16

17 **SUMMARY**

18 **Baleen whales (Mysticeti) are the largest animals on Earth, thanks to their ability to filter feed vast**
19 **amounts of small prey from seawater. Whales appeared during the latest Eocene, but evidence of**
20 **their early evolution remains both sparse and controversial [1, 2], with several models competing**
21 **to explain the origin of baleen-based bulk feeding [3-6]. Here, we describe a virtually complete**
22 **skull of *Llanocetus denticrenatus*, the second-oldest (ca 34 Ma) mysticete known. The new**
23 **material represents the same individual as the type and only specimen, a fragmentary mandible.**
24 **Phylogenetic analysis groups *Llanocetus* with the oldest mysticete, *Mystacodon selenensis* [2],**
25 **into the basal family Llanocetidae. *Llanocetus* is gigantic (body length ca 8 m) compared to other**
26 **early mysticetes [7-9]. The broad rostrum has sharp, widely-spaced teeth with marked dental**
27 **abrasion and attrition suggesting biting and shearing. As in extant whales, the palate bears many**
28 **sulci, commonly interpreted as osteological correlates of baleen [3]. Unexpectedly, these sulci**

29 converge on the upper alveoli, suggesting a blood supply to well-developed gums, rather than to
30 baleen. We interpret *Llanocetus* as a raptorial or suction feeder, revealing that whales evolved
31 gigantism well before the emergence of filter feeding. Rather than driving the origin of mysticetes,
32 baleen and filtering likely only arose following an initial phase of suction-assisted raptorial
33 feeding [4, 5]. This scenario strikingly differs from that proposed for odontocetes, whose defining
34 adaptation – echolocation – was present even in their earliest representatives [10].

35

36 RESULTS

37 Systematics

38 Cetacea; Mysticeti; Llanocetidae; *Llanocetus denticrenatus*

39 Holotype

40 National Museum of Natural History, Smithsonian Institution (Washington DC, USA; USNM), specimen
41 no. 183022; virtually complete skull (Figs 1–3, S1–7), partial hyoid apparatus, and assorted postcranial
42 material (Fig. S8).

43 Locality and horizon

44 Seymour Island, Antarctica; near the top of unit Teln 7 of the La Meseta Formation. Mollusc-based
45 $^{87}\text{Sr}/^{86}\text{Sr}$ dating suggest an age of 34.2 ± 0.87 Ma, or latest Eocene [11].

46 Emended diagnosis

47 Differs from all known cetaceans in having markedly palmate, widely-spaced teeth, and a robust a
48 mandibular crest [new term] immediately lateral to the lower tooth row. Differs from archaeocetes in
49 having a supraoccipital that projects anteriorly well beyond the anterior border of the squamosal fossa.
50 Shares with mysticetes, but not archaeocetes or odontocetes, the presence of a dorsoventrally flattened
51 maxilla, and a transversely thickened basioccipital crest. Further differs from odontocetes in lacking a
52 transversely expanded ascending process of the maxilla and a premaxillary foramen. Differs from all
53 known mysticetes in having palatal sulci that converge on the alveoli. Further differs from all mysticetes
54 except *Mystacodon* in having a sagittal trough on the parietals; from all mysticetes except
55 mammalodontids, *Mystacodon* and *Morawanocetus* in having teeth with strong enamel ornament both

56 lingually and labially; from all mysticetes except *Mystacodon* and eomysticetids in having extremely
57 elongate nasals; from all chaeomysticetes in retaining a functional dentition and unfused basi- and
58 thyrohyals; and from *Mystacodon*, mammalodontids and aetiocetids in its larger size, and in having a
59 lateral lamina of the pterygoid that underlaps the anterior process of the periotic.

60 **Overview and phylogenetic placement**

61 *Llanocetus denticrenatus* is the second-oldest described mysticete, exceeded in age only by *Mystacodon*
62 *selenensis* from the Late Eocene of Peru (ca 36 Ma) [2]. Our new material, discovered by REF in 1987, is
63 fragmentary but relatively complete, preserving fine details of the palate, dentition, and auditory region
64 (Figs 1–3). It represents the same individual as the type and only specimen, a fragmentary mandible and
65 cranial endocast originally described by Mitchell [1]. This identification is confirmed by two mandibular
66 fragments that perfectly connect with the original holotype (Fig. 3). A full description of the combined
67 specimen is included in the Supplementary Information.

68 The skeleton of *Llanocetus* is dominated by archaic traits, such as relatively minor cranial
69 telescoping, teeth, an elongate temporal fossa, a weakly-developed antorbital notch, a well-developed
70 superior process of the periotic, a non-rotated tympanic bulla that remains unfused to the periotic, a plate-
71 like coronoid process of the mandible, unfused basi- and thyrohyals, a massive sternum, and cervical
72 vertebrae with a round body (in anterior view) (Figs 1–3; S1-S8). As in basilosaurids, the dental formula
73 appears to have been 3.1.4.2/3.1.4.3. Nevertheless, the broad rostrum of *Llanocetus* strikingly differs
74 from the relatively narrow snout of archaeocetes (Fig. 1). Specifically, the elongate nasals suggest a
75 lengthening of the basal portion of the rostrum, resulting in a wider palate and an anterior repositioning of
76 the external nares that, temporarily, counteracted the long-term cetacean trend of facial telescoping [12].
77 A similar anterior shift of the nasal is apparent in *Mystacodon* and eomysticetids [2].

