## 2 1 INTRODUCTION

3 This readme file describes the analysis steps taken within the Excel files attached to the article  
4 “Quantifying the risk mitigation efficiency of changing silvicultural systems under storm risk  
5 throughout history”. The Excel models attached contain the quantitative basis which was used  
6 to determine the land expectation values (LEVs) resulting from timber production ( $\widehat{LEV}_{timber}$ )  
7 and carbon sequestration ( $\widehat{LEV}_{carbon}$ ) under storm risk.

8 As described in Fig. 1, various analysis steps were necessary to quantify  $\widehat{LEV}_{timber}$  and  
9  $\widehat{LEV}_{carbon}$  for three silvicultural systems under different historical assumptions. Within the  
10 article, we already describe in detail how we proceeded on the storm risk simulation. Therefore,  
11 in this readme file we set the focus on the analyses conducted to derive LEVs from timber  
12 production as well as carbon sequestration for silvicultural systems 1-3 under different  
13 historical assumptions.

## 16 2 ANALYSIS STEPS

### 17 2.1 BWinPro simulation

18 This article was based on three different stand growth simulations conducted with BWinPro  
19 (Nagel et al. 2017). Outcome of these simulations were:

- 20 - Stand growth specific data including standing volumes per simulation period and  
21 volumes harvested.
- 22 - Single tree specific data containing information about the time and properties of the  
23 trees harvested throughout one rotation period
- 24 - A carbon balance sheet giving insights into the carbon stock change per simulation  
25 period

### 26 2.2 Revenues and costs simulation

27 Based on the single tree specific data, as a second analysis step, we calculated the volumes  
28 of timber assortments sellable using BDAT algorithms (Kublin and Bösch 2007). Output of this  
29 analysis was finally matched with the different assortment specific timber prices representing  
30 the different timer periods in focus resulting in revenues from timber sales for system 1 and  
31 system 2.

32 To calculate harvesting costs related to system 1 and system 2, we adopted harvesting  
33 productivity functions as introduced in Müller and Hanewinkel (2018). The respective functions  
34 are combined with single tree specific data of the scenarios. Labor and machine costs for the  
35 respective timer periods are adopted from Müller and Hanewinkel (2018) as well.

36 For system 3, further analysis steps were necessary. After a recommended thinning period of  
37 90 years, this stand was converted into an uneven aged stand via group cutting starting at age  
38 95 following the silvicultural recommendations of (ForstBW 2014). The simulation data derived  
39 from this silvicultural system (system 3a) was downscaled on group size level. The size of the  
40 groups resulted from the stand conversion period of the initial BWinPro simulation. The size of  
41 the groups as downscaling factor was applied to the single tree and stand specific data from  
42 the initial BWinPro simulation until age 90 resulting in group specific revenues and costs.  
43 Finally, both cost and revenues were consolidated to derive simulated revenues and  
44 corresponding harvesting costs of an uneven aged stand as described in system 3.

## 45 2.3 LEV calculation

46 By combining harvesting costs and revenues from timber sales, we deduct the cashflows  
47 induced from timber harvesting throughout one rotation period for systems 1-3. To derive  
48 cashflows induced by carbon sequestration we calculated the net carbon stock change  
49 excluding roots for the different systems and for each simulation period of five years. Based  
50 on this net value we calculated the cashflows from carbon sequestration applying the deflated  
51 average CO<sub>2</sub> European Emission Allowances Price 2009 - 2018  $P_c$  of 9.27 EUR/t CO<sub>2</sub> (Insider  
52 Inc. and finanzen.net GmbH 2018).

53 All cashflows calculated are used to finally calculate the LEV of the simulated stands as the  
54 sum of k NPVs and a final LEV for rotation kT being k the number of rotations and T the rotation  
55 time.

## 56 3 EXCEL FILES AVAILABLE IN REPOSITORY

57 The Excel files available in this repository are containing all analysis steps as described in  
58 section 2. The Excel files include the following models:

- 59 • R3\_Cost and revenues from timber\_S1, R4\_Cost and revenues from timber\_S2,  
60 R5\_Cost and revenues from timber\_S3:
  - 61 ○ These models calculate revenues from timber sales for the respective  
62 silvicultural systems based on different historical price levels. Input data is  
63 based on price levels as identified in Müller and Hanewinkel (2018) and timber  
64 assortments from BDAT grading of the different BWinPro simulations. The  
65 models also calculate the harvesting costs related to the different systems  
66 under different productivity and price levels. For system 3, the model also scales  
67 the initially simulated even aged stand (S3a) and its related costs and revenues  
68 down on group level and finally extend it on uneven aged stand level.
- 69 • R6\_Supplement LEV calc\_S1, R7\_ Supplement LEV calc\_S2, R8\_ Supplement LEV  
70 calc\_S3:
  - 71 ○ These models calculate the harvesting costs related to the different systems  
72 under different productivity and price levels and the cashflows induced by  
73 carbon sequestration for the different systems. Furthermore, the models contain  
74 additional input data such as administration costs and discount rates applied.

75                   The models consolidate all cashflows and input data to calculate  $\widehat{LEV}_{timber}$  and  
76                    $\widehat{LEV}_{carbon}$  for the respective systems under different cost and price levels.
