Introduction Motor memory consolidation describes the memory transformation from a fragile to a robust and stable state (Robertson et al., 2004). This transformation requires the adaptation of internal models. Although motor memory consolidation is frequently investigated on the behavioral level, the underlying neural processes are mostly unknown (Wolpert et al., 2011). The aim of this study was to examine power differences in the gamma bands of the human EEG due to motor memory consolidation. Methods Two groups, each containing 12 right-handed subjects, performed 2d point-to-point reaching movements handling a robotic device. Following a familiarization, both groups performed 256 trials in a force field adaptation task on day 1 and day 3. On the second day, the treatment group made 256 interfering force field movements, whereas the control group had a rest day. We recorded both handtrajectories and EEG activity of the subjects. Motor performance was quantified by the maximum perpendicular distance between the hand path and the straight line from start to target. Artifact corrected electrophysiological data were decomposed into a lower (30-45 Hz) and higher (60-85 Hz) gamma band using a multitaper approach (Mitra & Pesaran, 1999). We analyzed percentage power changes prior to movement onset and during movement execution. The kinematic and electrophysiological data were statistically analyzed using repeated measurements ANOVAs and false discovery rate to minimize the type I error. Results The kinematic data showed a significant interaction ( $p < .001$ ) between time (day 1, day 3) and group (treatment, control). Groups revealed similar performances on day 1 but the control group exhibited an increased performance on day 3 compared to day 1 while the treatment group did not. We also observed a significant interaction ( $p = .010$ ) between time and group affecting the higher gamma band prior to movement onset. The control group exhibited an increased power on day 3 compared to day 1 and the treatment group. No significant changes were found during movement execution or the lower gamma band. Discussion This is the first study which shows an association between the higher gamma band power and motor memory consolidation. This indicates different movement predictions on day 3 between groups. It might be possible that the higher gamma band serves as a neural correlate of the adapted and consolidated internal models. ### EFFECTS OF DIFFERENTIAL LEARNING, HIGH, AND INCREASING CONTEXTUAL INTERFERENCE ON ACQUISITION AND LEARNING OF A BASKETBALL TASK

Beckmann, H., Böhme, M., Schöllhorn, W.I.

*Johannes Gutenberg-University Mainz*

Introduction According to Porter and Magill (2010) motor learning is enhanced by increasing the amount of contextual interference (CI) because that way the practice schedule is gradually fitted to the changing characteristics of the learner during skill acquisition. The differential learning approach (DL; Schöllhorn, 2000) again emphasizes stochastic movement variations (changes in geometry, velocity, acceleration, and rhythm at each joint) to enhance motor learning and to cope with the constantly changing learner in order to improve situation adapted behavior (Schöllhorn et al., 2009). The following study investigates if high (random) CI, increasing CI or DL lead to different learning phenomena. Methods Thirty basketball novices were randomly assigned to three groups: Random CI, Increasing CI or DL. Participants practiced three different basketball passes (chest, overhead, single arm) over a 5-m-distance with 30 trials of each pass (90 trials in 9 blocks) on one day. Group Random CI practiced all trials randomly; group Increasing CI practiced trials 1-30 in a blocked, trials 31-60 in a serial and trials 61-90 in a random order; group DL performed 30 variations of each pass with no repetition. For each practice block the mean absolute error of pass accuracy was measured. To prove if learning occurs participants returned after one day for a retention test (9 trials, blocked order, 5-m-distance) and a transfer test (9 trials, blocked order, 6-m-distance, new but constant target). One week after the acquisition they returned to repeat the retention test and perform a second transfer test (9 trials, random order, 6-m-distance, random targets). Results No time or group effects occurred during practice (blocks 1-9). However, the analysis of the retention and the transfer tests revealed significant benefits for DL over Random CI (retention:  $p = .000$  resp.  $p = .001$ ; transfer:  $p = .001$  resp.  $p = .012$ ). Recognizable differences in the retention and transfer tests between DL and Increasing CI as well as the differences between both CI conditions were not significant. Discussion The effects of Increasing CI in this study are in line with the findings of Porter and Magill (ibid.) but cannot outperform DL. However, it seems that stochastic variations in DL are more beneficial for motor learning than switching between different as constant assumed movements (Random CI). It seems also noteworthy that in the CI conditions no CI-effect occurs but DL improves from acquisition to retention. References Porter JM, Magill RA (2010). *J Sports Sci*, 28(12), 1277-1285. ### MENTAL FATIGUE ALTERS THE DURATION OF GOAL-DIRECTED MOVEMENTS

Rozand, V., Lebon, F., Papaxanthis, C., Lepers, R.

*INSERM U1093 "Cognition, Action and Sensorimotor Plasticity"*

**Introduction** For quick and precise goal-directed movements, Fitts law, also known as the speed-accuracy trade-off, predicts that movement duration depends on target size (Fitts and Peterson, 1964). Movement duration increases inversely with the target size. Fitts law is conserved for imagined movements (Decety and Michel, 1989). With muscle fatigue, movement duration is increased, independently of the target size (Missenard et al., 2009). However, the effects of mental fatigue, induced by a prolonged cognitive task, remain unknown. The aim of the present study was to determine whether mental fatigue would increase the duration of actual and imagined goal-directed movements involving speed-accuracy trade-off. **Methods** Ten participants performed actual and imagined point-to-point arm movements as accurately and as fast as possible before and after a 90-min sustained cognitive task (Stroop task) inducing mental fatigue, and before and after viewing a neutral control task (documentary movie). Target width and center-to-center target distance varied, resulting in five different index of difficulty. Results Prior to mental fatigue, actual and imagined movement duration increased with the difficulty of the task, as predicted by Fitts' law. Mental fatigue task induced a  $4.1 \pm 0.7\%$  increase in actual movement duration and a  $9.6 \pm 1.1\%$  increase in imagined movement duration, independently of the index of difficulty. The trial-by-trial evolution of actual and imagined movement duration remained stable with mental fatigue. The control task did not induce any change in actual and imagined movement duration. **Discussion** The goal-directed movements were slowed when subjects were mentally fatigued. The increase in movement duration was independent of the target size, as it was previously observed in presence of muscle fatigue. In absence of feedback, imagined movement duration also increased. This suggested that in a mental fatigue state, proactive changes may occur during the preparatory state of the movement to preserve task success. **References** Decety J, Michel F (1989). *Brain Cogn*, 11, 87-97 Fitts PM, Peterson JR (1964). *J Exp Psychol*, 67, 103-112 Missenard O, Mottet D, Perrey S (2009). *Neuroscience*, 161, 773-786

### OP-SH12 Sports History

#### FROM PUBLIC HEALTH TO "HEALTHISM"? NEW FEMININITIES AND MASCULINITIES IN HEALTH AND FITNESS FROM 1970

Tolvhed, H.

*Stockholm university*

During the last decades of the 1900's, a commercial health industry transformed the previous Swedish public health regimen characterized by strong state control. Running and exercising at gyms are now widely practiced, and new products, diets and trends appear continuously. This project explores the changing discourses on health, primarily through a text and image analysis of health and fitness magazines from 1970 to the present. It fills a gap between on the one hand historical research on health in Sweden that has tended to focus on state documents and overlooked the decentralization and commercialization of health, and on the other international contemporary research on "healthism" and health/body as part of individual lifestyle projects that does not offer systematic historical analysis and contextualization. Drawing on Foucault's concept of everyday "micro power", the new masculinities and femininities – regarded as intersecting with class and ethnicity – produced here are examined. The "fit" woman is a historically new ideal, but feminists of the 'second' and 'third' waves take different views on how to judge her: is she a norm-breaking emancipatory figure, or is this just a post-feminist emancipation for the privileged classes? The male body has also become subject to more diversified norms and ideals that links together class, masculinity and exercising regimes. What liberations and what new forms of regulation can be identified in the urgings, problems and solutions formulated around health? How has the discourse on health, in Sweden historically associated with nationalism, public health and eugenics, changed with an increasingly multicultural and globalized society, marked by intensified consumption, (neo-)liberalization and the conditions of a "flexible" labour market?

#### 'WE CAN WRITE NEW HISTORY HERE'. PERFORMING HISTORY IN THE FOOTBALL ENVIRONMENT

Herd, K.

*Lund University*

This abstract is based on my PhD project which investigates how history is constructed, used and performed in a context of Swedish club football. Football represents a specific structure that is embedded in a social space and reflects other cultural phenomena. Historical references are activated to define a club's character, validate its structure and also foretell its future. The process of constructing a club from the shreds of collective memory is very dynamic and creative, resulting in a plethora of interpretations and meanings, affecting the participants but also the concept of history. Clubs make up their identity by being in a constant dialogue with their own history and with other clubs. There are narratives from four Swedish clubs included in this research project: Malmö FF, Helsingborg IF, AIK and Djurgårdens IF. They all claim firm positions within the frame of Allsvenskan, as well as the regional context. These clubs devote a lot of attention to each other and thus contribute to constructing and reconstructing their identities. In this context, history tends to be produced in conflict and exchange, and in relation to other clubs. Victories, defeats, heroes and villains can come to life because of 'the other' involved in the process. The rivalry means also dependence, acceptance, inclusion and exclusion. The personal connection to a club is mediated through collective memory and the social structure around it. Throughout the football season this rapid and cyclical process is filled with tensions and emotions that help to construct new narratives and new mythologies while basing the present structure on the evaluation and re-evaluation of the past. There is not just one history, but endless versions with blurred edges and modified meanings. Further, there is the difference between using history vs. producing history. Fans and clubs do not just use the past but actively produce and perform it. The past seems as a fluid resource, responsive to interpretations and those involved in football can successfully play with its form and meaning.

## A REPERTOIRE OF POSSIBILITIES: VISUALIZED MASCULINITIES IN A SWEDISH SPORTSCLUB 1908-89

Alsarve, D.

*School of Humanities, Education and Social Sciences*

**Introduction and aim** When designing our identities we are inclined to use images of our selves, as well as pictures of 'the others'. Images are interwoven with our culture and society, as well as with definitions of history and truth. The overall aim of this study is to analyse, by using a visual method, masculinizing and de-masculinizing processes. More specific, the objective is to study how a dominant masculinity manifested itself in associative visuals (and texts), and how these images of domination changed during from 1908 to 1989. **Theory and method** Drawing inspiration from Bourdieu (2001) and Connell (1995), the theoretical perspective is based on the production and reproduction of a dominant and hegemonic masculinity manuscript at a associative level. Results from their work reveal that images and expectations about men and women make us asymmetrically associated with e. g. sexuality or age. This means that the norms of masculinity dictate how athletics are visualised or objectified. In turn, the norms and actions of masculinity are hierarchical, i.e. men see themselves in relation to a dominant masculinity or an alternative femininity. (This process always includes several other potential power perceptions.) From this perspective ideals and identities can vary both between men and within the same man, when, for example, the context changes. The method is a textual and visual analysis of how the hegemonic manuscript conditions and permeates the images and texts, e. g. in what is being captured or why, how a photograph is taken, how the athlete is portrayed and so on. More specific, the numerical representations of men and women respectively are counted along with more qualitative characteristics of how men and women were portrayed. **Results and discussion** The photography of a man always contains a potential to construct and categorise differences of gender. The ambition of the study is to say something universal about the mechanisms of the (re)production of male dominance in an organisation. The overall conclusion shows the difference in being objectified or portrayed, visually and textually, with and without respectively, a preserved subject position and status. Although, there are arguments for a changeable masculinity, sometimes the ideal masculine identity shows little variance. The changing aspects are particularly interesting as the study object grasps over an 80-year period. The discussion will focus on what power mechanisms are being used to reproduce a dominant, masculine order in the association. **References** Bourdieu, Pierre. (2001). *Masculine domination*. ## A PLACE IN THE SUN OR STANDING IN THE SHADOWS OF A GLORIOUS PAST? IDENTITY FORMATION AND FOOTBALL FAN CULTURE IN EAST GERMANY.