78 Our phylogenetic analysis groups *Llanocetus* with *Mystacodon* and a smaller, undescribed
79 specimen (OU GS10897) from the Early Oligocene of New Zealand (Fig. 4). Diagnostic features of this
80 clade, here equated with Llanocetidae, include the markedly elongate nasals, and a sagittal trough on the
81 parietals (Fig. 1). Unlike all other basal mysticetes, llanocetids furthermore retain large teeth with two
82 entirely separate roots, as well as strong labial and lingual enamel ornaments (uncertain in *Mystacodon*).
83 Our results suggest Llanocetidae to be the basalmost mysticete lineage, with the exception of

84 *Coronodon*. Previous studies support the basal placement of *Coronodon* [6, 8, 13], but – with one
85 exception [8] – interpreted *Llanocetus* as more crownward, and even as sister to Chaeomysticeti [6, 14,
86 15]. Crownward of Llanocetidae, our analysis recovered a ladder-like succession comprising
87 Mammalodontidae, *Morawanocetus*, Aetiocetidae, and Chaeomysticeti. Unlike in analyses based on
88 earlier versions of this data matrix [14, 16], mammalodontids and aetiocetids do not form a clade. This
89 arrangement further contradicts another recent study [6], but is upheld by a variety of slightly older papers
90 [3, 8, 17].

91

92 **DISCUSSION**

93 **Feeding apparatus**

94 The cheek teeth of *Llanocetus* are robust, notably emergent from the jaws, and, except for the first
95 premolar, highly denticulate. The upper and lower teeth would have faced each other to occlude properly;
96 the now-oblique upper teeth and adjacent rostral margin have been flattened by burial. Apical abrasion of
97 the main and accessory denticles is evident throughout the tooth row, and particularly so in m1 and m2
98 (Fig. 2). In addition, p4–m2 bear pronounced attritional shear facets (Fig. 2), indicating occluding teeth
99 capable of grasping and/or slicing prey. Prey processing, however, would have been impeded by the wide
100 diastemata, of uncertain function, which prevent a continuous cutting surface. Likewise, the broad,
101 flattened maxilla would likely be less resistant to large bite forces than the more tubular rostrum of
102 archaeocetes.

103 Among cetaceans, a broad rostrum is typical of filter feeders [3]. Thus, the unusually long and
104 palmate tooth crowns of *Llanocetus* could formed a lattice-like filtering sieve [6], as seen in extant leopard
105 and crabeater seals [18]. Purely tooth-based filtering is unlikely, however, because the adjacent large
106 diastemata would bypass such a filter. Furthermore, the pronounced dental wear implies biting of prey
107 and tooth-on-tooth shearing, and the teeth are (quantitatively) sharp, with no obvious adaptations for
108 water flow as seen in filter feeding seals [5].

109 Alternatively, filter feeding might be indicated by the presence of palatal sulci, which are widely
110 considered as an osteological correlate of baleen [3]. Contrary to expectations [6], however, the sulci in
111 *Llanocetus* converge directly on the upper alveoli, where baleen would be of little use, and there is no

112 vascularisation in the intervening diastemata (Fig. 2). Rather than baleen, we propose that the palatal
113 sulci of *Llanocetus* supplied well-developed gums that supported the emergent teeth. This interpretation
114 is consistent with the sulci being homologous with those of extant mysticetes, given that baleen develops
115 from the gingiva [19].

116 The absence of baleen is further indicated by shear facets on the posterior cheek teeth, which
117 suggest that the upper and lower jaws came into close contact during occlusion and approached each
118 other vertically, rather than mediolaterally as in extant mysticetes [4]. In addition, vertical jaw movements
119 are indicated by the high, straight coronoid process, which contrasts with the laterally bent structure
120 facilitating longitudinal (α) rotation of the mandible in chaeomysticetes [20]. In extant baleen whales
121 foetuses, teeth and baleen develop in approximately the same area of the maxilla, near the gingival edge
122 of the rostrum [21]. Any baleen in *Llanocetus* would therefore have been at risk of being crushed by the
123 interdigitating anterior teeth, or sheared between the posterior premolars and molars every time the jaws
124 closed.

