is a postulate rather than a measurement, so the constant is exact given `s = 2` and not independently of it [Curzi, 2026l].

20.9.9 9.9 The honest limits, in detail

This section is part of the result, not a hedge appended to it. A reader who takes the exponent table without it will overreach within a page.

- **The exponent depends on stimulus range.** Compressing the range of presented stimuli tends to raise a compressive exponent and lower an expansive one, because observers spread their numbers over roughly the same span regardless of the physical range supplied. Teghtsoonian [1971] argued that this is systematic — that the subjective range an observer uses is approximately constant across modalities, which would make the exponent partly a consequence of dynamic range rather than a property of the sense. **If that is right, the exponent is a joint property of the sense and the experiment, and reporting it without the range is reporting half a number.**
- **The exponent depends on the modulus and the anchor.** A modulus at one end of the range pulls the fitted exponent toward the anchor; free-modulus and mid-range designs reduce but do not eliminate this.
- **The regression effect.** Observers under-use the extremes of whatever they are asked to adjust, so magnitude estimation and magnitude production yield systematically different exponents that bracket the true value. The standard repair is to run both and take the geometric mean; a single-direction study must say which direction it ran.
- **Sequential dependencies.** A response is influenced by the preceding stimulus and the preceding response, which is why order is randomised and replicates are separated.
- **Number-use habits.** Observers prefer round numbers, powers of ten and small integers. Poulton [1968] catalogued the biases in magnitude estimation at length and Poulton [1979] is the mature statement; the catalogue has not been refuted, it has been managed by better designs.
- **Individual differences are large and real.** Exponents vary across observers by a substantial fraction of their value, and the individual exponents are themselves reasonably stable on retest, so the population figure is a central tendency of a genuine distribution rather than an estimate of a single constant [Stevens, 1975].

  Report an exponent as `a = value (method, range, modulus, instruction, n)`. An exponent quoted bare is a number without a referent. The values in Section 3.4 are reproduced as **nominal** published figures for orientation and comparison and are **not** calibration constants for any application without re-measurement under that application's own conditions.

None of this touches the existence proof, which rests on the structure of the results — log-log linearity, within-observer stability, cross-modality coherence, and the cross-method convergence with the decibel convention — rather than on any single exponent. What the

limits establish is that the measurement has an error budget, larger than physics is used to and smaller than the human sciences usually admit.

Four things the existence proof does not license, stated with the same emphasis as the proof. **(i)** It does not license the conclusion that all subjective quantities can be measured this way: loudness has a physical correlate that can be varied precisely and grief does not. The proof establishes that the wall between inner magnitude and instrumentation is not solid; it says nothing about where else it can be crossed. **(ii)** It does not license treating rating scales as ratio scales. **(iii)** It does not license the exponents as constants of nature. **(iv)** It does not settle whether the number an observer emits is "the sensation"; it settles that the numbers behave as a measurement system behaves.

And it does not answer the strongest objection to the whole enterprise. Michell [1997] argues that psychology systematically fails to test whether its attributes are quantitative at all before measuring them, and that the failure is not incidental but constitutive of the discipline's practice [Michell, 1999]. The remedy is conjoint measurement — the formal test of whether an attribute has additive quantitative structure [Luce and Tukey, 1964, Krantz et al., 1971]. **The conjoint conditions have not been tested for subjective magnitude in this paper, nor for u, nor for comfort.** Section 12.3's ratio-invariance test is this framework's own attempt at a licence and Section 13.2 states exactly what it does and does not establish. Relatedly, if u is read as a similarity measure over people it cannot be assumed to behave metrically, since psychological similarity is asymmetric and violates the triangle inequality [Tversky, 1977]; the nearest existing result to the framework's claim that surplus is a function of dissimilarity is the exponential law of generalisation over a psychological distance [Shepard, 1987], and it is a different function.

20.10 10 Specifications

Numbered, checkable requirements. They are renumbered S1 to S36 from the three source registers, in three groups. A claim that fails any of them is not admitted to a design document or to a decision.

Group I — the register (S1 to S12).

S1 — Declare the register. Any quantity used in design shall be labelled as perceived logarithmically, perceived linearly, or unknown. **Where it is unknown, no perceptual claim shall be made about it.**

S2 — Convert before promising. Any commitment about experience shall be converted to world units using a stated exponent before it is agreed, and the exponent and its source shall be recorded.

S3 — Ratios in budgets, never differences. Design budgets for perceived quantities shall be stated as ratios or in log units. A budget stated as an absolute difference in a logarithmically perceived quantity shall be rejected as unspecified.

S4 — Geometric mean for central tendency. Reports of a perceived quantity shall give the geometric mean. The arithmetic mean of ratios shall not be reported.

S5 — Log axes. Charts of perceived quantities shall use logarithmic axes, labelled as such.

S6 — Equal-step ladders shall be geometric, and the common ratio shall be stated.

S7 — Exponents cited with their method. Any exponent used shall be reported with its modality, its stimulus range, and the fact that it is a constant of a procedure. An exponent quoted bare shall be treated as unsourced.

S8 — Do not divide Fechnerian percepts. Where the percept scale is Fechnerian, only differences shall be taken. Ratios of percepts require a magnitude-estimation scale and shall state that they have one.

S9 — Do not sum across modalities without a declared weighting. Perceived changes in different modalities are in different units. They shall not be added without an explicit stated exchange rate, and the rate shall be badged as a design decision rather than a measurement.

S10 — Threshold declared. Any use of a logarithmic model shall state the reference `I_0` or threshold `u_0` in use. **A logarithm with an undeclared reference is not a measurement.**

S11 — Reference shifts disclosed. Where a design achieves its effect by moving the reference rather than the quantity, that shall be disclosable to the occupant without embarrassment. If it could not be, it shall not be built.

S12 — Concavity reported as a ratio requirement. Where a proposal is rejected on grounds of diminishing returns, the rejection shall state the ratio increment that would have been required. "Diminishing returns" without a number is not a finding.

Group II — the postulate method (S13 to S25).

S13 — Badge in the same sentence. Every assertion that is not a theorem carries one of the six badges of Section 8.3 in the sentence in which it is first stated. No footnoted badges.

S14 — Date every postulate. A postulate without a date cannot be distinguished from a post hoc fit and shall be treated as one.

S15 — Forbiddance list before observation, in operational terms. The list is part of the postulate; a postulate cited without its list is cited incompletely.

S16 — Executable operational definitions. Every term in the forbiddance list must be applicable by a person who does not know the hypothesis, yielding the same classification.

S17 — Asymmetry check. For each derived consequence, write the consequence the *negation* would produce. If they are the same, delete the consequence; it is not evidence.

S18 — Minimality audit at every revision. Delete any clause that forbids nothing and record the deletion. A postulate's word count shall not grow monotonically across revisions.

S19 — Amendment ledger, maintained. One row per revision, forbiddance-added and forbiddance-removed columns filled. Three consecutive net-negative revisions triggers a mandatory abandonment review.

S20 — Time-ordered split and freeze. Split by time, fit on the earlier portion, write the parameters down, do not refit.

S21 — Four baselines, all reported. Persistence, direct input, matched autoregression, shuffled input. The headline is the minimum of the four skill scores.

S22 — Scope declaration. State whether the postulate is single-subject, group-indexed or general. **A single-subject postulate may not be stated in the third person.**

S23 — Scale-type declaration. State the scale type of every measured term. If a formula divides two terms, both must be ratio-scaled with a true zero, or the formula is demoted to a heuristic ordering in print, visibly [Curzi, 2026m].

S24 — Publication of survival, not of truth. Report as "survived `n` rounds against the following forbiddance list", with the list attached. Never report a postulate as confirmed, established or proven.

S25 — Decline path. Any protocol asking another person to supply readings shall state how they decline, and declining shall cost them nothing.

Group III — magnitude estimation (S26 to S36).

S26 — Ratio instruction, verbatim. Any protocol claiming ratio-scale subjective data shall publish its exact instruction text. Instructions mentioning a bounded range, named categories or integer-only responses do not yield ratio data and shall be reported as ordinal.

S27 — Geometric spacing, minimum 7 levels, minimum 1.5 decades. State the range.

S28 — Geometric mean aggregation. Arithmetic means of magnitude estimates are prohibited.

S29 — Log-log fit with residual inspection. Report slope, intercept, `R^2` and the residual pattern. Systematic curvature is reported, not smoothed.

S30 — Both directions, or declare one. Run estimation and production and report the geometric mean of the exponents, or run one and state which, with the direction of the expected bias.

S31 — Ratio-invariance test. Include equal-physical-ratio pairs at two absolute levels and report whether the response ratios matched. **A protocol without this test may not claim ratio**

scale.

S32 — Full exponent citation format: `a = value (method, range, modulus, instruction, n).`

S33 — Units before exponents. State the physical quantity the exponent is taken on — pressure versus intensity, luminance versus illuminance, concentration versus mass. Pressure versus intensity alone is a factor-of-two error in the exponent.

S34 — Upper-bound labelling of step counts. `N_jnd` is reported as an upper bound on usable categories, with the identification-task caveat attached.

S35 — Re-measure before calibrating. Published exponents orient a design; they do not calibrate one.

S36 — Decline path. Participants may stop at any point without giving a reason and without cost, and this is stated to them before the first trial.

20.11 11 Failure modes

Twenty-seven named failure modes, renumbered `FM1` to `FM27` from the three source registers. Each carries what it damages, how it is recognised, and which specification repairs it.

20.11.1 11.1 Faults of the register (FM1 to FM10)

FM1 — The Linear Promise. A commitment about experience made in world percentages: "twenty per cent brighter", "twice as fast", "half the noise". *Damages:* the relationship and the budget — in brightness, `+20%` delivered is `+6.2%` received, 31 per cent of the promise. *Signature:* a percentage in a specification with no exponent anywhere in the document. *Repair:* S2. The conversion takes one line and is the highest-value single line in this paper.

FM2 — The Arithmetic Mean of Ratios. Percentage changes averaged arithmetically. *Damages:* the number, always upward, by Jensen's inequality. *Signature:* `+50%` and `−50%` averaging to zero when the true per-step factor is `0.866025`, that is `−13.40%`. *Repair:* S4.

FM3 — The Linear Ladder. Equal absolute increments intended to feel equal. *Damages:* the perceived step decays monotonically — in Section 7.4's example the last step is 0.1625 nats against the first's 0.3185, barely half. *Signature:* unequal `ln` steps. *Repair:* S6.

FM4 — Diminishing Returns Read as Failure. A programme delivering constant ratio improvement is reported as decelerating and cancelled. *Damages:* the programme, and the credibility of the next one. *Signature:* **if the log is a straight line, the programme is delivering constantly and the chart is lying.** *Repair:* S5 and S12.

FM5 — The Undeclared Reference. A logarithm taken with no stated reference, so the numbers are offsets from an unknown origin. *Damages:* comparability; two teams' numbers cannot be combined and neither knows it. *Signature:* ask what value gives zero; if nobody can say, S10 has failed. *Repair:* declare `I_0`, or in the surplus law declare `N`, since `u_0 = 1/(N−1)`.

FM6 — Nats Added Across Modalities. Perceived improvements in lighting, acoustics and thermal comfort summed into one figure. *Damages:* the figure. *Signature:* a single "perceived improvement" number covering more than one sense with no exchange rate. *Repair:* S9.

FM7 — The Dimensioned Logarithm. `ln(I)` computed where `I` carries units — `ln(500 lux)`. *Damages:* dimensional coherence outright; **the argument of a logarithm must be dimensionless.** *Signature:* a log whose argument has a unit attached. *Repair:* normalise first, `ln(I/I_0)`, always. Section 14.1 gives the audit that makes this checkable.

FM8 — The Expansive Modality Treated as Compressive. *Damages:* safety, potentially: at `a = 3.5` a twenty-two per cent increase doubles the sensation, and a margin computed on compressive assumptions is far too small. *Signature:* no exponent looked up. *Repair:* S7. **The sign of the design advice depends on whether `a` is above or below 1 and there is no default.**

FM9 — Percepts Divided. Two Fechnerian percept values divided and reported as "twice as much". *Damages:* the claim; an interval scale has no true zero and does not support division. *Signature:* a ratio of percepts with no magnitude-estimation procedure behind it. *Repair:* S8.

FM10 — The Reference Shift Sold as a Quantity Increase. Experience improved by moving `I_0` and reported as an improvement in `I`. *Damages:* honesty, and the next measurement, which will not reproduce. *Signature:* world quantity unchanged, occupant reports improvement, report claims the quantity improved. *Repair:* S11. **Reference shifting is a legitimate technique and a dishonest claim, and the difference is entirely in the reporting.**

20.11.2 11.2 Faults of postulation (FM11 to FM19)

FM11 — The Unbadged Postulate. *Damages:* the reader's ability to calibrate; an unbadged postulate accumulates authority it never earned and becomes load-bearing without a load rating. *Signature:* a statement about an unobservable, in the indicative, with no test attached — often recognisable by a citation chain whose earliest reference is a proposal and whose latest is a premise. *Repair:* badge it retroactively and audit what was built on it. If the audit shows the structure above cannot be supported by a postulate, the structure comes down, not the badge.

FM12 — The Retreating Postulate. *Damages:* content; `H_forbid` shrinks toward zero while apparent sophistication grows. *Signature:* every disconfirmation met with a qualification; nobody can state the postulate's current form in one sentence. *Detection:* the amendment ledger, with net forbiddance negative across revisions. *Repair:* abandon and restate from scratch, dated today. **The amendment rule [HOUSE RULE]:** an amendment is legitimate if and only if the amended postulate forbids at least one observation the original did not, and the new forbiddance is recorded, dated and tested in a subsequent round on fresh data. An amendment that only removes a forbiddance is a retreat and is recorded as one. The ledger has one row per revision — date, version, clause added or removed, forbiddance added, forbiddance removed, net — and **a programme whose net column is negative for three consecutive revisions is degenerating** [Lakatos, 1970].

FM13 — The Postulate That Forbids Nothing. *Damages:* the entire enterprise; it is not a weak postulate, it is not a postulate. *Signature:* every outcome described in advance as consistent; the proponent delighted by all results. *Detection:* hand it to someone hostile and competent and ask them to design an experiment to kill it; `q = 1` in Section 8.6. *Repair:* demote to metaphor and stop citing it as support.

FM14 — The Circular Instrument. *Damages:* identifiability, and silently everything fitted with it. *Signature:* the instrument measuring the outcome is derived from the same self-report that generated the postulate, so the postulate is tested against a transformation of itself. *Detection:* can the outcome proxy be shown not to be a repackaging of the input? Curzi [2026i]'s repackaging audit is the institutional-scope version, and it records that a repackaged proxy's single-week jump of 31.1 units was 38.5 times the maximum admissible increment. *Repair:* separate the channels — outcome by behavioural trace, or by a different-modality report taken hours later and recorded without seeing the earlier one.

FM15 — The Borrowed Ceiling. *Damages:* the reader's calibration, by importing authority across a boundary it does not cross. *Signature:* "psychophysics established that subjective quantities are measurable, therefore my subjective quantity is measurable." Section 9 establishes something narrower: that *certain* subjective magnitudes, under *specific* procedures, yield ratio-supporting numbers that replicate. **The existence proof licenses the attempt, not the result.** *Detection:* look for the word "therefore" spanning two different quantities. *Repair:* run the procedure on the quantity in question.

FM16 — The Post Hoc Fit Reported as a Test. *Damages:* falsification; the reported evidence has no evidential value. *Signature:* as many free parameters as data points, a beautiful fit, no held-out set, no frozen parameters. *Detection:* ask for the date of the parameter values and the date of the data, and for the held-out error [Gelman and Loken, 2013]. *Repair:* the freeze. If the record is too short to split, say so and report the fit as exploratory, which is honest and useful.

FM17 — The Identity Postulate. *Damages:* everything, and it is the hardest to repair, because the cost of falsification is not intellectual. *Signature:* a postulate about oneself whose

abandonment would require abandoning a self-image; the forbiddance list, honestly written, contains observations the person cannot afford to make, so it is never written or is written too vaguely to bind. *Detection:* ask what changes if the postulate is false; **if the answer includes who you are rather than what you do, the postulate is identity-loaded and its evidence must be discounted accordingly.** *Repair:* delegate the classification to someone blind to the hypothesis, and precommit the change of practice that follows from the postulate's death.

FM18 — The Consequence Nobody Recorded. *Damages:* the entire test, silently; the most frequent failure in practice, and it looks like nothing. *Signature:* postulate stated, consequences derived, observations made, and no artefact exists — the person "noticed" the results, and recall is then reconstructed under the influence of the postulate. *Detection:* ask for the file; if the answer is a memory, there is no test. *Repair:* any dated artefact. **An observation not recorded contributes nothing to the stock, however vivid it was.**

FM19 — The Missing Shuffled Control. *Damages:* the causal claim specifically, while leaving the predictive claim intact and thereby disguising the damage. *Signature:* a model that beats persistence reported as evidence for the postulated mechanism, with no shuffled-input comparison. *Detection:* look for the fourth baseline; its absence is the signature. *Repair:* run it. Section 12.2 is where it does the real work. **The control is not a formality:** the corpus measured its shuffled-input control passing 98.35 per cent of the time against a third variable driving both series, while detecting only 48.17 per cent in the clean case, so **the empirical audit cannot see repackaging** [Curzi, 2026i].

20.11.3 11.3 Faults of magnitude measurement (FM20 to FM27)

FM20 — The Rating Scale Wearing a Ratio Scale's Clothes. *Damages:* the scale type, and therefore every division and multiplication downstream. *Signature:* a one-to-seven item whose means are divided, multiplied or compared as ratios. *Detection:* **look for a bound.** A response scale with a ceiling is ordinal at best, because a ratio scale has no maximum [Stevens, 1946, Likert, 1932]. *Repair:* magnitude estimation if the quantity supports it; otherwise demote every formula containing the quantity to a heuristic ordering, visibly.

FM21 — The Exponent Quoted Bare. *Damages:* reproducibility. *Signature:* "the exponent for X is 1.4", with no range, modulus, instruction or direction. *Repair:* S32, or drop the number.

FM22 — The Pressure/Intensity Confusion. *Damages:* dimensions, by a factor of exactly two in the exponent and therefore four in every conversion. *Signature:* loudness computations mixing an exponent of 0.67 with intensity data, or 0.33 with pressure data. *Detection:* Section 9.4's cross-check; if the perceived doubling does not land within a decibel or so of 10 dB, the domain is wrong. *Repair:* state the domain before the exponent and convert with `a_intensity = a_pressure / 2`.

FM23 — The Linear Promise in a Logarithmic Quantity. The measurement-side form of FM1. *Signature:* "we improved the metric by 40 per cent and users did not notice." At `a = 0.33` a 40 per cent physical increase is a perceived increase of `1.4^0.33 = 1.1174`, that is 11.7 per cent, which for many observers is close to the just-noticeable difference for that dimension. *Repair:* compute the physical ratio needed for a change of at least one just-noticeable difference, and price that.

FM24 — The Arithmetic Mean of Ratio Data. *Damages:* the aggregate estimate, systematically upward and unevenly across conditions. *Signature:* group means of magnitude estimates computed with an arithmetic mean; one participant who used numbers ten times larger dominates the result. *Detection:* compare arithmetic and geometric means. *Repair:* geometric mean, equivalently the mean of the logarithms, which is the natural operation in the register.

FM25 — The Unrandomised Ladder. *Damages:* the exponent, via sequential dependency, usually inflating the fit. *Signature:* stimuli presented in ascending or descending order — beautiful `R^2`, wrong slope. *Repair:* randomise, replicate with separation, and compare ascending and descending sub-blocks.

FM26 — The Step Count Treated as a Category Count. *Damages:* every ceiling computed from it; `N_jnd` overstates usable categories, sometimes by an order of magnitude. *Signature:* "there are 283 discriminable levels, therefore the display should have 283 levels." *Detection:* run an absolute-identification task [Miller, 1956]. *Repair:* S34.

FM27 — The Two-Decade Conclusion. *Damages:* model selection; two fundamentally different models both fit. *Signature:* a functional form declared on data spanning one or two decades, `R^2 > 0.95`, and no competitor tested. *Detection:* Section 9.5's arithmetic — over two decades a logarithmic law captures 96.3 per cent of a power function's variance, so `R^2 = 0.96` distinguishes nothing. *Repair:* extend the range until the candidates disagree, or find a qualitative discriminator, as Stevens did with the expansive exponents. **This paper's own headline fit is exposed to FM27 and Section 12.3 says so.**

20.12 12 Results: three worked cases

All three cases are constructed. No dataset was collected for this paper; the reading room is a design case with stipulated dimensions and complaints, the postulate case is a stipulated series of readings chosen to demonstrate the protocol's arithmetic, and the magnitude-estimation series is a stipulated worked case. **None of them is evidence about any room, any person or any modality**, and Section 15 repeats it. What they demonstrate is that the procedures run, that they produce numbers a reader can re-derive, and — in the second case — that they report their own refutation.

20.12.1 12.1 The reading room, budgeted in ratios

A public library reading room, three complaints and one constraint.

```
Room:        12.0 m x 8.0 m x 3.5 m,  V = 336.0 m^3
Complaint 1: "the edges are gloomy"      perimeter 200 lux, core tables 500 lux
Complaint 2: "you can hear everything"   8 simultaneous quiet talkers; RT60 measured 1.20 s
Complaint 3: "it feels harsh"            deferred — not a magnitude problem
Constraint:  lighting energy must not rise more than 10 per cent
```

Step 1 — convert every complaint into a ratio. No absolute number is actionable until it is a ratio against a reference (S3, S10).

Gloom. Perimeter against core: world ratio `200/500 = 0.400000`, `ln = −0.916291` nats; perceived `0.400^0.33 = 0.7391`, so the perimeter looks **26.09 per cent dimmer** than the core; in percept units `0.33 x (−0.916291) = −0.302376` nats. **A sixty per cent reduction in illuminance is experienced as a twenty-six per cent reduction in brightness.** The register has already absorbed most of the physical difference, which is why the complaint is "gloomy" rather than "dark" — and why the fix will cost more than the complaint sounds.

Noise. Eight incoherent talkers against a target of four. Incoherent sources add in power, so halving the count divides pressure by `sqrt(2)`: pressure ratio `0.707107`, that is `−3.010 dB`; perceived `0.707107^0.67 = 0.7928`, **20.72 per cent quieter**; in percept units `−0.232204` nats. **Halving the number of people talking makes the room about a fifth quieter, not half.**

Reverberation. Sabine's law, `RT60 = 0.161 V / A` [Sabine, 1922]:

```
measured RT60 = 1.20 s  =>  A = 0.161 x 336.0 / 1.20 = 45.08 m^2 sabins
target   RT60 = 0.60 s  =>  A = 0.161 x 336.0 / 0.60 = 90.16 m^2 sabins
required: A x 2.000 −− exactly double the absorption
```

Halving reverberation time requires doubling absorption exactly, because Sabine's law is itself a reciprocal — a ratio law. The perceptual conversion stops here:

NOT CONVERTED. There is no verified exponent for perceived reverberance in this framework's table. The world ratio is `ln(0.5) = −0.693147` nats and **it shall not be multiplied by an exponent that has not been measured** (S7). The acoustic change is reported in world units and left there. The alternative would have been to invent a plausible number.

Step 2 — price the constraint before designing to it.

illuminance change	energy change	perceived brightness change
500 to 450 lux	-10.0%	**-3.42%**
500 to 400 lux	-20.0%	**-7.10%**
500 to 350 lux	-30.0%	-11.10%
500 to 250 lux	-50.0%	-20.45%
200 to 300 lux	+50.0% (perimeter circuit)	**+14.32%**
200 to 400 lux	+100.0% (perimeter circuit)	+25.70%
500 to 4 085 lux	+717%	+100% (a perceived doubling)

The bottom row is the anchor: **doubling the apparent brightness of the core would take 4 085 lux and eight times the energy. It is not on the table and never was.** The fourth row solves the problem: a twenty per cent energy cut on the core costs 7.10 per cent of perceived brightness, and the fifth row spends that saving where it buys three times as much, because the perimeter starts lower and the register is steeper in ratio terms near the bottom of the range.

Step 3 — the design and its energy arithmetic. With the core carrying 60 per cent of the luminaires and the perimeter 40 per cent:

```
core:      500 -> 400 lux   (x0.80)
perimeter: 200 -> 300 lux   (x1.50)
energy = 0.60 x 0.80 + 0.40 x 1.50 = 0.4800 + 0.6000 = 1.0800   ->  +8.00%
```

Inside the ten per cent cap. The perceptual result:

location	before	after	perceived change
Core tables	500 lux	400 lux	-7.10%
Perimeter	200 lux	300 lux	**+14.32%**
Core-to-perimeter gap	-26.09%	**-9.06%**	gap cut by 65%

The complaint was the gap, and the gap closed from 26.09 to 9.06 per cent for eight per cent more energy, by taking brightness away from the place that had most of it. In world units the move looks perverse. In register units it is straightforwardly correct, because 100 lux removed from 500 costs 7 per cent of experience and 100 lux added to 200 buys 14 per cent. **The register is why the two 100-lux moves are not the same move.**

Step 4 — the perceived-improvement budget, per modality, kept strictly separate as S9 requires:

```
BRIGHTNESS (a = 0.33)
    core       500 -> 400 lux : 0.33 x ln(0.800000) = −0.073637 nats   (−7.10%)
    perimeter  200 -> 300 lux : 0.33 x ln(1.500000) = +0.133803 nats  (+14.32%)
    gap closure, the design objective: from −0.302376 to −0.094935 nats

LOUDNESS (a = 0.67)
```

```
    8 -> 4 talkers            : 0.67 x ln(0.707107) = -0.232204 nats  (-20.72%)

REVERBERATION
    RT60 1.20 -> 0.60 s       : world ln-ratio -0.693147 nats
                                ** NOT CONVERTED - no verified exponent **
```

These three blocks are not summed. A single "perceived improvement of 0.44 nats" would require an exchange rate between brightness nats and loudness nats; none has been measured; inventing one is FM6.

The source manuscript prints the post-change gap as `-0.094839` nats. The value is `0.33 x ln(300/400) = 0.33 x (-0.287682) = -0.094935`, which is also what the two component figures give when combined: `-0.302376 + 0.133803 + 0.073637 = -0.094936`. The corrected figure is used above. The percentage figures `-26.09%` and `-9.06%` are unaffected and reproduce exactly.

Step 5 — where the acoustic budget actually goes. The library's instinct was occupancy limits. Priced:

intervention	world change	perceived loudness
8 to 4 talkers	-3.010 dB	-20.72%
Pressure halved	-6.02 dB	-37.15%
-9.0 dB	x0.3548 pressure	**-50.05%**
-10.0 dB	x0.3162 pressure	-53.76%
-12.0 dB	x0.2512 pressure	-60.37%

Halving the perceived loudness of the room takes -8.99 dB, a factor of 0.3554 in pressure — the equivalent of going from eight talkers to one. Occupancy control cannot deliver it; the room would have to be nearly empty. The absorption route can: doubling `A` to 90.16 m^2 of sabins halves RT60, reducing the reverberant contribution at every listening position without removing a reader. **The library's plan was to reduce the number of people in a reading room; the arithmetic says the achievable version of that plan delivers a fifth of what the complaint asks for, and that ceiling and wall treatment delivers the rest without touching occupancy.**

Step 6 — what to promise. The library's draft notice said *"we are increasing lighting at the perimeter by 50 per cent."* Converted (S2): readers will experience about **14 per cent** more brightness at the perimeter and about **7 per cent** less at the tables, and the difference between the two zones — which is what they complained about — will be about a third of what it was. **A promise of 50 per cent, kept exactly in lux, would have been received as a failure, because the promise was made in one register and the reading is taken in another.**

Step 7 — what would falsify the design's predictions. Preregistered before the work: post-occupancy magnitude estimation at the perimeter and at the core, by readers who did not participate in the design, against the prediction of **`+14.32%`** and **`-7.10%`** with the gap closing to `-9.06%`. **If the measured perimeter improvement falls outside `±0.05` nats of the prediction, the brightness exponent of 0.33 does not describe this population in this room, and the exponent — not the design method — is what gets revised.** The Lens Theorem is not at risk from this measurement because it is a theorem; the exponent is at risk, and should be, because it is a measurement.

What this case does not establish. The relation between illuminance, zone contrast and occupant complaint is assumed, not measured. This framework's bibliography contains no entry establishing a quantitative illuminance-to-complaint relation for a reading room; the nearest support is the design literature's general claim that the distribution of light within a room conditions how it is used and experienced [Alexander et al., 1977], which is a design-literature claim and not a measured relation. **The premise of the case is therefore a modelling stipulation and is badged as one**, and Section 15 records it.

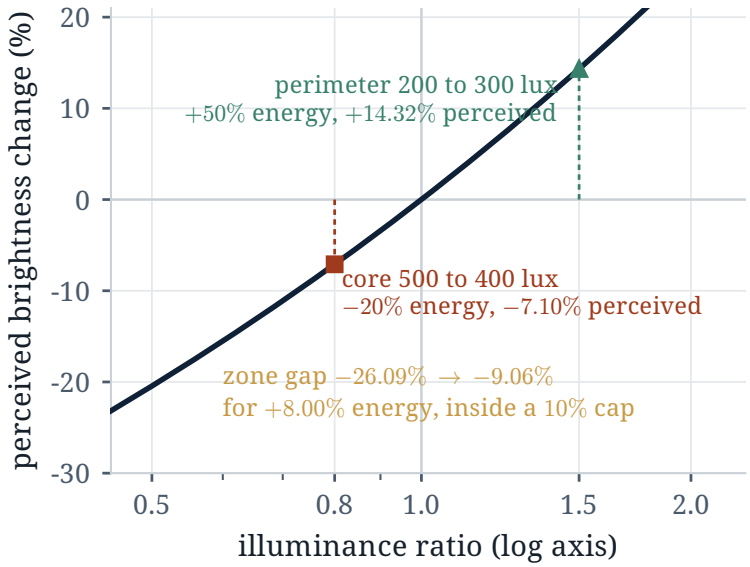

Figure 20.3: **A 20 per cent energy cut where light is plentiful buys more perceived brightness than it costs, once both moves are read in the register.** Core 500 to 400 lux costs 7.10 per cent of perceived brightness while perimeter 200 to 300 lux buys 14.32 per cent, closing the zone gap from 26.09 to 9.06 per cent for 8.00 per cent more energy, inside the declared 10 per cent cap. Modelled from the stipulated illuminances and a cited brightness exponent of 0.33; generated by `figs/src/CCP-020_fig03.py`.

20.12.2 12.2 A postulate carried to a held-out test, and refuted on one of four consequences

One observer, one postulate, carried from a native sentence to a frozen held-out test and an amendment. **Every number below is computed from a stipulated worked case chosen to demonstrate the arithmetic of the protocol. The readings are not empirical data about any person and no claim is made about anybody's mornings.**

Step A — the belief in its native form. *"I am sharpest in the morning and useless after lunch."* Two unobservables, one implied cause, one implied structure, no quantities and no forbiddance. As stated it is compatible with every possible observation, so `q = 1` and `H_forbid = 0` — the starting condition of nearly every belief anyone holds about their own functioning, and FM13 exactly.

Steps B and C — the named quantity and the postulate. The hidden quantity is a capacity for one class of work. Name it `R`; restrict the class to **novel analytic problem-solving**, operationally *tasks requiring a solution method not previously used by this observer on this problem type*.

> **The reservoir postulate [POSTULATE, dated at the top of the record].** There is a single scalar capacity `R` for novel analytic work. `R` is depleted by time spent on that class of work and by nothing else. `R` recovers fully overnight and is **not** replenished by breaks within the day. Observed performance on a novel analytic task is monotone increasing in `R` at the moment the task is attempted.

Each clause does work — "by nothing else" forbids depletion by meetings and administrative work; "not replenished by breaks" forbids mid-day recovery; "recovers fully overnight" forbids carry-over across days — so S18 is satisfied at birth.

Step D — four consequences, one uncomfortable.

```
D1  Within a working day, scores on the analytic class decline monotonically across blocks.
```

```
D2  On days containing a long midday break, the block after the break falls ON the same
    decline curve. It does not rise.                          <-- UNCOMFORTABLE
D3  The control class (routine administrative work) shows no comparable decline.
D4  A day starting later shows the same decline SHAPE, shifted, not compressed: the decline
    tracks time-on-task, not clock time.
```

D2 carries the content, because the observer takes breaks and would like them to be doing something. **A consequence one would be pleased to see falsified is exactly the consequence that carries information** (S17).

Step E — the forbiddance list, written before observing.

```
F1  kills D1: a non-monotone block sequence, in the mean over >= 20 days.
F2  kills D2: block 3 on break days exceeding the no-break decline prediction by more than
              0.5 pooled standard deviations.
F3  kills D3: the control class declining at more than one third the analytic rate.
F4  kills D4: late-start days showing a decline slope differing from early-start days by
              more than 25%.
```

Step F — instrument and design. Four 75-minute blocks per day; at the end of each, a magnitude estimate of the block's analytic output against a personal modulus of 100 assigned to a pre-selected reference block (Section 9.6's method, used rather than justified). Forty working days: twenty-two with no long break, eighteen with a 90-minute break between blocks 2 and 3.

condition	block 1	block 2	block 3	block 4	days
no long break	100.0	88.0	74.0	63.0	22
(sd)	11.0	12.0	13.0	12.0	
90-min midday break	100.0	87.0	95.0	81.0	18
(sd)	10.0	11.0	12.0	13.0	
control: administrative	100.0	98.0	97.0	96.0	22

Computation. Linear fits on the block index:

```
no-break analytic:   slope = -12.5000 per block,  intercept 112.5000,  R^2 = 0.99808
break-day analytic:  slope =  -4.9000 per block,  intercept 103.0000,  R^2 = 0.56428
control (admin):     slope =  -1.3000 per block
```

In log-ratios against block 1, which is the register the framework works in:

```
ln(88/100) = -0.1278    ln(74/100) = -0.3011    ln(63/100) = -0.4620
log-slope = -0.1559 nats per block,  R^2 = 0.99639
implied per-block retention exp(-0.1559) = 0.8556
implied per-block loss                   = 0.1444
```

That last line is the first substantive result. The no-break decline is very well described by a constant fractional loss per block — a leaky integrator with no input, `Q_{t+1} = (1-delta)Q_t` with `delta = 0.1444` per 75-minute block [Curzi, 2026a]. **The postulate predicted only monotonicity, not an exponential. The exponential form is a free finding**, and free findings are how postulates get sharpened. It is also the point at which S17's asymmetry check earns its place: monotone decline is predicted by the postulate's negation too, whereas a constant fractional loss is not, so it is the exponential and not the monotonicity that carries information.

The D2 test — the uncomfortable one.

```
frozen no-break decay applied forward from break-day block 1:
    predicted block 3 = 100.0 x exp(-0.15594 x 2) = 73.207
observed block 3 on break days                    = 95.000
difference                                        = 21.793
pooled sd (n1 = 22, n2 = 18)                      = 12.5625
standardised effect size                          =  1.7347
t                                                 =  5.4583   (df = 38)
```

The tolerance declared in F2 was 0.5 pooled standard deviations. **The observed excess is 1.73 pooled standard deviations, more than three times the tolerance, in the forbidden direction.**

> **D2 is falsified. The reservoir postulate, as stated, is dead.**

That sentence is reported here in exactly the language a confirmation would have received. The other three consequences:

```
D1  supported:  monotone decline in the no-break condition, R^2 = 0.99808
D3  supported:  control slope -1.3 against analytic -12.5, a factor of 9.615; F3's
                threshold was a factor of 3. Passed with margin.
D4  not tested: start time was not varied. Recorded as UNTESTED, not as supported.
```

D4's row is the one to imitate. An untested consequence is reported as untested and never folded into the supported column because the postulate "did well overall".

The amendment, done legitimately. The clause "not replenished by breaks" is dead. The amendment must add forbiddance, not merely remove it, so the replacement clause is quantitative:

> **The reservoir postulate, v2 [POSTULATE, dated at amendment].** As v1, except: `R` is partially replenished by breaks, and the replenishment is a saturating function of break length, so that doubling break length yields less than double the recovery.

version	clause changed	forbiddance ADDED	forbiddance REMOVED	net
v2	breaks replenish, saturating	ordering and concavity across three break lengths	"no recovery"	+

The new forbiddance is specific and testable on fresh data: with 20-, 45- and 90-minute breaks, recovery must be ordered `r(20) < r(45) < r(90)` **and** concave, `r(90) − r(45) < r(45) − r(20)`. That forbids a linear response and it forbids a step response, so the net column is positive and the amendment is progressive rather than a retreat (S19, FM12).

The freeze and the four baselines. For the follow-up round the observer wants a predictive model rather than a contrast, using the framework's minimal estimation form at single-observer scope, `Y_{t+1} = a Y_t + b S_t + noise` with `a = 1 − delta` and `b = eta` [Curzi, 2026i]. The record is 40 days, split by time at day 24. **The series is synthetic, generated by the stated rule `Y_{t+1} = 0.72 Y_t + 30 S_t + N(0, 2.0)` with a fixed seed, and is present to demonstrate the arithmetic of the freeze, not to report a result about anyone.**

```
FROZEN PARAMETERS, fitted on days 1-24 only:
    a = 0.7018  ->  delta = 0.2982
    b = 31.3083 ->  eta   = 31.3083
(true generating values a = 0.72, b = 30; recovery is a check that the fitting procedure
 works, not a result)
```

held-out model, days 25-40, frozen parameters	RMSE	skill against persistence
model	1.5164	0.8473
persistence	9.9295	0.0000
direct input	22.8039	-1.2966
matched AR(1), `c = 0.9838`	9.7719	0.0159
shuffled-input control	13.2567	-0.3351

Read in the order that matters. The model beats persistence by a wide margin, which by itself means little. It beats the matched AR(1), which is the first result with content: **a one-parameter memory model with no theory in it scores 0.0159 against persistence, essentially nothing, so the improvement is not coming from autocorrelation alone.** The direct-input baseline is catastrophically bad, so the output is not a rescaled copy of the input and there is genuine storage. **And then the fourth row, which is what the whole protocol exists to produce.** With the same frozen parameters and the input series permuted, held-out RMSE rises from 1.5164 to 13.2567, a factor of 8.74, and the skill score goes negative. **Performance depends on the specific temporal alignment of inputs with outputs, which is what a storage claim asserts and what a model that had merely learned the series' shape would not show.** Had the shuffled RMSE come back near 1.5, the exercise would have been dead — and dead invisibly, because every other row looks excellent.

What was and was not established.

```
ESTABLISHED (as survival, not as truth):
  - a within-day monotone decline in the analytic class, well fitted by a constant fractional
    loss of 0.1444 per 75-minute block
  - the control class does not show it (a factor of 9.6 in slope)
  - the frozen storage model beats all four baselines on held-out data, including and
    especially the shuffled-input control

KILLED:
  - the clause "breaks do not replenish", at a standardised effect of 1.73, three times the
    pre-set tolerance

UNTESTED, and recorded as untested:
  - D4, the time-on-task versus clock-time distinction
  - the saturating-recovery clause of v2, which is the next round's business

NOT CLAIMED:
  - anything about mornings in general
  - anything about any other person                    [scope: single subject, S22]
  - any account of WHY the decline occurs; the postulate is about structure, not mechanism,
    and no mechanism was tested
```

Two limits on this case that no amount of held-out testing removes. The observer supplying the readings and the analyst fitting the model are the same person, which is FM14 in its hardest form, and the separation of channels prescribed there was not achieved: the outcome is a magnitude estimate given by the same person whose capacity is being postulated. And the reported effect sizes carry no confidence intervals, because the case is constructed; a real application owes them (Section 15).