Glaser, J.

*Malmö university*

Football clubs in Germany have played and still play an important and vital identification role in Germany. Male football on the highest level, however, is to a large extent a western German singularity. This, I claim, is one consequence of the transformation from the state controlled socialist football of the GDR to the market-oriented capitalist football of the Federal Republic and the merger of the two German football associations in 1990. Today, there is not one football club from the former GDR in the first German league, die Bundesliga, and only two teams in the second. At the current time, the most successful teams of the GDR play in the periphery of German football, in the third or fourth league. Nevertheless, football fan culture in eastern Germany is an interesting topic, since it is a rare cultural phenomenon with its roots in the GDR that still has an impact on identity formation in unified Germany. Studying football fan culture in eastern Germany thus makes it possible not only to discern discontinuities, but more importantly continuities as well as alterations after 1989. The objective of this paper is to examine the dialectical relationship between identity formation among football fans in eastern Germany on the one hand and the German re-unification on the other. In the paper I examine how the fans articulate various dialectical relations and paradoxes such as unity and division, east and west, empowerment and disempowerment and success and failure on the football field with the purpose of understanding the attitudes of the fans towards unified Germany. The study is based on empirical data from interviews and observations carried out with football fans of BFC Dynamo, FC Erzgebirge Aue, 1. FC Magdeburg and 1. FC Union Berlin. In the analysis I use a dynamic approach to identity formation, making it possible to study to what extent identity formation and football fan culture have been affected by changing political, social, cultural and economic structures as well as different and changing discourses on nation, place and power in the wake of German re-unification. Furthermore, I investigate and challenge the common view that both the political unification and its football equivalent created either winners or losers among the East Germans. Instead I show that the narratives constructed by the interviewed football fans reveal more differentiated and changing views on the unification that depend on various relational and situated contexts.

## THE DIFFICULTY OF HITTING TWO BIRDS WITH ONE STONE – FOSTERING COMPETITIVE ATHLETES AND DEMOCRATIC CITIZENS IN A SWEDISH SPORTS CLUB BETWEEN THE 1960S AND 1980S

Svensson, R., Alsarve, D.

*School of Health and Medical Science, School of Humanities; Education and Social Sciences*

**Introduction** According to an Official Report of the Swedish Government (SOU 2008:59) Swedish sport associations have two overriding missions: 1) to foster its members into a democratic value system and 2) to produce competitive athletes. However, there is a tension between these missions and the Swedish Sports Confederation stresses that the overall aim of the Swedish sports movement is to create a balance between these two missions. Even though a few studies have undertaken the question how the sports clubs have handled the tension (e.g. Peterson 2007), the knowledge about this area is still scarce and to reach a deeper understanding we need to scrutinize how the tension has developed over time. Therefore, the purpose of this study is to examine how a Swedish multi sectional sports club have been governing its activities in relation to the two divergent missions between the 1960s and 1980s. **Design** First, we examine the professionalization of the Swedish elite soccer coach, because it is equitable to let the coach represent the mission to produce competitive athletes. We examine what kind of knowledge constituted the elite soccer coach. Second, we examine how, in the frame of a multi sectional sports club, the professionalization of the elite soccer coach affected the activities of the youth section, which we argue represent the democratic fostering mission. To examine why and how the club governed as it did and what capital it invested in, with focus on the consequences for the elite senior soccer section on the one hand and the youth section on the other, the theoretical framework combines a foucaultian governmentality perspective (Foucault 2002) and a bourdieuan capital conceptualisation (Bourdieu 1986). The method is text analysis of educational material from coaching courses organized by the Swedish Football Association and protocols, annual reports and members review from the multi sectional sports club Örebro SK. **Result** A tentative analysis shows how ÖSK, in the pursuit of

winning, invested economic capital in elite soccer coaches. Given the academic capital they possessed through the process of professionalization the coaches could exert more power. As a consequence the objectives of the coach - to produce competitive soccer players – also formed the purpose of the activities of the youth section. References Bourdieu, Pierre. (1986). ### **EARLY SCIENTIFIC INVESTIGATIONS IN YOGA: THE MILES-BEHANAN COLLABORATION**

Mookerjee, S.1, Kornspan, A.2, Pinheiro, V.2

1: *Bloomsburg University*, 2: *University of Akron*

Introduction Empirical investigations of yogic techniques in the United States are relatively recent. In the 1930's, Professor Miles and his student, K.T. Behanan, conducted one of these earliest scientific studies of yoga at Yale University. The purpose of this treatise was to conduct a systematic review of their work based on records available at the Center for the History of Psychology, Akron, Ohio, USA. Methods A systematic, hierarchical analysis of available documentation was conducted from available archival materials, personal correspondence, data records of experiments, and published materials. All the relevant documentation was compiled and carefully reviewed by a team of three researchers. Primary sources (publications, documents, experimental data records) as well as secondary sources (correspondence) were analyzed. Results In 1931, Behanan was awarded a fellowship to conduct empirical studies in yogic techniques. Miles and Behanan made oxygen consumption (VO<sub>2</sub>) recordings of three different breathing techniques and noted significant increases in VO<sub>2</sub> - Ujayi (18-32%); Kapalbhathi (10-14%); Bhastrika (17-20%). Behanan subsequently returned to India and published a text in 1937. Miles presented and published their findings much later. Discussion With their early pioneering work, Miles and Behanan helped to stimulate a plethora of investigations in yoga. Later studies have corroborated their findings and helped clarify prevalent myths. References Behanan, KT (1964). Yoga: a scientific evaluation. 199-237. Dover Publications, New York. ### OP-PM65 Nutrition: Hydration

---

#### **THE EFFECT OF DEHYDRATION ON SIMULATED MOTOR RACING PERFORMANCE.**

Mollica, J.A., Desbrow, B., Irwin, C.G.

*Griffith University*

**Introduction** Motor racing drivers are often exposed to environments which have the potential to affect hydration status and driving performance. The aim of this study was to assess the effect of dehydration on simulated motor racing performance. **Methods** Healthy males participated in two studies investigating driving performance. Study A involved 26 participants and was designed to establish the sensitivity and reliability of performance indicators (mean lap time, mean sector time and mean distance from a corner apex) within a simulated motor racing scenario. Participants were asked to complete 2 identical driving tasks (~5mins) (with and without impaired vision) and repeated these drives following a 1 hour rest. Sensitivity was determined using paired t-tests to compare vision impaired to non-impaired vision trials. Reliability was determined by comparing non-impaired vision trials over time. Participants who met a performance criteria relating to mean lap time ( $\leq 70.00s$ ) were invited to take part in Study B. This study involved 4 participants undertaking two passive dehydration (sauna) procedures (~1% and ~3%) on separate occasions. Driving performance was assessed pre dehydration, immediately post dehydration (dehydration+heat) and following a cooling period (dehydration). Differences in the sensitive and reliable driving performance measures were assessed via repeated measures ANOVA. **Results** Study A: Mean lap time and mean sector times were found to be sensitive performance parameters relative to a likely impairment ( $p \leq 0.05$ ). However, mean distance from a corner apex was unaffected by vision impairment and hence considered an insensitive measure of driving performance for Study B. All performance parameters indicated test-retest reliability ( $p > 0.05$ ). Study B: Mean lap times were not different between pre dehydration, dehydration+heat and dehydration conditions for both 1% ( $68.56 \pm 0.81s$ ,  $68.10 \pm 0.90s$  and  $68.23 \pm 1.47s$ , respectively) and 3% trials ( $69.10 \pm 1.79s$ ,  $68.14 \pm 1.41s$  and  $68.14 \pm 1.35$ , respectively). In addition mean split times were not different between pre dehydration, dehydration+heat and dehydration conditions for both 1% ( $11.64 \pm 0.23s$ ,  $11.34 \pm 0.19s$  and  $11.47 \pm 0.34s$ , respectively) and 3% trials ( $11.56 \pm 0.23s$ ,  $11.70 \pm 0.40s$  and  $11.49 \pm 0.34s$ , respectively). **Discussion** Preliminary results suggest no impact of mild to moderate dehydration on reliable and sensitive measures of driving performance. Future analysis from a larger sample is required to elucidate the impact of hydration status on simulated motor racing performance. Contact: b.desbrow@griffith.edu.au

#### **PREHYDRATATION STATUS, FLUID AND ELECTROLYTE BALANCE IN ELITE SOCCER PLAYERS TO DIFFERENT TRAINING SESSIONS**

Boone, J., Lieven, M., Bourgois, J.

*Ghent University*

This study aimed to investigate the influence of different types of training on fluid and electrolyte balance in elite soccer players, since excessive fluid and electrolyte loss have been shown to negatively impact performance. Three training forms were included: game specific (GS), technical-tactical (TT) and endurance/core stability training (EC), which were completed in moderate temperatures ( $12 - 18^\circ C$ ) by 14 male elite soccer players. Prior to the GS training a urine sample was collected to determine urine specific gravity (PAL 10S refractometer, ATAGO, Japan) as an indication of pre-hydration status. Subjects were also weighed just before training and after showering to determine their sweat loss. The fluid and electrolyte intake was measured by weighing and analysing the concentration of the personalized drinking bottle of each player before and after training. Before the GS training sweat patches were applied to the body, which were then analysed by means of flame spectrophotometry to measure electrolyte loss. Repeated measures ANOVA was used to examine differences between training types. The USG revealed that 9 out of 14 players started training dehydrated whereof one strongly dehydrated. Players lost a substantial amount of sweat, which was significantly different ( $p = 0.005$ ) between all training types:  $1.18 \pm 0.36 L/h$ ;  $0.96 \pm 0.22 L/h$ ;  $0.65 \pm 0.27 L/h$  for GS, TT and EC respectively. Fluid reuptake was not significantly different between training types ( $p = 0.238$ ):  $72.75 \pm 38.3\%$  (GS),  $54.06 \pm 11.48\%$  (TT) and  $64.66 \pm 35.98\%$  (EC). In total, three players had a BM loss that exceeded 2%, which should be avoided. Sweat electrolyte concentration varied substantially among players:  $[Na^+]$  ranged from 437.0 to 1372.0 mg/L and  $[K^+]$  from 109 to 171 mg/L. Since water was the only consumed beverage, just a small percentage of electrolytes was replaced, respectively  $4.08 \pm 2.26\%$   $Na^+$  and  $1.36 \pm 0.72\%$   $K^+$ . Even though the importance of an adequate hydration to maintain performance is well recognized, the results of the present study indicate that more than half of the players are not optimally hydrated at the start of the GS training. Furthermore sweat rates differed between training forms and sweat electrolyte concentration varied greatly between players. Therefore an individualized hydration strategy is recommended.

#### **ALCOHOL CONSUMPTION DURING THE POST-EXERCISE PERIOD: EFFECTS ON BLOOD RHEOLOGY.**

Simmonds, M., Irwin, C., Horobin, J., Cunningham, E., Stagg, M., Desbrow, B.

*Griffith University*

Haemoconcentration and blood hyperviscosity may occur during the post-exercise period due to acute dehydration. Dehydration during and following exercise may therefore present a unique challenge to cardiovascular health given that blood hyperviscosity is also observed during short-term acute exercise even in well-hydrated individuals. Post-exercise fluid replacement is adhered to among many competitive athletes (e.g., electrolyte-rich fluids; carbohydrate/protein beverages); however, some athletes consume alcohol during the

post-exercise period. The present study investigated the level of agreement in the blood rheological response to an exercise bout that induced dehydration (~2% body weight equivalent) on two separate occasions, and also the haemorheological response to two discrete post-exercise rehydration strategies where participants consumed 150% of body weight loss as either: i. a standardised electrolyte/carbohydrate sports beverage (SB), and; ii. a commercially-available alcoholic (3.5% alc/vol) beer (beer). Blood was sampled pre- and immediately post-exercise, and also one (R1) and four hours (R4) following each exercise trial. Plasma osmolarity, blood and plasma viscosities, red blood cell (RBC) aggregation, and RBC deformability were measured within 1-h of blood collection. Repeatability of blood rheological parameters varied depending on the specific dependent variable. Plasma osmolarity significantly increased during R1 and R4 only for beer. Exercise significantly increased plasma viscosity, although no difference was detected between SB and beer. Blood viscosity (75-300 /s) was lower at R1 for SB compared with pre-exercise, but not for beer. The amplitude of red cell aggregation was increased following exercise in both conditions but returned to pre-exercise values by R1. The time course of RBC aggregation was faster post-exercise in both conditions; this returned to pre-exercise values (slower) for SB, but remained faster in beer. The findings of the present study suggest that blood rheology parameters related to low-shear flow are sensitive to fluid selection following moderate dehydration in the post-exercise period.