125 **Origin of filter feeding**

126 Several models compete to explain the origin of mysticete bulk feeding, ranging from tooth-based filtering
127 as seen in extant crabeater and leopard seals [1, 6], to a transitional morphology combining teeth and
128 baleen [3], to an intermediary phase of suction feeding that gave rise to filtering only later [4, 5]. Previous
129 studies relied on palatal sulci to hypothesise the concurrent presence of teeth and baleen in another
130 archaic mysticete family (Aetiocetidae), and, consequently, argued for a direct evolutionary transition from
131 raptorial to baleen-based filter feeding [3, 22]. The peculiar rostral and dental morphology of *Llanocetus*
132 questions this idea, and instead suggests that mysticetes may have passed through an intermediate
133 stage involving neither filtering (sharp teeth, no evidence for baleen) nor purely raptorial feeding (widely
134 spaced teeth, flattened maxilla). Following earlier suggestions [4, 23-25], we propose that this
135 intermediate phase may have involved suction-assisted raptorial feeding or, possibly, pure suction
136 feeding, as seen in *Mammalodon* [8], an unnamed aetiocetid [4] and, possibly, *Mystacodon* [2].

137 Suction is widespread among extant marine mammals [23, 26], many of which may use this
138 ability to transport prey intraorally [27]. In *Llanocetus*, suction would have been facilitated by both the
139 broad rostrum and the presence of a strong sternohyoideus muscle, as inferred from the large sternum

140 (Fig. S8). In addition, suction plausibly accounts for the apparent decrease in effectiveness of the
141 dentition, relative to archaeocetes, as well as the presence of a mandibular crest immediately lateral to
142 the lower tooth row (Fig. 3). In lateral view, this crest partially obscures the teeth, and in life may have
143 supported a slightly raised lower lip that aided in reducing the lateral gape during suction. A similar bony
144 support is absent among extant right whales and rorquals, but occurs in the pygmy right whale, *Caperea*
145 *marginata*, beaked whales (precoronoid crest) and, arguably, the grey whale, *Eschrichtius robustus*.

146 **Gigantism precedes filtering**

147 Llanocetids markedly differ from each other in their overall size, feeding apparatus, and dental wear.
148 *Llanocetus*, in particular, is unusually large: at an estimated body length of nearly 8 m, its size is
149 comparable to that of extant minke whales, and exceeds that of any other toothed mysticetes [28],
150 eomysticetids [28], and – until the Late Miocene – even most crown mysticetes [9]. Notably, *Llanocetus* is
151 also larger than a *Morawanocetus*-like aetiocetid from Japan, which was previously reported as reaching
152 8 m [7]; this estimate seems to have been erroneous, with the real length being approximately 6 m.

153 Unlike *Llanocetus*, *Mystacodon* only reaches about 4 m, and is characterized by relatively closely
154 spaced teeth that have been obliterated by wear. At ca. 3 m, OU GS10897 is even smaller than
155 *Mystacodon*, yet has large teeth marked by shear facets. Such pronounced intrafamilial disparity is
156 consistent with comparable variation in mammalodontids (macroraptorial vs suction feeding) [8] and
157 aetiocetids (variable degree of homodonty, suction vs raptorial feeding, wide range of body sizes) [4, 7,
158 24], and supports earlier suggestions of a short-lived phase of morphological and behavioral
159 ‘experimentation’ early in mysticete evolution [14].

160 Overall, *Llanocetus* demonstrates that mysticetes have, at least sporadically, tended towards
161 gigantism since their very origin [28]. Crucially, neither llanocetids [2, 5] nor mammalodontids [8, 29]
162 seem to show any signs of filtering, and evidence for bulk feeding in *Coronodon* [6] and aetiocetids [3]
163 has been questioned on grounds of tooth function, dental wear, and stable isotope data [4, 5, 24, 30].
164 Together, these insights suggest that both the emergence of mysticetes in general, and the origin of large
165 body size in particular, preceded the origin of the key adaptation of modern whales: baleen and bulk
166 feeding (Fig. 4). This scenario markedly differs from that of odontocetes, whose major hallmark –
167 echolocation – appears to be as old as themselves [10, 31, 32].

291 CONTACT FOR REAGENT AND RESOURCE SHARING

292 Further information and requests for resources and reagents should be directed to and will be fulfilled by
 293 the Lead Contact, R. Ewan Fordyce (ewan.fordyce@otago.ac.nz).

294

295 METHOD DETAILS

296 Phylogenetic Analyses

297 The phylogenetic analysis was based on a modified and somewhat enlarged version (106 taxa, 275
 298 characters) of the total evidence matrix of Marx and Fordyce [14], fully illustrated with 6,340 individual
 299 specimen photographs. The analysis was carried out without any clock assumptions in MrBayes 3.2.6
 300 [34], on the Cyberinfrastructure for Phylogenetic Research (CIPRES) Science Gateway [35] (20 million
 301 generations, first 25% of generations discarded as burn-in). All partitions and settings replicated those of
 302 Marx and Fordyce [14].

303

304 **QUANTIFICATION AND STATISTICAL ANALYSIS**

305 **Estimates of Body Size**

306 Body length estimates were calculated based on the following equations, where TL is total body length
307 and BIZYG is bizygomatic width:

308 (1) $\log(TL) = 0.92 * (\log(BIZYG) - 1.72) + 2.68$ [36]

309 (2) $TL = 8.209 * BIZYG + 66.69$ [37]