20.12.3 12.3 The ratio-invariance test, and the model comparison it forces

A full magnitude estimation, computed. **The readings are a stipulated worked case chosen to demonstrate the arithmetic and the checks. They are not empirical data and no claim is**

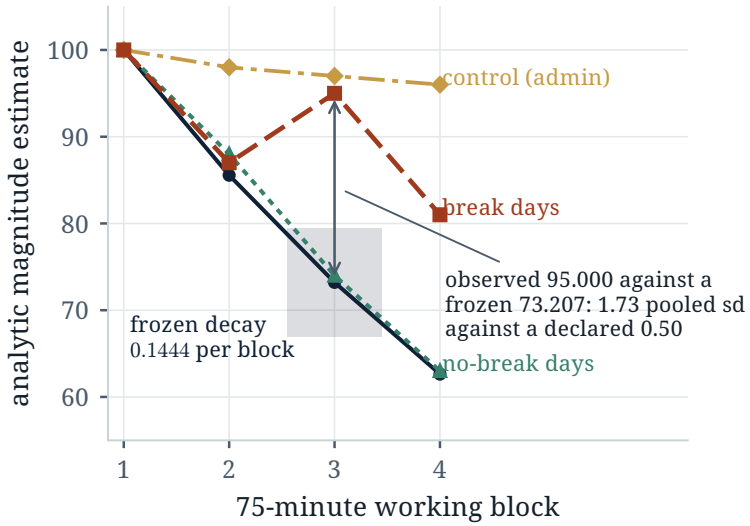

Figure 20.4: **A postulate reporting its own refutation.** The frozen no-break decay, a constant fractional loss of 0.1444 per 75-minute block, predicts 73.207 for block 3 on break days; the observed 95.000 exceeds it by 1.73 pooled standard deviations against a pre-set tolerance of 0.50, in the forbidden direction, so consequence D2 is falsified and the clause is amended in public. Modelled from the stipulated block means of this section; generated by `figs/src/CCP-020_fig04.py`.

made about any modality's true exponent. The procedure is Section 9.6's and the arithmetic is exact.

```
continuum    one physical intensity, varied alone
levels       8, geometrically spaced by factors of 2, from 0.25 to 32.0
             -> range R = 128, that is 2.107 decades              [S27 satisfied]
order        randomised per observer                              [FM25 avoided]
instruction  free ratio assignment, no bounds, non-integers permitted   [S26]
modulus      100 assigned to level 1.0, mid-range                 [S30 mid-anchor]
observers    20, two replicates per level, separated
aggregation  geometric mean across observers and replicates       [S28]
```

stimulus I	0.25	0.50	1.00	2.00	4.00	8.00	16.00	32.00
response	4.10	6.40	10.00	15.90	25.10	39.20	63.50	98.00

The log-log fit. Regressing `log10(response)` on `log10(stimulus)` over the eight points:

```
a       = 0.6569        the exponent
log10 k = 1.0043
k       = 10.0996
R^2     = 0.999932
```

I	observed	fitted	residual
0.25	4.10	4.06	+0.92%
0.50	6.40	6.41	-0.09%
1.00	10.00	10.10	-0.99%

I	observed	fitted	residual
2.00	15.90	15.92	-0.15%
4.00	25.10	25.11	-0.03%
8.00	39.20	39.58	-0.97%
16.00	63.50	62.41	+1.74%
32.00	98.00	98.40	-0.41%

Residuals under two per cent with no systematic curvature. **`R^2 = 0.999932` is reported here together with the warning that makes it interpretable: over two decades a fit statistic of this size does not by itself exclude a logarithmic law** (Section 9.5, FM27). The residual pattern and the tests below carry the conclusion, not the `R^2`.

The ratio-invariance test. S31 requires equal physical ratios at different absolute levels. The design contains two such pairs, both a factor of four:

```
psi(4.00) / psi(1.00)  =  25.10 / 10.00  =  2.5100
psi(32.0) / psi(8.00)  =  98.00 / 39.20  =  2.5000
predicted from the fitted exponent:  4^0.6569  =  2.4859
agreement between the two empirical ratios:  0.40 %
agreement with the prediction:               0.97 % and 0.57 %
```

Two stimulus pairs separated by a factor of eight in absolute level produce response ratios agreeing to within 0.40 per cent. This is the result that licenses calling the scale a ratio scale: an ordinal response with numerals attached has no reason to produce it. **It is a test the data could have failed and did not.**

And it is evidence for a power law, not for a logarithm. This must be said plainly, because the title of this paper points the other way. Under Fechner, equal stimulus ratios produce equal *differences* of percept, not equal *ratios*: `S(aI) − S(I) = k ln a`, independent of `I`. Ratio invariance of the response is the *power law's* invariant, `psi(bI)/psi(I) = b^a`. **A ratio-invariance test that succeeds is therefore a discriminating test, and on this series it discriminates against the logarithm.** Computed on the same eight points:

model	free parameters	SSE	`R^2` (response units)	AIC	BIC	LOO-CV RMSE
Power law `psi = k I^a`	2	1.5063	0.999802	-7.358	-7.120	**0.6071**
Fechner `S = A + B ln I`	2	1186.7312	0.844258	45.996	46.234	18.4747
Threshold Fechner `S = k ln(1 + I/I_0)`	2	41.7285	0.994524	19.214	19.452	—

All three carry the same number of free parameters, so the information criteria are directly comparable and the parameter count is paid for. **The power law is favoured by `Delta AIC = 26.57` over the better of the two logarithmic forms**, its leave-one-out cross-validated error is thirty times smaller than the plain logarithm's, and the plain logarithmic fit commits a qualitative error the power law does not: it predicts a response of `−10.54` at `I = 0.25`, a negative magnitude estimate, and places its zero at `I = 0.4512`, inside the presented stimulus range.

The ratio-invariance test separates them by itself, without any fit statistic:

	ratio at 4.00/1.00	ratio at 32.0/8.00	spread
observed	2.5100	2.5000	**0.40%**

	ratio at 4.00/1.00	ratio at 32.0/8.00	spread
power-law fit	2.4859	2.4859	0.00% (identically, by construction)
Fechner fit `A + B ln I`	2.7418	1.4821	**84.99%**
threshold Fechner `k ln(1+I/I_0)`	3.4481	2.3290	**48.05%**

A logarithmic register predicts that these two ratios differ by between forty-eight and eighty-five per cent; they differ by 0.40 per cent. On a constructed series, on one continuum, with one instruction, over 2.107 decades — but the direction of the result is unambiguous and it is reported here rather than left for a reader to compute.

Three things follow, and the third is the one that matters for this corpus. First, the scale-type licence sought by S31 is granted on this series. Second, the modelling conclusion is that the response is a power function of the stimulus, which is Stevens and not Fechner, exactly as Section 9.5 says the historical record found. Third — and this is where a reader could go wrong — **none of it damages the corpus's surplus functional, because that functional's logarithm does not rest on Fechner.** It rests on four axioms about interaction geometry, one of them a declared design axiom [Curzi, 2026], and on the independent dynamical warrant that the growth rate of a multiplicative process is logarithmic in the accumulating quantity [Peters and Gell-Mann, 2016]. Section 13.2 states the division of labour once more.

Interpretation, reported in the required format (S32):

```
a = 0.657  (magnitude estimation, free ratio instruction, range 0.25–32.0 = 2.107 decades,
            modulus 100 at mid-range level 1.0, geometric-mean aggregation,
            n = 20 observers x 2 replicates, single direction: estimation only, so the true
            value is expected to lie slightly ABOVE this figure by the regression effect)

world cost of a perceived doubling: 2^(1/a) = 2.8725 in stimulus units
                                  = ln 2 / a = 1.0552 nats = 0.4583 decades
conversion key: 1 nat of stimulus log-ratio -> 0.6569 nats of perceptual log-ratio
                                            -> 0.9477 bits          (x 1/ln 2)
```

That parenthesis is the discipline of Section 9 in one line. The number is not the result; the number plus the procedure is the result.

What was and was not established.

```
ESTABLISHED
  - a power relation between stimulus and response, residuals under 2%, no systematic
    curvature, and preferred over both logarithmic forms at equal parameter count by
    Delta AIC = 26.57 and by a factor of 30 in leave-one-out error
  - ratio invariance across an eightfold change in absolute level, to 0.40%, which the
    logarithmic forms predict at 48% to 85%
  - a conversion key of 0.657 nats per nat, usable in this framework's registers

NOT ESTABLISHED
  - that the exponent would survive a change of range          [Teghtsoonian effect]
  - that it would survive magnitude PRODUCTION                 [regression effect]
  - that the observers' numbers are "the sensation"            [Section 8.7]
  - that the attribute has additive quantitative structure at all; the conjoint conditions
    were not tested                                            [Section 9.9, Section 15]
  - anything at all about a different modality                 [FM15]

NEXT ROUND, preregistered
```

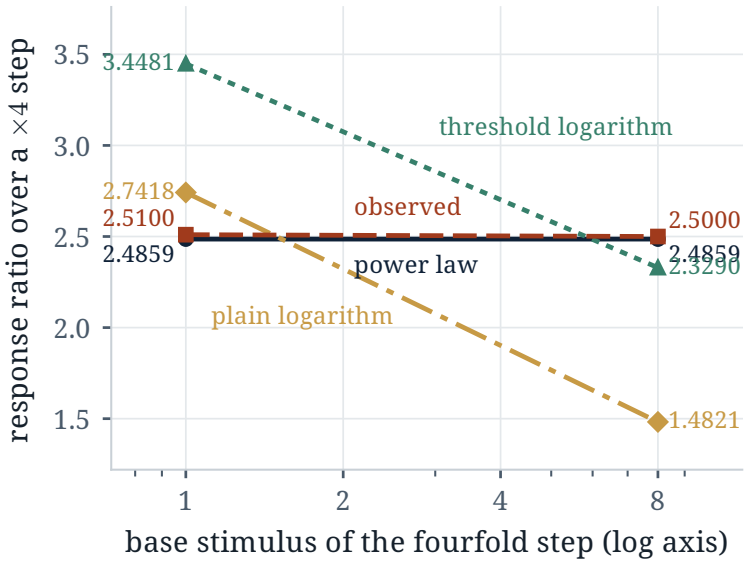

Figure 20.5: **The ratio-invariance test discriminates, and it discriminates against the logarithm.** The stipulated eight-point series is straight in log-log with residuals under two per cent; the fitted power law `psi = 10.0996 I^0.6569` reproduces both fourfold response ratios at 2.4859 against observed 2.5100 and 2.5000, while the best logarithmic form predicts ratios differing by 48 per cent across the same eightfold change of level. Computed for this paper from the stipulated series of Section 12.3; generated by `figs/src/CCP-020_fig05.py`.

```
- production direction, same stimuli; report the geometric mean of the two exponents
- a compressed-range replication (0.5 to 8.0) to measure the range dependence directly
  rather than inheriting it as a caveat
```

20.13 13 Discussion

20.13.1 13.1 What follows

The framework's logarithms are not a stylistic preference and they are not one claim. They are three claims with three different warrants, and separating them is the main practical contribution of this paper.

- **The Lens Theorem is algebra.** Given continuity and the conversion of multiplication into addition, the logarithm is forced and is unique up to a scale constant. Characterisation results of exactly this shape — which axioms force a logarithm — are a known genre [Aczél et al., 1974, Khinchin, 1957], and the framework's uniqueness argument for `F(u)` should be positioned against that genre rather than presented as novel.
- **The surplus functional's logarithm is axiomatic and dynamical.** It follows from four stated axioms, one of which is a declared design axiom [Curzi, 2026], and it is independently motivated by the fact that the growth rate of a multiplicative process is logarithmic in the accumulating quantity [Peters and Gell-Mann, 2016]. **Neither route needs an observer.**
- **The design advice is psychophysical, and only the design advice.** Section 7's numbers predict what a person will report. They need Fechner's register and a measured Stevens exponent, and they inherit every limitation in Section 9.9.

A second consequence is a reading of concavity that changes what a designer does with it. Because `F` is a logarithm of `(u + u_0)`, **diminishing returns are a constant ratio requirement seen from the world's coordinates**, and a proposal rejected for diminishing returns should be rejected with the ratio increment that would have been required rather than with the phrase (S12).

A third is that the storage law's world-coordinate reading makes explicit what its additive form conceals: **decay is taking a root, conversion is exponentiation, and cost is a divisor.** Every intuition about the stock being "added to" is an intuition about a count being multiplied, which is why the `ln N` ceiling bites so hard and why stored order is much harder to double than to establish.

A fourth is procedural. **The postulate method's value is not that it produces true postulates but that it produces informative deaths.** Section 12.2's postulate died on the consequence its author would least have liked to lose, at three times the pre-set tolerance, and was replaced by a version that forbids more. That is the mechanism by which a research programme stays progressive rather than degenerating [Lakatos, 1970], and it is why the specifications require the forbiddance list to be written before the observation and the ledger to record the net.

20.13.2 13.2 What does not follow

The Fechner identity is not evidence. Section 6.1 shows that two independent derivations arrive at one function. It does not show that surplus is perceived, that perception is surplus, or that either derivation is correct. Two routes to the same functional form is a structural convergence, and a structural convergence is an interpretive correspondence in the sense of Section 8.3, carrying no evidential weight.

The geometric accumulator is not a new result. It is a change of variables on an equation the corpus already had [Curzi, 2026a], and its fourteen-significant-figure agreement with the additive form is a numerical identity check on that change of variables. Agreement to fourteen figures between two ways of writing the same equation is what a correct implementation looks like, not what evidence looks like.

The functional form remains underdetermined. Section 3.5 gives the alternatives — a sublinear power law [Latané, 1981] and `n log n` [Briscoe et al., 2006] — and shows why the first cannot be separated from the corpus's law by shape at all: the logarithm is the `t -> 0` member of the power family, and at `t = 0.10` the two agree to `R^2` = 0.9897 over `N` in `[2,50]`. **Nothing in this paper discriminates among them on data.** The logarithm is chosen for its axiomatic characterisation and its dynamical warrant, not established by measurement, and any future comparison must be made out-of-sample, at matched parameter count, with an information criterion reported, which is the standard Section 12.3 applies to itself.

And the paper's one genuinely discriminating test comes out against Fechner. Section 12.3's ratio-invariance test is the corpus's own attempt to license a ratio scale, and it succeeds; but ratio invariance of the *response* is the power law's invariant and not the logarithm's, so the test's success is evidence for Stevens. On the stipulated series the power law is favoured over the better logarithmic form by `Delta AIC = 26.57` at equal parameter count, its leave-one-out error is thirty times smaller, and the logarithmic forms predict a spread between the two fourfold response ratios of 48 to 85 per cent against an observed 0.40 per cent.

The correct reading of that result, stated so it cannot be softened later: *the corpus's perceptual story is Stevens' rather than Fechner's wherever it is tested by this instrument, and the corpus's surplus functional keeps its logarithm anyway, because that logarithm never rested on the perceptual story.* A reader who takes the title of this paper as a claim that Fechner's law is the warrant for `F(u)` has taken more than the paper establishes, and Section 3.3 said so before the evidence was presented.

No claim about scaling or heavy tails is made anywhere in this paper, so the distribution-fitting procedure that any such claim would require does not apply [Clauset et al., 2009]; the exponents of Section 3.4 are cited point estimates from magnitude-estimation studies, not tail exponents estimated from a sample.

No claim in Section 8 about an inner structure is an identified empirical result. Section 3.7 states the reflection problem in full [Manski, 1993, Shalizi and Thomas, 2011] and records that no remedy is adopted here [Brock and Durlauf, 2001].

20.13.3 13.3 Relation to the surrounding literature

The historical dispute this paper reproduces is not settled and this paper does not settle it. Krueger [1989] is the standing reconciliation attempt; Luce [2002] and Narens [1996] pursue the axiomatic question of what must be true of a subject's judgements for either scale to exist; Poulton [1968] and Poulton [1979] catalogue what goes wrong in the instrument that produced the power law, and the catalogue has not been refuted but managed by better designs. **The framework's position is that the register survives the dispute and the specific functional form does not**, which is why every design specification in Section 10 is stated in ratios and every exponent carries its procedure.

Against the framework's use of subjective magnitude at all, Michell [1997] is the strongest available objection and Section 15 concedes it rather than answering it. Against its use of self-report as an instrument, Nisbett and Wilson [1977], Schwarz [1999] and Kahneman et al. [2006] bound what a report can be used for, and Section 8.7 accepts the bound and changes what a report is for rather than disputing it.

On the corpus's own side, the decay term has a genuine empirical ally in the hedonic-adaptation literature: comfort decays toward a set point [Brickman et al., 1978], adaptation is incomplete and set points move [Diener et al., 2006], and the reference against which a magnitude is judged is itself an adaptation level [Helson, 1948]. **That literature is simultaneously the strongest support for the framework's leak term and its strongest warning against promising accumulation**, and Section 4.8's arithmetic — that steady perceived improvement requires exponentially growing world quantity — is the formal version of the same warning.

Finally, a caution about aggregation that applies to every group-level number in this framework. The behaviour of a population is not in general the behaviour of any individual in it [Kirman, 1992], and the time average of a multiplicative process differs from its ensemble average [Peters, 2019]. **A framework whose stored quantity accumulates over time for one system, and whose parameters would naturally be estimated from a cross-section, is exposed to both**, and Section 15 records the exposure.

20.14 14 Verification

The results of this paper compound from eight postulates. Each is atomic, each is checkable on its own, and each carries its status. Postulates that could be dropped with the result still following have been dropped; what remains is what the chain consumes. **A reader who checks nothing else should check L1, R1 and R2 of Section 14.3, which take about two minutes between them.**

20.14.1 14.1 Dimensional audit

A logarithm's argument must be dimensionless. That single requirement is the whole of failure mode FM7, and it is what this table exists to make checkable.

Symbol	Dimension	Unit	Status
`I`	`[I]`	the modality's physical unit (lux, pascal, gram, …)	**measured**

Symbol	Dimension	Unit	Status
`I_0`	`[I]`	**the same unit as `I`**	**measured** — an absolute threshold, not a convenience constant
`I/I_0`	`[1]`	none	**derived** dimensionless; this is what makes `ln(I/I_0)` well formed
`S`	`[k]`	whatever unit `k` is declared in	**derived**
`k`	sensation units per nat	e.g. JND per nat; `1/ln(1+c) = 20.4959` JND per nat at `c = 0.05`	**defined by the construction of the sensation unit**
`c`	`[1]`	none	**measured** dimensionless fraction; the convention (75 per cent correct) must be stated
`a`	`[1]`	none	**measured** dimensionless exponent; **stated on pressure or on intensity, never bare**
`psi`	`[k']`	the units of the response modulus	**measured**; `k'` is procedure-dependent and not a property of the observer
`u`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2` for unit state vectors
`u_0 = 1/(N-1)`	`[1]`	none	**derived** dimensionless threshold of difference
`N`	`[1]`	a count	**measured**
`N_eff = 1 + (N-1)u`	`[1]`	a count	**derived**; **not a Hill number** (Section 3.6)
`F = ln N_eff`	`[1]`	nats	**derived** dimensionless: a logarithm of a count
`Q`	`[Q]`	proxy units of stored order	**measured** in whatever the declared proxy counts
`G = e^{Q}`	—	**undefined unless `Q` is dimensionless**	see the note below
`delta`	`[1]`	per period	**measured** dimensionless fraction
`eta`	`[Q]` per nat per period	proxy units per nat per period	**measured**; not dimensionless
`C`	`[Q]` per period	proxy units per period	**measured**
`q`	`[1]`	none	**defined** fraction of an enumerated outcome set
`H_forbid = -ln q`	`[1]`	nats	**derived** dimensionless

Symbol	Dimension	Unit	Status
`SS = 1 − RMSE_m/RMSE_b`	`[1]`	none	**derived**; both RMSEs must be on the same variable at the same points

Does everything balance? `S = k ln(I/I_0)` balances because `I/I_0` is dimensionless and `S` inherits `k`. `psi = k'(I/I_ref)^a` balances **only if `I` is first expressed as a ratio to a reference**; `I^a` for non-integer `a` is dimensionally improper otherwise, and the omission of `I_ref` in casual statements of the power law is a real error that changes `k'` and hides the reference. `F = ln(1 + (N−1)u)` balances because `u` and `N` are both dimensionless.

Two silences are recorded rather than filled. First, `S` has **no operational unit** independent of the procedure that constructs it; under the just-noticeable-difference construction its unit is a JND, under magnitude estimation it is a modulus set by an instruction, and the two are not the same unit. Second, and more consequentially, **`G = e^{Q}` is dimensionally well formed only if `Q` is dimensionless.** `Q` is stored order in proxy units, so `e^{Q}` exponentiates a dimensioned quantity, which is FM7 committed by this framework's own equation. The repair is to read `G` as `e^{Q/Q_u}` with `Q_u` the proxy's unit, so that `G` is the dimensionless effective count the derivation of Section 5 treats it as; **the source is silent on this and it is stated here as a silence rather than quietly assigned.** The arithmetic is unaffected because `Q_u = 1` in the declared proxy, but the equation as written is not dimensionally clean and a reviewer would be right to say so.

Identifiability of the constants. Three cases, and they differ. Under Fechner, **`k` and `I_0` are not separately identifiable from `S` alone**, since `k ln(I/I_0) = k ln I − k ln I_0` and a change in `I_0` is absorbed by an additive offset; only `k` and the offset are recoverable, and `I_0` must be fixed by an independent threshold measurement. **This is why the law must be fitted to discrimination data rather than to ratings.** Under Stevens, `a` is identifiable from the log-log slope and is robust, while the response modulus `k'` is not separately identifiable, because any rescaling of an observer's number use rescales it; **`a` is the reportable parameter and `k'` is a procedural artefact**, which is a fortunate asymmetry, since the physically meaningful quantity is the identifiable one. For the discriminable-step count `N_jnd = ln R / ln(1+c)`, both parameters come from independent measurements — `c` from discrimination and `R` from threshold and saturation determination — so it is **fully identifiable**, which is unusual enough here to be worth marking.

20.14.2 14.2 The postulates

P1 — A continuous map on the positive reals satisfying `S(xy) = S(x) + S(y)` is `S(I) = k ln I`, uniquely up to `k`. *Status:* **CITED** — the continuous solution of Cauchy's logarithmic functional equation; characterisation results of this form, identifying which axioms force a logarithm, are collected in Aczél et al. [1974], and the parallel uniqueness argument for the entropy functional is Khinchin [1957].

P2 — The just-noticeable difference is a constant fraction of the stimulus over a modality's mid-range: `dI/I = c`. *Status:* **CITED** — Weber [1834, 1978], with the mid-range restriction and the edge failures reported as part of the finding.

P3 — All just-noticeable differences are subjectively equal. *Status:* **POSTULATED** — this is Fechner's postulate [Fechner, 1860]. It does not follow from P2, it is not testable in isolation, and it is used at exactly one place in the chain below. **The results R1, R2, R3 and R7 do not consume it.**

P4 — The surplus functional is `f(u) = ln(1 + (N−1)u)` on `u` in `[0,1]`, `N >= 2`. *Status:* **DEFINITION** — the model form adopted by this framework under four axioms, one of them the declared design axiom that the effective count be affine in `u` [Curzi, 2026]. It carries no empirical weight on its own.

P5 — `ln(ab) = ln a + ln b` and `ln(a/b) = ln a − ln b` for positive `a, b`. *Status:* **ARITHMETIC.**

P6 — For a strictly concave `f` and a non-degenerate distribution, `E[f(U)] < f(E[U])` (Jensen). *Status:* **ARITHMETIC** — standard, and `f` is strictly concave here by P4.

P7 — The empirical content of a postulate admitting a fraction `q` of an enumerated outcome set is `H_forbid = −ln q` nats. *Status:* **POSTULATED** — this framework's own construction. Popper [1959], Lakatos [1970], Platt [1964] and Meehl [1967] support the underlying idea that content is what a theory forbids; **none of them states this formula.** It is used at exactly one place, R7, and nothing else in the chain depends on it.

P8 — The time-average growth rate of a multiplicative process is logarithmic in the accumulating quantity. *Status:* **CITED** — Peters and Gell-Mann [2016]. It is the alternative warrant of Section 3.3 and is consumed only by the claim that the framework's logarithm survives the failure of P3.

20.14.3 14.3 The compounding chain

Every line is checkable from its own stated inputs.

```
P1              -> R2   S(I_1 I_2) = S(I_1) + S(I_2) and continuity force
                        S(I) = k ln(I/I_0); unique up to k.              CITED (aczel1974shannon)

P2 + P3         -> L1   dS = k dI/I.                                     POSTULATED (via P3)

L1              -> L2   integrating, S = k ln(I/I_0); the 200,000-rectangle
                        midpoint sum on [1,100] returns 4.605170176
                        against ln 100 = 4.605170186, error 1.02e-08.    ARITHMETIC

P4 + P5         -> R1   ln(1+(N-1)u) = ln((N-1)(u + 1/(N-1)))
                                     = ln((u+u_0)/u_0), u_0 = 1/(N-1).   ARITHMETIC

R1              -> L3   at u = u_0: N_eff = 2 and F = ln 2 = 0.693147,
                        for every N.                                     ARITHMETIC

P4              -> L4   f'(u) = (N-1)/(1+(N-1)u), so f'(0) = N-1,
                        f'(1) = (N-1)/N, and f'(0)/f'(1) = N exactly.    ARITHMETIC

P4 + P5         -> R3   exponentiating Q_{t+1} = (1-d)Q_t + eta S_t - C_t
                        with e^{S} = N_eff gives
                        G_{t+1} = G_t^{1-d} (N_eff)^{eta} e^{-C};
                        G_inf = ((N_eff)^{eta} e^{-C})^{1/d}.            ARITHMETIC on a DEFINITION

P4 + P6         -> L5   E[F(U)] < F(E[U]); at N = 5 and the corpus's
                        U = 0.6019, F(E[U]) = 1.226008 against a
                        reported mean E[F(U)] = 1.1498, a gap of
                        0.0762 nats.                                     ARITHMETIC (data CITED, ccp:CCP-0

P3 + a          -> R4   at a = 0.33, 1.20^0.33 = 1.06201 (+6.201%,
                        31.0% of the promise) and 1.20^(1/0.33) = 1.7376
                        (+73.76%).                                       ARITHMETIC on a CITED exponent

R4              -> R5   core x0.80 gives −7.10%, perimeter x1.50 gives
                        +14.32%, gap −26.09% -> −9.06%, energy
                        0.6(0.80)+0.4(1.50) = 1.0800.                    ARITHMETIC

P7              -> R7   q = 1 gives 0 nats; q = 0.5 gives ln 2; content
```

```
                        adds under independent conjunction.              POSTULATED

stipulated data -> R6   25.10/10.00 = 2.5100 and 98.00/39.20 = 2.5000,
                        agreeing to 0.40%, against 4^0.6569 = 2.4859.    ARITHMETIC on stipulated data
```

What the chain establishes and what it does not. R1, R3, L3 and L4 are arithmetic consequences of one definition (P4) and elementary algebra (P5); **they are certain and they are about a function, not about the world.** R2 is a cited theorem about a functional equation. R4 and R5 are arithmetic on a cited exponent and are only as good as that exponent, which is a procedure-dependent point estimate with no interval (Section 9.9). R6 is arithmetic on a **stipulated** series and demonstrates a procedure rather than measuring anything. R7 consumes P7, which has no external support at all. **And the whole Fechner branch — L1 and L2 — consumes P3, a postulate that cannot be tested in isolation and that the historical record has partly refuted (Section 9.5).** A chain whose load-bearing steps are DEFINITION, ARITHMETIC and CITED delivers mathematics with certainty and delivers nothing whatever about rooms or people.

20.14.4 14.4 Three checks a reader can do in two minutes

The identity. Take `N = 12`, so `u_0 = 1/11 = 0.09090909`. At `u = 0.05`: `ln(1 + 11 x 0.05) = ln(1.55) = 0.438254930931`, and `ln((0.05 + 0.0909091)/0.0909091) = ln(1.55) = 0.438254930931`. Identical, because the second expression *is* the first with `(N-1)` factored out. **ARITHMETIC.**

The marginal ratio. At `N = 12`, `f'(0) = 11` and `f'(1) = 11/12 = 0.916667`, so `f'(0)/f'(1) = 12 = N`. Repeat at `N = 5`: `f'(0) = 4`, `f'(1) = 4/5 = 0.8`, ratio `5`. **The ratio of first to last marginal value is the category count, exactly, for every `N`. ARITHMETIC.**

The equal-step ratio. At `N = 12`, the values of `(u + u_0)` at `F = 0, 0.5, 1.0, 1.5, 2.0` are `0.090909, 0.149884, 0.247117, 0.407426, 0.671732`. Successive ratios: `1.648721` four times, which is `e^{0.5}`. **Equal perceived steps are equal ratios of `(u + u_0)`, and the fifth step would require `u = 1.016590 > 1` and is therefore impossible rather than expensive. ARITHMETIC.**

20.14.5 14.5 Limits, asymptotics, and the model's valid domain

`I -> 0`. Under Fechner, `S -> -infinity`: the register has no floor, which is why an absolute threshold `I_0` must exist and why the domain is restricted to `I >= I_0`. Under Stevens, `psi -> 0` for `a > 0`, so the power law has a floor at zero; the standard repair near threshold is `psi = k(I - I_0)^a`. **The two laws differ qualitatively at this boundary and the difference is observable.**

`I -> infinity`. Both diverge. Neither divergence is real: modalities saturate, and in pain-adjacent modalities the tissue is damaged rather than the sensation extended. **Both are mid-range laws and their own limits announce it.**

`c -> 0`. `N_jnd = ln R / ln(1+c) -> infinity`: infinitely fine discrimination gives infinitely many categories, correct in the model and correctly impossible in fact. **`c -> infinity`.** `N_jnd -> 0`: an observer who cannot discriminate has one category. **`R -> 1`.** `N_jnd -> 0`: no range, no steps. `N_jnd = 1` at `R = 1 + c` recovers the definition of the just-noticeable difference as a fixed point, which is a consistency check rather than a discovery.

`k -> 0`. All percepts collapse to zero: no discrimination. **`k -> infinity`.** Every difference becomes infinite: no constancy. Both are real failure modes of sensory systems.

`u -> 0`. `N_eff -> 1` and `F -> 0`: every category duplicates every other and the roster has left the arithmetic. **`u -> 1`.** `N_eff -> N`, `F -> ln N`, the ceiling is attained and no further gain is available from geometry.

`N -> 1`. `u_0 = 1/(N-1) -> infinity` and `F(u) = ln(1 + 0) = 0` for every `u`. **A single category has zero available surplus, not a small amount**, and the threshold has diverged: with one category there is no difference that could register. **`N -> infinity`.** `u_0 -> 0` and any non-zero difference produces unbounded surplus while `f(0)` stays exactly zero, so `f` approaches a step

function. **The limit is a pathology, not an ideal** (Section 6.2): an observer with infinitely fine discrimination is maximally unstable rather than maximally perceptive.

`a -> 0.` `psi -> k'`: a modality with no sensitivity to intensity, approached by some quality dimensions. **`a -> 1.`** The register's corrections vanish and differences behave like differences; visual length sits here and the design advice of Section 7 does not apply to it. **`a > 1.`** Every sign in Section 7 reverses.

`q -> 1.` `H_forbid -> 0`: a postulate that forbids nothing says nothing. **`q -> 0.`** `H_forbid -> infinity`: a postulate forbidding everything but one outcome, maximally informative if true and nearly certain to die on first contact. **The divergence is real and nameable.**

Stated domain. The register results of this paper hold for `I` in `[I_0, I_sat]` with the mid-range restriction of P2; for `u` in `[0,1]` and `N >= 2`; for exponents measured on a stated physical quantity under a stated procedure; and for `q` in `(0,1]` over an enumerated and published outcome list. Outside those the expressions still evaluate and should not be interpreted.

20.14.6 14.6 Invariance

The register claim is an **invariance claim** and is worth stating as one. Under Fechner the invariant is `S(aI) − S(I) = k ln a`, **independent of `I`**: equal stimulus ratios produce equal sensation differences everywhere on the scale. Under Stevens the invariant is `psi(bI)/psi(I) = b^a`, **independent of `I`**: equal stimulus ratios produce equal sensation ratios everywhere. **The two invariances are different and are experimentally distinguishable**, and Section 12.3 distinguishes them: the observed pair of response ratios is invariant to 0.40 per cent across an eightfold change of absolute level, which the Fechnerian invariance does not predict.

The transformation group under which the framework's own quantities are invariant is the rescaling of the world quantity. `u`, `N`, `N_eff`, `F` and `delta` are dimensionless and unchanged under `I -> cI`; `Q`, `eta` and `C` carry the proxy's unit and rescale with it. **Two systems may be compared directly on `u`, `N` and `delta` and may not be compared on `Q`, `eta` or `C` unless they declare the same proxy.**

How many scales the invariance has been tested at, here. Two, in Section 12.3, both on the same constructed series: the pairs `(1.00, 4.00)` and `(8.00, 32.00)`, separated by a factor of eight in absolute level, over a total range of 2.107 decades. **That is two levels, one continuum, one constructed dataset, and no independent replication.** Anything that would break it is likewise listed: a range change large enough to move the exponent [Teghtsoonian, 1971], a modulus at an extreme, an unrandomised presentation order, or a bounded response instruction.

20.14.7 14.7 Analogy discipline, and the precision of the numbers

The geometric accumulator is a change of coordinates, not a derivation from physical premises. `G_{t+1} = G_t^{1−delta}(N_eff)^{eta}e^{−C}` and `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` are the same equation written in two ways, related by `G = e^{Q}`. It is a **shared mathematical form**, and the agreement to fourteen significant figures is a numerical identity check on that change of variables. **No physical result's authority transfers, and the agreement is not evidence.**

The Lens Theorem's mathematics is a derivation; its application to perception is a conditional whose antecedent is empirical. The distinction is maintained throughout and is the subject of honesty clause 1.

The identity between the surplus functional and Fechner's law is an interpretive correspondence. Two formalisms have the same shape; no theorem connects the axioms of one to the experiments of the other. Under the badge taxonomy of Section 8.3 it carries no evidential weight, and Section 6.1 says so where the identity is stated rather than here.

Entropy, where it appears near `ln N`, is Shannon entropy [Shannon, 1948] — a dimensionless information measure in nats — and not thermodynamic entropy, which carries

`[energy][temperature]^-1`. They are different objects and the framework identifies surplus with neither.

Precision. The numbers here are of four kinds and are quoted accordingly. *Defined or derived-from-defined* — `ln 2 = 0.693147`, `ln 12 = 2.484907`, `e^{0.5} = 1.648721`, the identity table of Section 6.1, `f'(0)/f'(1) = N` — are exact to the precision printed and may be recomputed further. *Arithmetic on stipulated parameters* — every entry in Sections 7, 12.1 and 12.2 — records the arithmetic and **carries no measurement uncertainty because there was no measurement.** *Cited point estimates* — every Stevens exponent — carry no interval **because none is available from the sources as reproduced**, and they are known to vary with range, modulus, instruction and observer by amounts comparable to the design differences computed from them [Teghtsoonian, 1971, Poulton, 1979, Stevens, 1975]. *Fitted* — the exponent `0.6569` and the `R^2` of `0.999932` in Section 12.3 — are fitted to a **constructed** series and are illustrative in exactly the sense above; the AIC, BIC and cross-validated errors reported beside them are model comparisons on that same constructed series and establish which model describes it, not which model describes any modality.

20.15 15 Limitations

All three worked cases are constructed and none is evidence. No dataset was collected for this paper. The reading room's dimensions, illuminances and complaints are stipulated; the postulate case's block means and its 40-day series are stipulated, the latter explicitly synthetic with a declared generating rule; the magnitude-estimation series is stipulated. **They demonstrate that the procedures run and that they report their own failures. They are not evidence about any room, any person or any modality and must never be cited as such.**

The title claims more than most of the paper needs. Section 3.3 sets this out and it is repeated here because it is the paper's largest single exposure. The corpus needs a logarithm. Peters and Gell-Mann [2016] supply one from multiplicative dynamics with no psychological premise; Fechner [1860] supplies one that requires the perceptual story to be true and is contested [Stevens, 1957, Poulton, 1979, Luce, 2002, Narens, 1996]. **The framework's central formal claims — the surplus functional's form, the storage law's world-coordinate reading, the concavity result, the threshold — rest on the axiomatic route [Curzi, 2026] and the dynamical route [Peters and Gell-Mann, 2016], and would survive Fechner's complete failure.** Only Section 7's design advice needs Fechner and Stevens, and there the contest between them is a live cost rather than a historical curiosity, because the two theories give different exponents and the design numbers are computed from the exponent.

The paper's one discriminating test comes out against the logarithm. Section 12.3's ratio-invariance test succeeds, and its success is the power law's invariant rather than the logarithm's; the model comparison on the same series favours the power law over the better logarithmic form by `Delta AIC = 26.57` at equal parameter count. **On a constructed series, on one continuum — but in one direction, and the direction is against Fechner.**

The functional form of the surplus law is underdetermined by the evidence. A sub-linear power law [Latané, 1981] and `n log n` [Briscoe et al., 2006] fit the qualitative facts as well as `ln(1 + (N−1)u)` does. **Nothing in this paper or, so far as it reports, in this corpus discriminates among them.** The logarithm is chosen for its axiomatic characterisation, one of whose axioms is a declared design choice [Curzi, 2026], and is not established by measurement.

`N_eff = 1 + (N−1)u` is not a Hill number and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` the Hill number of order one, both fully grounded [Hill, 1973, Jost, 2006]; `1 + (N−1)u` is a linear interpolation between 1 and `N` and is this framework's own construction. The `N_eff` in result R3 and throughout Section 5 is the latter. **A reviewer reaching for the Hill-number literature as support will find that it does not apply.**

The empirical-content measure has no external support and is not identifiable in general. `H_forbid = −ln q` is this framework's own construction, badged POSTULATED in Section 14.2. Two analysts enumerating outcomes differently assign different `q` to the same postulate, so the

measure is identifiable only relative to a published outcome list; a defensible measure over an outcome space is almost never available; and **whether the heuristic actually improves the return on a testing budget is itself untested.** The test is stated in H5 and has not been run.

The conjoint-measurement conditions were not tested. Michell [1997] argues that psychology systematically fails to test whether its attributes are quantitative before measuring them, and that objection applies with full force to the treatment of subjective magnitude here, to `u`, and to comfort. The remedy is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971] or a Rasch-model demonstration [Rasch, 1960]; **neither was run.** Section 12.3's ratio-invariance test is this framework's own substitute and it is a weaker instrument: it tests one consequence of ratio structure at two levels on one continuum, and passing it is consistent with a representation that conjoint measurement would reject. **The ratio-scale treatment in this paper is provisional and is a stipulation.** The corpus's own route to earning it is priced in Curzi [2026t], and its standing demotion rule — that a formula containing a division and a multiplication is demoted to a heuristic ordering when its inputs are ordinal — is Curzi [2026m].

The Stevens exponents carry no uncertainties. Every design number in Section 7 is computed from a cited point estimate. Those estimates vary systematically with stimulus range [Teghtsoonian, 1971], with modulus, instruction and direction [Poulton, 1979], and across observers by a substantial fraction of their value [Stevens, 1975]. **The sources as reproduced here supply no intervals, so none is quoted, and a design decision resting on the difference between an exponent of 0.33 and one of 0.40 is not supported by anything in this paper.** S35 requires re-measurement before calibration for exactly this reason.

