Abstract. The identification, quantification and characterization of coronary atherosclerotic plaque has a major influence on diagnosis and treatment of coronary artery disease (CAD). Recent studies have reported the ability of Computed Tomography Coronary Angiography (CTCA) to identify non-invasively coronary plaque features. In this study, we present a novel methodology for the identification of the plaque burden of the coronary artery and the volumetric quantification of calcified plaques (CP) and non-calcified plaques (NCP), utilizing CTCA images in comparison with virtual histology intravascular ultrasound (VH-IVUS). The proposed methodology includes six steps: CTCA images pre-processing, vessel centerline extraction using Multistencil Fast Marching Method (MSFM), estimation of membership sigmoidal distribution functions, implementation of an extension of active contour models using prior shapes for the lumen, the outer wall and CP segmentation, detection and quantification of NCP and finally three-dimensional (3D) models construction. Bland–Altman analyses were performed to assess the agreement between the presented methodology and VH-IVUS. Assessment of CP and NCP volume and length of lesion length 18 lesions indicated excellent correlation with VH-IVUS, ($r = 0.92$, $p < 0.001$), ($r = 0.95$, $p < 0.001$) and ($r = 0.81$, $p < 0.001$), respectively.

1 Introduction

1.1 A Subsection Sample

Atherosclerotic disease, the underlying cause of coronary artery disease (CAD), is one of the leading causes of mortality and morbidity in western societies. Atherosclerosis is characterized by molecular and cellular events, such as the deposition of low-density lipoprotein (LDL) molecules, smooth cell proliferation, calcification and fibrosis, causing compositional and geometric changes in coronary vessels. Several of these changes can be identified by Computed Tomography Coronary Angiography (CTCA), a non-invasive imaging modality, which accurately detects the inner and the outer wall of coronary arteries and also permits the characterization of atherosclerotic plaque composition [1].

In the literature, different studies were presented to examine the diagnostic accuracy of CTCA for the detection of coronary plaques. Dey et al. [2] examined the accuracy of CTCA to detect CP and NCP using an automated scan-specific threshold level-based approach. Similarly, in another study, proposed by Brodoefel et al. [3], an automated software was implemented to analyze the atherosclerotic plaque composition based on CT attenuation values. On the other hand, Graaf et al. [12] studied the correlation between the plaque volume derived by CTA automatic software (QAngio CT 1.1, Medis medical imaging systems) and the plaque volume provided by VH IVUS, which was defined as the gold standard. Jawaid et al. [13] implemented a SVM classifier to identify the abnormal coronary segments and further proposed a derivative-based method to localize the position and length of the NCP inside the segment.

The proposed study is dedicated to present a semi-automatic methodology, which permits the 3D models construction of the inner wall and outer wall, as well as the detection and volumetric quantification of CP and NCP. The Virtual Histology Intravascular Ultrasound (VH IVUS) is used to validate the proposed study. The innovative aspect of this approach is that both the active contours models segmentation and the dynamic thresholding techniques are totally adapted to each CTCA image, and allow accurately 2D segmentation independently of the acquisition dose protocol.

2 Materials and Methods

The proposed methodology consists of eight steps: the preprocessing, the blooming effect removal, the vessel centerline extraction, the estimation of membership functions, the inner wall and outer wall segmentation, the CP and NCP segmentation and finally the 3D models construction.

2.1 Preprocessing

In this step, the Frangi Vesselness filter [4] is applied on the acquired axial DICOM CTCA images to detect the potential vessels regions.

2.2 Blooming effect removal

2.3 Centerline extraction

The implemented vessel centerline extraction approach, proposed by Metz *et al.* [5], is a minimum cost approach, based on the combination of the vesselness measure (w_{vessel}) and the lumen intensity (w_{lumen}) information. The considered cost function was defined as

$$V = w_{\text{vessel}} * w_{\text{lumen}} \quad (1)$$

, where w_{vessel} is calculated in the pre-processing step, whereas the (w_{lumen}) is a generalized bell-shaped function.

2.4 Estimation of memberships functions

In this step, three membership functions were estimated to compensate three different intensity protocols for the discrimination of the lumen, the outer wall and the CP. More specifically, the selected intensity ranges depend both on the literature and the extracted mean luminal intensity.

2.5 Segmentation of the lumen, the outer wall and CP

In this step, an active contour model [6], which incorporates a prior shape [7] is implemented to segment the inner wall, the outer wall and the CP. The 2D segmentation approach includes four different stages: the update of lumen intensities, the approximation of an initial binary image, the calculation of the curve speed function and finally the sparse field algorithm implementation. More specifically, we modify the estimated lumen membership function. Based on the extracted vessel centerline, we consider only the pixels of the CTCA image, whose distance from the centerline is lower than the value obtained by dividing an estimation of lumen radius by the pixel spacing of the CTCA image. Consequently, an initial image-shape φ is estimated to implement the active contour models. This image φ is a binary image, whose pixels are 1's, when the updated lumen membership function multiplied with a threshold value is larger than 500 HU. Except of the initial binary image φ , a shape function ψ and a labelling function L are introduced [7, 8]. In this approach, the defined speed function to evolve the curve is defined by:

$$E(\varphi, \psi, L) = E_{\text{cv}} + E_{\text{shape}} + E_{\psi} \quad (2)$$

, where E_{cv} is the Chan-Vese energy, E_{shape} is the shape comparison term and E_{ψ} is the labelling term. Finally, the sparse field

Sparse Field Algorithm implementation: The basic idea of Level set models is to accurately represent the curve, by minimizing the φ ($\varphi(x, y) \approx 0$). In this stage, the minimal representation of φ function is maintained by implementing the Sparse field algorithm [9]. Furthermore, the sparse field algorithm is implemented twice, in order to achieve a smooth segmented shape for the inner and the outer wall.