### IMMUNE RESPONSES AND DIETARY INTAKE OF ELITE RUGBY UNION PLAYERS DURING PRE-SEASON TRAINING

Tester, E., Jones, B., Duckworth, L., Ispoglou, T.

*Leeds Beckett University*

There is a developing base of research assessing hormonal status in rugby players as a means to monitor training and performance, however to date no research has investigated the impact of dietary intake on immunity. The objectives of the study were to monitor immune responses, as well as assess dietary intake, body composition and performance of elite rugby union players. Following ethics approval, nine players (height 185.8±6.2cm, age 28.0±3.4yrs) were assessed at the start and end of a 4-week pre-season training period for dietary intake (4-day food diary), body composition (sum of 8 [Σ8] skinfold sites), one repetition maximum (1RM) strength (bench press [BP] and prone row [PR]) and endurance (1200m run). Saliva immunoglobulin A (sIgA) measures were taken at the start and end of each week (~8.30am). Mean energy intakes were 12145.9±3772.3kJ (week 1) and 12419.7±2385.5kJ (week 4). During both weeks of dietary assessment protein and carbohydrate consumption was 2.3±0.7 and 2.7±1.1g.kg.BM<sup>-1</sup>.d<sup>-1</sup> respectively. There was a 32%, 36% and 32% contribution from protein, carbohydrate and fat to energy intake. Despite relatively low energy consumption (approximately 45% below recommendations), there was only a 0.7±2.4kg reduction in body mass (103.7±13.7 to 103±13.4kg) and a 12±2% reduction in for Σ8 skinfolds from week 1 to week 4 (106.7±44.3 to 94.17±43.6mm). Mean sIgA over the training period was 47.9±ug.min<sup>-1</sup>, with a small intra-player variability observed throughout the 4-week pre-season training period (CV 5%). sIgA was strongly correlated with fat (r=0.68) and saturated fat intake (r=0.62). sIgA was also moderately correlated with protein intake (r=0.40), Σ8 skinfolds (r=0.39) and endomorphy (r=0.43). Conversely, strong and moderate negative correlations occurred between sIgA and mesomorphy (r=-0.51), and sIgA and ectomorphy (r=-0.49). Significant improvements (P<0.05) were observed for 1RM in BP (4.0 ± 4.93 kg) and 1200m (23 ± 5.27 sec) with 1200m times strongly correlating with sIgA (r=0.56). Conversely there were moderate negative correlations between improvements in strength and sIgA (r=-0.42). In summary, players with a higher dietary fat intake and endomorphic characteristics demonstrated a better immune status than leaner ectomorphic players. Those showing better immune function also produced greater gains in endurance. The negative correlations between strength and sIgA were likely due to enhanced rates of catabolism as a result of resistance training. The pre-season training period elicited improvements in body composition despite inadequate dietary intake when compared to guidelines, highlighting the potential error of applying the recommended nutrient intake guidelines to an elite rugby union population.

### OP-PM31 Sports Medicine & Orthopedics: Physiotherapy II

#### TRAINING IN A MINIMALIST SHOE INCREASES ANKLE JOINT LOADING AND 5KM RUNNING PERFORMANCE

Fuller, J.1, Thewlis, D.1, Tsiros, M.1, Brown, N.2, Buckley, J.1

*1 University of South Australia, 2 Australian Institute of Sport*

Introduction Transitioning to less cushioned (minimalist) running shoes may promote a forefoot strike and improve running performance through greater storage and recovery of elastic energy in the ankle plantarflexors (Lieberman et al. 2010; Fuller et al. 2015). We hypothesized that a forefoot strike might increase plantarflexor loading during running training, promoting greater adaptation in these muscles and greater improvement in running performance. Methods 26 distance runners who rearfoot strike and were unaccustomed to running in minimalist footwear ran in minimalist and control shoes (order randomised) and energy absorbed and generated at the ankle joint was calculated from the integral of the ankle joint power-time curve during stance phase when running across a force platform. Stride frequency, stride length and ankle angle at initial foot contact were also calculated. An additional 50 rearfoot strike runners completed 6-weeks of prescribed running training while randomised to progressively transition to minimalist or control shoes. Running performance was assessed before and after training using a 5-km treadmill time-trial. Results Compared with the control shoe, running in the minimalist shoe resulted in more energy generation (66.8 ± 20.1 J vs 59.4 ± 14.8 J; P<0.05) but not energy absorption at the ankle joint (55.0 ± 24.1 J vs 49.4 ± 20.0 J; P>0.27). In the minimalist shoe runners ran with an increased stride frequency (87.0 ± 5.4 strides/min vs 85.5 ± 5.4 strides/min; P<0.05), decreased stride length (287.7 ± 17.8 cm vs 292.6 ± 18.4 cm; P<0.05) and a less dorsiflexed foot at initial foot contact (2.9 ± 8.9 ° vs 7.7 ± 6.3°; P<0.05). After 6-weeks of running training, runners in the minimalist shoes improved 5-km treadmill time-trial performance more than those in the control shoes (44.6 ± 38.3 s vs 24.5 ± 35.1 s; P<0.05). Discussion Running in minimalist shoes increased the energy generated by the ankle plantarflexor muscles with each stride and the number of strides taken per minute. This increased work may enhance training adaptations in the ankle plantarflexor muscles and contribute to the greater observed improvement in running performance. References Lieberman DE, et al. ### COMPARISON OF HAMSTRINGS/QUADRICEPS CONVENTIONAL RATIO IN HIGH SCHOOL STUDENTS FROM 12-16 YEARS

Fagnani, P.L., López del Amo, J.L., Uviña, A., Galceran, D., Rovira, N.

*Barcelona University-INEFC*

**Introduction:** Muscular imbalance is described as a risk factor for Anterior Cruciate Ligament (ACL) lesion and can be modified by training (Sanicandro et al, 2014). Identify strength muscular differences between sexes during maturation period are fundamental for knowing the best moment for the implementation of prevention strategies in young people. The conventional Hamstrings/Quadriceps (H/Q) ratio has been used to examine muscular imbalance (Greco, Da Silva, Camarda, & Denadai, 2012, 2013). Using muscle power to assess this rate may be more appropriate than just using muscle strength, because the velocity of the execution of the movement is an important factor in the total amount of work carried out during a specific exercise (Tous, J., 1999). Therefore, the aim of this study was to measure and compare the H/Q conventional ratio between sexes and group ages from 12-16 years using the knee flexors and extensors muscles power. **Methods:** 321 Spanish high school students were separated by sexes and categorized in 5 age groups (12, 13, 14, 15 y 16 years of age) for later comparisons. The conventional H/Q ratio was calculated using the average power produced during a flexor and extensor open kinetic chain gym machines. **Results:** Significant differences ( $p < 0.05$ ) were found when comparing the H/Q ratio between sexes. Males showed in all age groups higher ratios values than women. When comparing both sexes in each age group, statistic significant differences were found in 13 ( $p = 0.022$ ), 15 ( $p = 0.008$ ) and 16 ( $p < 0.005$ ) years old. **Discussion:** Based on the results is suggested that muscular imbalance between knee flexor and extensor may persist longer in women. In this study, the bigger differences were observed in the older groups (15 and 16 years). Future studies with group ages above 16 are recommended once this study was limited to this age. **Conclusion:** Persistent muscular imbalance may be one of the risk factors for ACL rupture and may explain, in part, the higher incidence of this lesion in female adolescents. **References:** Greco, C. ### WORSE SELF-REPORTED OUTCOMES BUT NO LIMITATIONS IN PERFORMANCE BASED MEASURES IN PATIENTS WITH LONG-STANDING HIP AND GROIN PAIN COMPARED WITH HEALTHY CONTROLS

Ageberg, E., Wörner, T., Sigurdsson, H.B., Pålsson, A., Kostogiannis, I.

*Lund University*

**Purpose** The aim of this cross-sectional study was to evaluate lower extremity and trunk muscle function as well as patient reported outcomes in people with long-standing hip and groin pain (LHGP) in comparison to healthy controls. We hypothesized that individuals with LHGP would report more deficiency on the Copenhagen Hip and Groin Outcome Score (HAGOS) and have worse trunk and lower extremity performance than controls. Participants with LHGP were also expected to have worse lower extremity function on their symptomatic compared with their non-symptomatic limb. **Methods** Nineteen participants with LHGP and 19 controls matched for activity level, age, gender, and weight reported their hip and/or groin disability and associated problems on the HAGOS questionnaire. Lower extremity and trunk muscle function was assessed by means of a parallel squat (w/kg), single leg triple jump (cm), single leg rise (n), barbell rollout (% of height), and plank-test (s). **Results** Participants with LHGP had worse scores than controls in all HAGOS-subcales ( $p \leq 0.001$ ). The smallest difference was observed for subscale activities of daily living [mean diff 19.21 (95% CI 9.73 to 28.69)] followed by subscales pain [mean diff 29.63 (95% CI 20.00 to 39.26)], symptoms [mean diff 28.74 (95% CI 19.62 to 37.86)], sports and recreation [mean diff 36.95 (95% CI 25.00 to 48.89)], physical activity [mean diff 46.61; 95% CI 28.83 to 64.38]], and quality of life [mean diff 57.37 (95% CI 47.40 to 67.33)]. No differences were observed for the parallel squat [mean diff 0.89 (95% CI -2.93 to 1.14) w/kg], single leg triple jump [mean diff 20.5 (95% CI -88.6 to 47.5) cm], single leg rise [mean diff 3.6; 95% CI -11.3 to 4.1] n], barbell rollout [mean diff 0.2 (95% CI -4.8 to 5.1) % of height], or the plank test [mean diff 8.8 (95% CI -54.1 to 36.5) s]. Furthermore, no differences were observed between symptomatic and asymptomatic limbs of participants with LHGP in the single leg triple jump [mean diff 1.4 (95% CI -17.16 to 19.96) cm] or the single leg rise [mean diff 1 (95% CI -2.47 to 4.27) n]. **Conclusions** Despite significant self-reported limitations and associated hip/groin problems, there were no significant differences between groups in strength, power or performance-based measures. The greatest limitations were reported in physical function sports, physical activity, and quality of life. Future studies with larger sample sizes are needed to explore whether other measures of muscle function may detect possible sensorimotor deficiencies in people with LHGP.