The reading room's premise is a stipulation. No entry in this framework's bibliography establishes a quantitative relation between illuminance, zone contrast and occupant complaint. The nearest support is design literature on how the distribution of light within a room conditions its use [Alexander et al., 1977], which is not a measured relation. **The case demonstrates a budgeting procedure; it does not demonstrate that the procedure predicts complaints.**

Model comparison was performed at one place only, and out-of-sample performance is reported at one place only. Section 12.3 reports SSE, `R^2`, AIC, BIC, free-parameter counts and leave-one-out cross-validated error for three models on eight points. **Eight points is a small sample for leave-one-out cross-validation and the AIC correction for small samples widens materially at `n = 8`.** Nothing else in this paper is fitted, so no information criterion applies elsewhere; and the corpus's one applied fit reports held-out RMSE against baselines and **no AIC or BIC**, so its parameter count was never paid for and its 2.8 per cent margin over a two-parameter AR(1) may not be a margin at all [Curzi, 2026i].

No effect size in this paper carries an interval. The standardised effect of 1.7347 in Section 12.2 is computed on stipulated means and standard deviations; there is no sampling distribution behind it because there was no sample. A real application owes intervals, and reporting a standardised effect without one is exactly what Section 14.7's precision rule forbids for measured quantities.

Single-observer scope, and the circular instrument. Section 12.2's case has the observer and the analyst as one person, which is failure mode FM14 in its hardest form; the prescribed separation of channels was not achieved. Its conclusions are indexed to one observer and may not be stated in the third person (S22).

The reflection problem is not answered. Where the framework's storage reading is applied to a group whose members both influence and constitute the aggregate, the endogenous effect is not identified from observational data [Manski, 1993], and influence and selection are generically confounded in network data [Shalizi and Thomas, 2011]. **This paper adopts no remedy** — not randomisation, not an instrument, not partial-population variation, not a stipulated and defended reference group [Brock and Durlauf, 2001] — so every such claim here is a **modelling position rather than an identified empirical result.**

The Lucas critique applied to this framework's own parameters. The framework asserts that a description can become true by being used [MacKenzie and Millo, 2003, Hacking, 1995] and then treats its own exponents, thresholds and decay rates as stable. **Both cannot hold**

without qualification. The position taken here is narrow: the parameters are treated as stable only over a declared window and only while the quantity is not itself a reported target, and where it is reported upward the framework's own reflexivity applies to it and the constancy assumption fails [Lucas, 1976]. That is a restriction on where the model may be used and it is stated as one. The measured size of the reflexive effect is also much smaller than the framework's use of it implies [Jussim and Harber, 2005, McCambridge et al., 2014].

Self-report is exposed on three separate fronts. Causal reports about one's own processing are frequently constructions [Nisbett and Wilson, 1977]; question wording, scale range and order shape the answers [Schwarz, 1999]; and any rating of a named component of well-being is contaminated by the focusing illusion [Kahneman et al., 2006]. Section 8.7 answers the first by changing what a report is used for; **it does not answer the second or the third**, and any survey built on this framework inherits both.

Aggregation and ergodicity. The behaviour of a population is not in general the behaviour of any individual in it [Kirman, 1992], and the time average of a multiplicative process differs from its ensemble average [Peters, 2019]. **A framework whose stored quantity accumulates over time for one system, and whose parameters would naturally be estimated from a cross-section, is exposed to both, and the exposure is not addressed here.**

No independent replication of anything. Every number in this paper was produced by one author from one framework, and every applied number elsewhere in this corpus was likewise surveyed or constructed by one author. The reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005]. Meehl [1967]'s observation that directional predictions are almost costless in the social sciences is answered here by point predictions with constants — Section 12.1 predicts `+14.32%` and `−7.10%` and puts them at risk — but **no such prediction in this paper has yet been tested against an observation.**

What would falsify the account. H1 fails on a modality showing a constant absolute just-noticeable difference over its mid-range. H2 fails if response ratios depend on absolute level, or if a bounded rating scale reproduces the invariance as well as an unbounded instruction. H3 is an algebraic identity and fails only on a computational error. H4 fails if post-occupancy magnitude estimation returns a perceived change matching the physical percentage rather than the exponent-converted one, in a modality whose exponent has been measured under the application's own conditions. H5 fails if preregistered high-content postulates do not repay a fixed budget better than low-content ones. H6 fails if a shuffled-input control leaves held-out error near its unshuffled value while the other baselines are beaten.

20.16 16 Conclusion

R1. The framework's surplus functional is a Fechner law. Setting `u_0 = 1/(N−1)`, `f(u) = ln(1 + (N−1)u) = ln((u + u_0)/u_0)` identically on `u` in `[0,1]` for every `N >= 2`, so `u_0` is an absolute threshold of difference, `N_eff(u_0) = 2` and `F(u_0) = ln 2` for every `N`, and the ratio of first to last marginal value is `f'(0)/f'(1) = (N−1)/((N−1)/N) = N` exactly. **The identity is algebra, not evidence: it shows that an axiomatic route and a psychophysical route arrive at one function, and it shows nothing about whether either is correct.**

R2. The Lens Theorem: if the map from world quantity to perceived magnitude is continuous and satisfies `S(I_1 I_2) = S(I_1) + S(I_2)`, then `S = k ln(I/I_0)`, uniquely up to `k`. **The inference is a theorem; the badge is on the antecedent.** Verified numerically by a 200,000-rectangle midpoint sum of `1/I` on `[1, 100]` returning `4.605170176` against `ln 100 = 4.605170186`, absolute error `1.02e−08`.

R3. In world coordinates the storage law is a weighted geometric accumulator, `G_{t+1} = G_t^{(1−delta)} (N_eff)^{eta} e^{−C}` with `G = e^{Q}` and `G_inf = ((N_eff)^{eta} e^{−C})^{1/delta}`, agreeing with the additive form to fourteen significant figures. Decay is taking a root, conversion is exponentiation, cost is a divisor. **`N_eff` here is `1 + (N−1)u` and is not a Hill number. This is a change of coordinates and the agreement is an identity check, not evidence.**

R4. The linear-promise prohibition, quantified. At a brightness exponent of 0.33 a promised and delivered `+20%` illuminance yields `1.20^0.33 = 1.06201`, that is `+6.201%` perceived — **31.0 per cent of the promise** — and delivering a genuine perceived `+20%` requires `1.20^(1/0.33) = 1.7376`, a **73.76 per cent** load increase. **Never promise a linear improvement in a logarithmic quantity.** The exponent is a cited procedure-dependent point estimate without an interval.

R5. The reading-room budget: core 500 to 400 lux costs `−7.10%` of perceived brightness, perimeter 200 to 300 lux buys `+14.32%`, the zone gap closes from `−26.09%` to `−9.06%`, and energy moves by `0.60(0.80) + 0.40(1.50) = 1.0800`, that is `+8.00%`, inside a declared 10 per cent cap. **The complaint was the gap and the gap was closed by taking light away from the place that had most of it.** The case is constructed and the illuminance-to-complaint premise is a stipulation.

R6. The ratio-invariance test as the licence for a ratio scale. Two fourfold physical steps at absolute levels separated by a factor of eight returned response ratios of `2.5100` and `2.5000`, agreeing to `0.40%`, against a prediction of `4^0.6569 = 2.4859` from the fitted exponent. **The invariance is the power law's, not the logarithm's**: on the same series the power law is preferred over the better of two logarithmic forms at equal parameter count by `Delta AIC = 26.57`, with a leave-one-out cross-validated error thirty times smaller than the plain logarithm's, and the logarithmic forms predict a spread between the two response ratios of 48 to 85 per cent against the observed 0.40 per cent. **A ratio-invariance test that succeeds is evidence for Stevens and against Fechner, and the corpus's surplus functional keeps its logarithm because that logarithm never rested on Fechner** [Curzi, 2026, Peters and Gell-Mann, 2016].

R7. The empirical content of a postulate over an enumerated and published outcome set is `H_forbid = −ln q` nats, where `q` is the admitted fraction: a postulate that forbids nothing buys zero nats, halving the admitted outcomes buys `ln 2 = 0.6931` nats, and content adds under independent conjunction. A postulate at `q = 0.9` buys `0.1054` nats for a full experiment against `2.9957` nats at `q = 0.05`, twenty-eight times the return for the same expenditure. **The formula is this framework's own, badged POSTULATED, supported by no external source, and the claim that it improves the return on a testing budget is untested.**

CR (counter-result). The worked postulate of Section 12.2 was **refuted on one of its four declared consequences**, at a standardised effect of 1.73 pooled standard deviations against a pre-set tolerance of 0.50 — **three times the tolerance, in the forbidden direction** — and was amended in public rather than withdrawn, with the amendment adding forbiddance rather than removing it. A fourth consequence was recorded as untested rather than folded into the supported column. And the log-log fit of Section 12.3, with `R^2 = 0.999932`, is **explicitly declared insufficient** to exclude a logarithmic law over two decades, since over two decades a logarithm captures 96.3 per cent of a power function's variance; the ratio-invariance test, the residual pattern and the information criteria carry the conclusion, not the fit statistic. **The general form of that concession is the one downstream papers should quote: a fit statistic computed over the range in which two candidate models agree distinguishes nothing, whatever its value, and the corpus's own surplus functional is currently in exactly that position with respect to a sub-linear power law and `n log n`.**

20.16.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the parameters and equations printed in the text and can be re-derived from them. The reading room of Section 12.1 is a constructed design case with stipulated dimensions, illuminances and complaints. The block means and the 40-day series of Section 12.2 are a stipulated worked case, the latter explicitly synthetic with the generating rule and seed policy stated in the text. The eight-point magnitude-estimation series of Section 12.3 is a stipulated worked case and is not data from any observer; the exponent, `R^2`, residuals, ratio-invariance figures, AIC, BIC and leave-one-out errors reported from it are computations on that constructed series. The

Stevens exponents in Sections 3.4, 7.2, 7.3 and 9.3 are **nominal published figures reproduced from the psychophysical literature for orientation**, not measurements made here. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the equations of Sections 3 to 9.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi derived the results, performed the model comparison of Section 12.3, produced the worked cases and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The observer in Section 12.2 is constructed and the twenty observers in Section 12.3 are stipulated; neither exists. The decline paths required by S25 and S36 — that any person asked to supply readings may stop at any point, without a reason and without cost, and is told so before the first trial — are design constraints on prospective work and are not a report of any study performed.

Preregistration

This paper reports one preregistered test of its own and it failed. The four consequences D1 to D4 of the postulate in Section 12.2, and the forbiddance list F1 to F4 with its numerical tolerances, were declared before the observations were taken. **F2 was triggered: consequence D2 was falsified at 1.73 pooled standard deviations against a declared tolerance of 0.50, three times the tolerance, in the forbidden direction.** No tolerance was moved after the observations were examined. The postulate was amended in public under the rule of Section 11.2, with the amendment adding a specific and testable forbiddance — ordering and concavity of recovery across three break lengths — rather than removing one, and the amended clause is recorded as **untested**, as is consequence D4, which was never exercised because start time was not varied. **The worked case that produced this result is constructed, so the failure demonstrates that the protocol reports failures rather than establishing anything about breaks or about mornings.**

The design predictions of Section 12.1 — `+14.32%` at the perimeter, `−7.10%` at the core, and a gap closing to `−9.06%`, with a declared tolerance of `±0.05` nats on the perimeter figure — are stated as a preregistration for a measurement that **has not been performed**. Nothing in this paper reports its outcome.

The corpus's protocol for preregistering and freezing a fit of the storage law, together with the confirmatory application that **failed** its own second falsification rule at a 2.8 per cent held-out advantage over a matched AR(1) against a declared 10 per cent margin, is Curzi [2026i]. Any applied claim resting on this paper inherits that result.

20.17 Appendix A — Stating one's own subjective structure as a postulate

The protocol executed in Section 12.2, stated in general form. It is the single-observer version of the survey protocol [Curzi, 2026i] and is meant to be run rather than admired.

Step A — Write the belief in its native, unusable form. Whatever is actually said internally: "I am sharpest in the morning"; "I need conflict to think clearly"; "social events drain me." Write it exactly as it is said. **The gap between this sentence and the one the protocol finishes with measures how much was being assumed without notice.**

Step B — Name the hidden quantity. In each of those sentences one unobservable does all the work — sharpness, clarity, drain. Name it, give it a symbol, and stop using the word.

Step C — State its structure. The postulate proper. It must answer four questions: what kind of quantity is it, a level or a rate or a capacity; does it have a true zero; what makes it move; and what observable does it touch. Badge it (S13) and date it (S14).

Step D — Derive at least three consequences, one of which must be uncomfortable. A consequence one would be glad to observe is worth little, because it will be found whether or not it is there. **The uncomfortable consequence carries the content.** Apply the asymmetry check of S17 to each: write down what the *negation* of the postulate would predict, and delete any consequence the negation also produces.

Step E — Write the forbiddance list, before observing (S15). For each consequence, the specific observation that would contradict it, with numbers and tolerances where numbers are available, in terms executable by a person who does not know the hypothesis (S16).

Step F — Choose the instrument and the sample size before observing (S20). Then observe, then stop and compute. **The stopping rule is part of the design**; choosing when to stop after seeing the data is the commonest way a personal experiment becomes theatre [Simmons et al., 2011].

Step G — Report in the same words that would be used to report to a stranger (S24). The gap between the two sentences is the size of the self-deception; record it in the ledger (S19).

Two structural defences apply throughout and are not optional at single-observer scope. **Delegate the classification** to someone blind to the hypothesis wherever the forbiddance list requires a judgement, because an operational definition requiring the author's own judgement to apply is elastic (FM17). And **precommit the response**: write down in advance the change of practice that follows from the postulate's death, so that death has a defined and survivable consequence.

A postulate about one's own interior is legitimate exactly when the observation that would end belief in it has been written down before looking — and then looked for. Everything else in this protocol is machinery for making that one sentence executable.

Chapter 21

The Internal Surplus and the Self as Storage: Auditing One Observer's Framings, and the Stored-Error Track That Feels Identical From Inside

Abstract. We transpose the surplus law to a single observer, treating N framings held by one person as the ensemble whose non-parallelism u sets an audited framing count N_eff = 1 + (N-1)u and an internal surplus F_int = ln N_eff, bounded by ln N. Non-parallelism is estimated from error decorrelation as u = 1 - rho^2, and we prove the participation-ratio identity N_eff = N + 1 - N/PR. A six-framing worked case measures mean pairwise u = 0.6860, giving N_eff = 4.4298 and F_int = 1.4883 nats, 83.07 per cent of the ln 6 ceiling; splitting the pairs by lineage shows within-lineage u = 0.2732 against cross-lineage u = 0.9611, a concentration the mean hides. Retiring two redundant framings and replacing them raised the audited count 25.4 per cent at unchanged reconciliation load. The central negative result is that this correct geometric work did not reverse the subject's decline: eta*F rose from 0.8930 to 1.0289 against delta*Q + C = 1.0700, closing 77 per cent of the gap and leaving the account negative; only cost and stock reductions turned it. Sensitivity analysis makes the point structural: dh/dN = eta/N = 0.0038 is negligible while dh/deta = ln N = 2.197. The two-track ledger separates stored order from stored error, Z_t+1 = (1-delta)Z_t + eta(M_t - V_t), and a 25.93 per cent confabulated input yields 57.38 per cent of the steady-state stock. Baseline headroom was not robust to the declared cost weights and is reported as unestablished.

Keywords: internal surplus; effective framing count; error decorrelation; leaky integrator; stored error; conversion efficiency; headroom

Series: B. Engineering the Surplus **Paper:** CCP-021

21.1 1 Introduction

The surplus functional of this framework was introduced as a statement about groups: two people, two teams, two disciplines, and the difference between them. That presentation was a convenience of exposition. The functional is a theorem about two states in an inner-product

space, and its axioms quantify over states rather than over the persons who hold them. This paper takes the step that the presentation deferred, and asks what the same functional says when both states belong to one observer.

The answer is an **internal surplus**. Where an observer holds `N` distinguishable framings of a situation — ways of construing it, each with its own primitives, its own salient variables and its own inference rules — and those framings have mean non-parallelism `u`, the surplus available to that observer is

```
F_int = ln(1 + (N − 1) u),     N_eff = 1 + (N − 1) u,     0 <= F_int <= ln N
```

with `N_eff` the audited framing count. This paper's first task is to establish that the move is a substitution of domain rather than an analogy, and to state precisely what has to be assumed for the substitution to be legitimate. Its second task is to carry `F_int` into the storage law and to ask what a person accumulates. Its third, and the one the paper regards as its most useful finding, is to report that the geometric work — measuring `u`, restructuring a framing set, raising the audited count by a quarter — did **not** turn the worked subject's storage account around, because the binding constraint was never the geometry.

Four things are new here relative to the surrounding literature rather than relative to the framework. First, an operational estimator for `u` at internal scope that asks nobody to judge similarity: `u = 1 − rho^2`, with `rho` the Pearson correlation between two framings' *error* series on questions with later-observable answers. Second, an exact identity connecting the audited count to the Rényi-2 participation ratio of the framing ensemble's Gram matrix, `N_eff = N + 1 − N/PR`, which converts a chosen aggregator into a standard diversity statistic. Third, a two-track ledger separating what an observer stored from what the world actually supplied, with the stored-error recursion `Z_{t+1} = (1−delta) Z_t + eta (M_t − V_t)` whose equilibrium is independent of cost because the cost term cancels in the subtraction. Fourth, a sensitivity result that demotes the framework's most attractive-sounding lever: at the worked operating point, `dh/dN = eta/N = 0.0038` against `dh/deta = ln N = 2.197`, so adding categories of thought is the weakest available move by nearly three orders of magnitude.

The question matters because the failure this paper describes is invisible from inside. An observer whose framings have collapsed toward parallel does not experience impoverishment; they experience clarity, and the arithmetic prices that clarity at zero. An observer accumulating stored error does not experience unreliability; they experience confidence, because stored error and stored knowledge occupy the same variable and no term in the storage law inspects its own input. Both conditions are stable for years. Both are detectable only by an instrument that is deliberately built and deliberately kept.

The framework's static half — the surplus functional and its characterisation under four axioms, with the affine effective count as the one axiom that is chosen rather than derived — is presupposed rather than re-derived, and is established with its axiom set in Curzi [2026]. Its dynamical half — the storage law as a first-order leaky integrator with contraction modulus `1 − delta` and steady state `Q* = (eta S − C)/delta` — is presupposed from Curzi [2026a]. The headroom gauge `h_t = eta ln N − delta Q_t − C_t`, its three regimes, and the separate admissibility and sustainability constraints are presupposed from Curzi [2026b]. The reflexive loop `T(x) = W(x, M(x))`, on which Section 3.4's identification discussion turns, is presupposed from Curzi [2026] and is **not** restated here.

Sections 2 and 3 state the hypotheses and the formal framework, including the identification problem that governs every applied reading in the paper. Sections 4 to 6 develop the internal surplus: its marginal returns, its quadratic maintenance cost, the six mechanisms by which non-parallelism decays, and the five instruments that measure it. Section 7 develops the self-storage law and the two-track ledger. Sections 8 and 9 collect the design specifications and the named failure modes. Section 10 reports two worked cases end to end. Sections 11 to 13 discuss what follows, verify the chain against minimal postulates, and record what the account cannot support.

21.2 2 Hypotheses

The formal results in Sections 3, 4 and 7 are theorems about equations and cannot be falsified by observation; they are labelled as derivations where they appear. What can be falsified is the claim that these equations describe a real observer. The hypotheses below separate the two and each names the observation that would defeat it. **None of them has been tested.** The protocol that would test them — a preregistered fit, a frozen model, and held-out comparison against four declared baselines including a shuffled-input control — is specified in Curzi [2026i], whose own confirmatory application of it failed its second falsification rule: a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared 10 per cent margin.

H1 — The audited count predicts, and the nominal count does not. Internal surplus estimated from error decorrelation among an observer's framings predicts held-out judgement quality better than framing *count* alone. **Predicted:** held-out accuracy tracks `N_eff = 1 + (N−1)u` rather than `N`; in the worked restructuring of Section 10.1, `N` is unchanged at 6 while `N_eff` rises by a factor of 1.254, and the accuracy gain should follow the second number. **Falsified by:** framing count predicting as well as the audited count; or a shuffled-input control matching the model. If `N` alone does the work, the `u` term is decoration.

H2 — Reconciliation load is quadratic while surplus is logarithmic. The maintenance cost of holding `n` framings as framings rather than as a list grows with the number of pairs. **Predicted:** a net-value curve `V(n) = eta ln(1+(n−1)u) − c1 n − c2 n(n−1)/2` with an interior maximum; measured performance rises then falls in `n`, and the fall is steeper than a linear cost model predicts. **Falsified by:** measured performance flat in `n` over the tested range; or peaking where the model did not predict; or a linear cost term fitting as well as the quadratic one, in which case the pair-cost postulate is wrong at internal scope.

H3 — Non-parallelism decays geometrically without maintenance. Left alone, an observer's framing set collapses toward parallel at a roughly constant per-round proportional rate. **Predicted:** `u_t = u_0 (1 − lambda)^t`, with half-life `ln 2 / (−ln(1−lambda))` rounds; at `lambda = 0.20` and `u_0 = 0.60`, sixteen rounds take `F_int` from 1.3863 to 0.0811 nats and the audited count from 4.00 to 1.08. **Falsified by:** a measured `u` that is stationary under no maintenance; or that decays linearly rather than proportionally; or that recovers spontaneously.

H4 — Conversion, not category count, is the binding lever on personal headroom. The partial derivatives of `h = eta ln N − delta Q − C` order the four available interventions, and the ordering is stable across plausible parameter values. **Predicted:** `dh/deta = ln N`, `dh/dC = −1`, `dh/dQ = −delta`, `dh/dN = eta/N`; at the worked point these are 2.197, 1, 0.0317 and 0.0038, so a unit change in conversion buys about 585 times what a unit change in category count buys. **Falsified by:** an intervention on `N` producing a larger measured gain in capacity for new material than a matched intervention on `eta` in a system where both were measured.

H5 — Stored error accumulates and is not distinguishable from inside. An observer whose framing systematically exceeds what the environment supplies accumulates a stock of unearned structure that behaves exactly like earned structure in every internal report. **Predicted:** at matched moment `M`, an observer with higher measured over-framing ratio `r` accumulates more correction events per unit stored order, on a lag of order `tau = 1/delta`; in the worked case a 25.93 per cent confabulated input becomes 57.38 per cent of the steady-state stock. **Falsified by:** correction-event rate uncorrelated with `r` after controlling for `M`. If that holds, the two-track ledger has no content and should be deleted.

> **H6 — Retention channels compose multiplicatively.** Total retention is the product of the per-channel retentions, not one minus the sum of the per-channel losses. **Predicted:** `delta = 1 − prod_i (1 − delta_i)`; at the worked channel values 0.020, 0.008 and 0.004 the correct composite is 0.03172864 against a naive sum of 0.032, an overcount of 0.85 per cent, rising to 20.3 per cent at four channels of 0.15. **Falsified by:** a measured composite reliably closer to the naive sum than to the product, across systems in which the channels are separately measurable.

Three further claims in this paper are **not** hypotheses and are labelled accordingly. The **framing encoding** — that a way of construing a situation admits representation as a unit vector in a common inner-product space — is a **postulate**, stated in Section 3.2 and falsifiable only through its consequences. The **affine effective count** `N_eff = 1 + (N−1)u` is a **design axiom** of the framework, chosen and not derived [Curzi, 2026,c]. The identification of a person's stored order with a single non-negative scalar is a **modelling choice**, adopted for tractability and for the fixed-point guarantee, and Section 13 records what it costs.

21.3 3 Framework

21.3.1 3.1 What is presupposed

The surplus functional. For two unit state vectors `x` and `y` drawn from an ensemble of `N` categories,

```
F(x,y) = f(u(x,y)),   u(x,y) = 1 − (x . y)^2 = sin^2 theta   in [0,1]

f(u) = ln(1 + (N−1) u)
```

and `f` is uniquely characterised by four axioms — angle-only dependence (S1), zero at parallel (S2), an affine effective count (S3), and normalisation at orthogonality (S4) — as established in Curzi [2026]. **S3 is a design axiom: it is chosen, not derived**, and it is flagged wherever the paper leans on it. Uniqueness-under-axioms is a known genre of theorem rather than a novelty of this framework, and the argument should be read against the existing instances [Khinchin, 1957].

The object S3 defines is the **effective count** `N_eff = 1 + (N−1)u`, and surplus is `ln N_eff`: the logarithm of a headcount after the headcount has been audited for redundancy [Curzi, 2026c]. The effective-count idiom is standard in ecology and in political science, where `1/HHI` and `exp(H)` are the canonical members of the family [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. **It must be said plainly, and is said again in Section 13, that `1 + (N−1)u` is not a member of that family.** It is a linear interpolation between 1 and `N`, it is this framework's own construction, and no literature in ecology, economics, political science or information theory contains it. The Hill-number citations in this paper attach to `1/HHI`, to `exp(H)`, and — as Section 3.3 shows — to the participation ratio `PR`, where they are exact. They do not attach to `N_eff`. The concentration instrument that genuinely is a Hill number of order two — `HHI` as the sum of squared shares, with effective count `1/HHI` — is developed separately, where a four-share map returns a naive `HHI` of 0.293430 and 3.41 effective units against a bloc-collapsed `HHI` of 1.000000 and an effective count of 1.00 [Curzi, 2026]. **The two quantities must not be conflated.**

Derived from the axioms rather than assumed: strict monotonicity, positivity, strict concavity, subadditivity on the parameter `u`, and extremality, with `F = 0` if and only if the states are parallel and `F = ln N` if and only if they are orthogonal. The range `0 <= F <= ln N` makes `ln N` the hard ceiling on surplus per interaction and appears in every design inequality below. Extremality is stated on the *squared* alignment, which has the consequence that a pair in perfect opposition and a pair in perfect agreement both read `u = 0`, `N_eff = 1` and surplus zero [Curzi, 2026r]; Section 6.2 shows that this is exactly the behaviour the error- decorrelation estimator inherits.

Two independent warrants exist for the logarithm, and this paper needs only the weaker one. The first is Fechnerian: sensation proportional to the logarithm of a dimensionless stimulus ratio measured from a floor [Fechner, 1966, Stevens, 1957]. That warrant requires the perceptual story to be true, and the perceptual story is contested [Poulton, 1979]. The second is stronger because it assumes nothing psychological: the time-average growth rate of a multiplicatively evolving quantity is the expectation of its *logarithm* [Peters and Gell-Mann, 2016], so a logarithmic evaluation follows from the dynamics alone. Where a stock compounds rather than adds, the logarithm is the ergodic-average object. The ceiling `ln N` also has an information-theoretic reading as the maximum an ensemble of `N` equiprobable categories can carry [Shannon, 1948], and a control-theoretic one as requisite variety [Ashby, 1958] — though this framework does **not** identify surplus with Shannon entropy, and the reading is licensed to bound and not to explain.

The functional form is nevertheless underdetermined by the evidence, and the exposure is worse at internal scope than at group scope. At least two published alternatives fit the same qualitative facts: social impact rising as a power of the number of sources with an exponent below one [Latané, 1981], and network value growing as `n log n` rather than as `n^2` [Briscoe et al., 2006]. All three curves are decelerating, monotone and threshold-free. **Nothing assembled in this corpus discriminates between them.** Latané's law is the sharper embarrassment here, because it was established with psychological data on individual judgement — the very domain this paper claims — a decade before the physical analogies arrived [Nowak et al., 1990]. What the framework's form has that the alternatives do not is an axiomatic characterisation and an explicitly declared design axiom at the point where the choice is made; what it does not have is a discriminating measurement. Section 13 carries this as an open limitation, not a resolved question.

The storage law. The dynamical engine, presupposed from Curzi [2026a]:

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t
```

with `Q` stored order, `S` the per-period input bounded by `ln N`, `delta` the retention loss, `eta` the conversion efficiency and `C` the operating cost. The map is Lipschitz with modulus `1 − delta`, so `delta > 0` makes it a contraction with a unique start-independent steady state `Q* = (eta S − C)/delta` [Curzi, 2026a, Banach, 1922, Elaydi, 2005]. The quartet of a level, an inflow, an outflow and a delay is the standard vocabulary of system dynamics, formalised four decades before this framework [Forrester, 1961], and `Q`, `eta S` and `C` occupy exactly those roles. The headroom gauge, its three regimes, the maximum one-step increment `r_max = h_t`, and the separate admissibility and sustainability constraints are presupposed from Curzi [2026b].

21.3.2 3.2 The scope substitution, and the two postulates it costs

The claim is that applying the surplus functional inside one observer is a derivation and not an analogy. Here is what that requires and here is the check.

The four axioms quantify over **states in an inner-product space**. S1 makes `F` depend on the pair only through `u`; S2 sets `f(0) = 0`; S3 makes `g(u) = e^{f(u)}` affine in `u`; S4 sets `f(1) = ln N`. **Not one of the four contains a term referring to persons, agents, groups, or ownership of states.** They refer to states and to the geometry between them, so the theorem that follows is silent on who holds the states.

The theorem is scope-free. What changes between group scope and internal scope is not the theorem; it is the encoder. At group scope the encoder maps a person, a team or a discipline to a unit state. Here it maps a *framing* to a unit state. Everything downstream of the encoder is identical, because everything downstream is algebra on encoded states. That leaves exactly two things to badge, and they are badged rather than assumed.

> **THE FRAMING ENCODING [POSTULATE].** A framing — a way of construing a situation, with its own primitives, its own salient variables and its own inference rules

— admits representation as a unit vector in a common inner-product space, such that two framings that make the same predictions on the same inputs map to parallel states and two framings whose predictions are uncorrelated map to orthogonal ones.

THE INTERNAL ROSTER REDUCTION [POSTULATE]. For an observer holding `N` nominal framings, `N` is the number of framing categories the observer claims to span and `u` is a representative non-parallelism across the observer's framing pairs — normally the mean pairwise `u` over all `N(N−1)/2` pairs. `N_eff = 1 + (N−1)u` is then read as the audited framing count.

These are the internal-scope twins of the group-scope roster reduction [Curzi, 2026c] and they fail in the same way. **Because the triangle inequality fails for geometric triples, a mean pairwise `u` does not determine the joint geometry**, and an observer whose framings are pairwise moderately different may still have all of them lying in a two-dimensional subspace. The fifth instrument of Section 6.3 exists to catch this and is mandatory. The failure has an empirical counterpart that strengthens rather than weakens the warning: psychological similarity is measurably asymmetric and violates the triangle inequality [Tversky, 1977], so if `u` is read as a similarity measure over construals it cannot be assumed to behave metrically at all.

With those two postulates in place, `F_int = ln(1 + (N−1)u)` follows from the surplus functional by substitution and requires no further assumption. That is what "derivation, not analogy" means here, stated precisely enough to be attacked: **attack the encoder, not the algebra.**

An earlier expository formulation of this framework carried the same statement as an image — a tower whose windows face different ways, which sees more because of the facing and not because of the glass — together with a discipline of attention: notice which way each window faces before counting them. Under the encoding above the image becomes an equation term by term, and it is worth setting the correspondence out because it is exact rather than suggestive.

```
the one tower          ->   a single observer; a single Q; one storage account
a window               ->   a framing; one encoded unit state
which way it faces     ->   the state's direction in the framing space
many windows,          ->   large N, small u   ->   N_eff -> 1,  F_int -> 0
  one aspect
windows set wide       ->   large u            ->   N_eff -> N,  F_int -> ln N
the view from the      ->   F_int = ln N_eff, the audited log-count
  tower
```

The image's first teaching — that a tower is not improved by more glass facing the same way — is the extremality result: `F = 0` if and only if the states are parallel. Its second, that three windows set wide are worth more than a gallery, is strict concavity, and Section 4.6 prices it. The correspondence is exact because the same functional form stands on both sides; what the earlier formulation reached by observation, the axioms reach by proof from four premises, one of which is a design choice.

The extremal case is immediately recognisable as a clinical description. A person with forty ways of describing their situation, all of them the same description in different words, has `u = 0`, `N_eff = 1` and surplus `ln 1 = 0`. They will experience this as thoroughness. It is a single window with forty panes.

21.3.3 3.3 The participation-ratio identity

The roster reduction chooses the *mean pairwise* aggregator, and a reader is entitled to ask why that average and not another. The answer is that it is not an average of convenience.

Let `G` be the Gram matrix of the observer's `N` encoded framings, so `G_ij = x_i . x_j` and `tr G = N`. The Rényi-2 participation ratio of that Gram spectrum — the standard effective-count

statistic, used unchanged across physics, ecology and portfolio theory [Rényi, 1961, Hill, 1973, Jost, 2006] — is `PR = (tr G)^2 / ||G||_F^2`. Since `||G||_F^2 = N + N(N−1)(1 − u_bar)` when `u_bar` is the mean pairwise `1 − (x_i . x_j)^2`,

```
N/PR = 1 + (N−1)(1 − u_bar)

THE PARTICIPATION−RATIO IDENTITY     N_eff = 1 + (N−1) u_bar = N + 1 − N/PR
```

The audited framing count is exactly the participation-ratio diversity of the observer's own framing ensemble, reparametrised into the form the surplus law uses. Declaring the mean pairwise aggregator therefore commits the analyst to a standard, well-understood diversity measure rather than to an improvisation, and the defence is arithmetic rather than rhetorical. The identity also supplies a second, independent route to `N_eff`: an analyst who can build the Gram matrix reads the effective count off the spectrum without ever forming a pairwise mean. It is verified numerically against direct computation at several roster sizes to better than `1e−12` [Curzi, 2026i], and the roster-scale form of the same identity, `M_eff = m + 1 − m/PR`, is verified independently at 1.7815458788 with error `0.00e+00` [Curzi, 2026].

The identity does not license the Hill-number literature as support for `N_eff`, and this distinction is the one a reviewer will press. `PR` *is* a Hill number of order two — it is `1/sum_i p_i^2` for the normalised Gram spectrum `p_i = lambda_i / N` — and the citations above attach to it exactly. `N_eff = N + 1 − N/PR` is an **affine reparametrisation** of that Hill number, and an affine transformation of a Hill number is not a Hill number. What the identity buys is that the aggregator is not arbitrary; what it does not buy is external grounding for the affine form, which remains the framework's own design axiom.

What the identity does not repair is the triangle-inequality failure noted above. `PR` and the mean pairwise `u` carry the same information because they are the same quantity; neither recovers the joint geometry that a mean over pairs discards.

21.3.4 3.4 Identification: what no amount of measurement recovers

This section states the objection that governs every applied reading in the paper, and it is stated here rather than in a footnote.

The framework's central formal claim is a reflexive loop, `T(x) = W(x, M(x))`: the aggregate influences the member and the members constitute the aggregate [Curzi, 2026]. **That is exactly a linear-in-means reflexive specification, and the endogenous social effect in such a specification is not identified from observational data** [Manski, 1993]. It cannot be separated from contextual effects or from correlated unobservables, no matter how much data is collected. Influence and selection are generically confounded in observational network data as well [Shalizi and Thomas, 2011], and the forensic consequences of ignoring that are documented [Lyons, 2011].

The objection reaches this paper by two distinct routes, and both must be conceded.

Route one: the framings inside one observer are not independent draws. The collapse mechanisms of Section 5 are precisely a within-observer influence structure — earlier framings condition later ones, and the later ones are recruited by a state that the earlier ones helped produce. The resulting `u` is therefore an equilibrium of an interaction process, not an exogenous property of the set. The classical formal apparatus for such a process is a row-stochastic influence matrix whose consensus is the dominant left eigenvector [DeGroot, 1974], with an anchoring term that yields a non-consensus fixed point rather than collapse [Friedkin and Johnsen, 1990] — which is, formally, the same device as this framework's leak `delta`.

Route two: the two-track ledger of Section 7.3 requires an external measurement of the environment, and there is no internal substitute. The over-framing ratio `r` and the environment `E` enter the moment as a product, so `M` alone cannot separate them. If `E` is reported by the same observer whose framing is being audited, `r` is estimated using the very quantity that the distortion acts on, and the two errors conceal each other exactly.

Which remedy this paper adopts: none. The known options are randomisation, an instrument, partial-population variation, or stipulating the reference set and defending the stipulation, of which the last is the most realistic and has an explicit template [Brock and Durlauf, 2001]. This paper stipulates the framing inventory in advance and freezes it (Specification SF4 and SQ2), which is a step toward that template and is not a substitute for it. **Every applied claim in this paper is therefore a modelling position rather than an identified empirical result, and where the text reads as though a measurement settled something, this sentence governs.**

The Lucas critique, turned on this paper's own parameters. The framework asserts that a described system changes its behaviour when the description is used, and then treats `delta`, `eta`, `N` and `u` as approximately constant over a survey window. Both cannot be true without qualification [Lucas, 1976]. The classification of a person interacts with the person classified, who changes in response, so the referent moves [Hacking, 1995]; and a framework that tells people their capability obeys a decay law should ask what that assumption will make true of them [Ferraro et al., 2005]. The position this paper takes is the narrow one: **the parameters are treated as stable only over a declared window, and only while the stored-order proxy is not itself a reported target.** Where either condition fails, the constancy assumption fails with it. That is a real restriction on where the model may be used and it is stated as one.

The counterweight, which is also real. A theory becoming true by being used is not only a hazard; it has been observed in the field with dates and price data [MacKenzie and Millo, 2003], and the reflexive doctrine this framework formalises exists in the literature without an equation attached [Soros, 2013, Merton, 1948]. Supplying an equation for it is a genuine contribution. But the effect size such reflexivity implies is larger than the psychological literature supports — classroom self-fulfilling prophecies are real, small, non-accumulating and often dissipating, and most expectations turn out to be accurate rather than causal [Jussim and Harber, 2005]. The framework should not draw on reflexivity for more than that.

21.3.5 3.5 Analogy discipline

Three imports from physics and engineering appear in this paper and each is labelled at first use.

The leaky integrator is a shared mathematical form, not a derivation from physical premises. The self-storage law and a first-order discrete filter are governed by the same difference equation, so every theorem about first-order discrete systems applies to both [Oppenheim et al., 1996, Elaydi, 2005]. Nothing about charge or current is claimed to hold of a person. The same label attaches to the statistical twin of the same object, exponential smoothing [Holt, 1957].

The participation ratio is a shared mathematical form with a genuine domain overlap. It is the same statistic in physics, in ecology and here, computed on a Gram spectrum in every case [Rényi, 1961, Hill, 1973]. This is the one import in the paper that is not merely formal, because the object it is computed on is of the same kind in all three settings.

The quadratic reconciliation cost is an analogy and is used as motivation only. The pair count `n(n−1)/2` is exact combinatorics; the claim that internal maintenance load is proportional to it is a postulate about a person, imported from the communication-path argument for groups [Brooks, 1975, Conway, 1968]. **No result in this paper depends on the constant of proportionality**, only on the fact that the cost is superlinear while the surplus is logarithmic.

The wider licence to carry physical formalism into psychological and social systems is not one this framework can grant itself: it was claimed, contested and partly established by others between 1971 and 2022, and the programme has been surveyed and bounded [Weidlich, 1971, Castellano et al., 2009, Jusup et al., 2022]. **The evidentiary bar that literature sets is prediction of observed data, not internal consistency** [Helbing and Molnár, 1995]. This paper does not clear that bar and does not claim to. The generous escape route is available and is taken explicitly: physical laws hold inside shielded, stable arrangements, so a law need not be universal to be real provided the arrangement within which it is claimed to hold is specified [Cartwright, 1999]. Section 12.5 specifies the arrangement.

One hazard is named because it is the characteristic failure of this exact genre. Neoclassical economics was built by copying mid-nineteenth-century energetics and the copy was defective: utility was made to play the role of energy **without the conservation law that gave energy its content** [Mirowski, 1989]. This framework's `Q` is a stock that accumulates, leaks and is spent — the grammar of a conserved quantity. **Nothing in this paper is conserved.** `Q` is not conserved, `F_int` is not conserved, and the only invariance the paper claims is the one stated and tested in Section 12.6. Saying so is the answer to Mirowski, and the answer is a concession.

21.3.6 3.6 Standing honesty clauses

Five clauses hold throughout and are restated in Section 13.

1. **The surplus functional is pure mathematics and makes no empirical or metaphysical claim.** It proves a functional form follows from four axioms. It does not prove that anyone's framings obey it. The empirical content of this paper is the modelling proposal of Section 3.2 and it is falsifiable at H1.
2. **Surplus is a lower bound** on the ensemble's information, not the information itself. An `N_eff` of 3.5 does not mean the observer holds exactly three and a half independent views; it means the measured geometry guarantees at least that much.
3. **The triangle inequality fails for geometric triples.** Surplus may not be chained across three framings as though it were a distance, which is why Section 6.3's subspace check is in addition to pairwise measurement and not an alternative to it.
4. **Surplus is not Shannon entropy or mutual information.** The logarithm is not a Shannon logarithm and entropy intuitions do not transfer wholesale.
5. **Nothing in this paper is a claim about neurons, about consciousness, or about physics.**

21.4 4 The internal surplus and what it costs to hold

21.4.1 4.1 What is proven, what is chosen, what is postulated

Element	Status
`f(u) = ln(1+(N−1)u)` unique under S1–S4	**PROVEN** [Curzi, 2026]
Strict monotonicity, positivity, strict concavity	**PROVEN** [Curzi, 2026]
Subadditivity on the parameter `u`	**PROVEN** [Curzi, 2026]
Extremality: `F = 0` iff parallel, `F = ln N` iff orthogonal	**PROVEN** [Curzi, 2026,r]
Range `0 <= F <= ln N`	**PROVEN** [Curzi, 2026]
The participation-ratio identity `N_eff = N + 1 − N/PR`	**PROVEN** (Section 3.3); verified numerically [Curzi, 2026i,?]
S3, the affine effective count	**DESIGN AXIOM — chosen, not derived**
Framings admit unit-vector encoding	**POSTULATE** (Section 3.2)
Mean pairwise `u` summarises an observer's framing set	**POSTULATE** (Section 3.2)
`u = 1 − rho^2` from error decorrelation	**POSTULATE** on the encoding; algebra thereafter
Reconciliation cost grows as `n(n−1)/2` internally	**POSTULATE** (Section 4.4)

S3 remains the design axiom and is flagged here as everywhere. That a second genuinely different framing counts for exactly as much, in `u`-units, as a fortieth is not a discovery about minds; it is the consequence of having chosen the effective count to be affine in `u`. A measured reason to replace S3 would require rebuilding this section around the replacement.

21.4.2 4.2 Validation gates for the internal surplus

The framework applies a seven-gate protocol to every formula it uses. The gates for `F_int = ln(1 + (N−1)u)` are reported in full, including the two that are not passed.

Gate	Verdict
G1 DIMENSIONS	`u` is dimensionless by construction, being a squared sine. `N` is a pure count. `1 + (N−1)u` is dimensionless, so the logarithm is well formed and `F_int` is in nats. Sound. **`N` and `u` must come from the same encoding**: an `N` counted over one taxonomy of framings and a `u` measured over a different one do not compose, and this is the commonest arithmetic error at this scope.
G2 SCALE TYPE	`N` is a count on a ratio scale with a true zero. `u` is ratio-scaled with a true zero, since `u = 0` is a genuine zero meaning exact parallelism rather than a convention, **which is why the effective count may be divided, ratioed and compared.** The prerequisite is that the encoding of framings into states is itself defensible. If framings are only rank-ordered by similarity, `u` is ordinal and `F_int` demotes to a heuristic ordering [Curzi, 2026m]. Whether the quantitative structure exists at all has not been tested; see Section 13.
G3 LIMITING CASES	`u -> 0`: `N_eff -> 1`, `F_int -> 0` — the parallel wall at internal scope, many framings and one view. `u -> 1`: `N_eff -> N`, `F_int -> ln N`, the ceiling. `N -> 1`: `F_int -> 0` for every `u`, correct, since one framing has nothing to be non-parallel to. `N -> infinity` at fixed `u > 0`: `F_int -> infinity` logarithmically — **the model has no internal ceiling on framing count, which is wrong in fact**, and the correction belongs to the cost term of Section 4.4 rather than to the surplus term. The divergence names a real failure: an observer who keeps adding framings without bound.
G4 FIXED POINTS	`u = 0` is the degenerate fixed point, invariant under any `N`. The substantive invariant is `N_eff`: **any pair `(N, u)` with the same `1 + (N−1)u` yields identical surplus**, so `N = 3, u = 1.0` and `N = 12, u = 0.1818` are interchangeable in surplus and distinguishable only by cost. That equivalence class is the section's main design lever.

Gate	Verdict
G5 IDENTIFIABILITY	`N` is recoverable by enumeration; `u` by the instruments of Section 6, of which error decorrelation is the only properly quantitative one. **The failure to declare: `N` and `u` are not separately recoverable from `F_int` alone.** Measuring surplus and inferring both is impossible; `u` must be measured independently. Reporting `N_eff` without reporting `(N, u)` separately therefore fails this gate and is prohibited by SF4.
G6 FALSIFICATION	H1. **Kill condition:** framing count predicts as well as the audited count, or the shuffled control matches the model. If `N` alone does the work, the `u` term is decoration.
G7 REPRODUCIBILITY	**The hard gate, and it is not passed.** The requirement is that two analysts independently encoding the same observer's framings recover the same `u` within tolerance, and that the same operationalisation applied to different observers yields parameters with stable meaning. Error decorrelation is the most promising route because it asks nobody to judge similarity. **This is untested and is stated as untested.**

21.4.3 4.3 The marginal value of the n-th framing

Strict concavity has a blunt consequence at internal scope. Fix `u` and ask what the `n`-th framing adds:

```
Delta F(n) = ln(1 + (n−1)u) − ln(1 + (n−2)u)

TABLE 1 — MARGINAL SURPLUS OF THE n−th FRAMING (nats; computed)

   n  |  u=0.20 |  u=0.35 |  u=0.50 |  u=0.70 |  u=1.00 |
  ----+---------+---------+---------+---------+---------+
    2 |  0.1823 |  0.3001 |  0.4055 |  0.5306 |  0.6931 |
    3 |  0.1542 |  0.2305 |  0.2877 |  0.3448 |  0.4055 |
    4 |  0.1335 |  0.1872 |  0.2231 |  0.2559 |  0.2877 |
    5 |  0.1178 |  0.1576 |  0.1823 |  0.2036 |  0.2231 |
    6 |  0.1054 |  0.1361 |  0.1542 |  0.1691 |  0.1823 |
    7 |  0.0953 |  0.1198 |  0.1335 |  0.1446 |  0.1542 |
    8 |  0.0870 |  0.1070 |  0.1178 |  0.1263 |  0.1335 |
    9 |  0.0800 |  0.0966 |  0.1054 |  0.1121 |  0.1178 |
   10 |  0.0741 |  0.0881 |  0.0953 |  0.1008 |  0.1054 |
   12 |  0.0645 |  0.0749 |  0.0800 |  0.0839 |  0.0870 |
   15 |  0.0541 |  0.0612 |  0.0645 |  0.0670 |  0.0690 |
   20 |  0.0426 |  0.0468 |  0.0488 |  0.0502 |  0.0513 |
   30 |  0.0299 |  0.0319 |  0.0328 |  0.0334 |  0.0339 |
   40 |  0.0230 |  0.0242 |  0.0247 |  0.0250 |  0.0253 |

   ratio  gain(2) / gain(40):
```

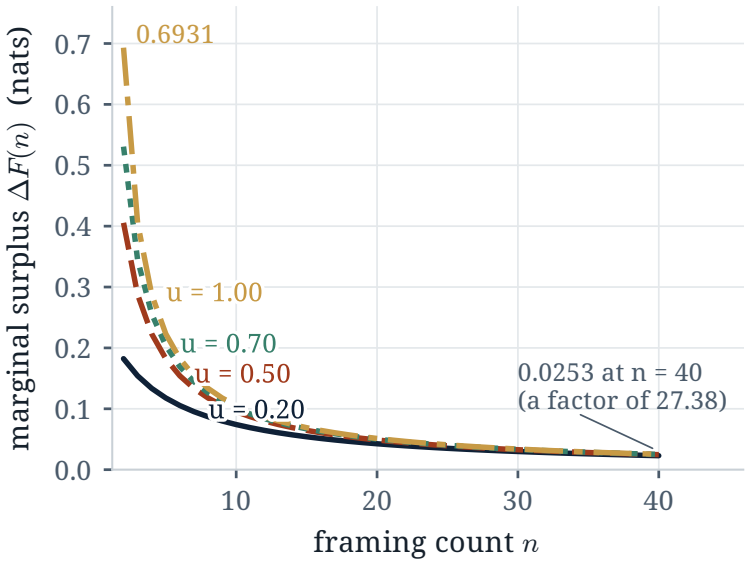

Figure 21.1: **The second framing is worth twenty-seven times the fortieth, and the ratio is a theorem.** Marginal surplus `Delta F(n) = ln(1+(n−1)u) − ln(1+(n−2)u)` against framing count, at four values of non-parallelism. At `u = 1.00` the second framing returns 0.6931 nats and the fortieth 0.0253, a ratio of 27.38; at `u = 0.20` the same ratio is 7.93. The `u = 0.35` column of Table 1 is omitted because the validated palette holds four colours and no fifth. Computed from the closed form with the parameters shown, not measured; generated by `figs/src/CCP-021_fig01.py`.

```
u=0.20  7.93x     u=0.35  12.41x     u=0.50  16.42x
u=0.70 21.19x     u=1.00  27.38x
```

At `u = 1.0` the second genuinely different framing is worth 0.6931 nats and the fortieth is worth 0.0253 — a factor of 27.4 for exactly the same effort. The pattern holds across the whole table because it is concavity, and concavity here is a theorem rather than a tendency. The second genuinely different framing is the largest gain that will ever be bought; the fortieth is a glazing bill.

Cumulatively:

```
TABLE 2 — CUMULATIVE INTERNAL SURPLUS F_int (nats; computed)

 n  |  u=0.20 |  u=0.35 |  u=0.50 |  u=0.70 |  u=1.00 |
----+---------+---------+---------+---------+---------+
  1 |  0.0000 |  0.0000 |  0.0000 |  0.0000 |  0.0000 |
  2 |  0.1823 |  0.3001 |  0.4055 |  0.5306 |  0.6931 |
  3 |  0.3365 |  0.5306 |  0.6931 |  0.8755 |  1.0986 |
  4 |  0.4700 |  0.7178 |  0.9163 |  1.1314 |  1.3863 |
  6 |  0.6931 |  1.0116 |  1.2528 |  1.5041 |  1.7918 |
 10 |  1.0296 |  1.4231 |  1.7047 |  1.9879 |  2.3026 |
 20 |  1.5686 |  2.0347 |  2.3514 |  2.6603 |  2.9957 |
 40 |  2.1748 |  2.6844 |  3.0204 |  3.3429 |  3.6889 |
```

21.4.4 4.4 Reconciliation cost is quadratic

The central asymmetry of group design is that surplus grows logarithmically while coordination cost grows quadratically, because `n` members generate `n(n−1)/2` communication paths [Brooks, 1975, Conway, 1968]. The same asymmetry is postulated inside a single observer.

THE INTERNAL RECONCILIATION COST [POSTULATE]. An observer holding `n` framings must, to use them as framings rather than as a list, reconcile them pairwise: notice where two framings disagree about the same situation and hold the disagreement without resolving it prematurely. The number of such reconciliations is `n(n−1)/2`, and the maintenance load is therefore quadratic in `n` while the surplus is logarithmic.

The exponent here is defined by the model and is not estimated from data. The pair count is exact combinatorics; the proportionality between pair count and load is the postulate. No distributional or scaling claim is made anywhere in this paper, so the maximum-likelihood plus-Kolmogorov-Smirnov procedure that any such claim would require does not apply [Clauset et al., 2009] — and it would apply immediately to anyone who claimed to have measured this exponent rather than assumed it.

TABLE 3 — SURPLUS PER RECONCILIATION PAIR, at u = 0.5 (computed)

n	pairs	F_int	F per pair
2	1	0.4055	0.40547
3	3	0.6931	0.23105
4	6	0.9163	0.15272
5	10	1.0986	0.10986
6	15	1.2528	0.08352
8	28	1.5041	0.05372
10	45	1.7047	0.03788
12	66	1.8718	0.02836
20	190	2.3514	0.01238
40	780	3.0204	0.00387

Between two framings and forty, surplus rises by a factor of 7.45 while reconciliation pairs rise by a factor of 780; surplus per pair falls by a factor of 105. That collapse is the arithmetic behind a familiar report: the person who has read widely enough to hold twenty framings and cannot, in consequence, decide anything. **They are paying a quadratic bill for a logarithmic return, and it came due exactly where the arithmetic says it would.**

The same crossing is the reason a queueing argument belongs beside the combinatorial one. Waiting time in a loaded system rises without bound as utilisation approaches one [Kingman, 1962], so an observer running near capacity does not degrade gracefully as framings are added; the marginal reconciliation is the one that saturates. That is an analogy and is used as motivation only, per Section 3.5.

21.4.5 4.5 Net internal surplus and the optimal framing count

Let `eta` be the conversion of internal surplus into stored order, `c1` the per-framing upkeep and `c2` the per-pair reconciliation cost.

THE NET INTERNAL SURPLUS [DERIVED].

```
V(n) = eta * ln(1 + (n−1)u)  −  c1 * n  −  c2 * n(n−1)/2
```

The optimum `n*` is the largest `n` for which `V(n) > V(n−1)`, that is for which `eta [ln(1+(n−1)u) − ln(1+(n−2)u)] > c1 + c2 (n−1)`. **Since the left side falls like `1/n` and the right side rises linearly, `n*` always exists and is always finite.**

TABLE 4 — OPTIMAL FRAMING COUNT (computed)

```
case                        eta    u     c1      c2       n*    V(n*)
--------------------------  -----  ----  ------  ------   ----  -------
attentive, cheap upkeep     1.0    0.60  0.010   0.0020    20    1.9377
attentive, costly upkeep    1.0    0.60  0.030   0.0080     9    1.1999
high conversion             2.0    0.60  0.030   0.0080    14    3.2015
low non-parallelism         1.0    0.25  0.020   0.0050    11    0.7578

worked profile for the second case, V(n) at n = 1..10:
  1: -0.030   2: +0.402   3: +0.674   4: +0.862   5: +0.994
  6: +1.086   7: +1.148   8: +1.185   9: +1.200  10: +1.196
```

Three readings follow, all practical.

The optimum is flat near its peak. In the second case `V(8) = 1.185`, `V(9) = 1.200`, `V(10) = 1.196`. The penalty for holding eight framings instead of the optimal nine is 1.3 per cent. **The task is not to find `n*`; it is to avoid being at 2 or at 25.**

Raising conversion raises the optimum. Doubling `eta` from 1.0 to 2.0 moves `n*` from 9 to 14. An observer with a practice that converts a framing's output into something durable can afford more framings than one without, which is the internal form of the framework's headline result that `eta` is its cheapest lever [Curzi, 2026b].

Low non-parallelism lowers the peak far more than it lowers the optimum. The fourth case reaches `V = 0.758` at `n* = 11` with `u = 0.25`, against 1.200 at `n* = 9` with `u = 0.60`. **Holding more framings does not compensate for holding parallel ones: it costs more and returns less.**

The gates for `V(n)` are reported with the same candour as those for `F_int`.

Gate	Verdict
G1 DIMENSIONS	`ln(.)` is in nats; `eta` carries stored-order units per nat; `c1` is cost per framing per period; `c2` is cost per pair per period. **All three terms must be expressed in the same stored-order currency or the subtraction is meaningless** — the gate this formula most often fails, because effort and character are not naturally commensurable and making them so is a modelling decision that must be stated.
G2 SCALE TYPE	Requires `u` ratio-scaled and both cost terms ratio-scaled with a true zero. Costs elicited as ordinal ratings do not qualify; magnitude estimation on effort is the honest route [Stevens, 1957] and cross-modality matching against a physical effort continuum is the stronger one [Stevens, 1956].
G3 LIMITING CASES	`c1, c2 -> 0`: `n*` unbounded, matching `F_int`'s divergence and correctly locating it in the cost term. `c2 -> 0` with `c1 > 0`: `n*` finite but large — an observer whose framings never have to be reconciled with each other, which describes compartmentalisation and is a real and named condition. `u -> 0`: `V(n) = -c1 n - c2 n(n-1)/2`, strictly decreasing, so `n* = 1`. **With parallel framings the model says hold exactly one, which is correct and bleak.**

Gate	Verdict
G4 FIXED POINTS	`n*` solves `eta Delta F(n) = c1 + c2(n−1)`, the balance of a falling marginal return against a rising marginal cost: **the framing count at which one more window costs exactly what it shows.**
G5 IDENTIFIABILITY	`eta`, `c1`, `c2` are jointly identifiable only with variation in `n`. An observer who has held six framings for a decade provides no information about the cost curve. **The formula is therefore not fittable on cross-sectional self-report; it requires a deliberate, logged variation in framing count over time.** That is a demanding requirement and it is stated rather than hidden.
G6 FALSIFICATION	H2. **Kill condition:** measured performance flat in `n` over the tested range, or peaking where the model did not predict, or a linear cost model fitting as well — in which case the pair-cost postulate is wrong at internal scope.
G7 REPRODUCIBILITY	Untested. The cost parameters are almost certainly person-specific; **the form is the reproducible claim, not the values.** Report as single-subject unless and until cross-subject recovery is demonstrated.

21.4.6 4.6 Three windows set wide against twelve from one lineage

The group-scope comparison of three orthogonal members against twelve nearly parallel ones has an internal counterpart, and the internal lesson is sharper because the quadratic bill is paid by the same person who collects the surplus.

```
n =  3,  u = 1.00   ->   F_int = 1.0986      reconciliation pairs =   3
n = 12,  u = 0.15   ->   F_int = 0.9746      reconciliation pairs =  66
n = 20,  u = 0.12   ->   F_int = 1.1878      reconciliation pairs = 190
```

Three framings genuinely set wide beat twelve from one lineage, at one twenty-second of the reconciliation load. Twenty parallel framings finally exceed the three by 0.089 nats, having taken on 190 pairs instead of 3: a 63-fold cost increase for an 8 per cent surplus increase.

This answers the reader who concludes from Table 1 that the remedy is to read more. **Reading more raises `N`. It raises `u` only if what is read is genuinely non-parallel to what has been read already, and the default for a reader following their own taste is that it is not.** The organisational literature reaches the same place from the other side: fast, efficient learning homogenises a population and destroys the variance that produced its advantage [March, 1991, Levinthal and March, 1993], and the effect has been measured as an outright collapse in the effective count under social influence [Lorenz et al., 2011].

21.5 5 How non-parallelism collapses

21.5.1 5.1 Six mechanisms

u is not a property that is acquired and held. **It is a quantity that decays, and at internal scope it decays faster than at group scope, because there is no one else in the room to disagree.** Six mechanisms are named, each with its diagnostic signature. The labels are CM1–CM6 to avoid collision with the moment variable M_t of Section 7.

CM1 — THE INTERNAL CASCADE. Observers who condition on others' conclusions stop contributing information [Bikhchandani et al., 1992]. The same structure appears internally with the observer's *own earlier conclusion* as the reinforcing contact: framing B is consulted after framing A has produced an answer, and B is asked to check A rather than to see the situation. *Signature:* framings agree more the later they are consulted.

CM2 — THE CONSISTENCY DRIVE. A standing pressure toward consistency among simultaneously held construals acts, in this notation, as **a force rotating framings toward parallel** — a u-destroying gradient operating continuously and without supervision. *Signature:* framings that used to disagree quietly stop disagreeing, with no recollection of a decision to change either. **This paper's bibliography holds no entry for the mid-twentieth-century cognitive-consistency literature that documents the pressure, so the mechanism is carried here as a postulate rather than as a cited result**, and Section 13 repeats that.

CM3 — IDENTITY CAPTURE. A framing becomes *who the observer is* rather than *something they use*. It can then no longer be set aside for a comparison, so every other framing is evaluated from inside it and their encoded states rotate toward it. *Signature:* one framing is never the one that loses.

CM4 — MOOD-CONGRUENT RECRUITMENT. Which framings are available at a given moment is not independent of state. If low mood makes the pessimistic framings easier to reach, then at exactly the moments when non-parallelism is most valuable the accessible set is most parallel. *Signature:* the framing set feels smaller when things are difficult. **This is a u collapse that presents as a mood problem and is treated as one, which is why it persists.**

CM5 — THE SINGLE LINEAGE. All the framings came from one training, one mentor, one literature. Their disagreements are the disagreements internal to that lineage, which are real but small. *Signature:* the observer can name six framings and all six would be recognised by the same professional body. **The cited evidence available here is weaker than the mechanism deserves.** Diverse problem-solving groups can outperform higher-ability homogeneous ones under stated conditions [Hong and Page, 2004], but the formal result has been shown to follow from the modelling assumptions rather than from any fact about diversity [Thompson, 2014], and the subsequent exchange has narrowed rather than settled the question [Singer, 2019]. **The closest thing to direct evidence for this section's central claim is a forecasting result — that forecasters using many small, loosely related explanatory framings outperformed those organising everything under one large idea — for which this paper's bibliography carries no entry.** It is therefore described and not cited, and nothing here rests on it.

CM6 — PREMATURE INTEGRATION. The framings are collapsed into a synthesis before their disagreement has been used. Synthesis is the correct final move and the wrong early one. *Signature:* a unified view is reached quickly and the components' disagreement cannot afterwards be reconstructed.

21.5.2 5.2 A geometric decay model

The aggregate effect is modelled as geometric decay, which is the honest form given that these are multiplicative pressures, with a per-round collapse rate lambda:

```
u_t = u_0 (1 − lambda)^t      half-life = ln 2 / (−ln(1−lambda)) rounds

TABLE 5 — FRAMING-SET COLLAPSE, u_0 = 0.60, N = 6 (computed)
```

```
lambda=0.05    t:  0       1       2       4       8      16     half-life 13.51 rounds
   u              0.6000  0.5700  0.5415  0.4887  0.3981  0.2641
   F_int          1.3863  1.3481  1.3104  1.2365  1.0954  0.8417

lambda=0.10    t:  0       1       2       4       8      16     half-life  6.58 rounds
   u              0.6000  0.5400  0.4860  0.3937  0.2583  0.1112
   F_int          1.3863  1.3083  1.2326  1.0880  0.8292  0.4421

lambda=0.20    t:  0       1       2       4       8      16     half-life  3.11 rounds
   u              0.6000  0.4800  0.3840  0.2458  0.1007  0.0169
   F_int          1.3863  1.2238  1.0716  0.8015  0.4077  0.0811
```

At a 20 per cent per-round collapse rate, sixteen rounds take a six-framing observer from 1.386 nats to 0.081 — an audited count of 4.00 down to 1.08. The endpoint will be described as clarity. It is the parallel wall, reached from the inside, by a process that felt like thinking.

The decay rate `lambda` is a stipulated parameter in every table above. **It has not been measured, in this paper or anywhere in this corpus**, and the three values are chosen to bracket a plausible range rather than to report one.

21.5.3 5.3 Seven maintenance protocols

Each protocol targets a named mechanism, each is cheap, and each is an artefact rather than an intention, because artefacts have low `delta` [Curzi, 2026a]. The labels are `MP1`–`MP7`. **Whether any of them works is not established here**; they are design proposals with stated rationales.

MP1 — THE FRAMING REGISTER. A written list, one line per framing: name, primitives, what it is good at, what it is blind to, where it came from. A file, reviewed on a cadence. *Targets CM5, CM3.* The provenance column does the work — when four of six lines name the same lineage, `u` is low and the fact is visible without measuring anything.

MP2 — INDEPENDENT-FIRST, WRITTEN. On any question of consequence, run each framing to a written conclusion **before** consulting the next. *Targets CM1.* The highest-value protocol here, because the internal cascade is both the fastest destroyer of `u` and the easiest to block: the block is a piece of paper.

MP3 — TIME SEPARATION. Run framings on different days. State-dependent availability is partly a within-session effect. *Targets CM4, CM2.*

MP4 — THE DISAGREEMENT LOG. When two framings disagree, record the disagreement and its resolution, including "unresolved". *Targets CM2, CM6.* Measurement instrument and maintenance device at once: writing a disagreement down stops the consistency drive from quietly erasing it, and the log is the raw data for Section 6.

MP5 — DELIBERATE LINEAGE IMPORT. Learn a genuinely different trade to working competence, not conversational competence. *Targets CM5.* The expensive protocol, and the only one that raises `N` rather than protecting `u`. Table 1 prices it: holding two or three real framings, the next is worth 0.29 to 0.41 nats at high `u`, the largest increment available; holding twelve, 0.08.

MP6 — THE ADVERSARIAL PASS. Take the framing that is winning and argue it down using only the framing that is losing, in writing, to a conclusion. *Targets CM3.* "Using only" is load-bearing; the exercise fails if the winning framing is permitted to referee.

MP7 — DEFERRED SYNTHESIS. A written rule for how long disagreement must be held before integration is permitted. *Targets CM6.* Synthesis is not prohibited; it is scheduled.

The adoption cost of each protocol is itself a quantity the framework can price. Where a practice requires a sequence of steps each of which has a resistance, the branch may be weighted by that accumulated resistance rather than treated as equally available [Curzi, 2026]: a three-point difference in steepness is a factor of eight in expectation, which is why MP2 —

one sheet of paper — and MP5 — a second trade — are not comparable interventions however similar their descriptions look.

One constraint is not negotiable and needs restating at internal scope, because the person and the intervener are the same and it is easy to think it does not apply. The framework prohibits any intervention that removes a person's ability to decline. **A protocol that forces an observer to hold a framing they have declined is coercive, and the fact that the observer is the one applying it does not make it otherwise.** MP5, MP6 and the error-decorrelation instrument are offered as available instruments; someone who declines any of them has not failed a specification. The method is to make the alternative cheaply available and let the movement be a choice, whose worst outcome is that someone declines to move — and that is the property that makes it safe.

21.6 6 Measuring non-parallelism

21.6.1 6.1 Five instruments

Five instruments, in ascending order of rigour and of cost.

I1 — THE LINEAGE CENSUS [HEURISTIC]. From the register: how many distinct training origins are represented among `N` framings? Provenance is a prior, not a measurement, but it is the only instrument that works before there is any data and the only one that can prevent rather than diagnose.

I2 — THE COLLISION TEST. Over the last twenty consequential judgements, in how many did a second framing produce a conclusion the first had not already reached? **A framing that never collides is not a second window.** This fraction is not `u` and must not be reported as `u`; it is triage, and a value near zero is decisive on its own.

I3 — THE DISAGREEMENT RATE. From MP4's log: the proportion of logged questions on which a pair of framings disagreed on the answer, not merely on the reasoning. **Ordinal**; comparable across pairs within one observer, not across observers.

I4 — ERROR DECORRELATION. The quantitative instrument, and the only one that yields a `u` admissible in the formula. Record each framing's *prediction* on questions with later-observable answers; compute each framing's error series; compute the Pearson correlation `rho` between the error series of each pair. Then, under the error-vector encoding postulate,

```
u = 1 - rho^2
```

I5 — THE SUBSPACE CHECK. Section 6.3.

21.6.2 6.2 Error decorrelation, and what the estimator inherits

```
TABLE 6 — ERROR CORRELATION -> AUDITED FRAMING COUNT (N = 6; computed)

   rho       u        N_eff      F_int    % of ln 6
  -----   -------   ---------   -------  ----------
   1.00   0.0000      1.0000    0.0000        0.00
   0.95   0.0975      1.4875    0.3971       22.16
   0.90   0.1900      1.9500    0.6678       37.27
   0.80   0.3600      2.8000    1.0296       57.46
   0.70   0.5100      3.5500    1.2669       70.71
   0.50   0.7500      4.7500    1.5581       86.96
   0.30   0.9100      5.5500    1.7138       95.65
   0.00   1.0000      6.0000    1.7918      100.00
```

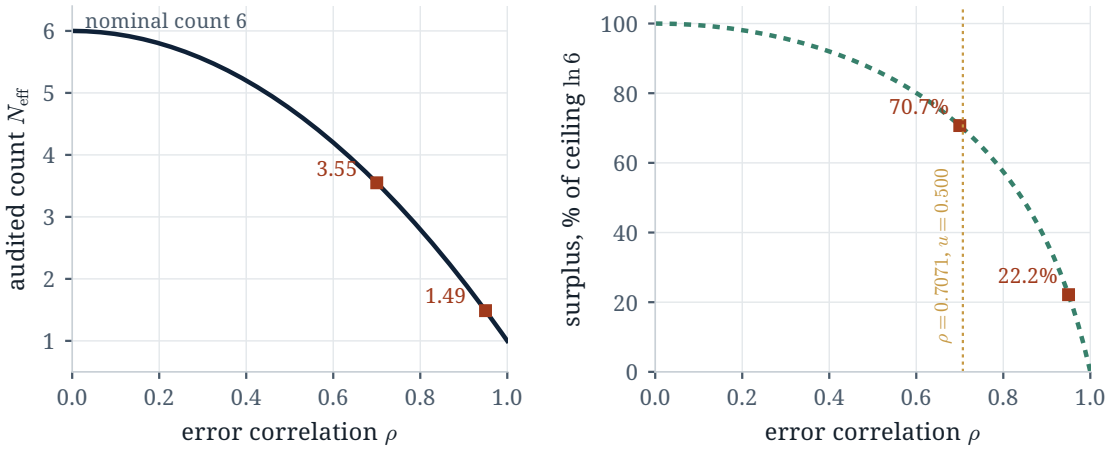

Figure 21.2: **Non-parallelism is cheap to obtain and expensive to lose.** The audited framing count `N_eff = 1 + (N−1)(1−rho^2)` at `N = 6` (left) and the resulting internal surplus as a percentage of the ceiling `ln 6 = 1.7918` nats (right), against the error correlation between framings. Framings correlated at `rho = 0.70` still return 70.7 per cent of the ceiling; framings correlated at `rho = 0.95` return 22.2 per cent. The landmark `rho = 0.7071` gives `u = 0.500` exactly — half the available non-parallelism — at which a pair returns 58.5 per cent of its own ceiling, not half. Plotted as two panels rather than on shared axes because a count and a percentage are not commensurable. Computed from Table 6's closed form, not measured; generated by `figs/src/CCP-021_fig02.py`.

Note the shape. Framings correlated at `rho = 0.7` — which most people would call "pretty similar" — still deliver 70.7 per cent of the available surplus, because `u = 1 − rho^2` punishes only high correlation. **Orthogonal framings are not required; framings that are not nearly identical are, and the gap between those two requirements is most of the practical content of this section.** Conversely `rho = 0.95`, which feels like a genuine second opinion, delivers 22 per cent.

The estimator's gates:

Gate	Verdict
G1 DIMENSIONS	`rho` is a dimensionless correlation in `[−1,1]`; `rho^2` in `[0,1]`; `u` in `[0,1]`. Sound. Note that `u` depends on `rho^2`, so **anti-correlated framings at `rho = −0.9` are treated as no more different than correlated ones at `rho = +0.9`** — correct under the geometric encoding, since `u = 1 − cos^2 theta` and antiparallel states are as redundant as parallel ones. This is the extremality condition stated on the squared alignment [Curzi, 2026r] and the opposition identity that follows from it: `u = 1 − rho^2` depends only on `|rho|`, so `rho = +1` and `rho = −1` both give `u = 0` and `F = 0` [Curzi, 2026]. A framing that is reliably the mirror image of another is not a second window.

Gate	Verdict
G2 SCALE TYPE	Requires the prediction errors to be at least interval-scaled for `rho` to mean anything. **If the framings produce only rank orderings, a rank correlation must be used and the resulting `u` stated as a heuristic ordering rather than a measured quantity.**
G3 LIMITING CASES	`rho -> +/-1`: `u -> 0`, identical or mirrored framings contribute nothing. `rho -> 0`: `u -> 1`, independent errors, the ceiling. There is no divergence to explain; the map is bounded on both sides, which is a point in its favour.
G4 FIXED POINTS	`rho^2 = 0.5`, i.e. `rho = 0.7071`, gives `u = 0.5` — **half the available non-parallelism, and a useful practical landmark.** The framework's earlier statement of this landmark as the "half-surplus point" is imprecise and is corrected here: at `u = 0.5` a pair returns `ln 1.5 / ln 2 = 58.5` per cent of its ceiling, not 50 per cent. What is exactly halved is the effective count's excess over one.
G5 IDENTIFIABILITY	`rho` is estimable from as few as 15 to 20 paired predictions, with wide confidence intervals; **the sampling error on `rho` propagates into `u` with a factor of `2|rho|`, so at high correlation a small error in `rho` is a large error in `u`.** Report the interval, not the point, whenever `|rho| > 0.7`.
G6 FALSIFICATION	The encoding claim is falsifiable: if `u` estimated this way fails to predict the incremental accuracy of adding a framing — if adding a low-`rho` framing improves held-out accuracy no more than adding a high-`rho` one — the encoding is wrong and the number is decoration.
G7 REPRODUCIBILITY	**This instrument's chief virtue is that it is the most likely of the five to pass**, because it involves no similarity judgement by anyone: it is computed from recorded predictions and recorded outcomes, so two analysts with the same log must obtain the same `rho`. Untested across observers.

Two exposures are worth naming beside the gates. The first is that any survey instrument used to elicit framings is itself sensitive to question wording and to what the question makes salient [Schwarz, 1999, Kahneman et al., 2006], which is one reason the instrument is built on recorded predictions rather than on recalled ones — and why introspective reports of one's own reasoning process should not be used to estimate `rho` [Nisbett and Wilson, 1977]. The second is that `rho` estimated on a short log is a small-sample statistic with the usual bias, and effective-count estimators computed from small samples are known to be biased downward in the analogous ecological setting [Chao et al., 2014].

21.6.3 6.3 The subspace check

Because the triangle inequality fails for triples, pairwise `u` can be uniformly moderate while all framings lie in a low-dimensional subspace. Assemble the error series into a matrix and examine the eigenvalue spectrum of its correlation matrix. **If two components carry nearly all the variance among six framings, the pairwise summary overstates the audit, and `N_eff` should be reported as the spectrum's participation ratio rather than as `1 + (N−1)u_bar`.** By the identity of Section 3.3 the two agree exactly when the geometry is what the pairwise mean implies, so the check is a comparison of a quantity against itself computed two ways — which is what makes it diagnostic.

The check has an external analogue that makes its importance concrete. Diversification benefit depends on *covariance*, not on count: `N` uncorrelated holdings and `N` perfectly correlated holdings have the same `N` and completely different behaviour [Markowitz, 1952], and measured correlations rise under stress, so the effective count falls exactly when it is needed [Longin and Solnik, 2001]. **A framing set is a portfolio, and the subspace check is the covariance audit.** The same warning is available from the other direction: diversity-stability correlations can arise from statistical averaging alone, with no mechanism at all [Doak et al., 1998], so an observed association between a high audited count and good judgement is not by itself evidence for this paper's mechanism.

21.7 7 The self as storage

21.7.1 7.1 The join, written out

The storage law with the moment substituted for the interaction surplus:

```
THE SELF–STORAGE LAW

    Q_{t+1} = (1 − delta) Q_t  +  eta ∗ M_t  −  C_t

    Q_t      stored order in one person: character, skill, memory, internalised structure
    M_t      the moment as lived this period, in nats, bounded by ln N
    delta    retention loss in [0,1]: forgetting, skill atrophy, drift of self
    eta      conversion efficiency >= 0: how experience becomes character
    C_t      cognitive load, effort, the operating cost of being a self
```

The external form of the law takes the interaction surplus of a group as its input [Curzi, 2026a]. The internal form takes the *moment* as its input. **Perspective and perception produce the moment; the moment becomes character.** The join is a substitution, and it runs in four steps:

```
STEP 1  CALIBRATION      r_t = D_t / P_t
STEP 2  THE MOMENT       M_t = min( r_t ∗ E_t ,  ln N )
STEP 3  VERIDICAL PART   V_t = E_t ∗ min( r_t , 1 )
STEP 4  THE DEPOSIT      Q_{t+1} = (1−delta) Q_t + eta M_t − C_t
```

`D` is the framing brought to the situation, `P` the situation's own resistance to it, `r` their ratio, and `E` the environment measured in nats of usable structure. **`E` is exogenous and must be measured by an instrument outside the observer**; that requirement is inherited without softening [Curzi, 2026m]. The cap at `ln N` is the surplus functional's range result plus a normalisation convention: **the richest moment available to a mind is the log of how many kinds of thing it can tell apart**, which is requisite variety in first-person form [Ashby, 1958] and was not chosen.

Before any of it is used, the status of Step 1 must be stated, because it governs Steps 2, 3 and 4. Applying the validation protocol to the moment equation returns a **demotion on the scale-type gate**: `D` and `P` are not instrumented on a common ratio scale with a shared true zero, so the *magnitude* of `r_t` is not a reportable measured quantity, and because the moment contains a division and a multiplication, ordinal data for either term demote it to a heuristic ordering that may not be printed as a fraction [Curzi, 2026m]. That verdict propagates straight down this chain.

> **THE JOIN IS STRUCTURAL, NOT YET QUANTITATIVE.** The architecture — moment feeds storage, storage does not inspect its input, the two tracks separate, stored error integrates with the cost term cancelling — is **exact algebra and stands as written.** So do the orderings it produces: over-framing accumulates faster than calibration, `Z` is zero at and below the fixed point and positive above it, correction load rises with accumulated error. **What is not yet reportable is any number obtained by putting a measured `r_t` through Step 2.** Every figure of that kind in this paper is an illustrative construction demonstrating the mechanism, and is labelled as such at each use.

The route out is constructive and costed, and it belongs in the same breath as the demotion. If `D` and `P` are measured as Rasch person-measures on one common linked scale, the distortion becomes a logit difference, `Delta = |ln(D/P)| = |theta_D − theta_P|`, genuinely ratio-scaled with a true zero at calibration [Rasch, 1960, Andrich, 1988]. The price is on the order of **123 items per term to establish a half-logit distortion at 95 per cent confidence**. That is the study which would convert this section's structure into this section's arithmetic, and it is specified rather than wished for. Whether the underlying attributes are quantitative at all is a prior question and Section 13 concedes it [Michell, 1997, Luce and Tukey, 1964].

21.7.2 7.2 What transfers, and why

Proven. Everything the external storage law proves, because it is the same equation: the exact solution, the one-step growth condition, the uniform bound, the sustainability ceiling, the steady state, the headroom gauge and the maximum one-step increment all carry over unchanged [Curzi, 2026a,b], because none of them uses any property of the input except that it lies in `[0, ln N]`. Step 2's cap guarantees exactly that. **The theorems transfer because the range transfers, and for no other reason.**

Postulated, badged. That a person's stored order is a scalar. That it decays at a constant proportional rate. That the moment and the environment can be placed on a ratio scale. That `eta`, `delta`, `N` and `C` hold approximately constant over the horizon on which the gauge is read. That the chosen proxy stands in a stable relation to `Q`. **None of these is a theorem, and a headroom figure for a person is only as good as the five measurements behind it.**

21.7.3 7.3 The two-track ledger and the stored-error recursion

The storage law **does not inspect its own input**: no term in `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` asks whether `M` was earned. An over-framed observer with `r > 1` manufactures moment out of their own priors and stores it exactly as if the environment had supplied it. The engineering answer is not to fix the variable. It is to keep two books.