2.6 NCP segmentation

The detection of NCP based on CTCA images remains a challenging problem, since their intensity range values depend on the luminal intensity and the acquisition dose protocol [10]. Furthermore, the segmentation of NCP could not be successfully achieved by implementing a level set based approach, since NCP intensity values are close to the ranges of the outer wall. Thus, in this study a dynamic threshold technique is applied in the region simultaneously outside the inner wall and inside the outer wall, which is considered as the region of interest (ROI). The main idea of the detection of NCP is the extraction of a critical intensity value, the mean lumen intensity (ml). This value corresponds to the mean intensity values of the pixels of the 50% of the image intensities. After the definition of ml value, the intensity value for the NCP segmentation ranges between 100 HU lower than ml and 100 higher than ml .

2.7 3D models construction

The 3D models for the lumen, the outer wall, the CP and the NCP are constructed based on the Marching Cubes approach [11], by applying a triangulation approach.

3 CTCA-IVUS comparison

The presented methodology was compared using the corresponding frames of VH IVUS modality. The accurate registration was achieved based on anatomical landmarks, such as side-branches, ostia and CP. Furthermore, the VH IVUS images were analyzed based on a previously published study, introduced by Bourantas et al. [12], whereas the NCP volume is calculated based on the Simpson-rule method [13].

The accuracy of the presented methodology to detect plaque burden and to quantify the CP and NCP is evaluated using two different metrics for each plaque type, the plaque volume and the length of lesion. The plaque volume corresponds to the volume of plaque between the proximal and distal ends of the coronary lesion, whereas the length of lesion is the distance between the proximal and distal ends of the coronary lesion.

4 Results

In the validation procedure, we used totally 18 coronary arteries (9 LAD, 3 LCX, 6 RCA). The correlation between the proposed CTCA based methodology and VH IVUS

images analysis is illustrated, implementing the Bland-Altman analysis and correlation plot analysis, as it is shown in Fig. 1 and Fig. 2, respectively.

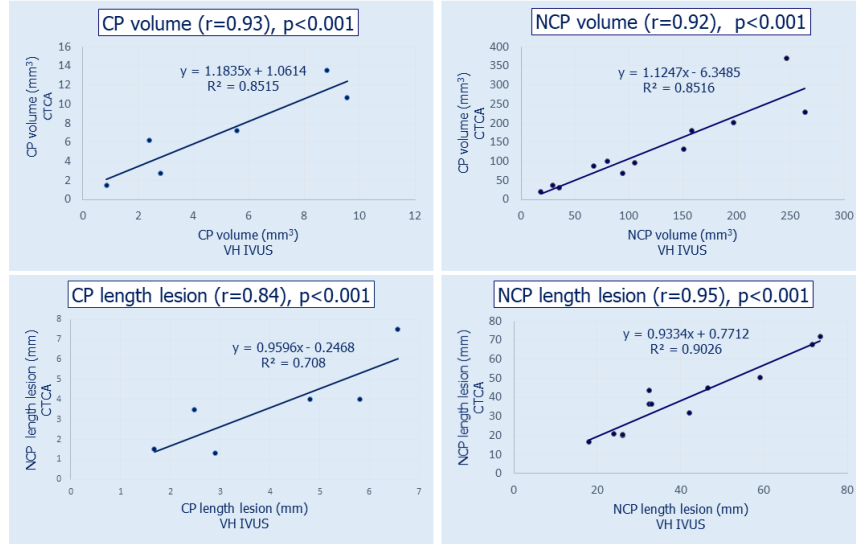

Fig. 1. A figure caption is always placed below the illustration. Short captions are centered, while long ones are justified. The macro button chooses the correct format automatically.

The evaluation procedure indicates that the CP and NCP extracted volumes and lesions of length derived from the proposed methodology correlate well with those derived by VH IVUS images analysis. More specifically, the Pearson's correlation (r) is 0.93 and 0.92 for the CP and NCP volume, respectively, whereas the Pearson's correlation (r) is 0.84, 0.95 for the CP and NCP length of lesion, respectively.

5 Discussion

In this work, a semi-automated methodology for the reconstruction of the lumen, the outer wall and the CP and NCP of coronary arteries is presented. The approach relies primarily on the active contour models, while the NCP detection is achieved by a dynamic threshold based approach. Although, level set based threshold techniques are promising approaches in the field of 2D segmentation, in case of NCP segmentation are not applicable, due to the lower intensity values of NCP, which are close to the outer wall intensities.

Furthermore, the methodology of the inner and outer wall detection, proposed in this study has already been validated using both manual annotations and IVUS modalit published study. Thus, in this manner an accurate plaque burden region is assumed to be accurately identified and as a result the quantification of CP and NCP is successfully achieved. In Table 3, compared the correlation of the proposed methodology with other methodologies proposed in the literature.

Moreover, the basic innovative aspect of the presented methodology is its adaption to each CTCA image. It has been demonstrated that the mean luminal attenuation value varies using different acquisition protocols, as well as between different patients. Contrary to others studies, in our approach the selected threshold values are not fixed, but fully dynamic and adapted to different CTCA images.

Another basic innovative aspect of our approach is the incorporation of blooming effect removal. This deconvolution procedure implementation prevents the vessel stenosis overestimation and reduce the volumetric quantification of CP. Additionally, our algorithm allows the 3D reconstruction of the full arterial coronary tree and as result the CP and NCP can be visualized in critical regions, such as the bifurcations.