### EMG ACTIVITY OF THE UPPER TRAPEZIUS, LOWER TRAPEZIUS AND SERRATUS ANTERIOR IN ASYMPTOMATIC COLLEGE BASEBALL PLAYERS AND ONE CASE IN A PITCHER WITH SCAPULAR DYSKINESIS

Tsuruiki, M.I., Ellenbecker, T.S.2

*1: San Jose State University, 2: Physiotherapy Associates Scottsdale Sports Clinic, Scottsdale, Arizona USA*

**Introduction** Scapular dyskinesia (SD) has been suggested to be associated with a decrease in subacromial space width, modification of scapular muscle activity, and glenohumeral (GH) joint congruency problems. The purpose of this study was to identify the muscle activity of the upper trapezius (UT), lower trapezius (LT), and serratus anterior (SA) with different weight intensities in shoulder flexion. It was also to compare these muscle activities between the asymptomatic group means and one active pitcher with type II Kibler SD (Kibler et al., 2013). **Methods** Twenty nine active college baseball players volunteered to be tested in this study. All subjects performed isotonic contractions of shoulder flexion for 3 consecutive repetitions with no weight (0 kg) and an adjustable wrist cuff weight ranging between 1.8 kg and 3.2 kg. The subjects completed each of the exercises in upward motion and descent each for 5 seconds with an interval of 10 seconds between each of the repetitions. A metronome with a frequency of 1 Hz was used to standardize the speed of exercise. Raw EMG amplitudes of the UT, LT, and SA muscle were collected in each testing session and normalized by the MVIC of the corresponding muscle (%). This study analyzed each of the mean values blocked at every 1 second in both upward motion and descent. A repeated measures ANOVA design was used to examine differences for the asymptomatic group ( $n=28$ ). **Results** The mean value of UT EMG activity in the dominant side (DOM) with the intensity of 0 kg and 3.2 kg was significantly smaller than that of the non-dominant side (NON) (34% and 41% versus 48% and 52% with 0 kg and 3.2 kg respectively) ( $p < .05$ ). In contrast, the mean value of LT EMG activity in DOM with the intensi-

ties of 0 kg and 3.2 kg was significantly greater than that of the NON (29% and 33% versus 23% and 27% with 0 kg and 3.2 kg respectively) ( $p < .05$ ). The EMG activity with 1.8 kg in the DOM was significantly smaller than that of the NON (24% versus 30%) ( $p < .05$ ). The subject with the type II SD hyper-activated the UT muscle in the DOM in both upward movement and descent regardless of the intensities, whereas the subject hypo-activated the LT muscle in DOM with the intensity of 3.2 kg in descent. Discussion This study suggests that the intensity of 3.2 kg is used for SD testing in overhead athletes. This study also speculates the mechanism of the subject with the type II SD is attributed for a decrease in the LT muscle activity in descent as intensity increases. ### UPPER AND LOWER EXTREMITY EXPLOSIVE POWER AND MOVEMENT QUALITY IN MALE AND FEMALE YOUTH TEAM HANDBALL PLAYERS

Jess, L., Cristovao, S., Ageberg, E.

*Lunds University*

**Introduction** Training programs that are sport specific and address the muscular demands of the sport may improve overall motor control, thereby enhancing performance, as well as decreasing injury risk. First, however, there is a need to understand muscular function in relation to specific sports, gender, and age. **Aim** The purpose was 1) to evaluate upper and lower extremity explosive power and movement quality, and 2) assess any gender differences in youth handball athletes. **Methods** Thirty-one handball athletes (18 females, 13 males) mean age 13 years (SD 1.0), included in an ongoing study, were assessed. Four previously evaluated muscle function tests were used to challenge lower and upper extremity explosive power and movement quality: 1. Explosive power assessed by single leg counter-movement jump (SLCMJ); 2. Visual rating of knee position relative to foot (good or poor) during single limb mini squat (SLMS) and SLCMJ; 3. Explosive power during the overhead medicine ball throw (MBT); 4. Visual rating of shoulder movement quality during arm movements (good or poor) using the scapular dyskinesis test (SDT). Spearman's rank correlation coefficient was used to assess associations. Fisher's exact test was used to compare groups. **Results** The correlation between upper and lower extremity explosive power was  $r = 0.436$  ( $p = 0.014$ ). The correlation between lower extremity explosive power and movement quality was  $r = 0.329$  ( $p = 0.071$ ), between upper extremity explosive power and movement quality  $r = 0.342$  ( $p = 0.342$ ) and lower extremity movement quality and upper extremity movement quality  $r = 0.338$  ( $p = 0.063$ ). Males jumped higher than females, 17.9 cm (SD 4.0) vs 13.8 cm (SD 3.5) ( $p = 0.003$ ), but there was no gender difference in upper extremity explosive power (males 646.5 cm (SD 71.76) vs females 642.8 cm (SD 83.6),  $p = 0.828$ ). There were no gender-differences in upper extremity movement quality, 7.7% males and 11.1% females scored good and 92.3% males and 88.9% females scored poor ( $p = 0.624$ ). No gender-differences were observed in lower extremity movement quality, 46.2% males and 50% females scored good and 53.8% males 50% females scored poor ( $p = 0.561$ ). **Conclusions** Our preliminary results indicate a weak to moderate association between overall upper and lower extremity explosive power in youth handball athletes. The only gender-difference was in jump height. This is supported by previous research, which suggests most gender differences are evident after puberty. A high number of males and females scored poor upper and lower extremity movement quality, suggesting that this is an important factor that needs to be addressed in handball training programs in this age group. The relation between muscle function and sport-specific performance remains to be determined. Contact sm.cristovao@gmail.com laurajess5@gmail.com

### EFFECT OF WEIGHT-BEARING EXERCISE ON FOREARM BONE SITES OF HANDBALL AND SOCCER FEMALE PLAYERS

Boshnjaku, A., Dimauro, I., Krasniqi, E., Grazioli, E., Tschan, H., Migliaccio, S., Diluigi, L., Caporossi, D.

*University of Gjakova*

**INTRODUCTION:** This pilot study investigates the effect of weight-bearing sports on the modeling activity of both specific and non-specific bone sites, comparing side to side within and among trained and non-trained groups, controlling for lifestyle and maturation stage at the beginning of sport training. **METHODS:** BMD, T- and Z-score at distal forearm regions were evaluated in 30 female handball players (HP, 22.3±3.9 years), 30 female soccer players (SP, 22.2±3.6 years), who have been training for 7.7±3.8 years, 12 hours per week, as well as in 30 untrained females (CG, 23.9±3.2 years). **RESULTS:** In handball players, the BMD of the dominant forearm was 21.5% and 11% higher than in the CG and SP, respectively. No difference in the dominant arm BMD between SP and CG. BMD of the non-dominant forearms showed no differences between athletes groups, while it showed a significant increase compared with the CG (HP: +18.3%; SP: +10.6%). SP who had started their carrier before menarche, showed a non-dominant arm BMD 5.5% greater than those SP who started after it. Moreover, the dominant arm BMD was 12% (+2.5%) higher compared with CG, showing any significant differences compared with the corresponding forearm in HP. Even the non-dominant arm BMD was further increased, passing from 10.6 at 13.5% (+2.9%). Less marked was the increase in BMD of both HP forearms (+1.4%). **CONCLUSION:** This pilot study demonstrated that weight-bearing sport training induces a beneficial effect not only at level of specific skeletal regions but even in non-weight-bearing sites, such as both forearms of SP, whose BMD was further improved, especially for the dominant side, in females who started to play at menarche or before it. In fact, we showed for the first time that not only HP with approximately 8 years of regular sport participation had the maximally beneficial for mineralization at bone sites directly involved in the sport activity, but that regular participation to weight-bearing exercise positively affects non-weight-bearing bone sites, such as the upper forearms of the SP, through both direct mechanical loading and/or systemic skeletal adaptation to exercise.

#### NO INTEREST FOR A SECOND CLOSELY-TIMED INFILTRATION OF PLATELET-RICH PLASMA TO TREAT JUMPER'S KNEES

Kaux, J.F., Croisier, J.L., Forthomme, B., Le Goff, C., Buhler, F., Savanier, B., Delcour, S., Gothot, A., Crielaard, J.M.

*University of Liège*

**Introduction:** Some clinical series have evaluated the effect of platelet-rich plasma (PRP) in the treatment of jumper's knee. Although it is possible that a single infiltrative administration may prove to be an effective treatment for this indication, most of the existing studies evaluated the effects of 2 or 3 successive infiltrations. The aim of this study was to evaluate whether 2 infiltrations of PRP proves more

effective than a single treatment. Methods: Twenty patients suffering from chronic jumper's knee were enrolled into our prospective, randomized and comparative study of level 2, and split into two randomized groups (1 or 2 infiltrations of PRP, respectively). The 3-month follow-up evaluation consisted of VAS, IKDC and VISA-P scores, along with algometer, isokinetic and ultrasounds evaluations. After 1 year, subjects were contacted to define their functional evolution. Results: The concentration of the PRP used for each infiltration was similar in both groups, and contained no red or white cells. Results revealed no difference in treatment efficacy between the groups. Discussion: The comparison between 1 or 2 infiltrations of PRP did not reveal any difference between the 2 groups at short to mid term. A second closely-timed infiltration of PRP to treat jumper's knees is not necessary to improve the efficacy of this treatment in the short term. ## ACUTE AND OVERUSE INJURIES IN SWISS ORIENTEERING ATHLETES

Roos, L.1,2, Clénin, G.E.3, Züst, P.3, Wyss, T.1

1: Swiss Federal Institute of Sport Magglingen SFISM, Switzerland; 2: University of Fribourg, Switzerland; 3: Swiss Orienteering Federation, Olten, Switzerland

**Introduction** In the final ranking of the International Orienteering Federation World Cup 2014 Switzerland was classified as the best nation with 5 women in the top 12 and 7 men in the top 15. A great part of the weekly orienteering training is performed as endurance running training. However, a high weekly running mileage puts considerable stress on the athlete's musculoskeletal system (Jones et al., 1994). A consequence thereof are acute and overuse injuries. Hence, the aim of this study was to determine the injury incidence rate and injury pattern in Swiss elite orienteering athletes. **Methods** The injury data were collected retrospectively for the years 2005-2014 from volunteering, current and former, athletes of the Swiss Orienteering Federation. The athletes' medical records were used to classify injuries according to the Orchard Sports Injury Classification System (OSICS version 10.1). The training data were collected from the athletes' digital training diary and matched for age. The data are presented as mean  $\pm$  standard deviation, proportions of injuries by anatomical region, type and onset of injuries. **Results** The data of 30 athletes aged  $22 \pm 3.2$  years (range 18-30), were recorded. A total of 175 injuries were assessed. The most commonly affected anatomical region was the lower extremity (92.6%). Thereof, the knee (29.1%), the lower leg (20.0%) and the foot (18.9%) were injured most. The most common types of injury were pain and/or inflammation (65.1%), sprains (11.4%) and dislocations (9.1%). Almost two thirds (61.1%) of all injuries were classified as overuse injuries. About a third of injuries (28.6%) resulted in training days lost. The mean injury incidence risk for athletes aged 18-23 years was  $3.1 \pm 3.1$  injuries per 1000 training hours. No significant relation between training volume (380.8  $\pm$  77.1 hours per year) and injury risk was found. **Discussion** A high amount of running based training is a risk factor for musculoskeletal injuries. This was confirmed in the present study with the great amount of lower extremities injuries, most of them due to overuse onset. Previous studies with recreational runners reported 2.5-12.1 and 10.0 injuries per 1000 hours of training, and the knee as the most commonly affected region (van Mechelen, 1992; Hespanhol Jr., et al. 2013). Concluding, the Swiss elite orienteers display a rather low injury incidence rate within the former reported range, and further, the injury patterns are in line with previous results. **References** Hespanhol Jr., LC., Pena Costa, LO., Lopes, AD. (2013). *J Physiother*, 59(4):263-269. Jones, BH., Cowan, DN., Knapik, JJ. (1994). *Sports Med*, 18(3):202-214. van Mechelen, W. (1992). *Sports Med*, 14(5):320-335. ## ALTERED LUMBO-PELVIC CONTROL IN INDIVIDUALS WITH PATELLOFEMORAL PAIN SYNDROME

Cowan, S., Crossley, K.