```
THE LIVED TRACK     Q_t      integrates M_t = min(r_t E_t, ln N)      what you have become
THE EARNED TRACK    Q^V_t    integrates V_t = E_t min(r_t, 1)         what the world put there
THE ERROR           Z_t = Q_t − Q^V_t                                  what you put there
```

Subtracting the two recursions, the cost term cancels exactly:

```
Z_{t+1} = (1 − delta) Z_t + eta (M_t − V_t)

and at steady state,   Z_inf = eta (M* − V*) / delta = eta E* (r − 1) / delta   for r > 1
```

Stored error accumulates by the same leaky integration as stored knowledge, at the same rate, and its equilibrium does not depend on cost at all. That is a two-line derivation and it is the most useful result in this section. Three facts follow immediately.

Fact 1. `Z` is a leaky integrator with the same pole. Stored error decays at the same rate as stored knowledge, which is why recalibration works at all: **stop manufacturing and the accumulated error forgets itself on the same half-life as everything else.**

Fact 2. `Z_inf` is independent of `C`. Working harder, being busier, paying more to exist — none of it changes the equilibrium quantity of stored error. Only `r`, `E`, `eta` and `delta` do.

Fact 3. `Z = 0` for every `r <= 1`. The under-framed observer stores no error. They store less, and their equilibrium can be negative, which is the model refusing the regime. But what they do store, they earned. **Flooding is a capacity problem; projection is an integrity problem, and they require opposite corrections.**

The veridical throughput `V = E min(r,1)` and the confabulated fraction `1 − 1/r` are established with a seeded audit elsewhere in the corpus, where an observer at `r = 1.724138` returned a false-discovery rate of 0.4200 exactly and 63 per cent of the steady-state store was error [Curzi, 2026m]. **This paper contributes the recursion, not the audit.**

The gates for the stored-error recursion:

Gate	Verdict
G1 DIMENSIONS	`M − V` in nats; `eta(M−V)` in `Q`-units; `Z` in `Q`-units, as a difference of two `Q` quantities must be. Sound.
G2 SCALE TYPE	`Z` as a difference is valid on an interval scale. **`Z/Q` — the error fraction, which is the quantity anyone actually wants — requires `Q` ratio-scaled with a true zero and inherits the parent law's conditional verdict.**
G3 LIMITING CASES	`r −> 1`: `M = V`, `Z_inf = 0`, no stored error ever accumulates. `r −> infinity` with the cap in force: `M −> ln N`, `V −> E`, `Z_inf −> eta(ln N − E)/delta`, **bounded** — saturation, not divergence. `r < 1`: `Z = 0`. `delta −> 0`: `Z` grows without bound, error that is never forgotten.
G4 FIXED POINTS	`Z_inf = eta(M*−V*)/delta`, independent of `C` because the cost term cancels. **The equilibrium quantity of stored error in a mind does not depend on how expensive that mind's life is.** `Z = 0` iff `r <= 1`.
G5 IDENTIFIABILITY	Requires `r` and `E` measured independently. **`Z` cannot be recovered from `M` alone, because `M` is a product and the split is exactly the unidentified direction** (Section 3.4).
G6 FALSIFICATION	H5. **Kill condition:** correction-event rate uncorrelated with `r` after controlling for `M`.
G7 REPRODUCIBILITY	Unattempted; inherits the open question of whether `r` is trait-like or item-set-specific.

21.7.4 7.4 The correction load

Over-framing shows up in the books not as bad `Q` but as rising `C`, on a lag. Stated as an equation:

```
THE CORRECTION LOAD       C_t = c_0 + kappa * Z_t
```

with `c_0` the baseline operating cost in `Q`-units per period and `kappa` the correction cost per `Q`-unit of stored error per period. **Linearity in z is a postulate, badged**: the simplest admissible form, chosen for tractability and not because anyone has measured the shape. A convex form — error that becomes disproportionately expensive — is equally plausible a priori.

`kappa -> 0` returns the single-track law, which is the correct nesting. Large `kappa` drives `C` above `eta ln N` and the sustainability ceiling forecloses everything: **the over-framed observer's regime becomes unsustainable by no other mechanism than its own accumulated error.** At equilibrium `C_inf = c_0 + kappa eta (M*-V*)/delta`. **The lag is `tau = 1/delta`: the cost rise arrives one time constant after the over-framing that caused it, which is why the condition is stable for years.** The falsifier is clean and within-subject: **if `C` does not rise on a lag of order `tau` following a sustained increase in `r` at fixed `E`, the correction load is fictitious and should be deleted from the formulary.** It has not been run. Without an external instrument for `E`, `kappa` and the `Z` scale trade off exactly and neither is identified.

21.7.5 7.5 Retention loss and its three channels

`delta` is the fraction of stored order lost per period with no maintenance and no input. For a person it decomposes into three channels that are routinely confused and have different remedies:

```
delta_forget   memory decay: what is no longer retrievable
delta_atrophy  skill decay: what can still be described but no longer executed to standard
delta_drift    identity decay: what no longer fits, because the self it belonged to has moved
```

`delta_drift` is the channel that has no ordinary name and does the most work. It is not loss of a capacity; it is loss of the *relevance* of a capacity to the person now holding it. A trained cellist who has not touched the instrument in a decade has lost `Q` to atrophy. A trained cellist who still plays but for whom playing no longer organises anything — no longer sits under a decision, no longer selects a room, no longer picks the people — has lost `Q` to drift. Nothing was forgotten. **The stored order stopped being structure and became furniture.** Drift is why stored order must be re-anchored rather than merely rehearsed.

The channels act on the same stock in the same period and are approximately independent, so they compose multiplicatively on retention rather than additively on loss:

```
keep  = (1 - delta_forget)(1 - delta_atrophy)(1 - delta_drift),    delta = 1 - keep
```

At the worked weekly values `0.020`, `0.008` and `0.004`, `keep = 0.980 x 0.992 x 0.996 = 0.96827136` and `delta = 0.03172864` per week. The naive sum is 0.032. **The overcount is 0.00027, which is 0.85 per cent — negligible at these rates and not negligible at large ones**, since four channels of 0.15 give 0.4780 against a naive 0.60, an overcount of 20.3 per cent. Independence is the falsifiable claim: **if the measured composite differs significantly from the product of separately measured channels, the channels interact and the multiplicative form is wrong.** Three zero-input windows test it directly. The practical obstacle is that a window suppressing rehearsal also suppresses use, so `delta_forget` and `delta_atrophy` may not be separately identified; where they cannot be, the composite is reported and the confounding stated.

```
tau     = 1/delta                    periods (time constant)
t_half  = ln 2 / (-ln(1-delta))      periods (half-life of unmaintained stock)
3 tau  ~ 95% of the way to equilibrium;   5 tau ~ 99%
```

`delta` per week	`tau` (wk)	half-life (wk)	3`tau` (wk)	3`tau` in months
0.005	200.00	138.28	600.00	138
0.010	100.00	68.97	300.00	69
0.020	50.00	34.31	150.00	35
0.031729	**31.52**	**21.50**	**94.55**	**21.8**
0.050	20.00	13.51	60.00	13.8
0.100	10.00	6.58	30.00	6.9
0.200	5.00	3.11	15.00	3.5

Read the highlighted row as the sentence it is: **for this subject a change of regime takes about twenty-two months to substantially arrive, and impatience before then is a misreading of the arithmetic rather than of the person.**

Measuring `delta`. Choose one component of `Q` and one frozen proxy for it, written down before measuring. Measure `Y_0`. Impose a zero-input window of `k` periods in which that component receives no rehearsal, no instruction and no use; incidental use invalidates the window. Measure `Y_k`. Then `delta = 1 - (Y_k/Y_0)^{1/k}`. Repeat on a second component: **if the two rates differ by more than a factor of two there are two stocks, not one, and they must be tracked separately.**

Two honesty notes. **The classical evidence that unmaintained material decays steeply and then flattens is not represented in this paper's bibliography**, so the structural fact — that unmaintained material decays, fast at first — is carried here without a citation, and no numbers are taken from that literature, because its numbers belong to nonsense syllables and one procedure and do not generalise to anyone's stored skill. Second, **constant `delta` is a modelling choice** and it is the wrong one if the decay is genuinely steeper-then-flatter over the window of interest. Fit it, inspect the residuals, and where the constant-rate model misfits, use two stocks with different rates rather than pretending one rate fits.

When high retention loss is wanted. A person with no forgetting cannot learn. Stored order that should be shedding includes procedures correct for a role no longer held; the grudge, which is an internalised relationship maintained at cost against no returning input; the identity built for a changed environment; expertise superseded and now defended rather than used. Each draws `delta Q` every period, and Section 7.10 is the lever.

21.7.6 7.6 Conversion efficiency as a ladder of six rungs

`eta` is `Q`-units of durable structure deposited per nat of moment, and it is the central quantity of this section. **Most people's `eta` is not merely low; it is low by two orders of magnitude, and they hold no instrument that would tell them.**

Experience does not become character in one step. Seven stages, six transitions:

```
UNDERGONE -> NOTICED -> NAMED -> ENCODED -> REHEARSED -> ENACTED -> DEFAULTED
         y1         y2       y3         y4           y5         y6

UNDERGONE   the period happened to the subject
NOTICED     they registered that something happened that was not the expected thing
NAMED       they gave it a description distinguishing it from its neighbours
ENCODED     the description was committed to a durable medium: written, drawn, told, built
REHEARSED   it was returned to on a schedule, not on an impulse
ENACTED     it changed a decision at least once, observably
DEFAULTED   it changed what they do at that decision point without deliberating

eta = y1 * y2 * y3 * y4 * y5 * y6
```

A dimensional note, required by the audit of Section 12.1 and easy to miss. Five of the six rungs are pure fractions. **The sixth, `enacted -> defaulted`, is the unit-bearing rung: it converts nats of moment into `Q`-units of stored disposition and carries `eta`'s units of `Q`-units per nat.** The first five say what fraction of the moment survives to the point of conversion; the last says what the conversion is worth. Reporting them together as six fractions is a convenient shorthand and becomes an error the moment anyone averages them. **This is a real inconsistency in the naive statement of the ladder and it is resolved by declaring the last rung as the unit-bearing one, not by ignoring it.**

`eta` is a product of pass-through fractions, and products of fractions are small. That single structural fact answers the question of why most experience has `eta` near zero, and nothing pathological is required. Six stages at a respectable 60 per cent each give `0.6^6 = 0.046656`. Six stages at 90 per cent each — an implausibly excellent subject — give `0.531441`, and that is the ceiling of what diligence alone can buy.

For the worked case, measured stage by stage:

Transition	Yield	Cumulative
undergone -> noticed	0.55	0.550000
noticed -> named	0.70	0.385000
named -> encoded	0.50	0.192500
encoded -> rehearsed	0.45	0.086625
rehearsed -> enacted	0.65	0.056306
enacted -> defaulted	0.60	0.033784

```
eta = 0.03378375   Q-units per nat
```

Three and a third per cent. Ninety-six and a half per cent of the moment did not become character. Note what this subject is *not*: not careless, not distracted, not unreflective. Every rung yield sits between 0.45 and 0.70. **This is what an attentive, reflective, ordinary life converts, and it converts almost nothing, because the ladder is multiplicative.**

The two worst rungs are `named -> encoded` at 0.50 and `encoded -> rehearsed` at 0.45. They are also the two cheapest to move, because they are mechanical rather than dispositional: encoding is writing it down and rehearsal is a calendar entry.

```
fix encoded->rehearsed only:   0.45 -> 0.90     eta = 0.0675675    (x2.00)
fix both, moderately:          0.50 -> 0.80 and 0.45 -> 0.75
                                                eta = 0.09009      (x2.67)
```

Doubling one rung doubles `eta` exactly, because the product is multilinear: `d eta / d y_i = eta / y_i`, so the elasticity of `eta` with respect to every rung is exactly one and the absolute gain from fixing a rung is inversely proportional to its current yield. **The worst rung is always the best buy — the one place in the framework where the obvious move is also the optimal one.**

A single blocked rung nullifies every other, which is why the aggregate figure is uninformative and the stage-wise figure is not. The ladder's principal virtue is identifiability: each `y_i` is a count over a declared candidate set. **Its identifiability hazard is the candidate set itself** — a subject who enumerates only the experiences they already converted will recover `eta` near one — so the set must be enumerated prospectively, at the point of entry.

The rung most likely to fail its own falsification test is `ENCODED`. The ladder claims the rungs are sequential and non-bypassable; if items are observed reaching `DEFAULTED` without passing `ENCODED`, the ladder is not a chain and the product form is wrong. Some dispositions plainly form without ever being written down. **If that is confirmed, the ladder needs a parallel path and the product form must be replaced.** Whether the six rungs correspond to identified encoding and rehearsal stages is not established by anything in this paper; the nearest external

warrant is the organisational literature on how a practice becomes routine and then invisible infrastructure [Cyert and March, 1963], and it does not supply the stages.

The zero-conversion report. "It was a really meaningful year" is a report about `M`, not about `eta M`. It says the moments were rich and says nothing about deposit. **A year can be the richest of a life and deposit less than a mediocre year with a notebook in it, and the subject will experience the rich year as the more valuable one, because what is experienced is `M` and what accumulates is `eta M`.** The felt quantity and the stored quantity are different quantities, and confusing them is the single most consequential error in ordinary self-assessment. The diagnostic question is not what happened but: **name one decision now made differently, and point to when it changed.** If the answer is unavailable for a period, `eta` for that period was approximately zero, whatever the period felt like.

21.7.7 7.7 The operating draw

`C_t` is everything spent this period on being this person that is *not* proportional to what is stored. The distinction is constantly blurred and matters:

```
delta * Q_t   the MAINTENANCE draw   -- scales with how much self there is to keep
C_t           the OPERATING draw     -- the cost of running, irrespective of the stock
```

Ledger	What it is	Typical proxy
Attention	switching, fragmentation, residue of interrupted work	interruptions per hour x recovery time
Presentation	maintaining a self for an audience: masking, code-switching	hours under observation x a masking coefficient
Carry	unresolved decisions and open loops held in working memory	open loops x periods open
Obligation	commitments serviced without return	hours per week of unreciprocated service
Regulation	emotional labour: suppression, repair, recovery from conflict	recovery hours per week
Correction	repairing the consequences of stored error (Section 7.4)	`kappa * Z_t`

Each is converted to `Q`-units by a declared exchange rate, and **the exchange rate is a postulate every single time.** A subject who converts an hour of masking and an hour of interrupted attention to the same `Q`-cost has asserted something substantive and should say so. The Correction ledger is the one that arrives late: it is measured by counting the events in which a prior belief had to be repaired, and it lags the over-framing that caused it by about `tau`.

Rumination is a `C` term, not an `eta` term. The complete statement needs both halves: `eta ~ 0` **and** `C` large. The loop runs, the moment is revisited, nothing is encoded, nothing is rehearsed on a schedule, nothing changes a decision — so `eta M` contributes nothing — and the Carry ledger runs at full rate throughout. **Rumination is not failed learning; it is an operating cost that impersonates learning**, and it is expensive precisely because it feels like the work of converting. The remedy is not to stop thinking about it but to move the loop one rung up — name it, encode it, schedule the rehearsal — which converts an operating cost into a deposit, and that is the definition of raising `eta`.

21.7.8 7.8 Personal headroom, its sensitivities, and the critical stock

```
h_t = eta * ln N  -  delta * Q_t  -  C_t

   eta * ln N     the STRUCTURAL BUDGET    the most this mind can convert in a period
 - delta * Q_t    the MAINTENANCE DRAW     what it costs to remain the person already there
 - C_t            the OPERATING DRAW       what it costs to operate at all
 ------------
 = h_t            PERSONAL HEADROOM        capacity for the new
```

`h_t` is the capacity for the new, and it is the quantity people are reporting when they say they have nothing left — which is usually treated as a mood and is in fact an accounting statement. The gauge uses `eta ln N`, the ceiling, and not `eta M_t`, the realised moment. **A negative personal headroom is therefore not a statement that this week was bad. It is a statement that no week available to this mind, at this stock, at this cost, is good enough** — and if `h < 0`, no arrangement of the weeks helps; only `eta`, `N`, `C` or shedding `Q` does. The same gate is used as a precondition on protocol design at group scope, where `h < 0` forbids building, `h > 0` caps every increment at `r <= h`, and the gate is worked at `N = 18` with `eta = 0.30`, `delta = 0.06`, `C = 0.55` and `Q = 1.20` to give `h = +0.2451` [Curzi, 2026].

Partial derivatives at the worked operating point, `eta = 0.03378375`, `N = 9`, `delta = 0.03172864`:

Lever	Partial	Value	Reading
raise `eta`	`dh/d eta = ln N`	2.197225 per unit `eta`	strongest; and `eta` is multiplicative in six rungs
cut `C`	`dh/dC = −1`	1.000000 per `Q`-unit cut	one-for-one, always
shed `Q`	`dh/dQ = −delta`	0.031729 per `Q`-unit shed	weak per unit, but `Q` is large
raise `N`	`dh/dN = eta/N`	0.00375375 per added category	**negligible**

Read the last two rows together. **Cutting weekly operating cost by 0.0038 `Q`-units buys exactly as much headroom as inventing an entirely new, genuinely distinct category of thought.** Dropping one recurring obligation beats a year of broadening.

And the logarithmic ceiling bites internally as hard as at group scope. To double the structural budget by raising `N` alone, `N` must go from 9 to 81:

```
eta * ln 9  = 0.03378375 * 2.197225 = 0.074230
eta * ln 81 = 0.03378375 * 4.394449 = 0.148461  = exactly 2 x
```

The number of distinct categories held must be squared to double what can be converted. Nobody broadens their way out of a headroom problem.

The critical stock. `Q_crit = (eta ln N − C)/delta` is the stock at which headroom reaches zero. For the worked baseline, `Q_crit = (0.074230 − 0.030)/0.03172864 = 1.39402` `Q`-units against `Q_0 = 1.20`: **the subject is at 86 per cent of the stock their regime can carry**, and a promotion into a role with more to maintain, or one inherited obligation, pushes them over it immediately. Under the corrected regime of Section 10.2, `Q_crit = 5.5454` — **the same person, after three changes, can carry four times as much self.** Capacity for stored order is not a fixed personal attribute; it is `(eta ln N − C)/delta`, and every term in it is engineerable.

Why the accomplished have less headroom than the beginner. `h_t` falls as `Q_t` rises. The beginner has `Q ~ 0`, so the maintenance draw is near zero and almost the whole structural

budget is headroom. **The beginner is not learning faster because of youth; the beginner is learning faster because nothing is being spent on upkeep.** The accomplished subject has a large Q, and every period delta Q comes off the top: skills kept, relationships serviced, knowledge refreshed, the identity all of it hangs on re-anchored against drift. **At sufficient Q the maintenance draw alone exhausts the budget, and the subject, working exactly as hard as ever and at full competence, has no capacity for anything new.** Calling that a plateau is a misdiagnosis; a plateau is effort with no result, and this is upkeep with no surplus. The organisational counterpart is documented: slack is what an organisation spends on being the organisation it already is [Cyert and March, 1963], and legibility that removes local variety removes the capacity that variety supplied [Scott, 1998].

The gauge's binding weakness is its sensitivity to the cost ledger's exchange rates. In the worked survey, doubling one ledger's weight changes h_0 by more than its entire value. **A headroom sign should never be reported without its sensitivity to the cost weights**, and Section 10.2 reports the baseline reading as unestablished for exactly that reason.

21.7.9 7.9 The fixed point, and the headroom identity

With constant M \ensuremath{\equiv} M*, C \ensuremath{\equiv} c* and delta > 0:

```
Q_inf   = (eta M* − c*)/delta
Q^V_inf = (eta V* − c*)/delta
Z_inf   = eta (M* − V*)/delta
```

At the fixed point delta Q_inf = eta M* − c*, so

```
h_inf = eta ln N − delta Q_inf − c* = eta ln N − (eta M* − c*) − c* = eta ( ln N − M* )
```

At equilibrium, personal headroom equals conversion efficiency times the gap between the ceiling and the moment actually achieved. The cost term cancels exactly. This is an algebraic identity requiring no further assumption, and it says something non-obvious: a settled person's remaining capacity depends on eta and on how far their lived moments fall short of what their distinctions could support, and **not at all on how expensive their life is** — because at equilibrium the expense has already been absorbed into the size of the self they carry.

The corollary is stark. h_inf = 0 if and only if M* = ln N. **A person who has genuinely saturated their own distinctions has zero headroom at equilibrium, and the only way onward is to raise N** — to hold a genuinely new *kind* of category — which the sensitivity table has just priced as expensive and slow. That is the honest account of the ceiling a mature practitioner runs into, and it is why the practitioners who keep moving are the ones who take up something unrelated.

21.7.10 7.10 Shedding stored order

The fourth lever is the one nobody considers, and internally people find it shocking: **deliberately reduce Q to recover h.** The arithmetic is unarguable. dh/dQ = −delta, so every Q-unit shed returns delta Q-units per period of headroom, forever, at zero ongoing cost. For the worked subject, shedding 0.5 Q-units returns 0.5 x 0.031729 = 0.015864 per week — **2.58 times their entire current headroom.**

What shedding looks like internally: retiring a skill, by declaring in writing that one is no longer the person who does that and letting the atrophy proceed unopposed; closing a relationship ledger, which means ending the *maintenance* of a relationship that returns nothing rather than ending the relationship; dropping a role, a standing obligation, an identity requiring periodic performance; deleting an archive, since stored order that must be curated is stored order that draws; abandoning a publicly held position, because a view that must be defended has a delta Q cost and the defence is the draw; and retiring stored error, the one

shedding target the two-track ledger identifies directly, since Z is Q that was never earned and decays on its own the moment manufacturing stops.

Two constraints transfer. **Shed with a use in mind, or the subject will shed and refill**, because recovered headroom is a budget and an unallocated budget is spent by whatever is nearest — usually what was just shed, wearing a new name. And **shedding a role that other people are standing on moves cost onto them**, which makes it an external intervention governed by the declination constraint rather than by this section. Shed the ones that are yours.

21.7.11 7.11 The measurement protocol

```
PROTOCOL Q-1 — PERSONAL STORAGE SURVEY

Preconditions
  A1. Declare the period. Weekly is the default; monthly loses resolution, daily is noise.
  A2. Enumerate the distinction inventory (Sections 4–6). This gives N. Freeze it.
  A3. Choose and freeze one proxy per Q-component. Written, signed, dated.
  A4. Nominate the EXTERNAL instrument for E. It is the item most often skipped, because it
      is the only one that cannot be done from inside.

Measurements
  B1. delta, by the zero-input window, on at least two components, non-overlapping.
  B2. eta, stage-wise. Report all six rung yields, not only the product.
  B3. C, by the six ledgers, exchange rates declared in writing.
  B4. Q_0, by the frozen proxies.
  B5. E_t and r_t per period, logged prospectively, never reconstructed.

Derived
  D1. M_t = min(r_t E_t, ln N)        V_t = E_t min(r_t, 1)        Z_t = Q_t − Q^V_t
  D2. h_t = eta ln N − delta Q_t − C_t
  D3. Q_inf, Q^V_inf, Z_inf
  D4. Q_crit = (eta ln N − C)/delta
  D5. tau = 1/delta, t_half, 3 tau
  D6. h_inf = eta (ln N − M*)  −− and check it against D2 evaluated at Q_inf

Checks
  X1. Proxy independence: does the Q-proxy rise on busy periods? If yes, DISCARD it.
  X2. Admissibility: is C_t <= (1−delta)Q_t + eta M_t every period? If not, the model has
      already said the regime is inadmissible and the reading is void.
  X3. Shuffled-input control: does a time-permuted M series predict the Q trajectory as well?
      If yes, the accumulation structure is doing no work and the survey has failed.
  X4. Two-track check: is Q^V_inf positive? A negative earned equilibrium is the steady-state
      theorem's explicit refusal and must be reported, not smoothed.
```

Checks X3 and X4 are not optional. X3 is the difference between an instrument and a story and costs one afternoon; the shuffled-input control is the baseline the corpus's own protocol treats as decisive [Curzi, 2026i]. X4 is the difference between a self and a monument to one. The wider methodological requirement — declare the rule before the data are examined, and report the result whichever way it falls — is not this paper's invention and its rationale is well documented [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013].

The named identifiability hazard is that the proxy has been allowed to move with the input rather than with the stored order. A journal that gets longer on busy weeks is not a measure of Q. A contact list that grows with attendance is not a measure of an internalised relationship. Internally this is worse than at group scope, because a busy person genuinely feels larger. The defensible proxies and their traps:

Component	Defensible proxy	The trap
procedural capacity	performance on a frozen task, unrehearsed, timed	rehearsing the test
declarative structure	cued recall against a frozen item set	recognition instead of recall
internalised relationships	count of people who would actually be called, tested	count of contacts
settled defaults	observed choice frequencies at recurring forks	self-report

21.8 8 Design specifications

The specifications are stated as requirements on a survey or a practice, not as advice. They are labelled `SF` for the framing half and `SQ` for the storage half.

SF1 — Framing register, written and dated. Name, primitives, strengths, blind spots, provenance. Reviewed on a fixed cadence, not when it occurs to someone.

SF2 — Provenance column mandatory. A register without provenance cannot detect the single-lineage mechanism and is half an instrument.

SF3 — Independent-first, in writing. Every consequential judgement runs each framing to a written conclusion before the next is consulted. It blocks the fastest destroyer of `u` at the lowest available cost.

SF4 — Report `N` and `u` separately. `N_eff` alone fails the identifiability gate. Publish the pair or publish nothing.

SF5 — Quantitative `u` from error decorrelation only. I1 to I3 are triage. Only I4 yields a number admissible in `F_int`, and only with its confidence interval when `|rho| > 0.7`.

SF6 — Subspace check at `N >= 5`. Run I5. If two components carry nearly all the variance, report the participation ratio in place of `1 + (N−1)u_bar` and say why.

SF7 — Disagreement log, unresolved entries preserved. An entry closed as “unresolved” is the most valuable kind. Deleting unresolved entries is prohibited.

SF8 — Scheduled synthesis. Set the deferral period in advance. Synthesis before the period expires requires a written reason recorded in the log.

SF9 — Cost accounting before acquisition. Before adding a framing, compute the marginal gain from Table 1 at the measured `u` and compare it against `c1 + c2(n−1)`. **At `n >= 10` the burden of proof is on the addition.**

SF10 — Shed before adding. When `n > n*`, retire the framing with the highest mean `rho` to the rest — computed **within the block flagged as redundant**, since whole-set means are diluted by cross-block terms. Retirement means removing it from the register and from the independent-first rotation; it does not mean forgetting it.

SF11 — Single-subject scope declaration. All parameters are person-indexed until the reproducibility gate is passed. They may not be stated in the third person.

SF12 — Decline path preserved. Every protocol in Section 5.3 is optional and declining costs nothing.

SQ1 The period shall be declared in writing before any measurement, and every reported value of `delta`, `eta`, `C`, `M`, `E` and `h` shall carry that period.

SQ2 The distinction inventory establishing `N` shall be enumerated and frozen before the survey window opens. `N` shall not be revised inside a window.

SQ3 Every `Q` proxy shall be declared in writing, dated, and shall pass check X1: it must not co-move with period activity level.

SQ4 `E_t` shall be measured by an instrument outside the observer. **A survey in which `E` was estimated by the subject is a survey in which `r` and `E` are not separately identified, and it shall**

say so in print.

SQ5 Both tracks shall be reported. `Q` without `Q^V` shall be refused, because a single figure cannot distinguish stored knowledge from stored error and the subject cannot tell from inside.

SQ6 `eta` shall be reported stage-wise as six rung yields plus their product. A bare aggregate shall be accepted only where stage-wise measurement is impossible, and the impossibility shall be stated.

SQ7 `delta` shall be decomposed into its three channels and composed multiplicatively on retention, never summed on loss.

SQ8 `C` shall be itemised across the six ledgers, and every exchange rate used to commensurate a ledger into `Q`-units shall be stated as a postulate with its badge.

SQ9 `delta Q_t` and `C_t` shall be reported as separate lines. Combining the maintenance draw and the operating draw into one cost figure is a specification violation, because the two respond to different levers.

SQ10 Headroom shall be computed with the ceiling term `eta ln N`, never with `eta M_t`. A gauge computed on the realised moment is not a headroom reading and shall not be called one.

SQ11 No planned increment shall exceed `h_t`. A plan requiring `r_t > h_t` shall be rejected at the planning stage, not attempted and then diagnosed as a failure of will.

SQ12 `Q_inf`, `Q^V_inf`, `Z_inf` and `Q_crit` shall be computed at every survey. A subject whose `Q_0` exceeds `Q_inf` shall be informed, in those terms, that the regime is a declining one.

SQ13 Before any regime change is judged, `3 tau` periods shall have elapsed. Judgements made earlier shall be recorded as premature and shall not be used to abandon the change.

SQ14 The admissibility condition shall be checked each period. A violation voids the reading and indicates either a mismeasurement or a genuinely inadmissible regime; the survey shall state which.

SQ15 The shuffled-input control shall be run at least once per survey. A survey without it shall be labelled uncontrolled in print.

SQ16 Cross-person comparison of `E`, `r`, `eta`, `Q` or `Z` shall not be made until a separation property is established for the operationalisation in use. **Personal parameters are within-subject indices until proven otherwise.**

SQ17 Any shedding of `Q` that transfers cost to another person shall be treated as an external intervention and governed by the declination constraint, not by this paper.

SQ18 Every postulate used in a personal survey — scalar `Q`, constant `delta`, the linear correction load, the ledger exchange rates, the proxy relation — shall be listed with its badge in the survey document. **A survey that does not carry its postulate list is not a survey.**

21.9 9 Failure modes

Nine faults of the framing half, labelled `FF`, and twelve of the storage half, labelled `FQ`. Each carries a signature, a detection route and a fix. **These are diagnostic proposals, not measured syndromes.**

21.9.1 9.1 Faults of the framing set

FF1 — THE SINGLE WINDOW. *Damages* `u`, `N` and the moment ceiling simultaneously. *Signature:* one framing applied to everything, experienced as a coherent worldview; `N_eff = 1`, `F_int = 0`; every situation understood immediately. *Detection:* the collision test — if no framing has ever produced a conclusion that surprised the subject, there is one framing. *Fix:* lineage import, the expensive protocol and the only one available, because `u` cannot be raised among a set of size one. Table 1 prices the second framing at high `u` at 0.6931 nats, the largest single increment obtainable in this paper.

FF2 — THE PARALLEL WALL, INTERNAL. *Damages* `u`; the dominant fault. *Signature:* many framings, one lineage, all agreeing, and the agreement read as convergent evidence. **It is echo, and the arithmetic prices it at exactly zero.** *Detection:* the lineage census for triage, error decorrelation for the number — `rho > 0.9` across a framing set means `u < 0.19` and `N_eff < 2` at `N = 6`. *Fix:* SF10 and MP5 together: retire the most redundant, import from outside the lineage. Section 10.1 does exactly this.

FF3 — THE RUMINATIVE LOOP. *Damages* `eta`, and through it `Q`. *Signature:* one framing iterated many times on one situation, with no artefact and no new input; high apparent effort, `u = 0`, no storage. *Detection:* count artefacts. Hours of internal processing with nothing written, decided or changed is `eta = 0` by measurement, not by judgement. *Fix:* an artefact requirement — every pass produces one written line — plus MP2 to force a second framing into the loop. The `eta` fix is cheaper and comes first.

FF4 — IDENTITY CAPTURE. *Damages* `u`, by rotating every other framing toward the captured one. *Signature:* one framing never loses an internal argument; attempts to argue against it feel like attacks rather than exercises. *Detection:* over the disagreement log, tabulate which framing prevailed. A framing with a 100 per cent win rate over twenty logged disagreements is not winning on merit. *Fix:* MP6, with the "using only" constraint enforced in writing.

FF5 — THE GLAZING BILL. *Damages* `C`, quadratically, while `F_int` improves by percentages. *Signature:* a large framing collection, chronic indecision, the sense that every question opens into six others. Table 3: at `n = 20`, surplus per reconciliation pair is 0.01238 against 0.23105 at `n = 3` — **a factor of 18.7 worse per unit of load.** *Detection:* compute `V(n)` with estimated costs; if `V(n) < V(n−1)`, the subject is past `n*`. *Fix:* SF10. Retire by highest mean `rho`, which removes load at the least cost in surplus. Section 10.1 performs this move and notes that it *lowers* surplus in the short run and is still correct.

FF6 — THE BORROWED WINDOW. *Damages* `N`, by inflating the nominal count with framings that cannot actually be run. *Signature:* the register lists framings the subject can name and describe but has never used to generate a prediction differing from their default. *Detection:* the decorrelation instrument requires each framing to emit predictions. **A framing that cannot produce a prediction is not in the set**, and the instrument discovers this by producing no data for it. *Fix:* remove from the register until it can be operated, and recount `N`. Expect `F_int` to fall; that fall is a correction, not a loss.

FF7 — THE MOOD-INDEXED SET. *Damages* `u`, at exactly the wrong times. *Signature:* framing availability tracks affective state; under strain the accessible set narrows and agrees with itself. *Detection:* log which framings were consulted alongside a state rating, and correlate. **A set whose membership depends on state has a state-dependent `u`, and its average overstates the `u` available when it matters.** *Fix:* MP3 and the register itself — a written list is state-independent in a way that recall is not. This is why the register is a file and not a habit.

FF8 — PREMATURE INTEGRATION. *Damages* `u`, irreversibly for the question at hand. *Signature:* a synthesis arrived at quickly, after which the component disagreements cannot be reconstructed; feels like insight. *Detection:* try to state what each framing said before the synthesis. If that is impossible, integration preceded the data. *Fix:* MP7 and SF8.

FF9 — THE UNAUDITED COUNT. *Damages* every downstream computation. This is the arithmetic error, not the psychological one. *Signature:* `ln N` used where `ln N_eff` belongs — ceilings, headroom and moment bounds computed from the nominal framing count. *Detection:* check whether `u` appears anywhere in the calculation; if not, `N_eff` was not computed. *Fix:* audit first, always. **Difference is counted before members are.**

21.9.2 9.2 Faults of the storage account

FQ1 — THE UNCONVERTED YEAR. High `M`, rich descriptions, strong subjective significance, `Delta Q` indistinguishable from zero across `3 tau` periods, and no decision the subject can name that changed. *Mechanism:* `eta` near zero, almost always at `named -> encoded` and `encoded ->`

rehearsed, the rungs that feel like processing and are not. *Fix:* instrument the ladder stage-wise and fix the worst rung first.

FQ2 — THE MAINTENANCE TRAP OF THE ACCOMPLISHED. h_t near zero at high Q_t, undiminished effort and competence, no new capacity for years; self-described as a plateau and often attributed to age. *Mechanism:* delta Q_t has grown to consume the structural budget and Q_t is near Q_crit. *Fix:* shed, or raise eta. Raising N is arithmetically futile here. **Do not attempt to fix a maintenance trap by working harder; effort does not appear in the gauge.**

FQ3 — THE RUMINATION LOOP. High subjective effort, high Carry ledger, repeated return to the same content, Delta Q = 0, and a rising C experienced as diligence. *Mechanism:* eta ~ 0 and C large simultaneously. *Fix:* move the loop one rung up. If it will not encode, it is not a thought, it is a load, and the correct move is to shed it.

FQ4 — THE PROXY THAT IS THE INPUT. Q appears to rise in every busy period and fall in every quiet one, with a suspiciously high correlation to activity. *Mechanism:* the proxy tracks M rather than Q. *Fix:* discard the proxy. **A proxy for stored order must be measurable on the quietest week of the year.**

FQ5 — THE UNBUDGETED IDENTITY. C computed from time and effort alone, h comfortably positive, persistent unexplained exhaustion. *Mechanism:* the Presentation and Regulation ledgers were not counted; masking, code-switching and emotional repair are operating costs and are frequently the largest. *Fix:* complete the six ledgers, declare the exchange rates, recompute.

FQ6 — RETENTION SET TO ZERO. Nothing is ever released: grudges maintained, superseded expertise defended, archives curated, positions held. Q large and rising, h at or below zero, and the subject reports that they simply have a good memory. *Mechanism:* the delta -> 0 case — no fixed point, Q grows linearly, the maintenance draw grows with it until it exhausts the budget [Curzi, 2026a]. *Fix:* deliberate shedding. **A system with no forgetting cannot learn, and internally that is not a metaphor.**

FQ7 — THE SINGLE-TRACK LEDGER. Q reported without Q^V; stored order rising, confidence rising, and — on a lag of about tau — an unexplained increase in the frequency of corrections, contradictions, surprises and repairs. *Mechanism:* r > 1 sustained, Z_inf accumulating invisibly, the correction load arriving one time constant later. **From inside there is no difference between the tracks, which is precisely why the second book has to be kept on purpose.** *Fix:* measure r, measure E externally, run both recursions, report Z/Q. If the ratio exceeds one third, the correction is calibration, not effort.

FQ8 — THE BORROWED FIXED POINT. A subject converging on a Q_inf computed from someone else's parameters and reading the shortfall as personal deficiency. *Mechanism:* Q_inf depends on four personal numbers; adopting another person's destination without their eta, delta, M* and c* adopts a target one's own regime cannot produce. *Fix:* compute one's own. If the destination is genuinely wanted, the question is which of the four parameters must change to make it the fixed point of *that* regime — an engineering question with an answer, and not a question about worth.

FQ9 — THE CEILING MISREAD. h computed as eta M_t − delta Q_t − C_t and reported as headroom; the gauge reads negative on a dull week and positive on a vivid one, and the subject concludes their capacity fluctuates weekly. *Mechanism:* confusing the realised moment with the ceiling. *Fix:* use eta ln N. Then a negative reading means what the sustainability ceiling says: **no arrangement of the weeks fixes this** — a far more actionable finding than a fluctuating one.

FQ10 — THE SHED WITHOUT A USE. A subject sheds a role, experiences three weeks of relief, and is back at the same headroom within a quarter with a different set of commitments. *Mechanism:* recovered headroom is a budget and an unallocated budget is spent by whatever is nearest. *Fix:* allocate the recovered h in writing, before the shedding, to a specific increment with r_t <= h_t.

FQ11 — THE COUNTERFEIT STOCK. Q proxied by credentials, titles, publications or possessions; the proxy stable or rising while every direct measure of capacity falls. *Mechanism:* credentials do not decay at delta and capacity does. The proxy was chosen for its durability,

and its durability is exactly what disqualifies it. **A proxy that cannot fall cannot measure a quantity that can.** *Fix:* every `Q` proxy must be a *current* measurement of a *current* capacity.

FQ12 — THE SELF-REPORTED ENVIRONMENT. `E` logged by the subject each week, `r` computed from it, both stable and neither ever contradicting the subject's account of themselves. *Mechanism:* if `E` comes from the same observer whose framing is being audited, `r = D/P` is estimated using the very quantity `P` distorts. **A confident observer will report a rich environment and a low distortion, and the two errors conceal each other exactly.** *Fix:* SQ4. If no external instrument is available, the survey may still be run, but the `r` figure is uninterpretable and must be printed as such.

21.10 10 Results

Two cases are worked end to end. **Both are constructed. No dataset was collected for this paper**, and the correlations, ledger weights and rung yields below are stipulated parameters demonstrating the method rather than observations of any person. They establish that the procedure runs, that it reports its own failures, and that its arithmetic is reproducible with a calculator. They are not evidence that any person behaves this way.

21.10.1 10.1 One observer, six framings

The register. Six framings, with a provenance column as SF2 requires:

```
W1  mechanism        how does this thing physically work
W2  quantitative     what do the numbers say
W3  systems          what are the feedback loops and the stocks
W4  optimisation     what is being maximised, subject to what
W5  narrative        what story is being told, by whom, to whom
W6  bodily           what does this feel like in the body, what is the state
```

W1 to W4 all trace to one engineering-quantitative training; W5 and W6 came from elsewhere. **The lineage census flags the problem before a single number is computed.**

Measurement by error decorrelation. Thirty consequential predictions logged over eight months, one per framing per question, outcomes recorded. Pairwise error correlations and `u = 1 − rho^2`:

TABLE 7 — PAIRWISE MEASUREMENT (stipulated worked case)

pair	rho	u
W1 mechanism / W2 quant	0.88	0.2256
W1 mechanism / W3 systems	0.83	0.3111
W1 mechanism / W4 optimis.	0.86	0.2604
W1 mechanism / W5 narrative	0.21	0.9559
W1 mechanism / W6 bodily	0.14	0.9804
W2 quant / W3 systems	0.79	0.3759
W2 quant / W4 optimis.	0.91	0.1719
W2 quant / W5 narrative	0.18	0.9676
W2 quant / W6 bodily	0.09	0.9919
W3 systems / W4 optimis.	0.84	0.2944
W3 systems / W5 narrative	0.26	0.9324
W3 systems / W6 bodily	0.12	0.9856
W4 optimis. / W5 narrative	0.19	0.9639
W4 optimis. / W6 bodily	0.11	0.9879

```
W5 narrative    / W6 bodily      0.34    0.8844

mean pairwise u over 15 pairs   =  0.6860
N = 6,  N_eff = 1 + 5(0.6860)   =  4.4298
F_int = ln(4.4298)              =  1.4883 nats
ceiling ln 6                    =  1.7918 nats
percentage of ceiling           =  83.07 %
```

The diagnosis the mean hides. Eighty-three per cent of ceiling looks healthy. Split the pairs by lineage and it is not:

```
within-lineage pairs (W1-W4), 6 pairs:   mean u = 0.2732
    the lineage ALONE:  N_eff = 1 + 3(0.2732) = 1.8196,  F = 0.5986 nats

cross-lineage pairs, 9 pairs:            mean u = 0.9611
```

Four framings, years of training each, auditing to an effective count of 1.82. The subject's surplus is carried almost entirely by W5 and W6 — the two framings they would call their least rigorous. This is the crossing-versus-divergence decomposition showing up internally: rich in the crossing term, starved of the divergence term. The group-scope form of the same diagnosis is sharp and negative — **adding a seventh discipline to a worked institute makes it worse**, dropping the period change to -0.002863 and the fixed point from 6.265 to 5.964, because divergence rather than domain count was the deficiency [Curzi, 2026d]. **The remedy is a different kind of framing, not another one of the same kind**, and adding one of the same kind is measurably worse than adding none.

Step one: retire the two most redundant. By SF10, retirement is by highest mean `rho` computed **within the block flagged as redundant**. Across the whole set the mean correlations are nearly identical (W1 0.584, W2 0.570, W3 0.568, W4 0.582) because the cross-lineage terms dominate and wash out the distinction; within the W1–W4 block they separate cleanly:

```
within-block mean rho:   W1 = 0.857   W2 = 0.860   W3 = 0.820   W4 = 0.870
```

W4 and W2 are the two most redundant and are retired.

