### ABSTRACT

There are various conventional methods used to improve stability of slope and surface erosion. They all have merits and demerits, but the use of vegetation has many advantages such as root does not corrode, they are self-repairing, regenerating and environmental friendly. This discipline has gained a global recognition for a long time and has been addressed as a new entity, “Ecological Engineering” which is defined as the design of sustainable ecosystem that integrates human society with its natural environment for the benefit of both. This paper considers the potential engineering influences of vegetation and how it can be characterized on site within a geotechnical framework for stability assessment. To gain more understanding on its soil-root interaction and effects on slope stabilization, the mechanical and hydrological effect of vegetation would be combined and their overall effect on slope stabilization and slope stability analyses would be evaluated. The results obtained for the Vetiver Grass and Lime Tree will be considered. In overall the results show the considerable improvement in the slope stability by applying vegetation on finite slope depending to their location on slope. The results also indicate that Vetiver Grass can cause significant improvement in the slope stability compare to the Lime Tree even when it is located at the crest of slope due to its roots geometry and lower weight.

**Keywords:** Soil, Vetiver Grass, Lime Tree, slope stability.

### 1. INTRODUCTION

The influence of vegetation can be divided into hydrological and mechanical factors, which can be beneficial or adverse to slope stability [1]. The hydrological and mechanical parameters reflecting the

effect of vegetation in stability analysis are: an additional effective cohesion; an increase in weight of slice due to the vegetation; a tensile reinforcement force by the roots present on the base of each slice; wind force; possible changes in undrained soil strength due to moisture removal by the vegetation; and changes in pore water pressure. These parameters have been further explained and discussed within a geotechnical framework. Root reinforcement is a determining factor when evaluating the influence of vegetation on slope stability. There are five main functions that the plant may perform within the soil bioengineering system in vegetative structure: support, anchor, drain reinforces and armour, depending upon the type of plants used in the soil bioengineering, the nature of slope and soil characteristics. The importance of vegetation in slope stabilization and surface erosion control is enormous.

#### 1.1. Slopes

Slopes may be man-made as in: cuts and fills for highways and rail-roads, earth dams, dykes for containment of water, landscaping operation for industrial and other developments, banks of canals and other water conduits and temporary excavation.

Slopes may also be naturally formed as hillsides or stream banks. At all locations where the ground is not level, there are forces which tend to cause movements of the soil from higher points to lower points. The significant importance of such forces is the component of gravity, which acts in the direction of the probable motion. Also important, but also not well recognized, is the force of seeping water. These several forces produce shear stresses throughout the soil mass and a movement will occur unless the

shearing resistance on every positive failure surface throughout the mass is sufficiently larger than the shearing stress.

## 1.2. Cause and mechanism of slope failure

The causes of major failure of slopes are the insufficient control of surface water and the presence of local weaknesses, discontinuity, sheet jointing. Adoption of deficient geological or hydro-geological modes of slope design is the most important factor of major failures in engineered slopes. Another problem associated with the large slides is adverse groundwater conditions undetected during design and construction stage [2].

Minor slope failures are caused by surface water, the mechanism mainly involves concentrated surface run-off leading to erosion and water ingress during intense rain, inadequate maintenance generally takes the form of blocked or cracked drainage channel, and inadequate attention to proper detailing. Another cause of minor failure in slope is local weakness in the ground mass, most in soil cuts and rock cuts are associated with the presence of local weakness of weak geological material and adverse ground water build up of local transient perched water table.

Common failure mechanism of a fill slopes are flow slides due to inadequate compaction, washout and sliding and those for soil cut slopes are washout and sliding [3].

The second mechanism of failure is liquefaction which is the sudden collapse of metastable soil structure within a loose soil mass in a slope when it is subjected to a high degree of saturation under sustained shear stresses, resulting in a significant reduction of soil shear strength and leading to a flow slide type of failure which is a special case of sliding failure.

The third mechanism is washout which is detachment of part of the soil mass induced by the scouring action of running surface water.