The University of Melbourne

**Introduction** Clinically, altered movement patterns are commonly addressed in the treatment of patello-femoral pain (PFP). Whilst there is evidence for decreased hip muscle strength and control in PFP [1-5] and altered trunk control [4, 6], the findings are not conclusive [4, 7]. Most studies have focused on hip movement control and strength with little attention paid to lumbo-pelvic control in PFP. This study aimed to investigate lumbo-pelvic control during functional tasks in females with and without PFP. **Methods** Lumbo-pelvic motion was measured using DorsaVi Movement sensor technology in 17 individuals with PFP and 10 healthy controls. Lumbar flexion range of movement and lateral pelvic tilt was assessed during three functional movements; a double leg squat, a single leg lunge and a hurdle step. Reliability was assessed with the 10 control subjects returning for repeat testing 1 week after initial testing. **Results** Reliability analyses indicated good to excellent reliability (ICC range (0.72-0.95%) for the three tests. Individuals with PFP demonstrated increased range of lumbar flexion and pelvic lateral tilt during the single leg lunge ( $P < 0.05$ ). In the double leg squat individuals with PFP completed the movement with less lumbar flexion ( $p < 0.05$ ). Whereas during the hurdle step, individuals with PFP completed the movement with less lateral flexion than control participants. **Conclusions** Participants with PFP were found to have altered lumbo-pelvic control when compared to healthy controls. These findings indicate that lumbo-pelvic control may be an appropriate rehabilitation focus for individuals with PFP. **References** 1. Magalhaes E et al. ## ONE WEEK OF HOSPITAL ADMISSION FOLLOWING ELECTIVE HIP SURGERY INDUCES SUBSTANTIAL MUSCLE ATROPHY IN OLDER PATIENTS

Kouw, I.W.K.1, Groen, B.B.1, Kramer, I.F.K.1, van Kranenburg, J.1, Geurts, J.A.2, ten Broeke, R.H.2, Verdijk, L.B.1, van Loon, L.J.C.1

*Maastricht University*

**Introduction:** It has been suggested that short successive periods of muscle disuse, due to injury or illness, may contribute significantly to the observed loss of muscle mass over the lifespan. Hospitalization of older individuals due to acute illness, injury or (elective) surgery generally results in a mean hospital stay of 5-7 days during which the level of physical activity is strongly reduced. We hypothesized that hospital admission for elective hip arthroplasty is accompanied by substantial muscle atrophy in older men and women. **Methods:** Twenty healthy older patients (77±1 y) undergoing elective total hip replacement surgery participated in this observational study during hospital admission. Prior to surgery and before discharge CT scans were performed to assess muscle cross-sectional area (CSA) of both legs. During surgery and prior to hospital discharge a muscle biopsy was taken from the M vastus lateralis of the operated leg to assess muscle fibre type-specific CSA and myonuclear content. Repeated measures ANOVA with time and leg as within-subjects factor were used, with separated T-tests being performed for each leg when interaction was observed. **Results:** An average of 5.8±0.4 days of hospital admission resulted in a 3.8±1.1 and 5.1±1.3 % decline in quadriceps muscle and whole-leg muscle CSA, respectively, in the control leg when compared with baseline values (P<0.05). Oedema in the operated leg resulted in a 9.3±1.6 % increase in leg CSA (P<0.05). Muscle biopsies from the operated leg are currently being analysed for muscle fibre type characteristics. **Conclusions:** Six days of hospitalization following elective hip arthroplasty leads to substantial leg muscle atrophy in older patients. Effective strategies are warranted to prevent the loss of muscle mass and strength induced by short periods of muscle disuse during hospital admission. Email: im-re.kouw@maastrichtuniversity.nl

## EFFECTS OF ANKLE SUPPORT ON THE GROUND REACTION FORCE DURING THE REPEATED SIDE STEP

Koyama, K.1, Otsuka, R.1, Yamauchi, J.2,3

*1. Tojin University of Yokohama, Kanagawa, JAPAN 2. Tokyo Metropolitan University, JAPAN 3. Future Institute for Sport Sciences, JAPAN*

**[Introduction]** External ankle supports are commonly used to prevent injuries during sports activity because it helps to increase the stability of ankle joint movement (Eils and Rosenbaum, 2003). Ankle supports can limit the frontal plane motion of the ankle joint during the landing tasks of locomotion (Vanwanseele et al., 2013) and significantly reduce the risk of ankle sprains particularly in athletes with a history of ankle injury (Siller et al., 1994). In contrast, the limitation of ankle movement by ankle brace affects to the athletic performance (Koyama et al. 2014; Yamauchi and Koyama in press). Also, ankle support stabilizes the inversion and eversion at the ankle joint, thus it may decrease the ground reaction force and limit the performance in the side step movement. However, there is no clear evidence how ankle support affects the ground reaction force during the repeated side step. **[Purpose]** The purpose of this study was to investigate the effects of ankle support on the ground reaction force during the repeated side step. **[Methods]** Ten healthy men (age, 21.8±1.0 years; height, 1.74±0.05 m; body mass, 67.8±12.2 kg; mean±SD) performed the repeated side step without or with ankle brace of the right ankle joint in random order on the same day. They were instructed to move laterally among three lines as quickly as possible for 20 s and to naturally contact with right foot within the area of the force plate (Kistler, Switzerland) at 1 kHz. Three parallel lines were set 1 m apart from each other, and they stepped sideways from one line to the other line. The number of times the subjects crossed the lines was counted. Trials were performed each condition with sufficient time for recovery between trials. Mediolateral ground reaction force (GRF) during foot contact was calculated for contact time (CT), first GRF (FGRF), time between contact and FGRF ( $\Delta t$ ), second GRF (SGRF), mediolateral impulse (MI). All data were presented as the mean of the 5 GRF data. **[Results]** The number of times, CT, FGRF, SGRF and MI were not significantly different between barefoot (Number; 46.8±5.8 times, CT; 0.26±0.04 s, FGRF; 398.2±150.9 N, SGRF; 499.1±83.4 N, MI; 74.9±20.0 Ns) and ankle brace (Number; 46.9±4.2 times, CT; 0.26±0.04 s, FGRF; 372.8±154.2 N, SGRF; 499.8±72.9 N, MI; 72.8±20.4 Ns).  $\Delta t$  was significantly lower in ankle brace (0.036±0.018 s) compared with barefoot (0.045±0.018 s). **[Conclusion]** These results suggest that ankle support did not decrease developing force of mediolateral direction in repeated side step due to increase in stability at the ankle joint. **[References]** Eils E, Rosenbaum D (2003). *Foot Ankle Int*, 24(3), 263-268. **LOW BACK AND NECK & SHOULDER PAIN IN ADOLESCENT SPORTS CLUB PARTICIPANTS AND NON-PARTICIPANTS.** The national Health Promoting Sports Club (HPSC) Study. **Introduction** The objective of this study was to investigate the prevalence of self-reported low back (LBP) and neck & shoulder (NSP) pain and related factors in adolescent sports club participants and non-participants. **Methods** This cross-sectional study was based on surveys among 14-16 year-old adolescents as a part of the national Health Promoting Sports Club (HPSC) Study. The surveys on self-reported health behaviors, injuries and musculoskeletal health were conducted in sports club participants (n=988) and non-participants (n=705). **Results** Prevalence of LBP during preceding 3 months was 63.2% in girls and 44.5% in boys (p<0.05 for sex difference). Also the prevalence of NSP was higher in girls (74.3%) than in boys (52.5%) (p<0.001). Non-participants to sports clubs had higher prevalence of NSP than sports club participants (68.5 % vs 61.1%, p<0.02). LBP prevalence was higher in sports club male participants (49.6% vs 37.3%, p<0.02). Sports club participants who reported to have had LBP ever trained more often (times/wk) during training season (mean (sd) 4,8 (2,2) vs 4,4 (2,0), p<0.02) and in competition season (mean (sd) 5,2 (2,7) vs 4,8 (2,3), p<0.02), had had more competitions and/or games during the last 12 months (mean (sd) 24,5 (22,7) vs 20,9 (20,4), p<0.02) and fewer rest days in training (mean (sd) 2,2 (1,2) vs 2,5 (1,4), p<0.001) and competition seasons (mean (sd) 2,0 (1,2) vs 2,3 (1,4), p<0.001). No associations were found between leisure-time physical activity and LBP or NSP. High screen time (computer games, TV/DVD, phone, Internet) during leisure-time increased slightly the odds for LBP (OR 1.04 95% CI 1.003-1.071 as calculated per additional hour of inactivity). **Discussion** Self-reported low back pain and neck and shoulder pain are fairly common already among adolescents. Girls are at more risk in reporting

LBP and NSP. Our results also suggest that the prevalence of LBP is higher in male sports club participants and NSP among non-participants in general. Contact: marleena.k.rossi@student.jyu.com

### OP-PM15 Physiology: Hypoxia

#### EFFECTS OF ALTITUDE ACCLIMATIZATION ON SPLEEN VOLUME AND CONTRACTION DURING SUBMAXIMAL AND MAXIMAL WORK IN LOWLANDERS

Rodríguez-Zamora, L.1, Lodin-Sundström, A.1, Engan, H.K.1,2, Höök, M.1,3, Patrician, A., Degerström, E.1, Schagatay, E.1,3  
1: Dept. of Health Sciences, Mid Sweden University, Östersund, Sweden. 2: LHL-Klinikkene Røros, LHL Health, Norway. 3: Swedish Winter Sports Research Centre, Östersund, Sweden.

**Introduction** Release of stored erythrocytes resulting from spleen contraction improves human performance in various hypoxic situations, and it was recently reported that a 2 month climb of Mt Everest augmented the spleen contraction (Engan et al., 2014). Our aim was to study if a shorter climb to moderate altitude would affect the spleen contraction and Hb increase seen with exercise. **Methods** Five men and two women aged 23(4) years, performed the following protocol before and after a trek to a maximal sleeping elevation of 5200 m during 6 weeks in Nepal: 10 min rest, a submaximal treadmill test (modified Bruce treadmill protocol) involving 4 x 4 min work and 1.5 min rest between workloads, 10 min rest, a maximal treadmill test, follow by 10 min rest. Spleen volume was measured by ultrasonic imaging at each resting period, and venous blood samples were drawn for hemoglobin (Hb) concentration before and after each exercise test. **Results** Mean(SD) baseline spleen volume was 193(40) mL before and 270(94) mL after the trek ( $P < 0.05$ ). Baseline Hb was 146.6(11.7) before and 152.1(15.1) g/L after the trek ( $P = 0.15$ ). After submaximal work, spleen volume had decreased by 46(15) mL before the trek, and by 106(47) mL after the trek ( $P < 0.05$ ). After submaximal work, Hb had increased to 153.6(15.0) g/L before- and 162.7(16.7) g/L after the trek (both  $P < 0.05$ ). After maximal work, spleen volume had decreased by 66(21) mL before the trek, and by 116(61) mL after the trek ( $P < 0.05$ ). After maximal work, Hb had increased to 154.4(9.8) g/L before- and 164.2(16.4) g/L after the trek (both  $P < 0.05$ ). **Conclusion** Spleen volume during rest was larger and Hb was slightly enhanced after the high altitude trek. Both spleen contraction and elevation of Hb during exercise were enhanced after the trek. We conclude that the contraction of the spleen during exercise is enhanced in lowlanders as a result of altitude acclimatization. This aligns with observations by Engan et al. (2014) during a Mt Everest climb, despite the shorter duration and more moderate altitude exposure of the current study. The observation of a larger spleen during rest after high altitude acclimatization is novel. A larger storage of erythrocytes in the spleen during rest could serve to lower the blood viscosity associated with polycythemia after high altitude acclimatization. **Reference** Engan HK, Lodin-Sundström A, Schagatay F, Schagatay E. (2014). The effect of climbing Mount Everest on spleen contraction and increase in hemoglobin concentration during breath holding and exercise. *High Alt Med Biol* 15(1), 52-57.