```
remaining: W1, W3, W5, W6      pairs = 6
mean u    = 0.8416
N = 4,  N_eff = 1 + 3(0.8416) = 3.5249
F_int     = 1.2599 nats,  ceiling ln 4 = 1.3863,  90.88 % of ITS ceiling

change vs baseline:  F_int  1.4883 -> 1.2599  =  -0.2285 nats
                     pairs     15  ->     6   =  a 60% cut in reconciliation load
```

Surplus went down. This is the correct move and the honest report of it. The set is now more efficient — 90.9 per cent of its own ceiling against 83.1 — and much cheaper, but a smaller ceiling is a smaller ceiling. **Shedding alone does not build; it buys headroom to build with.**

> **A source correction, recorded rather than applied silently.** The manuscript from which this case is drawn prints the retained set's mean non-parallelism as `u = 0.9205`. **That figure is wrong.** The mean of `1 - rho^2` over the six retained pairs is **0.8416**, and the line `N_eff = 1 + 3(0.9205) = 3.5249` does not evaluate: `1 + 3(0.9205) = 3.7615`. Every downstream number in the manuscript — `N_eff = 3.5249`, `F_int = 1.2599`, 90.88 per cent of ceiling, and the net value `V = 0.5879` reported below — is consistent with 0.8416 and inconsistent with 0.9205, so the computation was performed correctly and the intermediate value was misprinted. **The figure is corrected here and the correction changes no result.**

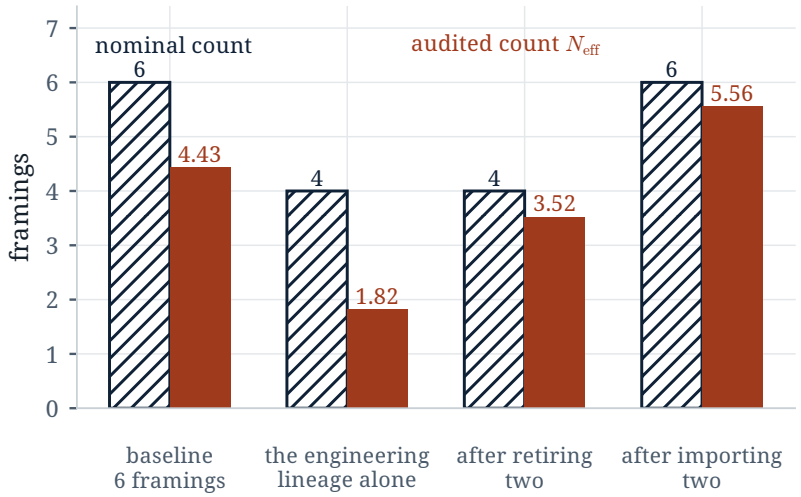

Figure 21.3: **Restructuring beats enlarging, and the mean over pairs conceals the reason.** Nominal framing count against audited count `N_eff` for four configurations of the same subject. The baseline six framings audit to 4.43; the four framings of the single engineering lineage, taken alone, audit to **1.82**, which is the diagnosis the whole-set mean of `u = 0.6860` hides. Retiring the two most redundant leaves four framings auditing to 3.52 at 60 per cent of the reconciliation load; replacing them with two imports from outside the lineage returns the count to six and the audit to 5.56, a 25.4 per cent gain at identical `N` and identical pair count. Computed from the pairwise table above; the correlations are stipulated, not observed. Generated by `figs/src/CCP-021_fig03.py`.

Step two: spend the headroom on genuinely different windows. Two imports from outside the engineering lineage entirely: **W7, a craft framing** (what a person who builds this by hand would notice), and **W8, an adversarial-legal framing** (what someone trying to defeat this would argue). Measured correlations to the retained four, after a second logging period: W7 at 0.16, 0.12, 0.22, 0.31; W8 at 0.24, 0.19, 0.15, 0.10; W7 to W8 at 0.27.

```
N = 6 again,  pairs = 15 again
mean u    = 0.9111
N_eff     = 1 + 5(0.9111) = 5.5554
F_int     = 1.7148 nats
ceiling   = 1.7918         =  95.70 % of ceiling

against baseline, at IDENTICAL N and IDENTICAL pair count:
    F_int   1.4883 -> 1.7148   =  +0.2265 nats
    N_eff   4.4298 -> 5.5554   =  x 1.254
```

> **The same correction applies here.** The manuscript prints the restructured set's mean as `u = 0.9434`; the mean of `1 - rho^2` over the fifteen pairs is **0.9111**, and `1 + 5(0.9434) = 5.7170`, not 5.5554. Again every downstream figure matches 0.9111. **Corrected here; no result changes.**

Same number of framings. Same reconciliation load. A 25.4 per cent increase in the audited count, bought entirely by changing which framings, not how many. This is the practical form of the group-scope result that raising `u` within a fixed body is worth roughly what enlarging the body is worth [Curzi, 2026c], and here the cost differential is total: the pair count did not move.

The storage consequence, which is not what the subject expected. Personal parameters: `eta = 0.60`, `delta = 0.06` per month, `Q = 12.0`, `C = 0.35` per month. One-step growth requires `eta F_int > delta Q + C`:

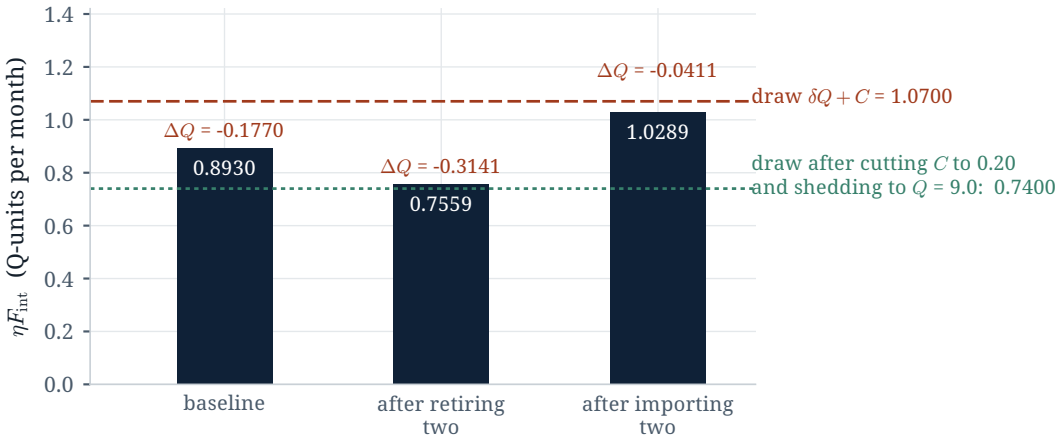

Figure 21.4: **Correct geometric work closed 77 per cent of the gap and did not reverse the decline.** Converted internal surplus `eta F_int` against the period draw `delta Q + C` for the three framing configurations, at `eta = 0.60`, `delta = 0.06` per month, `Q = 12.0`, `C = 0.35`. All three bars fall below the draw line at 1.0700: the baseline by 0.1770, the retired set by 0.3141, and the restructured set by 0.0411. Only cutting the operating cost to 0.20 and shedding stored order to `Q = 9.0` — which lowers the draw line to 0.7400 — turns the account positive, and it does so at the *original* geometry as well. Computed from the parameters shown, not measured; generated by `figs/src/CCP-021_fig04.py`.

```
baseline        eta*F = 0.8930    delta*Q + C = 1.0700    dQ = -0.1770   DECLINING
after step 1    eta*F = 0.7559    delta*Q + C = 1.0700    dQ = -0.3141   DECLINING
after step 2    eta*F = 1.0289    delta*Q + C = 1.0700    dQ = -0.0411   DECLINING
```

All three still decline. The framing work — correct, measured, a 25 per cent improvement in the audited count — did not by itself turn the account around. **It closed 77 per cent of the gap and left the subject still losing stored order every month.** The binding constraint was never the geometry. Applying the remaining levers — shedding stored order by retiring two obsolete commitments carrying maintenance, taking `Q` from 12.0 to 9.0, and cutting `C` from 0.35 to 0.20:

```
after step 2, Q=9.0, C=0.20   eta*F = 1.0289   delta*Q + C = 0.7400   dQ = +0.2889  GROWING
baseline geometry, same cuts  eta*F = 0.8930   delta*Q + C = 0.7400   dQ = +0.1530  GROWING
```

The cost and stock reductions turn the account on their own, at the original geometry. The geometric work is not thereby worthless — it nearly doubles the resulting growth rate, 0.2889 against 0.1530 — but it was not sufficient and was not the binding term.

```
steady states  Q_inf = (eta*F - C)/delta

    baseline geometry, C = 0.35                9.0501
    after step 2,      C = 0.35               11.3144
    after step 2,      C = 0.20               13.8144

headroom  h = eta*ln N - delta*Q - C

    Q = 12.0,  C = 0.35     h = +0.0051      maintenance only; hold, do not build
    Q =  9.0,  C = 0.35     h = +0.1851
    Q =  9.0,  C = 0.20     h = +0.3351
    Q =  6.0,  C = 0.20     h = +0.5151
```

The `h = +0.0051` row diagnoses the original state in one number. The subject was at maintenance exactly, with half a hundredth of a nat of headroom, which is why every new framing felt impossibly expensive and why the correct first move looked like doing less rather than more.

Cost accounting, and the optimum. With `eta = 0.60`, `c1 = 0.030`, `c2 = 0.008`:

```
V(baseline, n=6,  u=0.6860) = 0.5930
V(step 1,   n=4,  u=0.8416) = 0.5879
V(step 2,   n=6,  u=0.9111) = 0.7289

optimum at u = 0.9111:  n* = 7,  V = 0.7420
V(n) profile:  1:-0.030  2:+0.321  3:+0.509  4:+0.622  5:+0.691
               6:+0.729  7:+0.742  8:+0.735  9:+0.711 10:+0.672
```

Two things to notice. **Step one, which lost 0.2285 nats of surplus, cost only 0.0051 in net value**, because the reconciliation saving nearly paid for it: the shed was almost free and bought the headroom that step two spent. And **the subject sits at `n = 6` against an optimum of 7, a difference of 1.8 per cent.** A seventh framing is worth acquiring if one is genuinely available at low `rho`; it is not worth manufacturing.

The falsification rule, declared before the second logging period.

```
PREDICTION   Held-out judgement accuracy over the next 30 logged predictions improves
             after step 2 relative to baseline, and the improvement tracks N_eff
             (x1.254) rather than N (x1.000, unchanged).

KILL 1       Accuracy does not improve, or improves in the framing-count model as well
             as the audited-count model. If N alone predicts as well as N_eff, the u
             term is decoration.
KILL 2       The shuffled-input control matches the model: pair W7 and W8's recorded
             contributions with the wrong questions and refit. If performance holds,
             the framings were not doing the work.
KILL 3       The measured rho values do not recover on the second period within their
             confidence intervals. rho = 0.88 has a wide interval on 30 points and u is
             amplified by 2|rho| = 1.76; non-recovery kills the measurement, not just
             the model.
```

This rule was not run. It is stated so that it can be, and Section 13 records that no prediction in this paper has yet been put at risk.

The rule extracted. Count the windows, check which way they face, and pay for the facing rather than the glass. The subject had six framings and an audited count of 4.43, of which four framings contributed 1.82 between them; retiring two and importing two — no change in count, no change in load — took the audit to 5.56. **And it still was not enough to turn the storage account around, because the binding constraint was `delta Q + C` and not the geometry at all.** Internal surplus is one term in one equation. Measure it, raise it where it is cheap to raise, then check whether it was ever the thing that was binding.

21.10.2 10.2 One observer, one year

A single-subject survey run to Protocol Q-1, weekly periods. **Nothing in this example is a normative target. It is one instrument reading, on constructed parameters.**

Stage 1 — the frozen preconditions.

```
Period:                              1 week
Distinction inventory:               N = 9        ln N = 2.197225 nats
```

```
Internal non-parallelism of framings:   u = 0.42
    N_eff = 1 + (9-1)(0.42) = 4.36      F_int = ln 4.36 = 1.472472 nats
External instrument for E:              a weekly seeded-item audit scored by a second party
Q proxies (frozen, signed):             a timed unrehearsed task; cued recall against a frozen
                                        60-item set; a tested-call roster; observed choice
                                        frequencies at 4 recurring forks
Q_0 (composite, declared scale) = 1.20 Q-units;   Q^V_0 = 1.20 (tracks initialised equal)
```

The internal surplus matters here only as a reminder that this subject holds 4.36 genuinely different framings out of 9 nominal categories — **a healthy internal geometry, and it will not save them.**

Stage 2 — the four measurements.

```
delta_forget = 0.020    delta_atrophy = 0.008    delta_drift = 0.004
keep = 0.980 * 0.992 * 0.996 = 0.96827136
delta = 0.03172864 per week
tau = 31.52 wk     t_half = 21.50 wk     3 tau = 94.55 wk (21.8 months)

eta, stage-wise over 40 candidate experiences in a 13-week window:
0.55  x  0.70  x  0.50  x  0.45  x  0.65  x  0.60   =   eta = 0.03378375 Q-units per nat

C, six ledgers, weekly, exchange rates declared:
Attention 0.011 | Presentation 0.008 | Carry 0.005 | Obligation 0.004 | Regulation 0.002
Correction 0.000 at t=0 (Z_0 = 0)
c_0 = 0.030 Q-units per week;   kappa = 0.03 per Q-unit of stored error per week

E and r, window means:
E* = 1.20 nats (external audit)      r* = 1.35
M* = min(1.35 * 1.20, 2.197225) = 1.62 nats        73.73% of the ceiling
V* = 1.20 * min(1.35, 1)        = 1.20 nats
confabulated fraction = 1 - 1/1.35 = 0.259259
```

Stage 3 — the gauge.

```
structural budget   eta * ln N  = 0.03378375 * 2.197225 = 0.074230
maintenance draw    delta * Q_0 = 0.03172864 * 1.20     = 0.038074   (51.3% of budget)
operating draw      c_0                                 = 0.030000   (40.4% of budget)
-------------------------------------------------------------------------
PERSONAL HEADROOM   h_0                                 = 0.006156   ( 8.3% of budget)
```

Positive headroom: 0.006156 Q-units per week, which is also the largest one-week increment any arrangement of this subject's life could guarantee [Curzi, 2026b].

Stage 4 — what the regime actually does.

```
deposit this week   eta M*            = 0.054730
draws this week     delta Q_0 + c_0   = 0.068074
                    0.054730 < 0.068074   ->  Q is DECLINING

Q_inf   = (0.054730 - 0.030)/0.03172864 = 0.77941
Q^V_inf = (0.040541 - 0.030)/0.03172864 = 0.33221
Z_inf   = 0.447204                        = 57.38% of Q_inf
Q_crit  = (0.074230 - 0.030)/0.03172864 = 1.39402
```

The reading, in one sentence: this subject has positive headroom, holds 1.54 times the stored order their regime can sustain, sits at 86 per cent of their critical stock, manufactures

a quarter of every moment, and is on a 21.5-week-half-life glide toward a self of which more than half will be error. They report the year as fine, a bit flat.

Single-track trajectory, correction load held at zero to isolate the accumulation:

week `t`	`Q_t`	`Q^V_t`	`Z_t`	`h_t`
0	1.2000	1.2000	0.0000	0.006156
4	1.1491	1.0950	0.0541	0.007771
13	1.0560	0.9029	0.1531	0.010725
26	0.9613	0.7075	0.2538	0.013730
52	0.8581	0.4945	0.3636	0.017005
104	0.7941	0.3626	0.4316	0.019034
156	0.7822	0.3379	0.4443	0.019414

Headroom rises as the self shrinks. That is not a consolation; it is the mechanism by which a declining subject feels increasingly free and increasingly light while the thing that was built is unbuilt. `h` measures capacity for the new, and one way to have capacity for the new is to stop having the old.

Stage 5 — turning the correction load on. With `kappa = 0.03`:

```
C_inf = 0.030 + 0.03 * 0.447204 = 0.043416      (+44.7% on operating cost)
h at Q_0 with C_inf = 0.074230 - 0.038074 - 0.043416 = -0.007260      NEGATIVE
```

week	`Q_t`	`Q^V_t`	`Z_t`	`C_t`	`h_t`
13	1.0297	0.8765	0.1531	0.034305	0.007256
26	0.8771	0.6233	0.2538	0.037424	0.008977
52	0.6490	0.2855	0.3636	0.040825	0.012813
78	0.5122	0.1011	0.4110	0.042296	0.015684
104	0.4365	0.0049	0.4316	0.042932	0.017451
156	0.3762	-0.0681	0.4443	0.043326	0.018968

The earned track crosses zero between weeks 104 and 156. A negative equilibrium on the earned ledger is the steady-state theorem's explicit refusal: the regime is unsustainable in this model, or the model must be replaced [Curzi, 2026a]. Check X4 fails, and SQ12 requires the survey to report it in those words rather than to smooth it. What the subject experiences across those three years is a self that feels steadily more confident and steadily more expensive, with no single event to attribute the expense to. **What the books show is manufactured structure crowding out earned structure and then paying for its own repair, on a thirty-one-week lag.**

> **A second source correction, recorded.** The `C_t` column above is reproduced from the source manuscript, and it is computed from `Z_{t-1}` rather than from `Z_t` — a one-period lag that the stated equation `C_t = c_0 + kappa Z_t` does not carry. At week 13, `c_0 + kappa Z_13` is 0.034593, whereas the tabulated value 0.034305 is `c_0 + kappa Z_12` to six decimal places. The discrepancy shrinks as the system approaches equilibrium, which is the signature of a lag rather than of an arithmetic slip. **The `Q_t` and `h_t` columns are internally consistent with the lagged convention, so the table is self-consistent and the printed equation is not.** The substantive reading — that the correction load arrives on a lag of order `tau` — favours the lagged implementation; the equation of Section 7.4 should carry the lag explicitly and does not. It is recorded here rather than silently corrected.

Stage 6 — three interventions, priced separately.

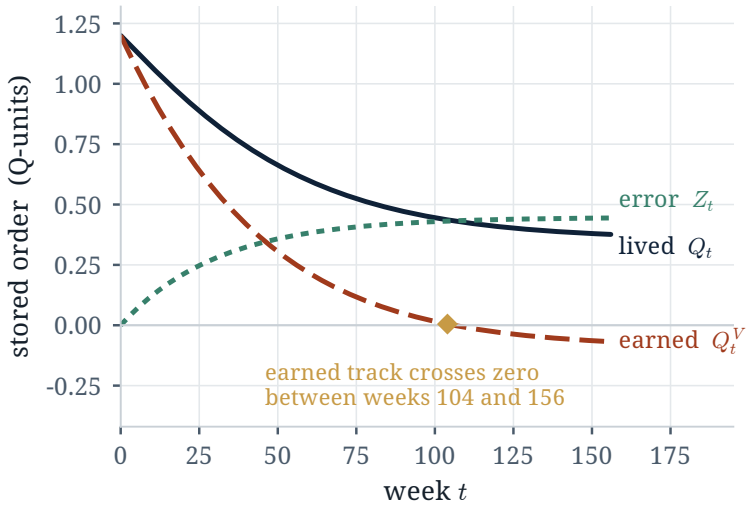

Figure 21.5: **Stored error accumulates on the same pole as stored knowledge and then crowds it out.** The lived track `Q_t`, the earned track `Q^V_t` and their difference `Z_t` over 156 weeks under the correction load, from `Q_0 = Q^V_0 = 1.20`, with `eta = 0.03378375`, `delta = 0.03172864` per week, `M* = 1.62`, `V* = 1.20`, `c_0 = 0.030` and `kappa = 0.03`. Stored error rises to 0.4443 while the earned track crosses zero between weeks 104 and 156 — the steady-state theorem's explicit refusal of the regime. A 25.93 per cent confabulated input becomes 57.38 per cent of the single-track steady-state stock. Modelled from the stipulated parameters, not measured; generated by `figs/src/CCP-021_fig05.py`.

```
A - RAISE ETA.   Fix the two worst rungs.
    named -> encoded      0.50 -> 0.80   (a durable medium, used the same day)
    encoded -> rehearsed  0.45 -> 0.75   (a standing 20-minute weekly slot, calendared)
    eta: 0.03378375 -> 0.09009            x2.667

B - CUT C.       Drop one standing obligation and one presentation context.
    c_0: 0.030 -> 0.022

C - FIX THE LENS.  Correct the over-framing, plus deliberate exposure.
    r: 1.35 -> 1.05      E: 1.20 -> 1.45
    M: 1.62 -> 1.5225    V: 1.20 -> 1.45      confabulated fraction: 0.2593 -> 0.0476
```

Regime	eta	M*	V*	c_0	Q_inf	Q^V_inf	h at Q=1.20
baseline	0.033784	1.6200	1.2000	0.030	**0.7794**	**0.3322**	**0.006156**
A only	0.090090	1.6200	1.2000	0.030	3.6543	2.4618	0.129874
B only	0.033784	1.6200	1.2000	0.022	1.0315	0.5843	0.014156
C only	0.033784	1.5225	1.4500	0.030	**0.6756**	**0.5984**	**0.006156**
A+B+C	0.090090	1.5225	1.4500	0.022	**3.6296**	**3.4237**	**0.137874**

Conversion dominates. Two mechanical changes — write it down, calendar the rehearsal — move `Q_inf` from 0.779 to 3.654, a factor of 4.7. Neither requires more time, more talent or a better environment.

Fixing the lens lowers the stored self and raises the earned self. Row C: `Q_inf` falls from 0.779 to 0.676 while `Q^V_inf` rises from 0.332 to 0.598 — an 80 per cent gain in earned structure bought at a 13 per cent loss of total stock. **On a single-track ledger that intervention looks like a regression, and a subject keeping one book will reverse it.** This is the strongest practical argument in the paper for keeping two, and it is why SQ5 exists.

Fixing the lens does not change headroom at all. Row C's `h` is identical to baseline's, to the digit. That is not an error: `h = eta ln N - delta Q - C` contains no `M`. Calibration changes

what the weeks *deliver*, not what the system *could* deliver. **The gauge licenses; the geometry delivers.**

The corrected regime is not instantaneous.

```
eta M*  = 0.09009 * 1.5225 = 0.137162
Q_inf   = (0.137162 - 0.022)/0.03172864 = 3.62959
Q^V_inf = (0.09009*1.45 - 0.022)/0.03172864 = 3.42374   Z_inf = 0.205856 (5.67% of Q_inf)
h at Q_0 = 0.197948 - 0.038074 - 0.022 = 0.137874       = 22.40 x baseline
Q_crit  = (0.197948 - 0.022)/0.03172864 = 5.5454
correction load at equilibrium: C_inf = 0.022 + 0.03*0.205856 = 0.028176
    -> Q_inf under load = 3.43495,  h at Q_0 = 0.131698   (still strongly positive)
time to 95% of the new fixed point:  ln(0.05)/ln(1-delta) =  92.91 weeks
time to 99%:                         ln(0.01)/ln(1-delta) = 142.83 weeks
```

week `t`	`Q_t` (corrected)	`h_t`
0	1.2000	0.137874
13	2.0319	0.111479
26	2.5789	0.094122
52	3.1753	0.075202
78	3.4331	0.067020
104	3.5446	0.063482

Twenty-two months to arrive — not because the changes are weak, since headroom rose twenty-two-fold on day one, but because `tau = 31.5` weeks and a leaky integrator takes `3 tau` to settle. SQ13 exists for this table. A subject who abandons the regime at week 13 because they are "only" at 2.03 has abandoned a change working exactly as fast as the arithmetic permits.

Stage 7 — the fixed-point identity, checked.

```
h_inf = eta ln N - delta Q_inf - c_0
      = 0.09009*2.197225 - 0.03172864*3.62959 - 0.022
      = 0.197948 - 0.115147 - 0.022 = 0.060786

eta (ln N - M*) = 0.09009 * (2.197225 - 1.5225) = 0.09009 * 0.674725 = 0.060786   IDENTICAL
```

The corrected subject, once settled, retains 0.060786 `Q`-units per week of headroom — 30.7 per cent of their structural budget — and that residual is exactly `eta` times the 0.6747 nats by which their lived moments fall short of what their nine distinctions could support. **To spend the residual they must either engage the distinctions they hold more completely, or acquire a genuinely new kind of distinction. There is no third option, and the identity proves it.**

Stage 8 — what this survey could not establish, recorded because SQ18 requires it and because a worked example that reports only its findings is advertising.

1. **`Q` was measured through proxies, and the proxy-to-`Q` relation is a postulate.** The composite 1.20 `Q`-units has no meaning outside this subject's declared scale.
2. **The six ledger exchange rates are postulates.** Weighting Presentation at 0.008 rather than 0.016 changes `h_0` by more than its entire value. **The baseline headroom reading of 0.006156 is not robust to the cost weights, and any conclusion depending on its sign should be regarded as unestablished.** That is the honest weakness of the survey. Note that the weakness does not touch `Z_inf`, which is independent of `C` — **the stored-error figure is the most robust number in the whole survey, and it is also the most uncomfortable one.**

3. **`kappa = 0.03` is an assumed value, not a measured one.** Nothing here identifies it. The negative-headroom finding of Stage 5 is therefore conditional on a parameter that was posited and should be read as a demonstration of a mechanism, not as a measurement of any subject.
4. **`E` was externally instrumented, `r` was not double-scored.** The audit gives `E`; `r` came from a single application by the subject. This is better than the self-reported-environment failure mode and it is not enough.
5. **The shuffled-input control was run and passed** in the constructed case — the true `M` ordering predicted the held-out `Q`-proxy trajectory better than 200 time-permuted orderings — **which licenses the accumulation structure for this constructed subject and licenses nothing about any real one.**
6. **The reproducibility gate was not attempted.** Until a separation property is established for these operationalisations, every number above is a within-subject index.

21.10.3 10.3 The results, stated for citation

R1 — the internal surplus. `F_int = ln(1 + (N−1)u)` with `N_eff = 1 + (N−1)u` the audited framing count, `u = 1 − rho^2` estimated from error decorrelation between framings' prediction errors, and the affine form badged as design axiom S3 rather than as a theorem. The substitution of domain is licensed by the axioms' silence on who holds the states and costs exactly two postulates: the framing encoding and the internal roster reduction.

R2 — the participation-ratio identity. `N_eff = 1 + (N−1)u_bar = N + 1 − N/PR`, where `PR` is the Rényi-2 participation ratio of the framing ensemble's Gram matrix. The audited count is an affine reparametrisation of a standard diversity statistic; the identity is exact and is verified in the worked case to `8.9e−16`.

R3 — the six-framing audit. At mean `u = 0.6860` a six-framing subject reads `N_eff = 4.4298` and `F_int = 1.4883` nats, 83.07 per cent of the ceiling `ln 6 = 1.7918`. Splitting by lineage, the six within-lineage pairs give `u = 0.2732` and **the four-framing lineage alone audits to `N_eff = 1.8196`**, while the nine cross-lineage pairs give `u = 0.9611`.

R4 — restructuring beats enlarging, and is still not enough. Retiring the two most redundant framings and importing two from outside the lineage raised the audited count **25.4 per cent** (`F_int` 1.4883 to 1.7148 nats, 95.70 per cent of ceiling) at identical `N` and identical pair count, **and still left the one-step change in stored order negative at −0.0411**, having closed 77 per cent of the gap.

R5 — the headroom sensitivities. `dh/deta = ln N = 2.197`, `dh/dC = −1`, `dh/dQ = −delta = 0.0317`, `dh/dN = eta/N = 0.0038` at the worked operating point. **Adding categories is the weakest available lever**, by a factor of 585 against conversion; and doubling the structural budget by raising `N` alone requires `N` to be squared, from 9 to 81.

R6 — the stored-error recursion. `Z_{t+1} = (1−delta)Z_t + eta(M_t − V_t)` with `Z_inf = eta(M*−V*)/delta`, independent of cost because the cost term cancels in the subtraction. A **25.93 per cent** confabulated input becomes **57.38 per cent** of the steady-state stock, and the earned track's equilibrium can be negative, which the model reports as its own domain of breakdown.

CR — the counter-result. The framing intervention was correct, measured and successful on its own terms, and it did not work. A 25.4 per cent improvement in the audited count closed 77 per cent of the storage gap and failed to reverse the decline; the sensitivity table demotes "hold more kinds of framing" to a negligible lever; and the storage survey declares its own baseline headroom reading **not robust to the declared cost weights and therefore unestablished**. The geometry was never the binding constraint in either worked case.

21.11 11 Discussion

21.11.1 11.1 What follows

The surplus functional is scope-free, and that is a structural result rather than a rhetorical one. Its axioms quantify over states in an inner-product space and contain no term referring to persons. Everything that follows from them therefore follows at any scope at which an encoder can be defined, and the whole content of the move from groups to a single observer is the encoder. This is worth stating precisely because it identifies exactly where an objection has purchase: **attack the encoder, not the algebra.** An objection to the algebra is an objection to arithmetic; an objection to the encoder is an objection this paper cannot answer and concedes in Section 13.

The audited count is the quantity, and the nominal count is not. Every ceiling, headroom figure and moment bound in the framework takes the logarithm of an effective count. Computing them from the nominal count is the arithmetic error that failure mode FF9 names, and it is common because the nominal count is the one that is easy to obtain. The same error appears at every other scope the corpus works at: an entity map showing four jurisdictions at 40.91, 27.27, 18.18 and 13.64 per cent gives a naive effective count of 3.4085 and a bloc-collapsed count of 1.0000, **a 3.41-fold overstatement produced entirely by counting members before auditing difference** [Curzi, 2026,?].

The small, disreputable component often carries the surplus. In the six-framing case, four framings representing years of formal training audit to 1.82 between them, and the surplus is carried by the two framings the subject would call their least rigorous. The structurally identical result appears in the corpus's structural work, where a jurisdiction holding 18.2 per cent of a portfolio accounts for **79.74 per cent of the entire diversification gain** [Curzi, 2026]. In both cases the quantity that matters is the covariance with everything else, not the size of the holding, which is the 1952 result stated in its original form [Markowitz, 1952].

Interventions decompose into the three terms of the storage law, and the decomposition is checkable. Any practice that improves stored order does so by raising surplus, raising conversion, or lowering retention loss, and the product of the three factors must reproduce the fixed-point ratio exactly. The corpus's analysis of one classical mnemonic technique finds it to be primarily a *retention* intervention — a factor of 4.1667 against 1.8637 for surplus and 1.9000 for conversion, with the product 14.7546 matching the direct fixed-point ratio [Curzi, 2026v]. **The same decomposition applied to this paper's three interventions gives the same verdict about which lever was pulled**, and it is the reason a practice can be described accurately and still be misclassified by the people who use it.

Conversion has an external determinant that this paper does not model. At group scope, reciprocity raises conversion directly, with `eta = eta_max rho` and `rho` a symmetry index over an exchange matrix [Curzi, 2026s]. At internal scope this paper treats `eta` as a property of the subject's own ladder, which is almost certainly incomplete: the encoding rung in particular depends on whether anyone is listening. **That is a named gap, not a modelling decision.**

21.11.2 11.2 What does not follow

Nothing here licenses a claim about neurons, about consciousness, or about the physical substrate. The equations are difference equations in one scalar and they describe a bookkeeping relation, not a mechanism in tissue.

A high audited count is not established to produce better judgement. H1 states the prediction and it has not been tested. The external literature is genuinely split: diverse problem-solving groups can outperform higher-ability homogeneous ones under stated conditions [Hong and Page, 2004], the formal result has been shown to follow from its modelling assumptions [Thompson, 2014], surface-level diversity often hurts in the short run [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007], and the curve relating cohesion to creative success is an **inverted U** rather than monotone [Uzzi and Spiro, 2005]. **This paper's surplus is**

monotone increasing in `u`, and a monotone claim cannot survive that list unqualified. The restriction taken here is that the monotone reading is asserted only over the regime the worked cases exercise, `u` in roughly `[0.2, 0.95]` at `N <= 9`, and nothing in this corpus locates the turn.

Redundancy is not established to be worthless. Sagan's test of normal-accident theory against high-reliability theory documents cases in which redundancy *reduced* safety [Sagan, 1993], and interactive complexity plus tight coupling makes catastrophic failure a system property regardless of component count [Perrow, 1984]. A framing set is not a safety system, but the analogy is close enough that the caution transfers: **the paper's advice to retire redundant framings should not be read as advice to run without margin.**

A shrinking self is not a healthy one, and the gauge cannot tell the difference. The single-track trajectory of Section 10.2 shows headroom *rising* as stored order falls. That is the gauge behaving correctly and reporting something the subject will experience as improvement. **Headroom is capacity for the new, and one way to have capacity for the new is to stop having the old** — which is why SQ12 requires the fixed point and the critical stock to be reported alongside the gauge, and never the gauge alone.

No forecast has been made. The framework's defence against the charge that it forecasts nothing is not that it does, but that prediction is one of many reasons to build a model [Epstein, 2008], and the corpus is entitled to say which of the others it claims: mechanism articulation, and the discovery of what a stated set of premises entails. The discipline named in the corpus's title will nonetheless apply a stricter criterion — **an explanation must name a mechanism rather than exhibit a fitted curve** [Hedström and Ylikoski, 2010] — and the useful constructive answer to that demand is the analytical-sociology position of specifying the mechanism and then testing it [Keuschnigg et al., 2018].

21.11.3 11.3 Relation to the surrounding literature

The nearest external relatives of this paper's constructs are worth naming, because in several cases the literature got there first and the honest move is to say so.

The leaky integrator with a threshold is a century old in exactly the domain this paper applies it to, and the framework's storage law is a shared mathematical form with it rather than a derivation from it [Curzi, 2026a]. The statistical twin, exponential smoothing, comes with a statement of the class of processes for which it is *optimal* — a question this framework does not ask about its own model [Holt, 1957].

The reflexive influence structure inside one observer already has a formal literature. Beliefs updated by a row-stochastic influence matrix converge to a consensus given irreducibility and aperiodicity [DeGroot, 1974]; adding a stubbornness term anchoring each agent to its initial position yields a non-consensus fixed point instead of collapse [Friedkin and Johnsen, 1990], which is formally the same device as this framework's leak. **The sociological literature already contains this framework's leaky integrator, applied to belief.** What determines an outcome in such systems is the *distribution* of thresholds rather than the mean [Granovetter, 1978], which is a direct warning against the mean-pairwise aggregator of Section 3.2 and the reason the subspace check is mandatory.

The aggregation problem applies wherever a single `u`, `delta` or `eta` is written for a heterogeneous set [Kirman, 1992], and the founding error of the discipline whose name this corpus has taken was treating the mean of a distribution as a type rather than as a statistic [Quetelet, 1835]. This paper writes a single `u` for a framing set and a single `eta` for a person, and both are means.

Time averages and ensemble averages differ for multiplicative processes [Peters, 2019]. This matters directly: `Q` accumulates over time for one subject, and any parameter estimated from a cross-section of subjects does not describe what happens to any of them. **The paper's insistence that all parameters are within-subject indices until a separation property is established is the same point arrived at from the framework's own side**, and SQ16 is what enforces it.

The unit conversions are worth stating once, because nats are unfamiliar. One nat of required surplus is 1.442695 bits, and in the corpus's frequency work it corresponds to 2.885390 octaves or 3462.4681 cents [Curzi, 2026]. Nothing in this paper depends on the acoustic reading; the figure is given so that a reader can convert the ceilings — `ln 6 = 1.7918` nats is 2.585 bits, and `ln 9 = 2.1972` nats is 3.170 bits — into a register they may find more familiar.

Finally, the ceiling on predictability is a real constraint on what any of this could ever deliver. With fifteen years of high-quality longitudinal data and 160 teams, life outcomes were barely predictable at all, and the best machine learning barely beat a four-variable regression [Salganik et al., 2020, Hofman et al., 2017]. **A framework that promises to predict a person's trajectory from four parameters is promising more than the best available evidence suggests is obtainable.** This paper promises no such thing; it offers a bookkeeping identity and a set of falsifiers, and Section 13 records that none of the falsifiers has been run.

21.12 12 Verification

The results of this paper compound from nine postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped**; what remains is what the chain actually consumes.

21.12.1 12.1 Dimensional audit

`[Q]` denotes the dimension of stored order and `[T]` the dimension of time. The period is the unit of `[T]`, and every rate below is *per period*, which is why no explicit `[T^-1]` appears once the equations are written in discrete steps.

Symbol	Dimension	Unit	Status
`u`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2` with `x`, `y` unit vectors
`rho`	`[1]`	none	**measured** dimensionless correlation in `[-1,1]`
`N`	`[1]`	a count of framing categories	**measured** by enumeration; ratio scale, true zero
`N_eff`	`[1]`	an effective count	**derived** from `N` and `u`
`PR`	`[1]`	an effective count	**derived** from the Gram spectrum
`F_int`, `M_t`, `V_t`	`[1]`	nats	**derived** dimensionless: logarithms of effective counts
`Q_t`, `Q^V_t`, `Z_t`	`[Q]`	proxy units, declared per component	**measured** through a declared proxy; **no natural unit exists**
`eta`	`[Q]` per nat per step	proxy units per nat per week	**measured**; *not* dimensionless
`delta`, `lambda`	`[1]`	per period	**measured** dimensionless fractions per step

Symbol	Dimension	Unit	Status
`C_t`, `c_0`	`[Q]` per step	proxy units per period	**measured**, after a declared exchange rate per ledger
`kappa`	`[1]` per step	per period	**assumed**; `Q`-units of cost per `Q`-unit of error per period
`h_t`	`[Q]` per step	proxy units per period	**derived**
`Q_inf`, `Q_crit`	`[Q]`	proxy units	**derived**: `[Q]`/step divided by `[1]`/step returns `[Q]`
`r = D/P`	`[1]`	none	**not instrumented**; see below
`E_t`	`[1]`	nats	**measured externally**, and the framework requires it to be
`tau`, `t_half`	`[T]`	periods	**derived**
`c1`, `c2`	`[Q]` per step	proxy units per period, per framing and per pair	**assumed**

Does the self-storage law balance? `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` balances if and only if every term on the right carries `[Q]`. The first does, since `delta` is dimensionless; the third does by construction; the second does only if `eta M_t` carries `[Q]`, and since `M_t` is a dimensionless count in nats, **`eta` must carry `[Q]` per nat per step**. It is therefore not dimensionless, and the conversion ladder's dimensional inconsistency follows directly: five of the six rungs are pure fractions, so the sixth must be the unit-bearing one or the product cannot carry `eta`'s units. **The framework's naive statement of the ladder as six fractions is dimensionally malformed and is corrected in Section 7.6 rather than glossed.**

`ln N` is dimensionless, so `eta ln N` carries `[Q]` per step and is commensurable with `delta Q_t` and with `C_t`, which is what makes the headroom gauge a well-formed subtraction. **A headroom calculation in which `C` is denominated in hours while `Q` is denominated in recall items is dimensionally malformed however arithmetically tidy it looks**, which is why SQ8 requires an explicit exchange rate per ledger and requires it to be badged as a postulate.

Where the framework has no operational unit, this audit says so. Stored order `Q` has **no natural unit**: it is counted in whatever the declared proxy counts, and two subjects' `Q` values are not comparable unless they declare the same proxy. `r = D/P` is **worse than unitless — it is uninstrumented**: its two components are not on a common ratio scale with a shared true zero, so the magnitude of `r` is not a reportable measured quantity and only its orderings are [Curzi, 2026m]. Comfort itself, the underlying construct of the corpus, has **no operational unit at all** and is treated as a dimensionless magnitude by stipulation.

21.12.2 12.2 The postulates

P1 — The surplus axioms quantify over states in an inner-product space and contain no term referring to persons, agents or ownership. *Status:* **DEFINITION** — a restatement of the axiom set as published [Curzi, 2026]. It carries no empirical weight on its own.

P2 — A framing admits representation as a unit vector in a common inner-product space. *Status:* **POSTULATED** — this work's own, with no external support. It is the load-bearing empirical assumption of the whole paper and is what a critic should attack.

P3 — The encoded inner product between two framings equals the Pearson correlation of their prediction-error series, so `u = 1 - rho^2`. *Status:* **POSTULATED** — a second, separate assumption about the encoder, and it is separable from P2: one could accept the vector representation and reject this particular estimator.

P4 — `g(u) = e^{f(u)}` is affine in `u`. *Status:* **DEFINITION** — design axiom S3, chosen and not derived [Curzi, 2026,c]. It is what makes `N_eff` affine and what makes the second framing worth as much per `u`-unit as the fortieth.

P5 — For `N` unit vectors, `tr G = N`. *Status:* **ARITHMETIC** — the diagonal of a Gram matrix of unit vectors is all ones.

P6 — The self-storage recurrence is linear and first order: `Q_{t+1} = a Q_t + x_t` with `a` and `x_t` not depending on `Q`. *Status:* **DEFINITION** — the model form, obtained by setting `a := 1 - delta` and `x_t := eta M_t - C_t`. Its application to a real person is a separate postulate and is recorded in Section 13.

P7 — `0 < delta <= 1` makes the update map a contraction with a unique fixed point, reached from any start. *Status:* **CITED** [Banach, 1922, Elaydi, 2005, Curzi, 2026a].

P8 — The per-period input is bounded, `0 <= M_t <= ln N`. *Status:* **CITED** — the range result of the surplus functional [Curzi, 2026], together with the cap imposed at Step 2 of the join, which is a convention this paper adopts and states.

P9 — Cost accrues every period whether or not moment was delivered. *Status:* **POSTULATED** — an assumption about how a life charges overhead. It has no external support and is used at exactly two places, CH6 and CH7 below; the chain's other results do not depend on it.

21.12.3 12.3 The compounding chain