## 1.3. Mechanical effect of vegetation

### 1.3.1. Root reinforcement

Roots embedded in soil form a composite material consisting of fibres of relatively high tensile strength and adhesion within a matrix of lower tensile strength. Researches show that vegetation could contribute the shear strength to the slope via root

reinforcement and identified a series of empirical and physical based relationship between root development and soil strength. Even low root density can provide substantial increase in shear strength and the magnitude additional apparent cohesion varies with the distribution of the roots within the soil and with the tensile strength of the individual roots. [4,5].

Root reinforcement is a function of root strength, interface friction between root and soil and the distribution of root within the soil and root-reinforced soil is more able to resist continued deformation without loss of residual strength than soil alone [5]. The magnitude of the mechanical reinforcing effect of vegetation is a function of the following root Properties: density, tensile strength, tensile modulus, length/diameter ratio, surface roughness, alignment; straightness and angularity and orientation to the direction of principal strains [1].

### 1.3.2. Root area ration

The ability of a tree to reinforce soil will depend, not only in the depth to which its root systems extend but also on the total cross-sectional area of its roots at the given depth [6, 7, 8 and 9].

### 1.3.3. Root tensile strength

Nilaweera and Nutalaya [10] pointed out that the pull-out resistance of a tree is generally controlled by its root strength and morphological characteristics and the pull-out resistance of the tree increased with root length distribution and the depth of root penetration.

### 1.3.4. Anchorage, arching and buttressing

The taproot and the sinker roots of many tree species penetrate into the deeper soil layers and anchor them against down-slope movement.

### 1.3.5. Surcharging

Surcharge is the effect of the additional weight on a slope resulting from the presence of vegetation. Surcharge could have adverse effects, although it can be beneficial depending on the slope geometry, the distribution of vegetation cover and the properties of the soil.

### 1.3.6. Wind loading

Wind loading is usually only significant when the wind speed is stronger than 11m/s. The forces induced in vegetation by wind can sufficient to disturbed upper soil layer thus, initiate landslips [1].

**Figure1.** Additional forces due to vegetation, reinforcement and hydrological changes [19]

**3. Results and discussion**

The analyzed Factor of Safety (FOS) will be discussed by applying the vegetation at three different positions on the slope as shown in Figure 2.

**Figure2.** Slope profile showing the position of the vegetation on the slope

Referring to Table 1, the use of lime tree at the toe of the slope has shown an increase of 8.75% in the Factor of Safety (FOS) and an increase of 3.75% at the middle of slope. However, it has a reverse effect when the lime tree was used at the crest of slope with the difference of 2.75%. On the other hand, the use of Vetiver Grass at the toe, middle and at the crest of slope has indicated increased percentages of FOS especially at the middle of the slope, by showing an increase of 3%.

**Table1.** Comparisons of the different Factor of Safety (FOS) and the percentage difference without the effect of vegetation, with the effect of Mature Lime Tree and with the effect of the Vetiver Grass

Position	FOS Without Effect of the Vegetation	FOS with the Effect of the Mature Lime Tree	Percentage of difference	FOS with the Effect of the Vetiver Grass	Percentage of difference
Toe of slope	1.6	1.74	+8.75	1.64	+2.4
Middle of slope	1.6	1.66	+3.75	1.65	+3.00
Crest of slope	1.6	1.54	-2.5	1.64	+2.4

**4. CONCLUSION**

From the results obtained, it can be concluded that the parameters discussed play important roles in the slope stability. Upon completing this research, the overall conclusion indicates the positive effect of vegetation on the analyzed Factor of Safety (FOS). These results have shown even more that 8.75% increase in the FOS when the lime tree was located at the toe of slope. On the other hand by using the Vetiver Grass, the FOS at the toe of slope has shown only 2.4% increase compare to the situation without any effect of vegetation. This can be due to the effect of the weight of lime tree which is much heavier than the weight of the Vetiver Grass on the slope which can be positive in this situation. It has been observed that the effect of the weight of tree can be reversed when the lime tree located at the crest of the slope and shows the reduction in FOS. On the other hand at the middle of slope both the Vetiver Grass and Lime tree have an equal positive effect on slope stabilization and the FOS has increased approximately 3% in compare to the situation of without any vegetation.