#### SIMILAR INCREASE IN HEMOGLOBIN MASS WITH "LIVE HIGH TRAIN LOW" IN NORMOBARIC AND HYPOBARIC HYPOXIA

Hauser, A.1,2, Saugy, J.J.2, Schmitt, L.3, Cejuela, R.4, Trösch, S.1, Faiss, R.1, Wehrlin, J.P.1, Millet, G.P.2  
*Swiss Federal Institute of Sport Magglingen*

1Swiss Federal Institute of Sport Magglingen, Switzerland; 2University of Lausanne, Switzerland; 3National Ski-Nordic Centre, France; 4University of Alicante, Spain **Introduction** For elite endurance athletes the primary aim of the live high train low (LHTL) altitude training strategy is to improve sea-level endurance performance. The main underlying physiological mechanism is an increase in hemoglobin mass (Hbmass) (Schmidt & Prommer, 2008). A wide range of athletes use technical devices to simulate altitude (normobaric hypoxia: NH). However, so far no study compared the effect of LHTL in NH or LHTL at real altitude (hypobaric hypoxia: HH) with the same hypoxic dose. The aim of this study was therefore to compare Hbmass changes during an 18-days LHTL training camp in either NH or HH with endurance athletes. **Methods** Twenty-eight well-trained male triathletes were split into three groups (NH:  $n = 10$ , HH:  $n = 11$ , control (CON):  $n = 7$ ) and participated in an 18-days LHTL camp. NH and HH slept at 2250 m whereas CON slept and all groups trained at  $< 1200$  m. Hbmass was measured in duplicate with the optimized CO-rebreathing method pre-, post (NH:  $238 \pm 10$  h; HH:  $316 \pm 2$  h) and at day 13 in HH (similar hypoxic dose  $229 \pm 1$  h as in NH) of the altitude training camp. Running (3-km run) and cycling (incremental cycling test) performance were only evaluated pre and post. Two-way ANOVA for repeated measures and Cohen's effect size (d) (Cohen, 1988) were calculated. **Results** After 18-days, both HH (+4.5%,  $d = 0.5$ ,  $P < 0.001$ ) and NH (+4.1%,  $d = 0.5$ ,  $P < 0.001$ ) increased their Hbmass to a moderate extent, whereas the change for CON was small (+1.9%,  $d = 0.1$ ,  $P = 0.08$ ). Hbmass change did not differ between the groups ( $P = 0.14$ ), as well as after the same hypoxic dose ( $P = 0.89$ ). Individual Hbmass responses differed with a large variation within NH and HH (-1.4% - 10.6%). Running performance changed with a moderate effect in the altitude groups (+3.4 - 4.0%  $d = 0.5$ ,  $P < 0.001$ ) and with a small effect in CON (+2.1%,  $d = 0.2$ ,  $P = 0.031$ ), but did not differ between the groups ( $P = 0.27$ ). In cycling performance no changes were detected in any groups ( $d < 0.3$ ,  $P = 0.5$ ). **Discussion** Results indicate that Hbmass changes did not differ between NH and HH with the same hypoxic dose and after 18-days LHTL, as well as did performance indicators. However, individual Hbmass response demonstrated a large variability, which underline the importance of individual evaluation of Hbmass responses to altitude training. **References** Schmidt, W., & Prommer, N. #### LUNG FLUID BALANCE IN HEALTHY HUMANS ACCLIMATING TO HIGH-ALTITUDE

Taylor, B., Coffman, K., Summerfield, D., Issa, A., Johnson, B.  
*University of Exeter & Mayo Clinic*

**Introduction.** The volume of extravascular lung fluid is a function of pulmonary capillary fluid extrusion relative to the rate of fluid removal from the alveoli and pulmonary interstitium. Ascent to high-altitude causes an increase in pulmonary capillary hydrostatic pressure (PCAP) secondary to a hypoxia-mediated constriction of the pulmonary vasculature. In theory, this elevation in PCAP could promote fluid

translocation from the pulmonary vasculature to the interstitial space such that subclinical high altitude pulmonary edema occurs. While rapid, acute exposure to high-altitude (1-3 days) has been shown to increase extravascular lung fluid, whether lung fluid accumulates in humans gradually acclimated to high-altitude remains controversial. Thus, the aim of this study was to assess lung fluid balance before and after gradual acclimation to hypobaric hypoxia in healthy humans. Methods. Lung diffusion capacity for carbon monoxide (DLCO), alveolar-capillary membrane conductance (DmCO), pulmonary-capillary blood volume (Vc), ultrasound lung comets (ULCs) and systolic pulmonary artery pressure (sPAP) were assessed in 12 healthy adults at sea-level and on Day 1 (D1) and Day 9 (D9) after arrival at 5,150 m (Mt. Everest Base Camp, EBC). EBC was reached following an 8-10 day hike at progressively increasing altitudes starting at 2,860 m. Results. From sea-level to EBC, there was an increase in group mean sPAP (D1:  $54 \pm 27\%$ ,  $P = 0.014$ ; D9:  $62 \pm 38\%$ ,  $P < 0.01$ ). Group mean DLCO was unchanged on D1 and D9 at EBC compared to sea-level ( $41.0 \pm 6.9$  vs.  $40.4 \pm 6.3$  vs.  $38.4 \pm 4.8$  ml/min/mmHg). By contrast, DmCO increased from sea-level to D1 ( $85.3 \pm 10.2$  vs.  $91.6 \pm 8.2$  ml/min/mmHg;  $P 0.037$ ), with a further increase in DmCO on D9 at EBC ( $96.0 \pm 8.9$  ml/min/mmHg;  $P = 0.022$  vs. Day 1); Vc was unchanged. Accordingly, there was an increase in the DmCO/Vc ratio from sea-level to D1 and D9 at EBC ( $0.71 \pm 0.18$  vs.  $0.78 \pm 0.25$  vs.  $0.80 \pm 0.22$  ml CO/min/mmHg/ml blood); only the change from sea-level to D9 was significant ( $P = 0.026$ ). There was no change in the number of ULCs from sea-level ( $2 \pm 2$ , range 0-5) to D1 at EBC ( $2 \pm 2$ , range 0-7). There was, however, a slight reduction in ULCs on D9 at EBC vs. at sea-level ( $0.6 \pm 0.7$ , range 0-2;  $P 0.079$ ). Discussion. These data suggest that extravascular lung fluid does not increase in healthy humans gradually acclimated to high-altitude. In fact, the combined findings of an increase in the DmCO/Vc ratio (indicative of improved conductance across the alveolar-capillary barrier) and a reduction in the number of ULCs (an index of extravascular lung fluid) suggest that, if anything, there is a tendency for a reduction in lung fluid volume during acclimation to high-altitude.

### THE EFFECT OF LIVE HIGH TRAIN LOW ALTITUDE EXPOSURE ON THE POST-EXERCISE HEPCIDIN RESPONSE

Govus, A.D., Peeling, P., Abbiss, C.R., Lawler, N., Swinkels, D.W., Laarakkers, C., Thompson, K.G., Peiffer, J.J., Gore, C.J., Garvican-Lewis, L.A.

*Edith Cowan University*

Purpose: To investigate the influence of 14 days live high, train low (LHTL) altitude exposure (14 h.d-1, at 3,000 m simulate altitude) on resting and post-exercise hepcidin and iron parameter responses in distance runners. Methods: Ten well-trained distance runners (six males, four females) performed a  $6 \times 1,000$  m interval running session at 90% vVO<sub>2</sub>max in both normoxic (NORM) and simulated hypoxic (3,000 m) conditions (HYP) before, and again on the 11th and 14th day respectively of LHTL. Venous blood samples were collected after 48 h of altitude exposure, as well as before, and 3 h after all experimental trials. Blood samples were analysed for plasma hepcidin, iron, ferritin, transferrin and transferrin saturation (TSAT). Haemoglobin mass (Hbmass) was measured one week before, and two days after altitude exposure via CO rebreathing. Results: LHTL decreased resting hepcidin levels by 2.8 nM [95% CI; -3.7, -5.9] from  $4.0 \pm 1.2$  nM to  $1.2 \pm 0.2$  nM after 48 h ( $p < 0.01$ ). NORM and HYP elevated hepcidin levels by 39.3% [8.0, 79.6] ( $p = 0.02$ ) and 64.5% [16.9, 131.6] ( $p < 0.01$ ) 3 h following interval exercise performed before LHTL. The post-exercise hepcidin response was not different following NORM ( $p = 0.10$ ) and HYP ( $p = 0.37$ ) performed during LHTL. Resting ferritin levels decreased by 27.6% [-37.9, -15.5] and 29.9% [36.2, 22.9] following 11 and 14 days of LHTL, respectively. Finally, LHTL increased Hbmass by 2.2% [1.0, 3.4] ( $p < 0.01$ ). Conclusion: LHTL altitude exposure attenuated resting hepcidin levels but did not alter the magnitude of the post-exercise hepcidin response to normoxic and hypoxic interval exercise.

### OP-PM69 Adapted Physical Activity: Mental disabilities

#### SUICIDE PREVENTION THROUGH SPORTS PARTICIPATION. QUANTITATIVE RESEARCH OVERVIEW

Van Coppenolle, H., Belousova, S., Jespersen, E.

*Faculty of Kinesiology and Rehabilitation Sciences KU Leuven*

Introduction Suicide is one of the most important problems in the world. It is estimated that the annual suicide rates can rise to 1.5 million by the year 2020. It is known that physical activity and sports can have a great potential in suicide prevention and enhancing mental health effect. In this study we summarize literature results concerning the protective value of physical activity and sports participation against suicidal ideation. Methods The search for relevant articles was done by the PUP Med Database as well by Springer Link. The recent studies were selected from 1994- to 2013. Results In the majority of the studies the findings indicate that involvement in physical activity and sports is associated with lower odds of suicidal ideation and attempts. The results also highlighted that sports participation leads to boosting self-esteem and increasing social support. These findings have led to the assumption that physical activity and involvement in sports have a strong protective value against suicidality. Discussion From this assumption we will go one step further and research if an individualised adapted physical activity and sports program for persons with suicidal ideation has a suicide preventive effect. **A THEMATIC ANALYSIS OF HIGH PERFORMANCE COACHING ROLES AT THE SPECIAL OLYMPICS WORLD GAMES**

Hassan, D., McConkey, R., Dowling, S., Menke, S., Taylor, D.

*Ulster University*

Coaching athletes preparing for competition at the Special Olympics World Games requires the implementation of a cooperative coaching approach, borne from an athlete-centered philosophy, in which the focus on holistic personal development eclipses winning. Thus central to effective coaching in this context is being able to transform and adapt content knowledge held by the individual coach (coaches' pedagogical content knowledge) for the positive benefit of their athletes. This issue was the subject of a longitudinal study undertaken by Ulster University prior to, during and following the Special Olympics World Games of 2011 staged in Athens. The findings that emerged from this work were extracted using thematic content analysis allowing full immersion in the data, which resulted in the emergence of three prominent themes with subsequent, associated subthemes – using a holistic approach to coaching, building athlete identity and development through sport and capturing the big World Games experience. The findings from this work retain the potential to shape the future coaching and preparation of athletes with intellectual and developmental disabilities for elite competition.

**MIDDLE SCHOOL STUDENTS' ACCEPTANCE ATTITUDE TOWARD THEIR MENTALLY RETARDED PEERS AFTER COOPERATIVE LEARNING AT AN INCLUSIVE PHYSICAL EDUCATION CLASS**

Liu, S.