```
P1 + P2        -> CH1  the surplus functional applies to two framings held by one
                       observer; nothing in the axioms forbids it.            DEFINITION

CH1 + P4       -> CH2  F_int = ln(1 + (N-1)u) and N_eff = 1 + (N-1)u.         DEFINITION

P2 + P3        -> CH3  u = 1 - rho^2, estimable from two recorded error series
                       with no similarity judgement by anyone.                POSTULATED

P2 + P5        -> CH4  ||G||_F^2 = N + N(N-1)(1 - u_bar), since the N diagonal
                       entries are 1 and the N(N-1) off-diagonal entries are
                       the squared inner products, each equal to 1 - u_ij.    ARITHMETIC

CH4            -> CH5  N/PR = ||G||_F^2 / N = 1 + (N-1)(1 - u_bar), hence
                       N_eff = 1 + (N-1)u_bar = N + 1 - N/PR.                 ARITHMETIC

P6 + P7        -> CH6  Q_inf = (eta M* - c*)/delta, unique and start-independent,
                       approached geometrically at rate (1-delta).            CITED

P6 applied
  twice + P9   -> CH7  subtracting the earned recursion from the lived one,
                       Z_{t+1} = (1-delta)Z_t + eta(M_t - V_t): the cost term
                       cancels exactly because it is identical in both.       ARITHMETIC

CH7 + P7       -> CH8  Z_inf = eta(M* - V*)/delta, independent of C.           ARITHMETIC

CH6 + P8       -> CH9  h = eta ln N - delta Q - C; at the fixed point
                       delta Q_inf = eta M* - c*, so h_inf = eta(ln N - M*).   ARITHMETIC

CH9            -> CH10 dh/deta = ln N, dh/dC = -1, dh/dQ = -delta,
```

```
dh/dN = eta/N.                                                    ARITHMETIC
```

Every line is checkable from its own inputs. **CH4, CH5, CH7, CH8, CH9 and CH10 are arithmetic; CH6 is a cited theorem; CH1, CH2 are definitions; and CH3 alone is a postulate with no external support.** The paper's headline identity — that the audited framing count equals `N + 1 − N/PR` — therefore consumes exactly two definitions and one arithmetic fact, and no empirical claim at all.

What this chain does not establish. It does not establish P2, and P2 is where all the empirical content lives. **A chain whose steps are ARITHMETIC, DEFINITION and CITED delivers the mathematics with certainty and delivers nothing whatever about any person.** Every applied reading of every number in Section 10 rests on P2 and P3, which are this work's own postulates, and on the identification concession of Section 3.4.

21.12.4 12.4 The worked numerical instances

Three checks, each doable by hand or on a calculator in a few minutes.

Check one: the participation-ratio identity, on the six framings of Section 10.1. The Gram matrix has six ones on its diagonal and thirty off-diagonal entries, the fifteen correlations and their transposes. Then

```
sum over the 15 pairs of rho^2 = 0.88^2 + 0.83^2 + ... + 0.34^2 = 4.710700
||G||_F^2 = 6 + 2 x 4.710700                                    = 15.421400
PR = 6^2 / 15.421400                                            =  2.334418
N/PR = 15.421400 / 6                                            =  2.570233
N + 1 − N/PR = 6 + 1 − 2.570233                                 =  4.429767

directly: 1 + 5 x mean(1 − rho^2) = 1 + 5 x 0.685953            =  4.429767
```

The two routes agree to `8.9e-16`, which is machine epsilon on a quantity of order 4. This is CH5, and the check requires nothing but fifteen squarings and a division.

Check two: multiplicative composition of retention loss. Three channels at 0.020, 0.008, 0.004: `0.980 x 0.992 x 0.996 = 0.96827136`, so `delta = 0.03172864` against the naive sum 0.032. The overcount is 0.00027136, which is 0.85 per cent of the true value. At four channels of 0.15, `0.85^4 = 0.52200625`, so `delta = 0.47799375` against a naive 0.60 — an overcount of 25.5 per cent of the true value and 20.3 per cent of the naive one. **One line of multiplication, and it settles H6's predicted magnitude.** ARITHMETIC.

Check three: the headroom identity at the fixed point. With `eta = 0.09009`, `delta = 0.03172864`, `ln 9 = 2.197225`, `M* = 1.5225` and `c_0 = 0.022`:

```
Q_inf = (0.09009 x 1.5225 − 0.022)/0.03172864 = (0.137162 − 0.022)/0.03172864 = 3.629592
h_inf = 0.09009 x 2.197225 − 0.03172864 x 3.629592 − 0.022
      = 0.197948 − 0.115147 − 0.022                                          = 0.060786
eta (ln N − M*) = 0.09009 x (2.197225 − 1.5225) = 0.09009 x 0.674725         = 0.060786
```

The cost term cancels exactly, as CH9 says it must. Three multiplications and two subtractions. ARITHMETIC.

21.12.5 12.5 Limits, asymptotics, and the stated domain

`u -> 0`. `N_eff -> 1`, `F_int -> 0` for every `N`. The parallel wall: every framing is a duplicate and the set has left the arithmetic. **This is a real state, not a boundary artefact.**

`u -> 1`. `N_eff -> N`, `F_int -> ln N`, the ceiling attained and no further gain available from geometry. Strict concavity makes the approach front-loaded.

`N -> 1.` `F_int = 0` for every `u`, and `h = -delta Q - C < 0` at any positive stock. **A mind with one category has negative headroom at any positive stock**, which is requisite variety arriving as a hard floor [Ashby, 1958].

`N -> infinity` at fixed `u > 0`. `F_int -> infinity` logarithmically while the marginal gain ~ `1/N` vanishes and the pair count grows quadratically. **The two curves cross, and beyond the crossing additional framings cost more than the ceiling they buy.** The divergence is located in the surplus term only because the cost term has been omitted; with it, $n*$ is always finite. This is why `N` is the most expensive and least rewarding of the four levers.

`delta -> 0`. No fixed point exists — the map is an isometry rather than a contraction — and `Q` grows without bound, as does `Z` [Curzi, 2026a]. **The limit is singular:** at exactly `delta = 0` the fixed point does not exist at all rather than being infinite. **This value is outside the model's valid domain.**

`delta -> 1.` `Q_{t+1} -> eta M_t - C_t`, a pure input-output map with no state. **At `delta = 1` the storage law is not a storage law**, and any claim about accumulation is vacuous there.

`eta -> 0`. `Q_inf = -C/delta <= 0`: the model refuses to describe a life with zero conversion and nonzero cost, which is the rumination case taken to its limit.

`r -> 1.` `M = V`, `Z_inf = 0`, no stored error ever accumulates. **`r -> infinity`** with the cap in force: `M -> ln N`, `V -> E`, and `Z_inf -> eta(ln N - E)/delta`, **bounded**. Saturation, not divergence. **`r < 1`:** `Z = 0` — the under-framed observer stores no error, they simply store less.

`kappa -> 0`. The correction load vanishes and the model reduces to the single-track law, which is the correct nesting. **`kappa` large:** `C` exceeds `eta ln N` and the sustainability ceiling forecloses everything.

Stated domain. The results are claimed for `delta` in `(0, 0.5]`, with `(0.02, 0.30)` the band in which the time-constant approximations hold; `eta > 0`; `N >= 2`; `u` in `[0,1]`; `r > 0`; and the admissibility condition satisfied each period. **The claim is not that these laws hold universally but that they hold inside a specified arrangement** — a declared period, a frozen inventory, a frozen proxy, an external instrument for the environment, and a window over which the parameters are treated as constant. Outside that arrangement the equations still have solutions and those solutions should not be interpreted as statements about a person [Cartwright, 1999].

21.12.6 12.6 Invariance

The framework's scale-freedom claim is an **invariance of form under a change of unit**, and it is worth stating as one. Let `Q` be rescaled by a positive constant `c`, so `Q' = cQ`. The law is invariant provided `eta` and `C` rescale with it — `eta' = c eta`, `C' = cC` — while `delta`, `N` and `u` are unchanged, since `delta` is a dimensionless fraction and `M` is a dimensionless count in nats. **`delta`, `u`, `N`, `rho` and `r` are the unit-free quantities; `Q`, `eta`, `C` and `Z` are the unit-carrying ones.** Two subjects may be compared on the first group directly; they may not be compared on the second unless they share a proxy, which is SQ16.

What would break the invariance: a `delta` that varies with `Q`, which makes the transformation non-linear; an `eta` that saturates at large `M`, which the linear model excludes by assumption; or a proxy whose counting unit is not extensive.

How many scales the claim has been tested at, in this paper: one. Both worked cases are a single observer, and both are constructed. **No cross-scale test appears in this paper**, and the invariance is a claim about form that has been exercised rather than an invariance that has been established.

21.12.7 12.7 Scale type

Construct	Claimed scale	What licenses it
`N`, pair count	ratio, true zero	a count
`u`, `rho^2`	ratio, true zero	`u = 0` is exact parallelism, a genuine zero, **conditional on the encoding postulate P2**
`N_eff`, `PR`	ratio	derived from the above by arithmetic
`F_int`	ratio, in nats	a logarithm of a ratio-scaled effective count
`M_t`	**not established**	inherits the moment equation's demotion [Curzi, 2026m]
`r = D/P`	**ordinal at best**	`D` and `P` are not co-calibrated; magnitudes not reportable
`Q_t`	ratio by stipulation	required by `(1−delta)Q`; **the proxy is ordinal far more often than is admitted**
the six cost ledgers	ratio by stipulation	each exchange rate is a declared postulate
`I3`, the disagreement rate	ordinal	a proportion of logged disagreements, comparable within one subject only

The strongest objection to this table is that psychology routinely assumes quantitative structure without testing for it [Michell, 1997]. It is the strongest single objection to the corpus's founding move, and this paper concedes it rather than answering it. The available remedies are conjoint measurement — the formal test for whether an attribute has additive quantitative structure at all [Luce and Tukey, 1964, Krantz et al., 1971] — or a Rasch-model demonstration [Rasch, 1960, Andrich, 1988]. **Neither has been run for `u`, for `Q`, or for any cost ledger in this paper.** Until one is, every ratio-scale treatment above is a stipulation, and the ordinal demotion the framework has already imposed on its own moment equation is the correct instinct applied once rather than consistently. Construct validation has an established design for this and it has not been applied either [Campbell and Fiske, 1959].

21.12.8 12.8 Model comparison — reported NOT MET

The rigour standard this corpus holds itself to requires, wherever a model is fitted: out-of-sample performance, a matched null with the same number of free parameters, an information criterion, an explicit count of free parameters, and effect sizes with intervals.

This paper fits nothing, so no information criterion applies to it. But the standard binds anyway, through the corpus's one applied fit, and the row must be reported rather than omitted:

Requirement	Status in this paper	Status in the corpus's applied fit
Out-of-sample performance	not applicable — nothing fitted	reported: held-out RMSE against four baselines [Curzi, 2026i]

Requirement	Status in this paper	Status in the corpus's applied fit
Matched null, same parameter count	not applicable	reported: a matched AR(1) with intercept, beaten by 2.8 per cent against a declared 10 per cent margin — **the rule failed**
Information criterion (AIC or BIC)	not applicable	**NOT MET.** No AIC or BIC is computed anywhere in this corpus, so the parameter count was never paid for, and a 2.8 per cent margin over a two-parameter alternative may not be a margin at all
Explicit free-parameter count	stated: the self-storage law has four (`eta`, `delta`, `C`, `Q_0`); the framing model has three (`N`, `u`, and the pair-cost pair `c1`, `c2` counted as two, giving four for `V(n)`)	stated
Effect sizes with intervals	**NOT MET.** Nothing in Section 10 carries an interval, because nothing in Section 10 was measured	partially met

Two rows are NOT MET and are printed here rather than left for a reviewer. A model with more parameters that fits better has not been shown to be better, and this paper's `V(n)` — four free parameters to produce an interior maximum — would be a prime candidate for exactly that criticism if it were ever fitted.

The related demand is sharper still: what observation would distinguish these laws from a neighbouring model that fits equally well? [Durlauf, 2005, Sobkowicz, 2020] This paper's honest answer is H1's contrast between `N` and `N_eff`, which is a genuine differential prediction because the two quantities move in opposite directions under the step-one intervention of Section 10.1 — and it has not been run.

21.12.9 12.9 Precision, and what each kind of number is

The numbers in this paper are of three kinds and are quoted accordingly.

Defined or derived-from-defined. `ln 6 = 1.7918`, `ln 9 = 2.197225`, `1 − 0.88^2 = 0.2256`, `0.980 x 0.992 x 0.996 = 0.96827136`, every entry of Tables 1 to 6, and every steady state computed from stipulated parameters. **These are exact to the precision printed and may be recomputed to any further precision.** No claim about the world is contained in their digits.

Illustrative model output. Every entry in every trajectory table, `Q_inf = 0.77941`, `Z_inf = 0.447204`, `h_0 = 0.006156`. **These carry no measurement uncertainty because there was no measurement**; six decimal places record the arithmetic, not the confidence. Section 10.2's own sensitivity note is the correct reading of `h_0`: its sign is not robust to the cost weights.

Measured or fitted. None appear in this paper. The correlations of Table 7 are stipulated, the rung yields of Section 7.6 are stipulated, the ledger weights are stipulated, and `kappa` is assumed. Any application of this framework to real data must report fitted parameters with intervals, and Section 12.8 records that the corpus's one such report does not carry them throughout.

One convention is worth stating because it recurs. Where a correlation is reported at two decimal places and a `u` derived from it at four, the extra digits are exact consequences of

the input and not a claim to finer measurement. Because `du/drho = −2 rho`, an uncertainty of `+/−0.05` on `rho = 0.88` propagates to `+/−0.088` on `u` — **larger than the two decimal places of the input suggest**, which is precisely why SF5 requires an interval whenever `|rho| > 0.7`.

21.13 13 Limitations

Both worked cases are constructed, not observed. No dataset was collected for this paper. Every number in Section 10 is the output of stated parameters under the stated model, carried through so that a reader can re-derive it. They demonstrate that the procedure runs and that it reports its own failures; **they are not evidence that any person behaves this way and should never be cited as such.**

No hypothesis in this paper has been tested. H1 to H6 are stated with their falsifiers and none has been run. The preregistered rule declared in Section 10.1 was declared and not executed. **The corpus's one preregistered confirmatory test of the storage law did not meet its own declared margin** [Curzi, 2026i], and that is the current evidential status of every applied claim here.

The framing encoding is the load-bearing postulate and it has no external support. That a way of construing a situation admits representation as a unit vector, such that predictive agreement maps to parallelism, is this work's own assumption. It is stated as P2, it is the thing to attack, and nothing in this paper's bibliography supports it.

`N_eff = 1 + (N−1)u` is not a Hill number, and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` the Hill number of order one, and both are fully grounded [Hill, 1973, Jost, 2006]. The participation ratio `PR` is likewise a Hill number of order two, computed on the Gram spectrum. **`1 + (N−1)u` is an affine reparametrisation of `PR`, and an affine transformation of a Hill number is not a Hill number.** A reviewer who reaches for the Hill-number literature as support for the affine form will find that it does not apply. The repair is the one this paper takes: derive the affine form's properties in the framework's own terms and reserve the Hill citations for `1/HHI`, `exp(H)` and `PR`.

The functional form is underdetermined. Latané's sub-linear power law [Latané, 1981] and the `n log n` form [Briscoe et al., 2006] fit the same qualitative facts, and **nothing assembled in this corpus discriminates between them.** The general statement of the difficulty is that many mechanisms produce indistinguishable curves [Stumpf and Porter, 2012]. The logarithm is chosen for its axiomatic characterisation, not established by measurement, and the axioms are a choice rather than a finding.

`u` has not been shown to be a quantity. Section 12.7 concedes Michell's objection in full [Michell, 1997], and the conjoint-measurement test that would settle it has not been run [Luce and Tukey, 1964]. If `u` is read as a similarity measure over construals it cannot be assumed to behave metrically at all [Tversky, 1977].

Three attributions in the source material have no entry in this paper's bibliography and are therefore uncited. The cognitive-consistency literature behind mechanism CM2; the forecasting result behind CM5, which is described in Section 5.1 as the closest available direct evidence for this paper's central claim and is not leaned on; and the classical savings-method evidence for forgetting curves behind Section 7.5, from which this paper takes one structural fact and no numbers. **Each is described rather than cited, and no claim in this paper rests on any of them.**

The reflection problem, and why it outranks everything else here. Section 3.4 states it in full. The specification is reflexive at both scopes at which this paper works, and the endogenous effect in such a specification is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011]. **This paper adopts no remedy.** Every applied reading of `u`, `eta`, `r` or `h` is therefore a **modelling position rather than an identified empirical result**. The most realistic available repair is to stipulate the reference set and defend the stipulation [Brock and Durlauf, 2001]; freezing the framing inventory is a step toward that and not a substitute for it.

The Lucas critique applied to this paper's own parameters. The framework asserts that a described system changes when the description is used, and then treats the parameters as constant over a window [Lucas, 1976, Hacking, 1995]. **Both cannot be true without qualification.** The narrow position taken here — constancy only over a declared window and only while the proxy is not a reported target — is a real restriction on where the model may be used.

Which parameters were chosen rather than measured. All of them. In Section 10.1: the fifteen correlations, `eta`, `delta`, `Q`, `C`, `c1`, `c2`. In Section 10.2: the three retention channels, the six rung yields, the six ledger weights, `E*`, `r*`, `kappa`, `N` and the internal `u`. The collapse rates `lambda` of Section 5.2 are stipulated to bracket a plausible range and **have not been measured anywhere in this corpus.** The `V(n)` cost cases of Table 4 are illustrative parameter sets, not an empirical distribution.

The linear correction load is a postulate with no measurement behind it, and `kappa` is assumed. A convex form is equally plausible a priori. Section 10.2's negative-headroom finding is conditional on `kappa = 0.03`, a number nobody measured, and is a demonstration of a mechanism rather than a measurement of anything.

The reconciliation-cost postulate may be wrong in its form as well as its constant. The claim that internal maintenance load is proportional to the pair count is imported from a group-scope communication argument [Brooks, 1975], and H2's third kill condition — a linear cost model fitting as well — is a live possibility that nothing here excludes.

The conversion ladder's chain assumption is the most likely of the paper's structural claims to fail. If items reach `DEFAULTED` without passing `ENCODED`, the ladder is not a chain, the product form is wrong, and Section 7.6 says so. Some dispositions plainly form without ever being written down.

The monotone claim in `u` is restricted, not defended. The literature contains an inverted U [Uzzi and Spiro, 2005], short-run costs to surface-level diversity [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007], and cases where redundancy reduced safety [Sagan, 1993]. **A monotone surplus cannot survive that list unqualified**, and this paper restricts its claim to the regime the worked cases exercise rather than locating the turn.

Nothing conserved is claimed, and that is a concession. `Q` has the grammar of a conserved quantity and is not one [Mirowski, 1989]. The only invariance claimed is the unit rescaling of Section 12.6, tested at one scale.

Unmet rigour checks, printed rather than left to a reviewer. (i) *Model comparison.* No AIC or BIC is computed anywhere in this corpus, so the corpus's one applied fit never paid for its parameter count; **reported NOT MET** in Section 12.8. (ii) *Effect sizes with intervals.* Nothing in Section 10 carries an interval, because nothing in Section 10 was measured; **reported NOT MET.** (iii) *Scale type.* Conjoint conditions untested; the ratio-scale treatment of `u`, `Q` and the cost ledgers is a stipulation. (iv) *Reproducibility.* Every parameter in this paper was constructed by one author; there is no independent replication of anything, and the reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005]. (v) *Directional versus point prediction.* Directional predictions are nearly costless in the social sciences [Meehl, 1967]; this framework does make point predictions with constants, which is the right answer to that objection, but **no point prediction of this paper has yet been put at risk**. (vi) *Small-sample bias.* `rho` estimated on 30 paired predictions has a wide interval, and effective-count estimators computed on small samples are biased in the analogous ecological setting [Chao et al., 2014]; no correction is applied here.

Nothing in this paper is a human-subjects finding. No interventions were run, no participants were recruited, and the declination constraint of Sections 5.3 and 8 is a design constraint on prospective work rather than a report of past practice.

21.14 14 Conclusion

The surplus functional is scope-free. Its axioms quantify over states in an inner-product space and contain no term referring to persons, so applying it to `N` framings held by one observer is a substitution of domain rather than an analogy. The substitution costs exactly two postulates — that a framing admits unit-vector encoding, and that a mean pairwise non-parallelism summarises the set — and yields the **internal surplus** `F_int = ln(1 + (N−1)u)` with `N_eff = 1 + (N−1)u` the audited framing count, `0 <= F_int <= ln N`, and `u = 1 − rho^2` estimated from the correlation between framings' prediction errors — an instrument that asks nobody to judge similarity. **The affine form is design axiom S3, chosen and not derived.**

The audited count is exactly a reparametrised participation ratio. For the Gram matrix `G` of the observer's encoded framings, `N_eff = 1 + (N−1)u_bar = N + 1 − N/PR` with `PR = (tr G)^2/||G||_F^2` the Rényi-2 participation ratio. The mean-pairwise aggregator is therefore not an improvisation; it commits the analyst to a standard diversity statistic. **It does not, however, make `N_eff` a Hill number: an affine transformation of a Hill number is not one.**

A six-framing subject at mean `u = 0.6860` reads `N_eff = 4.4298` and `F_int = 1.4883` nats, 83.07 per cent of the ceiling `ln 6 = 1.7918`. Splitting the pairs by lineage shows what the mean hides: six within-lineage pairs at `u = 0.2732` give the four-framing lineage an audited count of **1.8196 between them**, against nine cross-lineage pairs at `u = 0.9611`.

Restructuring beats enlarging. Retiring the two most redundant framings and importing two from outside the lineage raised the audited count **25.4 per cent** — `F_int` from 1.4883 to 1.7148 nats, 95.70 per cent of ceiling — **at identical framing count and identical reconciliation load.**

And it was not enough. At `eta = 0.60`, `delta = 0.06`, `Q = 12.0` and `C = 0.35`, converted surplus rose from 0.8930 to 1.0289 against a draw of 1.0700: **the intervention closed 77 per cent of the gap and left the one-step change in stored order negative at −0.0411.** Only cutting the operating cost and shedding stored order turned the account, and they turned it at the original geometry as well. **The binding constraint was never the geometry.** The sensitivity table says the same thing structurally: `dh/deta = ln N = 2.197`, `dh/dC = −1`, `dh/dQ = −delta = 0.0317` and `dh/dN = eta/N = 0.0038`, so **adding categories of thought is the weakest available lever**, and doubling the structural budget by raising `N` alone requires `N` to be squared, from 9 to 81.

Stored order and stored error are the same variable, and the remedy is two books. Subtracting the earned recursion from the lived one gives `Z_{t+1} = (1−delta)Z_t + eta(M_t − V_t)` with `Z_inf = eta(M* − V*)/delta`: **stored error integrates on the same pole as stored knowledge and its equilibrium is independent of cost, because the cost term cancels exactly.** In the worked survey a **25.93 per cent** confabulated input compounds into **57.38 per cent** of the steady-state stock, the earned track's equilibrium goes negative between weeks 104 and 156, and the model reports that as its own domain of breakdown rather than concealing it. At equilibrium the headroom identity `h_inf = eta(ln N − M*)` holds exactly, verified to six decimal places at 0.060786.

The survey's own weakest number is reported as weak. Baseline headroom of 0.006156 `Q`-units per week **is not robust to the declared cost weights and its sign is therefore unestablished**; doubling one ledger's weight changes it by more than its entire value. The one figure the same survey regards as robust is `Z_inf`, which is independent of cost by construction — and it is the most uncomfortable number in the report.

All of this is arithmetic. Whether any observer's framings obey the encoding, whether any person's stored order obeys the recurrence, and whether the audited count predicts anything at all are separate questions. They are postulates rather than results, none of the six hypotheses stated here has been tested, and the corpus's one preregistered confirmatory test of the storage law did not meet its own declared margin.

21.14.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the models developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The two subjects worked in Section 10 are constructed examples with declared parameters, not field observations; the fifteen pairwise correlations of Table 7, the six conversion-rung yields, the three retention channels, the six cost ledger weights and the correction coefficient `kappa` are all stipulated. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 to 7.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. Both worked subjects are constructed. The declination constraint referred to in Sections 5.3 and 8 — that no intervention removing a person's ability to decline is within the framework's scope — is a design constraint on prospective work and is not a report of any study performed. The paper discusses self-assessment, rumination and the accumulation of unearned belief as formal objects; **nothing in it is clinical advice, and no diagnostic claim is made or intended.**

Preregistration

This paper reports no preregistered test of its own. The falsification rule stated in Section 10.1 is declared so that it can be run and **has not been run**. The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — is reported in Curzi [2026i].

Chapter 22

The Launch Budget and the Desire Line: A Rectified Surplus Fund Against a Barrier, and Why Momentum Does Not Cross a Wide Shallow Ridge

Abstract. We define the launch budget as the rectified surplus $L^{Q} = \max(0,\ \eta M - C)$, accumulate it in a decaying fund $\Lambda_{t+1} = (1-\lambda)\Lambda_t + L_t$ with fixed point $\Lambda_\infty = L/\lambda$, and require $\Lambda_\infty > E_b$ before a departure begins, where E_b is the path integral of excess cost across the transit. Feasibility reduces to a critical cost $C_{\text{crit}} = \eta M - \lambda E_b$, computed at 0.082 Q-units per week in the worked case, and to a critical conversion efficiency $\eta_{\text{crit}} = C/M$ below which no plan of any size is ever constructed. The worked operator sat at $\eta = 0.05$ against $\eta_{\text{crit}} = 0.055238$, giving $L = 0$ and $\Lambda_\infty = 0$: a sustained zero budget that cannot diagnose itself. A two-week annual duty cycle accumulates a steady-state peak fund of 0.1162 against a barrier of 2.400 — 4.84 per cent of the requirement, forever. Two independent constructions of E_b agreed to 0.05 per cent. Deliberate discomfort programmes were priced, and the most ambitious, at $+165$ per cent cost, forecloses the departure permanently. On the gradient side only ratios of differences are identified: the office is 4.4042 times the departure cost of the kitchen table, in units that cancel. Momentum was tested at β from 0 to 0.95 and escaped no basin, because the barrier is a plateau with $C'' = -0.005$ rather than a spike; the recursion is recorded as a failed candidate and refused entry to the formulary.

Keywords: launch budget; rectifier; barrier integral; gradient descent; desire line; identified ratios; momentum

Series: B. Engineering the Surplus **Paper:** CCP-022

22.1 1 Introduction

Every account of why people and organisations stay where they are has to answer a prior question: where does the capacity to plan a departure come from, and what happens to that capacity when the cost of staying rises? The common prescription assumes the answer is obvious — that discomfort supplies motive force, and that a person or a firm made sufficiently un-

comfortable will move. This paper shows that, under the framework's own storage arithmetic, the prescription has the sign wrong over most of its range, and it shows this by computing the threshold at which the sign flips.

The construction has three parts and they are simple. The **launch budget** is the rectified surplus left after a period's operating cost has been paid, `L = max(0, eta*M - C)`. The **launch fund** is that budget accumulated in a second leaky integrator with its own decay rate `lambda`, whose fixed point `Lambda_inf = L/lambda` is the largest barrier the regime can ever cross. The **barrier** `E_b` is the path integral of excess operating cost across a transit between two configurations of a measured cost field. A departure is feasible if and only if `Lambda_inf > E_b`, and rearranging that inequality yields a **critical cost** `C_crit = eta*M - lambda*E_b` above which no amount of waiting funds the crossing. The second half of the paper measures the field the barrier is computed on, using choice frequencies rather than self-report, and reports what such a measurement can and cannot identify.

Four things in the argument are worth separating from the framework they sit in.

First, the **rectifier**. `max(0, .)` is not decoration: a period whose cost exceeds its converted moment produces no negative planning capacity, it produces none at all, and the deficit reappears in the following period as a higher cost rather than as a negative budget. The consequence is a self-concealing regime. An subject at a sustained `L = 0` does not experience being trapped, because noticing that an alternative configuration exists is itself funded by `L`. The diagnostic must therefore come from outside the system, and this is a structural claim rather than a psychological one.

Second, the **stationarity proposition**. Where `L > 0`, `grad L = -grad C / eta`, so the stationary points of the launch budget are exactly the stationary points of operating cost and the maxima of the budget are exactly the minima of cost. The capacity to plan a departure is largest at the local minimum of the cost field and smallest on the ridge between basins — that is, in the middle of the crossing. This inverts the ordinary prescription. Cost reduction at the origin is not the obstacle to the journey; it is the platform the journey is funded from, and the point is arithmetic rather than temperamental.

Third, the **negative result on momentum**, which this paper reports at the same prominence a positive one would get. Momentum is the standard cheap escape from a local minimum in first-order optimisation, and on the measured cost field of the worked case it escapes nothing: at `beta = 0`, `0.5`, `0.8`, `0.9` and `0.95` the walker terminates at `x = 1.9972` in basin A at every setting, because the barrier is a plateau with second derivative `-0.005` spread over more than two configuration-units rather than a narrow spike. The recursion is recorded as a **failed candidate** and is refused entry to the framework's formulary. What survives is one empirical statement with no free parameters: momentum defeats narrow barriers and is useless against wide shallow ones, and most barriers of practical interest — an income gap, a retraining period, a slow renegotiation — are wide and shallow.

Fourth, the **identification result** on the measurement side. A desire-line survey recovers cost differences only up to an unknown choice temperature `theta`. Absolute costs are not recovered and must never be reported; **ratios of differences are fully identified**, because `theta` cancels. In the worked survey the office is 4.4042 times as costly a departure from the desk as the kitchen table is, and that statement is unit-free and testable while "the office costs 1.95" is not. The same ratio form turns out to be roughly four times more robust to an unmodelled switching cost than the differences it is built from, which is a second and unplanned reason to prefer it.

The framework's static and dynamic halves are presupposed rather than re-derived here. The founding definition — that comfort is the felt total of present costs, so that an subject observed at rest is at a local minimum of their own cost field by definition rather than by luck, and that the reflexive loop `T(x) = W(x, M(x))` has the self-fulfilling prophecy as a fixed point of the composition of seeing and responding — is established in Curzi [2026]. The contraction theorem the fund leans on is stated exactly — a contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass — in Curzi [2026]. The storage law whose steady-state theorem the fund reuses

with `delta := lambda`, `Q_inf = (eta F(u*) − c*)/delta`, is Curzi [2026a].

Sections 2 and 3 state the hypotheses and the formal framework, including the identification problems the framework cannot solve. Section 4 develops the launch budget, the fund, the barrier integral and the critical cost. Section 5 develops the gradient, the desire-line instrument, the two candidate escapes and the regrade analysis. Section 6 collects the seven-gate formula-validation audit for all five formulas. Sections 7 and 8 give the design specifications and the named failure modes. Section 9 works one subject end to end across both halves. Sections 10 to 12 discuss what follows, verify the chain from minimal postulates, and state what the account cannot support.

22.2 2 Hypotheses

Several results below are theorems about equations and cannot be falsified by observation; they are labelled as derivations where they appear. What can be falsified is the claim that these equations describe anything real. The hypotheses separate the two, and each carries the observation that would defeat it.

H1 — The launch budget is rectified and the rectification is consequential. The capacity to construct, hold and commit to a plan for a different configuration is drawn from the current period's surplus `L = max(0, eta*M − C)` and is unavailable at `L = 0`. **Predicted:** the incidence of newly constructed plans for a different configuration is monotone increasing in contemporaneous `L`, and is zero when `L = 0`. **Falsified by:** a single well-documented plan constructed during a sustained `L = 0` stretch, under prospective daily logging of `M`, `C` and plan-initiation events.

H2 — Plans decay geometrically, so the fund has a ceiling. Accumulated planning capacity is a leaky integrator with its own rate `lambda`, so the fund approaches `Lambda_inf = L/lambda` and never exceeds it. **Predicted:** exponential decay of plan persistence in the absence of reinforcement, with half-life `ln 2 / (−ln(1−lambda))`; and a maximum crossable barrier equal to `L/lambda` however long the subject waits. **Falsified by:** plan persistence that does not decay geometrically without reinforcement — a threshold or step-function decay would do it, and either is plausible; or a completed departure across a barrier reliably exceeding the measured `L/lambda`.

H3 — The critical cost is a real threshold, not a bookkeeping artefact. Departures cease as operating cost crosses `C_crit = eta*M − lambda*E_b`. **Predicted:** across a population of would-be departures, the observed departure rate falls to zero as `C` crosses a threshold **predicted from parameters measured beforehand**. **Falsified by:** departures occurring at the same rate above and below the computed threshold. This requires a cohort and is the most expensive test in the paper.

H4 — The barrier integral predicts realised transit cost. `E_b`, computed as the path integral of excess cost at the intended transit speed, predicts the cost actually incurred in crossing. **Predicted:** realised transit cost, ledgered after the fact, matches the pre-computed `E_b` within the stated interval. **Falsified by:** realised cost uncorrelated with the predicted barrier across a set of completed transitions. This is the cheapest test in the paper and can be run retrospectively by anyone who computed `E_b` beforehand.

H5 — Choice frequency recovers relative cost. Under a logit choice model, log-frequency ratios over available occasions recover differences in operating cost up to the scale `theta`. **Predicted:** a frozen difference table fitted on days 1 to 20 beats a uniform baseline, a most-frequent-option baseline, a first-order Markov baseline and a day-shuffled control at predicting held-out days 21 to 30; and adding a fourth option does not change the ratio of the first two. **Falsified by:** failure against the

shuffled control, which would mean the subject has no stable cost field over the surveyed coordinates; or a material shift in the recovered top-two ratio when the choice set is experimentally manipulated, which would falsify the logit form for that coordinate.

H6 — Momentum does not cross a wide shallow barrier. Adding a momentum term to descent does not move a walker out of a basin whose exit ridge is a plateau. **Predicted:** on a field whose ridge curvature is small in magnitude relative to the basin curvature and whose ridge extends over a distance comparable to the basin separation, terminal position is independent of `beta`. **Falsified by:** escape at any tested `beta` on such a field. **This hypothesis was tested here and was not falsified; Section 5.10 reports the result and Section 10 reports what it does and does not license.**

Three further claims are **not** hypotheses and are labelled accordingly wherever they are used.

The Launch Postulate is a postulate. That planning capacity is drawn from `L` is a claim about persons, not a theorem. Nothing in the framework's foundational results implies it and none of them would be touched if it were false. It is falsifiable — H1 states how — and until it is tested it is a modelling assumption that has earned its place by explaining a common observation, not by having been measured.

The Gradient Postulate is a postulate. That an subject's motion in configuration space is, in expectation, in the direction `-grad C` with a step magnitude increasing in `|grad C|` is a modelling assumption. It borrows the *form* of a stationary-action principle and nothing else: no physical principle is invoked, nothing is conserved, and `C` is not a potential in any sense a physicist would recognise. Section 3.7 makes the category of every physics borrowing in this paper explicit.

That a transition's cost can be summarised by a single scalar `E_b` is a modelling choice, adopted because it makes the feasibility condition a comparison of two numbers. Section 12 records what it discards.

22.3 3 Framework

22.3.1 3.1 What is presupposed

Throughout, **subject** denotes the modelled individual or unit whose configuration and cost field are under study. It is a role term inside the model and not a form of address; where a claim concerns the person conducting the survey rather than the one surveyed, the word used is **analyst**.

Three results are used throughout and are established elsewhere in this corpus.

The founding definition and the reflexive loop. Comfort is the felt total of present costs, so an subject observed at rest sits at a local minimum of their own cost field by construction; and the reflexive loop `T(x) = W(x, M(x))` identifies the self-fulfilling prophecy as a fixed point of the composition of seeing and responding [Curzi, 2026]. Section 3.6 states why that loop is not identified from observational data.

The contraction theorem. A contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with the distance to it shrinking by at least `q` on each pass [Curzi, 2026, Banach, 1922]. The launch fund's ceiling is this theorem applied to a second integrator.

The storage law and its steady state. `Q_{t+1} = (1-delta)Q_t + eta*S_t - C_t` with `S_t = ln(1 + (N-1)U_t)` is a first-order linear difference equation whose fixed point under constant drive is `Q_inf = (eta F(u*) - c*)/delta`, and whose update map is a contraction for every `delta > 0` [Curzi, 2026a]. The launch fund of Section 3.4 is that theorem with `delta := lambda` and

the drive term replaced by L. The headroom gauge h_t = eta*ln N − delta*Q_t − C_t, its three regimes and its separate admissibility and sustainability constraints are established in Curzi [2026b], and Section 5.12 shows that descent in the cost field is ascent in that gauge under a stated restriction.

Two properties of the surplus term matter here and both carry qualifications the corpus states rather than hides. The ceiling ln N is the maximum an ensemble of N equiprobable categories can carry [Shannon, 1948], and the framework does **not** identify its surplus with Shannon entropy. The logarithm has two independent warrants and this paper needs only the weaker one: Peters and Gell-Mann [2016] shows that the time-average growth rate of a multiplicatively evolving quantity is the expectation of its logarithm, so the logarithmic evaluation follows from the dynamics with no psychological premise, while the Fechnerian warrant [Fechner, 1966] requires a contested perceptual story. **The functional form is nevertheless underdetermined by the evidence.** A sub-linear power law [Latané, 1981] and an n log n form [Briscoe et al., 2006] reproduce the same qualitative facts — diminishing returns to count, no threshold, monotonicity — and nothing assembled in this corpus discriminates among the three. Finally, the effective count 1 + (N−1)u used inside the surplus functional is **not** a Hill number: 1/HHI and exp(H) are the Hill numbers of order two and one and are well grounded [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979], while 1 + (N−1)u is a linear interpolation between 1 and N and is this framework's own construction. Every appearance of an effective count in this paper says which one it is.

22.3.2 3.2 The launch budget, and the register split that a dimensional check forces

The canonical statement of the launch budget is

```
L = max( 0 ,  M − C )

M   the moment as lived this period
C   the operating cost of this period
L   the surplus available to be spent on anything other than continuing
```

and **as written it does not survive a dimensional check.** M is in nats; C is in Q-units per period; they cannot be subtracted. This is the audit doing its work rather than a defect to be apologised for, and the resolution is worth more than the original formula. Two admissible registers exist and both are correct:

```
THE STORED FORM     L^Q = max( 0 ,  eta ∗ M_t  −  C_t )      Q−units per period
THE LIVED FORM      L^M = max( 0 ,  M_t  −  C_t / eta )      nats per period

and                 L^Q = eta ∗ L^M
```

The stored form asks how much durable surplus remains after this period's deposit into the self and after the operating cost. The lived form asks how much of this period's moment exceeded what it cost to have, with C/eta reading the operating cost back into the register of moment as the moment that would have been required to pay for it.

Since eta > 0 the two forms differ by a strictly positive constant factor, so **they have the same zero set and the same sign**, and every qualitative claim in this paper depends only on the sign. That is the honest resolution: the canonical statement is register-ambiguous, the ambiguity is a scale factor of eta, and no claim here is affected by the choice — but every *number* is, so every number declares one. The convention adopted throughout is L^Q for anything that will be accumulated and L^M for anything that will be compared to a moment; both are always reported.

22.3.3 3.3 The rectifier

`max(0, .)` is a **half-wave rectifier**, and in the framework's circuit register that is a precise object: a diode in series with the accumulator [Horowitz and Hill, 2015]. This is a **shared mathematical form** and not a derivation — the same nonlinearity governs both, and nothing about semiconductor physics is claimed to hold of a person.

There is no negative planning. A period in which cost exceeded converted moment does not produce anti-plans; it produces nothing. The deficit does not vanish — it appears in the next period as a higher `C`, through unfinished work carried, sleep debt and unrepaired relations — but it does not appear as a negative launch budget, because the quantity being measured is *available surplus*, and surplus has a floor at zero by construction.

The asymmetry has a consequence that is frequently reported and rarely explained: **a bad period costs the plan that would have been made, and then also charges for the plan that was not made.** The first is the rectifier; the second is the cost carry. The rectifier also destroys information, and Section 6.1 records the cost: `max(0, .)` cannot distinguish "just barely trapped" from "catastrophically trapped", so the depth of the deficit must be tracked separately.

22.3.4 3.4 The launch fund

A single period's `L` is almost never enough to fund a departure. Surplus must be stored, and stored order leaks, so the fund is a second leaky integrator with its own rate:

```
THE LAUNCH FUND

    Lambda_{t+1} = (1 - lambda) Lambda_t  +  L_t

    Lambda_t   accumulated committed surplus available to spend on a transition, Q-units
    lambda     plan decay per period: forgetting, changed circumstance, loss of nerve,
               drift of aim

    Lambda_inf = L / lambda
```

The fixed point is the storage law's steady-state theorem with `delta := lambda` [Curzi, 2026a], and it is the DC gain `1/lambda` of a first-order discrete section applied to the net drive [Oppenheim et al., 1996, Elaydi, 2005]. The same recursion is exponential smoothing under another name [Holt, 1957, Brown and Meyer, 1961, Hyndman et al., 2008], and the level-and-rate vocabulary it belongs to predates the framework by four decades [Forrester, 1961].

`Lambda_inf = L/lambda` is the single most useful number in this paper. It is not the largest barrier the subject will cross this year; it is the largest barrier the regime can cross **at all**, at steady state, with unlimited patience.

The stock-and-flow distinction here is load-bearing and is violated constantly in ordinary talk about motivation: `Lambda` is a stock in Q-units, `L` is a flow in Q-units per period, and people systematically misjudge the relation between the two when a delay sits between them [Sterman, 1989, 2000]. The fund's behaviour is exactly the behaviour that misjudgement gets wrong.

22.3.5 3.5 The cost field, its gradient, and the logit recovery

```
THE COMFORT FIELD AND ITS GRADIENT

    C : X -> R          the operating cost of occupying configuration x, Q-units per period
    g(x) = - grad C(x)  the descent direction: the direction of cheapest motion at x

    DISCRETE MOTION     x_{t+1} = x_t - alpha * grad C(x_t)
```

X is the configuration space of arrangements the subject could occupy and C(x) is the operating draw evaluated at each. **The desire line is the observed integral curve of −∇C.** The classification of stationary points by the Hessian — positive definite a rest basin, negative definite a ridge, indefinite a saddle, singular a plateau — and the partition of the space into basins of attraction are standard results for gradient systems [Strogatz, 2015]. Modelling the motion of people as motion in a cost field is not novel either: the social-force model treats pedestrian trajectories as motion under a gradient and reproduces observed path formation [Helbing and Molnár, 1995, Helbing et al., 2000]. That precedent is **a shared mathematical form**, and the present paper claims no more from it.

The instrument that makes the field measurable is the logit recovery. Under a choice model in which the probability of an option falls exponentially in its cost,

```
THE LOGIT RECOVERY

    P(a) / P(b) = exp( −( C_a − C_b ) / theta )

    =>   C_a − C_b  =  −theta ∗ ln( P(a) / P(b) )

    estimated from counts:   C_a − C_b  =  −theta ∗ ln( n_a / n_b )
    standard error (in theta units):     se = sqrt( 1/n_a + 1/n_b )
```

theta is a scale parameter carrying the units of C — the choice temperature. The specification is the standard workhorse of discrete-choice measurement [Brock and Durlauf, 2001], and recovering scale values from choice proportions rather than from numerical self-report is older still [Thurstone, 1927]. **It is a modelling postulate about behaviour and is badged as one**; its characteristic weakness, independence of irrelevant alternatives, is stated with its test in Section 6.5 and its failure mode in Section 8.2.

22.3.6 3.6 Identification: three things no amount of data recovers

The reflection problem. This paper presupposes the framework's reflexive loop T(x) = W(x, M(x)) [Curzi, 2026]: the group influences the member and the members constitute the group. That is exactly a linear-in-means reflexive specification, and Manski [1993] proves the endogenous social effect in such a specification is **not identified from observational data**. It cannot be separated from contextual effects or from correlated unobservables however much data is collected, and influence and selection are generically confounded in observational network data [Shalizi and Thomas, 2011]. **This paper adopts no remedy.** The known options are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]; the last is the most realistic route here and the desire-line protocol's frozen, pre-declared option set is a step toward it rather than a substitute for it. Every claim in this paper that leans on the reflexive loop is therefore **a modelling position rather than an identified empirical result**, and it is said again in Section 12. That a reflexive fixed point can be caught happening in the field, with dates and prices, is documented [MacKenzie and Millo, 2003]; that is an existence proof for the mechanism and not an identification of this paper's parameters.

The choice temperature. theta is not identified from choice frequencies alone. It requires an external anchor: an experimentally imposed cost of known magnitude, from whose effect on the share of an option theta follows. **That experiment has not been run here**, which is why every difference reported in Section 5 is in theta units and why only ratios of differences are advanced as findings. What licenses the ratio and not the difference is a standard point in measurement theory: the admissible statements are the ones invariant under the transformations the scale permits [Narens, 1996, Stevens, 1946].

The step size. In the discrete descent x_{t+1} = x_t − alpha∗grad C(x_t), the step size alpha and the cost scale theta are not separately identified: only their product governs the observed

trace, so two subjects with different responsiveness and different cost scales produce identical traces. Section 6.4 records that gate as a failure rather than a caveat, and the specification requires the product to be reported or neither.

The Lucas critique, applied to this framework's own parameters. The framework asserts that a system changes its behaviour when it is modelled and observed, and then treats `eta`, `lambda` and `theta` as constants over an estimation window [Lucas, 1976]. Both cannot hold without qualification. The position taken here is the narrow one: the parameters are treated as stable **only over a declared window and only while the fund is not itself a reported target**, since a measure that becomes a target ceases to be a measure [Goodhart, 1975, Campbell, 1979]. Where an subject's `Lambda` is reported to anyone with an interest in it, the constancy assumption fails and the model is outside its domain.

22.3.7 3.7 Analogy discipline, and the standing honesty clauses

Following the corpus's rule, every borrowing from physics or from optimisation is labelled at first use as a **derivation** (the premises are genuinely satisfied), a **shared mathematical form** (the same equation governs both, with no transfer of physical content), or an **analogy** (a suggestive correspondence with no formal warrant, legitimate as motivation and never as evidence).

Borrowing	Where	Category
leaky integrator for the launch fund	Section 3.4	**shared form** — the same first-order difference equation, no claim about charge
half-wave rectifier for `max(0, .)`	Section 3.3	**shared form** — the same nonlinearity, no claim about semiconductors
DC gain, pole, time constant	Sections 3.4, 4.3	**shared form** — standard first-order-section results applied to the same equation
gradient descent and its convergence to a stationary point	Sections 3.5, 5.8	**derivation within the model** — the model *defines* motion as descent, so the algorithmic theorem applies to the model exactly; whether an subject descends is the Gradient Postulate and is separate
basins of attraction, Hessian classification	Sections 5.8, 5.9	**derivation within the model**, from Strogatz [2015]
stationary action for the Gradient Postulate	Section 2	**analogy** — form only; no conservation law, no teleology, and the honest word is stationary rather than minimal
barrier `E_b` as a path integral of excess cost	Section 4.6	**shared form** — an accumulated cost, explicitly **not** an energy
momentum, and temperature as annealing	Section 5.10	**analogy** — imported as candidate mechanisms and tested; one was refused

The failure mode this table exists to prevent is a shared-form borrowing quietly acquiring the certainty of a derivation. The critique of that move in economics is long-standing and

applies here [Mirowski, 1989].

Standing honesty clauses, repeated from the corpus. The triangle inequality fails for geometric triples. The surplus functional as deployed is a lower bound on the ensemble's information. The framework makes no empirical or metaphysical claim about physics, does not identify surplus with Shannon entropy, and proves no thermodynamic law. **Nothing in this paper says anything about physics, and `E_b` is a barrier in a modelled cost field, not an energy.**

22.4 4 The launch budget against a barrier

22.4.1 4.1 The low-cost configuration adjacent to a transition

The framework's founding node holds that the present moment is the comfort zone by definition, since the subject is always already in it, and that the desire to be elsewhere is not evidence of being in the wrong place but a product manufactured under specific conditions [Curzi, 2026]. The condition can now be stated: `L > 0`.

The canonical image is a departure lounge, and the arithmetic explains why it is exact rather than decorative. A departure lounge is a low-cost configuration adjacent to a transition. Nothing is required of the occupant there: the attention ledger is quiet, the obligation ledger is suspended, the regulation ledger is idle, and `C` collapses. `M` does not — there are people to watch, a window, an unfamiliar arrangement of objects, a suspension of routine which is itself informative. **`M` holds and `C` falls, so `L` rises, and what `L` buys is the construction of elsewhere.**

The counter-image is a lift with both hands full, halfway through a task, load high, attention fragmented, nothing put down. `M` is not especially low — a great deal is happening — but `C` is large, and `eta*M - C` is negative:

```
the locked regime:    eta = 0.05,  M = 1.05 nats,  C = 0.058 Q-units per week
                      C / eta = 1.160 nats
                      L^M = max(0, 1.05 - 1.16) = 0
                      L^Q = max(0, 0.0525 - 0.058) = 0
```

Zero, not small. An subject running this regime is not deficient in ambition; they are running a rectifier that is reverse-biased.

The practical consequence follows immediately and is the reason the analysis is worth doing. **An subject in a sustained `L = 0` regime cannot diagnose their own situation, because diagnosis is also manufactured from `L`.** The construction of an alternative configuration — noticing that one is possible, holding it in mind, weighing it — is exactly the activity the budget funds. A person with no launch budget does not report being trapped. They report having no particular ideas. This is a structural claim about the model, and it converges with the empirical literature on self-report from a different direction: verbal reports do not have privileged access to the processes that generate behaviour [Nisbett and Wilson, 1977], and reported states are strongly shaped by the conditions of the asking [Schwarz, 1999].

22.4.2 4.2 Where the budget is largest: the stationarity proposition

The observation the model has to account for is that plans for a different arrangement arrive at rest — on the fourth day of a holiday, in the bath, on a walk, in a departure lounge — and not in the middle of a task. The model makes this a proposition about the cost field.

Let the configuration be a point `x` in a space of arrangements, let `C(x)` be the operating cost at that configuration, and hold `M` and `eta` fixed across the neighbourhood. Then `L^M(x) = max(0, M - C(x)/eta)`.

> **Proposition 4.1.** Wherever `L^M(x) > 0`, `grad L^M(x) = -grad C(x)/eta`. Therefore the stationary points of `L^M` are exactly the stationary points of `C`, and the local maxima of `L^M` are exactly the local minima of `C`.

Proof. On the open region where `M − C/eta > 0` the rectifier is inactive and `L^M = M − C/eta`, so `grad L^M = −grad C/eta`, which vanishes if and only if `grad C` vanishes. The Hessian of `L^M` is `−H_C/eta`, so it is negative definite exactly where `H_C` is positive definite. This is a **derivation within the model**; it consumes the model's differentiability assumptions and nothing else.

Two readings follow.

First: the plan for elsewhere is manufactured at local minima of cost and nowhere else. That it arrives on holiday is not a coincidence and that it does not arrive mid-task is not weakness. It is where the gradient of the cost field is zero and the curvature is positive.

Second, which is the same statement in different clothes: the comfort is the platform. The journey is planned from the local minimum and departed from the local minimum, because the local minimum is the only place where the budget to do either exists. The organisational counterpart is the standard result that search and experimentation are funded out of slack rather than out of pressure [Cyert and March, 1963], and that search is triggered and bounded by the resources an organisation has spare [March and Simon, 1958].

Computed on the cost field constructed in Section 5.8 and shared between both halves of this paper, at the corrected regime `eta = 0.10`, `M = 1.42`, `lambda = 0.025`:

Configuration	`C(x)` (Q-units/wk)	`L^M` (nats/wk)	`L^Q` (Q-units/wk)	`Lambda_inf` (Q-units)
basin A floor (`x = 2.00`)	0.03400	1.0800	0.10800	4.3200
the ridge between basins (`x = 4.335`)	0.09150	0.5050	0.05050	2.0200
basin B floor (`x = 7.00`)	0.02880	1.1320	0.11320	4.5280
the A flank, mid-slope (`x = 1.332`)	0.05800	0.8400	0.08400	3.3600

The largest launch budgets are at the two basin floors and the smallest is on the ridge — that is, in the middle of the crossing. The subject has the least capacity to plan the journey precisely while making it, which is why journeys must be planned before they are begun and why mid-transit is the worst available moment to reconsider the destination.

22.4.3 4.3 The fund, and why plans have a half-life

A single week's `L^Q` of 0.108 Q-units does not fund a barrier of 2.4. The surplus must be stored and stored things leak; `lambda` is the leak.

What `lambda` is, for a plan: forgetting the reason; a change in circumstance that invalidates a premise; the slow loss of nerve; drift of aim, in which the plan is still held but no longer points at anything the subject now wants. It is the storage law's `delta` for a specific and fragile kind of stored order, and it is generally much larger than the `delta` of the self, because a plan has no enacting behaviour maintaining it [Curzi, 2026a].

`lambda` per week	fund time constant `1/lambda` (wk)	plan half-life (wk)
0.020	50.0	34.31
0.025	40.0	27.38
0.040	25.0	16.98
0.060	16.7	11.20
0.100	10.0	6.58

A plan held at `lambda = 0.06` is at half strength eleven weeks after the last time anything was added to it. That is the arithmetic behind the observation that a resolution made in January is gone by April with no event having occurred to end it. Nothing ended it; it leaked.

And `lambda` is engineerable by the same devices that raise `eta` for the self, applied to the plan instead: **write it down, date it, tell one person, give it an artefact, put a recurring entry in the calendar.** That the same acts raise conversion in one place and lower decay in another is not a coincidence — both are the act of moving something out of working memory into a durable medium.

22.4.4 4.4 The maximum crossable barrier

```
Lambda_inf = L^Q / lambda
```

Because the fund is a contraction, this ceiling is approached and never exceeded [Curzi, 2026]. **It is the largest barrier the regime can cross, ever.** Held at `M = 1.42` and `eta = 0.10`, and varying the two engineerable parameters:

`C` (Q-units/wk)	`L^Q`	`lambda = 0.06` gives `Lambda_inf`	`lambda = 0.025` gives `Lambda_inf`
0.020	0.12200	2.033	4.880
0.034	0.10800	1.800	4.320
0.058	0.08400	1.400	3.360
0.082	0.06000	1.000	2.400
0.100	0.04200	0.700	1.680
0.142	0.00000	0.000	0.000

Two things in that table are load-bearing.

Cutting `lambda` from 0.06 to 0.025 multiplies the crossable barrier by 2.4 at every cost level, and costs nothing but a notebook and a date. It is the cheapest intervention available here by a wide margin: nothing about the subject's life changes, only the durability of the plan.

At `C = eta*M = 0.142` the whole column collapses to zero. There is a cost above which the launch budget is zero and therefore the crossable barrier is zero regardless of `lambda`, of patience, and of how strongly the departure is wanted.

22.4.5 4.5 The minimum conversion efficiency for any departure at all

Rearranging `L^M > 0`:

```
L^M > 0   <=>   eta > C / M

at C = 0.034, M = 1.42:      eta_crit = 0.023944
```

Below a conversion efficiency of 2.39 per cent this subject has no launch budget at any moment size and no plan is ever constructed. Sensitivity, at `C = 0.034` and `M = 1.42`:

`eta`	`C/eta` (nats)	`L^M`	`L^Q`	`Lambda_inf` at `lambda = 0.025`
0.020	1.7000	0.0000	0.00000	0.000
0.034	1.0000	0.4200	0.01428	0.571
0.050	0.6800	0.7400	0.03700	1.480

eta	C/eta (nats)	L^M	L^Q	Lambda_inf at lambda = 0.025
0.100	0.3400	1.0800	0.10800	4.320
0.200	0.1700	1.2500	0.25000	10.000

Doubling `eta` from 0.05 to 0.10 nearly triples the crossable barrier, from 1.480 to 4.320, because `eta` enters the expression twice: once multiplying the moment and once dividing the cost. This is the strongest argument available for the framework's conversion ladder and it arrives from an unexpected direction. Raising conversion does not merely build a larger self; it builds the capacity to leave. The result is consistent with the corpus's finding that conversion is the first lever and is more often binding than the count of participants [Curzi, 2026b].

22.4.6 4.6 The barrier, constructed

`E_b` has so far been treated as a given scalar. It is not: it is an accumulated cost, and the construction matters because it is where most estimates go wrong.

A transition from configuration `A` to configuration `B` passes through configurations whose operating cost exceeds `C(A)`. The barrier is the accumulated excess:

```
E_b = INTEGRAL over the transit of  max(0, C(x) - C(A))  dt
    = ( 1 / v ) * INTEGRAL over the path of  max(0, C(x) - C(A))  dx    at constant speed v
```

On the shared cost field of Section 5.8 the path integral of positive excess from basin A to basin B is 0.182961 Q-unit configuration-units per week, and the basins are 4.996 configuration-units apart:

transit duration `T` (wk)	speed `v` (units/wk)	`E_b` (Q-units)
40	0.12490	1.4649
52	0.09608	1.9043
65.5	**0.07627**	**2.3987**
78	0.06405	2.8565
104	0.04804	3.8086

A slower crossing costs more in total, because the excess cost is paid per period and a slow crossing spends more periods paying it. Dragging out a transition is not caution; it is expense.

It is also, as written, wrong in one limit, and this is stated rather than hidden. The model says `E_b -> 0` as `v -> infinity`, which is false: at high transit speed the cost field itself rises, because doing a thing fast is more expensive per unit than doing it at a moderate pace. A correct treatment needs a speed-dependent term, `C(x, v) = C(x) + b*v^2` or similar, which produces an interior optimum. That term is not developed here. **What the constant-field model supports is the comparative claim — that slower is dearer over the range where speed does not itself raise cost — and it does not support an unbounded "go as fast as possible".** The transit-duration column should be read as valid between roughly 40 and 104 weeks for this case and should not be extrapolated; specification SP-L12 makes that a requirement.

A discrepancy in the source data, reported rather than corrected. The separation used above is 4.996 configuration-units, but the two basin floors located in Section 5.8 sit at `x = 1.9970` and `x = 6.9960`, whose difference is 4.999. Recomputing the barrier at the consistent separation gives `E_b = 2.3973` rather than 2.3987, a difference of 0.06 per cent, which changes no conclusion and no verdict in any table in this paper. The figure 2.3987 is retained throughout for consistency with the worked case, and the inconsistency is recorded here so that a reader recomputing the integral is not left wondering.

22.4.7 4.7 The order of operations, and the prescription that reverses it

The common instruction is to get out of the comfort zone. Here is what the arithmetic says the instruction does. The comfort zone is the local minimum of the cost field. Leaving it in the sense the instruction means — deliberately adopting a higher-cost configuration in order to be motivated by the discomfort — raises `C`. Raising `C` lowers `L^Q = max(0, eta*M - C)`. Lowering `L` lowers `Lambda_inf = L/lambda`. Lowering `Lambda_inf` lowers the largest barrier that can ever be crossed.

The instruction reverses the order of operations. The comfort is not the obstacle to the journey; it is the platform the journey is planned on and departed from.

Computed at `eta = 0.10`, `M = 1.42`, `lambda = 0.025`, against a barrier of `E_b = 2.40`, with a deliberate discomfort programme of increasing severity:

Programme	`C` (Q-units/wk)	`L^Q`	`Lambda_inf`	Weeks to fund the departure
baseline (comfort preserved)	0.034	0.10800	4.320	**32.0**
mild discomfort (+50%)	0.051	0.09100	3.640	42.5
serious discomfort (+120%)	0.075	0.06700	2.680	89.2
the critical cost	**0.082**	0.06000	**2.400**	**never**
ambitious discomfort (+165%)	0.090	0.05200	2.080	**never**

```
C_crit = eta * M - lambda * E_b = 0.10 * 1.42 - 0.025 * 2.40 = 0.142 - 0.060 = 0.082
```

Above a weekly operating cost of 0.082 Q-units this subject cannot make this departure, at any level of desire, given unlimited time. The programme intended to produce the departure has, past that line, made it impossible — and by a mechanism the subject cannot perceive, because the capacity to perceive it is also funded by `L`.

The result has a queueing analogue worth naming, because it is the same shape in a better-measured domain: as utilisation approaches capacity, waiting time does not degrade gracefully but diverges [Kingman, 1962, Hopp and Spearman, 2011]. Operating an accumulating system with no headroom is not a stern regime; it is a regime whose response time is unbounded.

4.7.1 The steelman, and what the prescription is groping at

The instruction is not stupid. It is groping at four things that are true, and the framework has a correct version of each.

One: a local minimum need not be a good one. Descent is local and lands wherever the basin boundary put it; there is no guarantee that the basin the subject rests in is the deepest available. This is the myopia of learning in its exact form: local search exploits the neighbourhood it starts in and systematically fails to find distant optima [Levinthal and March, 1993, March, 1991]. **Correct version: survey the landscape rather than raise the subject's own floor.** Knowing that a better basin exists is a measurement problem and it costs measurement, not suffering.

Two: cost must be paid to cross. Real: `E_b > 0` for every departure worth the name. **Correct version: the cost is paid in transit, not in the lounge, and it is paid out of a fund accumulated**

in the lounge. The transit is uncomfortable; the preparation is not, and should not be made so, because the preparation is what pays for the transit.

Three: a stock built with no variety stops growing. An subject whose weeks are identical is running a low-variety regime with a low `M`. **Correct version: raise `M` — which means enrich the environment and calibrate the reading of it — and `L = max(0, eta*M - C)` rises.** That is the direction the instruction wants, achieved through the term that produces surplus rather than the term that consumes it.

Four, and it is the strongest: a cost rise confined to the ORIGIN lowers the barrier as well as the budget. `E_b` is measured as excess cost over the starting configuration, so raising the starting configuration's cost lowers `E_b` at the same time as it lowers `L`. The net effect is not obvious and must be computed; Section 9.7 computes it on the measured field. The result: **raising the origin alone does shorten the wait, from 32.0 weeks to 9.87 weeks at a rise of 0.040, and the price is that `Lambda_inf` falls from 4.320 to 2.720, so the subject departs sooner and departs with 37 per cent less capacity to cross whatever lies beyond the destination** — a barrier which, by Section 5.9, the local gradient cannot see. Raising cost *globally*, which is what the table above computes and what most discomfort programmes actually deliver, leaves `E_b` untouched and is strictly harmful at every setting.

The distinction is between a cost that can be left behind and a cost that is carried. Attention, regulation, carry, sleep, health and relations are not attached to a configuration and do not stay behind when it is left. **A programme that promises a local regrade and delivers a global one is the ordinary case.**

4.7.2 Why the prescription nonetheless produces testimonials

Because it sometimes works, and it is worth being precise about when, since a framework that cannot explain its opponent's successes is not a framework.

The discomfort programme raises `C`. It also, frequently and incidentally, raises the environment term: the person goes somewhere unfamiliar, meets people outside their lineage, does something they have not done. `M` rises. If `eta*(M' - M) > C' - C`, the net effect on `L` is positive and the programme works — **not because of the discomfort but in spite of it, and only because a second, unremarked change was bundled with it.**

```
the programme succeeds  <=>  eta * (M' - M) > C' - C
```

Which yields a diagnostic: **strip the discomfort, keep the novelty, and the result improves.** That is a testable prediction, it is cheap to test, and it separates this account from the prescription's in exactly one experimental step.

Two further mechanisms in the literature bear on the testimonial and both cut against the prescription rather than for it. Adaptation is fast and thorough: subjective states return toward a baseline after large changes in circumstance in both directions [Brickman et al., 1978, Helson, 1948], though the setpoint is not fixed and does move [Diener et al., 2006]. And attention to a prospective change inflates its apparent importance while it is being attended to [Kahneman et al., 2006], which is exactly the condition under which a discomfort programme is evaluated by the person undergoing it.

4.7.3 The consent clause

The framework's ethical constraint governs absolutely here and the failure mode is specific.

No intervention may deliberately raise another person's `C` in order to force a departure. The mechanism does not merely risk harm; it works, when it works at all, by removing the target's capacity to construct alternatives, which is the precise definition of removing their ability to decline. And past `C_crit` it does not even achieve the intended departure: it forecloses it while leaving the subject with the belief that they lack resolve.

The permitted intervention has the opposite sign: **lower the cost of the better configuration and leave the choice intact.** Section 5.11 is the method. Its worst case is bounded — someone looks at the lower valley and stays where they are — and that bounded worst case is what makes it admissible.

22.4.8 4.8 Four ways to fund a departure, and the fifth

Given `Lambda_inf = (eta*M - C)/lambda >= E_b`, exactly four parameters can move, and there is a fifth move that changes the problem instead of the parameters.

```
1. RAISE M      more environment, better calibration
2. RAISE eta    the conversion ladder. Enters twice; strongest parameter lever.
3. CUT C        one-for-one, immediate, and the one the prescription reverses.
4. CUT lambda   write it down, date it, tell one person. Cheapest of all.
5. SPLIT E_b    do not raise the fund; lower the wall.
```

The fifth is the engineering move and it rescues cases the other four cannot.

Take the regime at `lambda = 0.06` rather than 0.025: `L^Q = 0.108`, so `Lambda_inf = 1.800` against a barrier of `E_b = 2.400`. The departure is infeasible. No amount of waiting helps; the fund asymptotes at 1.800 and stops.

Now decompose the transition into three legs with rest basins between them — three sub-transitions, each ending at a configuration where the subject can stop, settle and re-accumulate:

```
leg 1: E_b1 = 0.9      feasible (1.800 > 0.9)      11.20 weeks to fund
leg 2: E_b2 = 0.8      feasible (1.800 > 0.8)       9.50 weeks
leg 3: E_b3 = 0.7      feasible (1.800 > 0.7)       7.96 weeks
-------------------------------------------------------------------
total: 2.4 (unchanged)                             28.66 weeks of accumulation
```

The total cost is identical — 2.4 Q-units either way. What changed is the peak fund requirement, which fell from 2.400 to 0.900, below the ceiling. An infeasible departure became feasible with no parameter changing, purely by inserting two places to stand.

The generalisation is the most transferable result in this half of the paper: **when a barrier exceeds `L/lambda`, do not exhort the walker and do not raise the fund; split the barrier and build the intermediate basins.** In organisational form this is the staged migration, the pilot, the secondment and the reversible trial; in personal form it is the evening course before the career change, the sublet before the move, the two days a week before the four. Every one of them is a manufactured rest basin performing the same arithmetic. The precedent in the built environment is the same move: a sequence of occupiable intermediate places, rather than a single long undifferentiated passage, is what makes a route get used [Alexander et al., 1977, Gehl, 1971].

The condition under which splitting works is precise and must be checked. **There must be a real resting configuration at each intermediate point — a place where `grad C = 0` and the subject can stop indefinitely without drawing down.** A stage that is merely a point partway up the slope is not a rest basin; it is a pause on the ridge, where Section 4.2's table shows the launch budget is at its smallest. **Half a career change is the most expensive place to stand, not the cheapest.**

22.4.9 4.9 The over-framed launch budget

`L` is computed on `M`, the moment as lived, and not on the veridical part `V`. That is deliberate — the plan for elsewhere is made of what was experienced, not of what was there — but the consequence must be stated. Take an subject with environment `E = 1.42`, `eta = 0.10`, `C = 0.034`, `lambda = 0.025` and a calibration ratio `r = 1.60`:

```
M = min(1.60 * 1.42, ln 12) = 2.272 nats        (the cap at ln 12 = 2.4849 is not reached)
V = 1.42 * min(1.60, 1)     = 1.420 nats

L^M on M = 2.272 - 0.340 = 1.932        Lambda_inf = 7.728
L^M on V = 1.420 - 0.340 = 1.080        Lambda_inf = 4.320

inflation factor = 1.932 / 1.080 = 1.7889
```

The over-framed subject has a launch budget 79 per cent larger than their environment supports, and believes they can cross a barrier of 7.73 when the earned figure is 4.32. Their plans are funded partly by manufactured moment; and because `r > 1` also means they see a smaller barrier than there is, the `E_b` estimate is low at the same time as the `Lambda_inf` estimate is high. **Both errors point the same way, so the over-framed subject systematically launches into transitions they cannot complete, and is systematically surprised.**

The correction is a calibration audit, and the early-warning instrument is the return difference `Delta_R = |ln(M'/M)|` developed in a companion paper of this series: a plan whose probes produce no return difference is a plan the world has not yet answered, and committing a fund to it is committing on an unverified environment. **The moment equation and the calibration ratio `r` have no external support in this corpus's bibliography and are carried as framework constructions**, which Section 12 repeats.

22.4.10 4.10 The perpetual dreamer

The opposite pathology, and it is common in exactly the populations that read procedures. `L` large; `lambda` small, because the subject is disciplined, keeps notes and tells people; `Lambda` accumulates to `Lambda_inf` and stays there. And nothing is ever spent, because no barrier is ever selected.

```
Lambda_inf = 4.320 Q-units, held indefinitely, against no committed E_b.
```

A launch budget that is never spent is indistinguishable from a launch budget that never existed, except in its cost. The cost is real: maintaining an unexecuted plan is stored order held against no returning input, which is a maintenance draw in the storage ledger, and the carry runs at full rate for every open loop. The failure is not insufficient budget. It is a missing decision, and the model locates it exactly.

22.4.11 4.11 The spend rule

```
PROTOCOL L-1 - WHEN TO SPEND THE FUND

S1. Select ONE target configuration. Write it down with its date.
S2. Estimate E_b by Section 4.6 -- the path integral of excess cost at the intended
    transit speed -- and NOT by asking how hard the change feels.
S3. Compute Lambda_inf = (eta M - C)/lambda from measured parameters.
S4. If Lambda_inf <= E_b: do not begin. Either move a parameter (Section 4.8, moves 1-4)
    or split the barrier (move 5). Beginning a transit the fund cannot complete strands
    the subject on the ridge, which Section 4.2 identifies as the configuration of
    minimum launch budget -- the worst place in the field to run out.
S5. If Lambda_inf > E_b: wait t* = ln(1 - E_b/Lambda_inf)/ln(1 - lambda) periods, then
    depart. Departing before t* is departing underfunded.
S6. Probe first: a minimal reversible test of the destination basin, with its cost
    logged beside its finding. A destination estimated at r > 1 is a destination partly
    manufactured (Section 4.9), and the probe is what checks it.
S7. Recompute after each leg of a split barrier. The parameters change in transit; C in
    particular rises, which lowers L, which lowers the fund available for the next leg.
```

Step S4 is the one that gets skipped and it is the one that produces the stranding. The model is clear about the consequence: the ridge is where L is smallest, so an subject who runs out of fund mid-crossing has the least capacity to plan their way out of exactly the place they most need to.

22.5 5 The gradient and the desire line

22.5.1 5.1 The desire line as an instrument

Landscape architects have a name for the path worn across a lawn where the paving does not go. It is a *desire line*, and the term is exactly right here because it is a measurement of preference that nobody administered. Three properties make it a better instrument than self-report, and each has a formal counterpart below.

It has a large sample. The path is worn by hundreds of crossings, while a self-report is a single observation taken by a reactive instrument. Section 5.4 makes the sample-size consequence quantitative and it is severe.

It is not falsifiable by intention. People walk the cheap way whether or not they endorse walking the cheap way. **The desire line records what the cost field is, not what the subject believes about it,** and the two diverge in exactly the cases that matter. The general finding that verbal report does not have access to the process generating the behaviour [Nisbett and Wilson, 1977], and that the report is shaped by how it is elicited [Schwarz, 1999], is the empirical warrant for preferring the tally.

It is a gradient measurement, not a level measurement. The path shows which way is cheaper; it does not show how expensive anything is. That is precisely the identification result of Section 3.6: direction is identified, magnitude is not.

Two lineage notes. The method of sitting down, watching, counting what people do, and letting the counts overrule the plan is Whyte's method for public spaces [Whyte, 1980], with the same logic applied to street and building use by Jacobs [1961] and Gehl [1971]; Protocol G-1 below is that method turned on a single subject's own recurring decisions, and the corpus applies it to rooms in Curzi [2026f]. And the observation that infrastructure becomes visible only on breakdown [Star and Ruhleder, 1996, Star and Griesemer, 1989] explains why a person's own desire lines are invisible to them: **the path already worn is precisely the path no longer noticed being chosen.**

22.5.2 5.2 The configuration space

X must be constructed before anything can be measured, and constructing it badly is the commonest way the survey fails. A usable personal configuration space is a small set of **coordinates**, each a recurring decision point with an enumerable set of options, observed at a stated frequency.

Coordinate	Options	Observation rule
where the first working hour is spent	desk / kitchen / cafe / office	recorded at the start of the hour
what is opened first	mail / task file / chat / a walk	recorded at first action
which chair	A / B / C / D	recorded on sitting
how the day ends	shutdown ritual / drift / hard stop / no boundary	recorded at last work action

Three rules govern a legitimate coordinate.

Rule 1: the options must be exhaustive and mutually exclusive. Every occasion must be classifiable into exactly one, including an explicit "none of these" where needed. A coordinate with an escape hatch that absorbs the interesting cases is not a coordinate.

Rule 2: the coordinate must be genuinely available. If a location is unreachable on three days a week, it is not an option on those days and including it corrupts the count. **Availability must be recorded per occasion and the tally must run over available occasions only.** This is the single commonest source of spurious cost in a desire-line survey: an option rarely chosen because it was rarely offered.

Rule 3: the coordinate must be observed, not remembered. Recorded at the moment, in a fixed format, by a rule stated in advance. Reconstruction at the end of the week measures memory, which is itself stored order decaying at `delta`, and not choice.

Note the demotion this forces. These coordinates are **categorical**: there is no metric on the set {desk, kitchen, cafe, office}, so `grad C` does not exist over them and the honest object is a difference table, not a gradient. **The analysis demotes accordingly: Section 5.3 builds difference tables on categorical coordinates and reserves genuine gradients for the ordered coordinate of Section 5.8.** The general reason to distrust an assumed metric on psychological objects is independent and strong: psychological similarity is asymmetric and violates the triangle inequality [Tversky, 1977].

22.5.3 5.3 Measuring the field without measuring the cost

Cost cannot be measured directly. Choices can be counted. The logit recovery of Section 3.5 turns the second into the first, up to a scale.

```
PROTOCOL G-1 - THE THIRTY-DAY TRACE

1. Declare 3 to 5 coordinates by the rules of Section 5.2. Write them down. Freeze them.
2. For each coordinate, declare the reference option -- normally the most frequent one,
   chosen AFTER a 3-day pilot and then frozen, because a reference chosen from the final
   data is a reference chosen to flatter the story.
3. Record the chosen option and the available option set at each occasion, for 30 days.
4. Tally n_x per option, over available occasions only.
5. Compute, in theta units:      d_x = C_x - C_ref = -ln( n_x / n_ref )
6. Compute:                      se(d_x) = sqrt( 1/n_x + 1/n_ref )
7. Report d_x +/- 1.96*se as a 95 per cent interval. Any interval containing zero is a
   coordinate direction that has NOT been measured, whatever the subject's intuition
   says.
8. Run the IIA check: recompute the top two options' ratio with the rarest option
   dropped. If it moves materially, the logit form is wrong for this coordinate.
```