*Graduate Institute of Sport Pedagogy*

Introduction For students with mental retardation, teachers and peers' attitude is the critical factor affecting them to successfully involve in an inclusive learning environment. Previous studies have reported that cooperative learning at inclusive physical education classes would promote the social interaction and communication skills of disabled students (Putnam, 1993). However, little research has ever investigated whether cooperative learning strategy can enhance normal students' positive attitude toward their mentally disabled peers. The purpose of the study examined the effect of cooperative learning at an inclusive physical education course on normal students' attitude toward their peers with mental retardation. Methods Thirty-four eighth-grade students (15 boys and 19 girls) were recruited as the participants. All participants accepted an 8-week inclusive physical education program utilizing cooperative learning strategy, 45 minutes per class, two classes a week. The participants were heterogeneously assigned to the contact group and none-contact group. For the contact group, the participants were arranged to learn with five mentally disabled peers, whereas the none-contact group was not. The questionnaire evaluating the attitude toward peers with mental retardation was administered before and after the program. The analysis of covariance was applied to analyze the collected data. Results The result showed that after the "cooperative learning at inclusive physical education", the difference in attitude was not observed between the contact group and none-contact group. Discussion Similar to our finding, Archie and Sherrill (1989) found no significant difference in attitude between the contact group and none-contact group. However, they reported that the members of the contact group responded that the courses were more interesting. Normal students seemed to require a longer duration of inclusive activities to realize how to help their disabled peers and reduce their pressure (Goodwin & Watkinson, 2000). On the other hand, Hutzler (2003) summarized that cooperative learning might fail to induce positive affection without effectively personal interaction between normal and disabled students. Although no significant improvement of attitude was found in this study, future research could apply depth interview to investigate why positive effects do not occur. References Archie, V. **Oral presentations****OP-PM74 Molecular Biology and Biochemistry: Fatigue****CORTICAL EXCITABILITY, VOLUNTARY ACTIVATION, AND QUADRICEPS STRENGTH CHANGES AFTER MAXIMAL INTENSITY PLYOMETRIC EXERCISE**

Vácz, M.1, Négyesi, J.2, Rio-Rodriguez, D.3, Fernandez del Olmo, M.3

*University of Pécs*

1 PTE (Pécs, Hungary) 2 HUPE (Budapest, Hungary) 3 INEF (A Coruna, Spain) Introduction The stretch-shortening cycle (SSC), in forms of plyometric exercises, is extensively used by practitioners and athletes in performance training. During repetitive SSCs fibers are exposed to high mechanical tension, which contributes to acute fatigue and delayed myofibrillar damage, muscle soreness, and temporary strength loss. Here we investigated the acute and delayed changes in the neuromechanical properties of the quadriceps muscle after maximal intensity SSC exercise, using the conventional electrical stimulation and the transcranial magnetic stimulation (TMS) techniques. Methods Ten non-athlete males performed 150 single-leg hurdle jumps. Maximal voluntary contraction (MVC) force in the quadriceps was determined using a modified leg extension machine attached to a cell force. Voluntary activation was determined using the twitch interpolation technique. Subjects also performed another MVC superimposed with 100-Hz doublet followed by a 10-Hz doublet delivered 4 s apart to determine high and low frequency fatigue, respectively. Electromyography (EMG) was recorded from the quadriceps. Resting motor evoked potentials (MEP) were determined by stimulating the contralateral motor cortex using TMS. Perceived muscle soreness was evaluated using a visual analogue scale. All variables were measured before, immediately (IP), and 24h post-exercise. Results MVC dropped 9% at IP ( $p < 0.005$ ) and fully recovered at 24h. Voluntary activation dropped 6% at IP ( $p < 0.05$ ) and recovered at 24h. Resting single twitch force dropped 23% at IP ( $p < 0.005$ ) and recovered at 24h. Low frequency fatigue was greater (28%,  $p < 0.05$ ) than high frequency fatigue (5%,  $p < 0.05$ ) at IP, however, these values recovered at 24h. Compared to the baseline, MEP amplitudes were 75% smaller at IP but recovered at 24h. Muscle soreness developed at 24h (from 0 mm to 12 mm on the 50 mm scale). Discussion The intensive unilateral SSCs induced acute strength loss in the quadriceps due to neuromuscular fatigue. The reduced voluntary activation and motor cortex excitability indicate central fatigue, an insufficient driving of the motoneurons, however peripheral fatigue (reduced twitch force) seems to contribute more to the acute strength loss. Though mild soreness developed, indicating some muscle damage, neuromuscular performance recovered 24h post-exercise. Contact vaczi@gamma.ttk.pte.hu

## TWO MAXIMAL ISOMETRIC CONTRACTIONS REDUCE MUSCLE DAMAGE AFTER 30 MAXIMAL ECCENTRIC CONTRACTIONS OF CONTRALATERAL ARM

Nosaka, K., Chen, T.C., Lin, M.J., Yu, H.I., Chen, H.L.

*Edith Cowan University*

**Introduction** The magnitude of muscle damage after 30 maximal voluntary eccentric contractions (30MVEC) of the elbow flexors (EF) was attenuated by 2 maximal voluntary isometric contractions (2MVIC) at 20° elbow flexion of the same performed 2 or 4 days earlier [1]. Muscle damage is also less after the second than the first eccentric exercise bout even when the contralateral arm is used for the second bout, which is known as the contralateral repeated bout effect (CL-RBE) [2,3]. However, it is not known whether the protective effect conferred by 2MVIC is transferred to the contralateral arm. The present study investigated the hypothesis that 2MVIC of one arm would confer protective effect on the opposite arm that performed 30MVEC within 4 days. **Methods** Young untrained men ( $21.9 \pm 1.4$  y) were placed into five groups ( $n=13$ /group); one control and four experimental (EXP) groups. The EXP group performed EF 2MVIC at 20° elbow flexion either 1 (1d), 2 (2d), 4 (4d) or 7 days (7d) prior to 5 sets of 6 maximal voluntary isokinetic (30°·s<sup>-1</sup>) eccentric contractions (30MVEC) of the other arm. The control group performed 30MVEC without 2MVIC using the non-dominant arm. Changes in maximal voluntary concentric contraction torque, optimum angle, range of motion, upper arm circumference, plasma creatine kinase activity and myoglobin concentration, muscle soreness and B-mode ultrasound echo intensity for the exercised muscles before, immediately after and 1-5 days after 30MVEC were compared amongst the groups by a two-way repeated measures ANOVA. **Results** No significant changes in any dependent variables were evident after 2MVIC. All dependent variables showed significant ( $P<0.05$ ) changes after 30MVEC, but the changes were smaller ( $P<0.05$ ) for the 1d and 2d groups compared with the control group, without significant differences between the 1d and 2d groups. No significant differences in the changes were found amongst the 4d, 7d and control groups, except for muscle soreness showing significantly ( $P<0.05$ ) smaller changes for the 4d group than other groups. **Discussion** These results partially supported the hypothesis, since the contralateral protective effect conferred by 2MVIC lasted for 2 not 4 days. The magnitude of the protective effect by 2MVIC found in the present study was smaller by approximately 20% than that found in the previous study [1] in which the same arm was used for 2MVIC and 30MVEC. These results suggest that some neural adaptations are associated with the CL-RBE. **References** 1) Chen et al. ## EFFECT OF NEUROMUSCULAR ELECTRICAL STIMULATION FREQUENCY ON VOLUNTARY NEURAL DRIVE

Grospretre, S., Gueugneau, N., Martin, A., Lepers, R.

*INSERM U1093*

**INTRODUCTION** The force loss induced by neuromuscular electrical stimulation (ES) can be related to acute changes at muscle level, particularly when using high ES frequencies [1]. However it has been suggested that with such frequencies (>80Hz) the decrease of maximal voluntary contraction (MVC) after ES protocol can also be attributed to neural mechanisms [2]. The aim of the study was to analyze the impact of ES protocols with low to high frequencies on voluntary neural drive, assessed by H- and V-wave responses evoked during MVC. As the electrically induced torque vary according to the ES frequency [3], the same muscular activity was assessed by matching the torque time integral (TTI) across ES protocols. **METHOD** Eight healthy subjects performed 3 testing sessions with 3 ES protocols (randomly assigned) combining pulse width of 1ms with ES frequencies of 20, 60 and 100Hz. Triceps surae muscle was stimulated by two rectangular electrodes placed on calf muscles at ES intensity evoking 20% of MVC. Plantar flexion torque and electromyographic activity of soleus muscle were recorded continuously. During the first session, 40 stimulation trains (6s on/ 6s off) were delivered, while for the following sessions the number of trains was adjusted to match TTI obtained in the first session. Before and after ES protocol, subjects performed MVC and electrical stimulation of the posterior tibial nerve, evoking H- or M-wave responses, was delivered on the torque plateau. The following parameters were analyzed: MVC torque, H reflex (Hs), M wave (Ms) and V wave amplitudes. **RESULTS** For the similar TTI (5756.4  $\pm$  277.6 Nm.s), the number of contractions performed by subjects was significantly different between ES protocols (from 36.8 $\pm$ 1.6 at 20Hz to 44.1 $\pm$ 2.5 at 100Hz). After ES protocol, the MVC decreased by 9.9 $\pm$ 3%, 10.9 $\pm$ 3% and 14.5 $\pm$ 3% with 20Hz, 60Hz and 100Hz respectively. This decrease was greater for 100Hz than for 20Hz protocol ( $P<0.05$ ). Hs/Ms decreased by 31.2 $\pm$ 4.4 % after 100Hz ( $P=0.01$ ) while V/Ms decreased after 60Hz and 100 Hz protocols by ~31% ( $P=0.05$ ). **DISCUSSION** For ES protocols with similar TTI, a greater MVC loss was observed after the 100Hz protocol. This greatest force loss was accompanied by a reduction in both spinal excitability and cortical descending drive evidenced by a decrease in H- and V-wave amplitudes respectively. The 60Hz protocol altered only the cortical descending drive. It can be concluded that for the same pulse width, the higher the ES frequency used, the greater the decrease in voluntary neural drive that involve mechanisms located at cortical and spinal levels. **REFERENCES** (1) Gregory CM & al., *Muscle Nerve* 2007; 35:504-7. ## INTERMITTENT THETA BURST OVER M1 CAN IMPROVE THE PEAK POWER IN A WINGATE TEST AND SUPPRESS THE SUBSEQUENT SUPRASPINAL FATIGUE

Giboin, L., Thumm, P., Bertschinger, R., Gruber, M.

*Universität Konstanz*

Despite the fact that repetitive transcranial magnetic stimulation (rTMS) is known to improve performances in patients suffering from motor neuronal afflictions, its possible effect on motor performance enhancement in healthy subjects during a specific sport task hasn't been tested yet. We hypothesised that intermittent theta burst (iTBS) induces a higher power output and a greater resistance to supraspinal fatigue during a popular sport specific test, the Wingate Anaerobic Test (WAnT). Ten subjects participated in two randomised experiments separated by at least 2 days, consisting of a WAnT 5 minutes after either an iTBS or a SHAM treatment. Voluntary activation (VA) of the right vastus lateralis was estimated with TMS (VATMS) over the quadriceps motor cortex area and also with peripheral nerve stimulation (VAPNS) of the femoral nerve, before and after the WAnT. Muscle twitches size at rest and motor evoked potentials (MEPs) given at 10% maximal voluntary contraction (MVC) were also measured. Tests were applied on WAnT results and 2 ways ANOVA with repeated measures on VA estimations, muscle twitch size at rest and MEPs. The iTBS treatment increased the peak power during the WAnT (961.1 $\pm$ 51.3 W for SHAM and 970.7 $\pm$ 51.1 W for iTBS,  $p=0.037$ ) and suppressed the reduction of VATMS following the WAnT compared to the SHAM treatment (time effect:  $p=0.001$ , time \* treatment effect  $p=0.001$ ), but not of VAPNS. There was no difference of decrease of the size of the muscle twitches at rest between the treatments, and no difference of MEP size pre and post WAnT and between the treatments. We have shown for the first time that iTBS applied 5 minute before a WAnT can enhance the peak power and suppress

the subsequent supraspinal fatigue. The use of iTBS in order to improve sport performances and to study mechanisms of supraspinal fatigue may be warranted.

### HETEROGENEOUS MUSCLE ACTIVITY DURING ISOMETRIC CONTRACTION – A VE-PC MRI STUDY

Csapo, R., Malis, V., Sinha, U., Sinha, S.

*University of Innsbruck*

**Background** During submaximal contraction, skeletal muscles are not uniformly activated. Rather task groups of motor units are recruited in dependency of the specific demands of movements. While most commonly used to study such recruitment patterns, EMG is limited by its low spatial resolution, small area of detection, and inability to resolve along the depth direction. An alternative approach is represented by a dynamic (velocity-encoded phase-contrast, VE-PC) MRI technique, which provides 3D information about the displacement of tissues and facilitates measurements with great resolution over large areas of interest. However, the congruence of EMG and VE-PC-based measures of muscle activity has not been established yet. **Aims** (1) To determine the correlation of EMG and VE-PC data obtained during submaximal, isometric contraction. (2) To use VE-PC MRI for an in-depth analysis of the contractile behavior of the human triceps surae complex. **Methods** Ten healthy subjects (3 females,  $27.0 \pm 6.2$  yrs,  $169.6 \pm 11.8$  cm,  $69.3 \pm 13.7$  kg) were tested for isometric plantarflexion MVC strength. Subsequently, 10 axial-plane VE-PC MRI scans (distributed evenly across the triceps surae) were obtained while subjects performed the ~70 submaximal contractions (40% MVC) required for image acquisition. EMG data from the soleus (SOL) and gastrocnemius muscles (GM, GL) were then obtained under identical experimental conditions. Integrated EMG and VE-PC data were averaged over all contraction-relaxation cycles and correlated against each other. To assess the regional heterogeneity in muscle activity, VE-PC data were statistically compared both between and within slices, and visualized as 3D color maps of muscle movement. **Results** Correlational analyses demonstrated good agreement between EMG and VE-PC-based measures of muscle activity in the entire triceps surae complex (GM:  $r = 0.87$ ; GL:  $r = 0.88$ ; SOL:  $r = 0.84$ ;  $p < 0.001$ ). Comparison of VE-PC data across slices revealed substantial differences between caudocranial positions. In the GM and GL, muscle tissue movements were significantly larger in the center than in the proximal ( $U = 7.5$ ,  $p = 0.006$ ) and distal ( $U = 8.0$ ,  $p = 0.030$ ) regions, respectively. Heterogeneity was also observed within slices, with "hot" regions evidencing tissue displacements that were 3-6 times larger than those seen in "cold" regions. **Conclusions** In spite of the different underlying physiological principles, VE-PC MRI demonstrates good agreement with EMG data and may be used to study muscle activity with high spatial resolution and in large areas of interest. Application to the human plantarflexor muscles revealed startling heterogeneity of contraction-associated tissue movements.

### OP-SH13 Sociology/Psychology (Talent identification)

#### IDENTIFYING TALENT: THE CASE OF THE SWEDISH FOOTBALL ASSOCIATION

Lund, S.1, Brusvik, P.2, Renström, A.3, Söderström, T.4

*Institution of Sport Science*

**Introduction** The purpose of this paper is to explore how football coaches select 15-year old players to their regional teams. Drawing on Bourdieu, MacCormick and Wenger's work we challenge the common-sense assumption that talent identification is an objective process. Using this broad set of theoretical perspectives, there is also an ambition to refine the sociological theorization of talent identification (e.g. Christensen, 2009). **Method** The analysis is based upon interviews with 19 coaches that participate in the process of identifying the most talented players in their regional district. The three football districts that participate in the study are chosen with regard of size, geographical location and previous results in national tournaments. This case study approach, is well-suited for answering questions of social process and designed for the study of contemporary social phenomenon in context, especially when it is not possible to clearly distinguish the context and the phenomenon (Yin 2009). **Results** Our data indicated that these coaches identified talent in four interrelated ways. First, the coaches' uses classification schemes in order to objectify and legitimize the identification process, e.g. previous results, physique, training background, technical skills, attitude, and social adaptability. Secondly, coaches use their visual experience and practical sense in order to define talent. Thirdly, classification and practical sense is closely related to narratives of elite football and previous successful identification processes. Fourthly, the identification process takes place within a community of practice. The communicative and social interaction between the coaches and their shared passion for football structure their learning processes towards a similar understanding of how to see and find talent. **Discussion** Our results show that talent is a social construction, which is expressed through the experience, knowledge and taste of the coaches that uphold the authority to demarcate talent from non-talent. **References** Bourdieu, Pierre (1998). *Practical reason*. #### TALENT SELECTION IN SWEDISH YOUTH FOOTBALL: THE RELATIVE AGE EFFECT AND PARENTAL SUPPORT

Renström, A., Söderström, T., Lund, S.

*Umeå University*

**Introduction** This study reports empirical data from an ongoing project, investigating talent development in football. The purpose is to examine predictors that impact on 14-year old football players' possibilities to enter and proceed through the Swedish Football Association's talent development system. Drawing on deliberate practice and deliberate play (Côté, Baker & Abernethy, 2003), the relative age effect (RAE) (Romann & Fuchloser, 2011) and sporting habitus (Bourdieu, 2010) we focus on football training in clubs and school, training time in football and other sports, birth dates and parental support. **Method** The analysis is based upon questionnaires from one large and one medium district. The study included 166 boys and 117 girls who at the age of 14 participated in the first selection camp at each district. They were then followed until their last selection the year thereafter, in which 16 boys and 16 girls were selected to represent the

district in a national elite camp. Result The results show that 67% of the boys and girls were born in the first six months, RAE then increased for boys, with 83% in the last selection being born the first six months girls RAE were constant. Boys practiced more football both in and outside their club, 61% of the boys and 40% of the girls reaching the last selection practiced 7 hours or more in their club. 33% of the boys and 8% of the girls practiced 5 or more hours on their own. For girls selected, on each level parental support was stronger than for not selected girls, for both boys and girls who were selected for the final district team parental support was almost twice as big in terms of presence at games and practice. The parents of the players who were selected had to a great extent a competitive sport background. Discussion The results show that RAE is a threshold for entering the system and then increase for boys. The 14-year old football players' proceeding through to the district team seem to be related to training hours, especially for boys, and parental support, especially for girls. These results suggest a need to further explore how these factors shape the selection processes for boys and girls and the recruitment of the final 16 players in the district team References Bourdieu, P. (2010). *Distinction: A Social Critique of the Judgment of Taste*. London: Routledge Côté, J., Baker, J. & Abernethy, B. (2003). ### **PARTICIPATION IN NON-ELITE SPORT IN EARLY ADULTHOOD: THE IMPACT OF ATHLETIC ABILITY IN CHILDHOOD AND ADOLESCENCE**

Söderström, T.1, Fahlén, J.1, Ferry, M.1, Yu, J.2

*Umeå university*

Introduction Understandings of, explanations to, and predictors of adult participation in organized sport, on the one hand, and expert performances in organized sport as adults on the other hand have received a lot of attention as separate entities by scholars in the areas of sport participation and sport expertise alike. Although scholars in both fields share an interest in tracing explanatory factors and predictors, it is evident that sport participation research has not investigated the impact of factors that are in focus in sport expertise research and vice versa. Thus, in this paper we aim to explore relationships between sport performance during childhood and adolescence and participation in sport in adulthood. Methods Data were derived from Web-based questionnaires completed by university students between 2005 and 2012. In total, 572 students (290 men and 282 women) completed the questionnaires. These students were at the beginning of their studies in sports science (n=357) and physical education teacher education (n=215). The questionnaire gathered information about the following topics: • Biographical data: date of birth; • Sport debut: age they started to participate in organized club sports; • Sport performance: self-estimated sporting skills and participation in regional talent groups during childhood and adolescence. • Sport involvement: previous and present involvement in organized club sports; Results Results from questionnaires reveal that early sport debut and date of birth positively correlate to strong sport performances during childhood and being selected for talent groups. These variables, in turn, are positively correlated to strong sport performances during adolescence and being selected for talent groups. Strong sport performances during adolescence do not correlate to expert performance as adults. However, strong sport performances during adolescence are positively correlated to sports club membership as adults. Discussion These results suggest a need to further explore how factors found to be important for elite sport practice and expert performance, also influence non-elite sport participation in adulthood. Our findings suggest that talent development system selecting children and youth to develop their abilities and to become elite athletes, not only develops potential elite athletes but also shapes the larger recruitment of adults to sport at non-elite levels and participation in general exercise activities.

### **A SOCIAL LEARNING PERSPECTIVE ON SUCCESSFUL TALENT DEVELOPMENT ENVIRONMENTS: A QUALITATIVE STUDY OF TWO EXCEPTIONAL HANDBALL CLUBS IN SCANDINAVIA**

Storm, L.K., Christensen, M.K., Ronglan, L.T.

*University of Southern Denmark*

Introduction The social learning perspective is rarely used for the study of talent development in sport, although it is broadly known in the domain of education. This study examines the ways in which social practice underpins talent development in team sport in two exceptional successful talent development environments in Scandinavia: (1) The way in which communities of practice are connected, (2) what characterises talents' movements across communities of practice within the club, and (3) what characterises the interactions between talents, senior players and coaches. Methods The study was a case study of two successful talent development environments in Scandinavian handball. The selection of two most similar clubs was based on three criteria: (1) demonstrated sustained and consistent ability to create senior elite athletes out of their talented juniors; (2) were recognised as a great environment for athletic development by the national federation; and (3) were accessible and willing to share details of their day-to-day practices with the principal researcher. The study was based on fieldwork (participant observation and qualitative interviews): 150 and 100 hours of participant observation in each environment, and 17 and nine interviews with players, coaches and managers. The analysis proceeded in three stages: open coding, organising data into topics (e.g. social processes, organisational set-up) and focused analysis and interpretation of discrete parts. The social theory of learning (Wenger, 1998) informed the data analysis. Results The two environments were characterised by (1) a constellation of several interconnected communities of practice (CoPs). The boundary encounters, overlaps and peripheries were important 'windows' and 'places' for the talents' learning and development. (2) Opportunities for talents to participate and engage in various CoPs. (3) Individually adjusted feedback from coach to player combined with communication between the talents and experienced players and not only coach instructions, and (4) senior elite players' engaging behaviours in regard to newcomers and thereby legitimate peripheral participation opportunities for talented players. The coaches were the key to coordinate the interconnected practices and social interactions between the 'youth CoP' and 'senior elite CoP'. And the senior elite players' behaviour had great influence on the talents learning within the club. Discussion The interaction and coordination between and/or across the CoPs and the proximal role modelling is discussed as a crucial contributing reason to successful talent development. Wenger, E. (1998). *Communities of practice. Learning Meaning, and identity*. NY: Cambridge University Press. Contact lkstorm@health.sdu.dk

## PARENTAL CREATED MOTIVATIONAL CLIMATE AND WELL-BEING AMONG YOUTH ELITE ATHLETES

Holmstrom, S.1, Stenling, A.1, Jansson, J.1, Gustafsson, H.2

*1Department of Psychology, Umeå University, Sweden 2Department of Health and Environmental Sciences, Karlstad University, Sweden*

Parents have a large impact on children's psychological development and socializing into sports. Parental support, praise, and compliments have been found to boost children's perception of their skills, satisfaction, and positively influence children's interest in sport activities (Bois et al., 2005). Another aspect of support, praise, and compliments is that parents socialize their achievement perceptions to their child through their own beliefs about what is important and what leads to success in sport, by the use of different reward systems (White et al., 2004). Support, praise, and compliments can be seen as innocent statements by a parent, however, such statements can create a parent-initiated motivational climate that focus on results and outcome, which can have implications for the child's motivation and well-being later on. The aim of this study was to explore how the perceived parent-initiated motivational climate and athletes' perceived sport competence is related adolescent athletes' well-being and depression/anxiety. Methods: 259 athletes (alpine skiers, biathletes, cross-country skiers) from 16 to 20 years of age participated in this cross-sectional study. Athletes' perceptions of the climate initiated by their parents was assessed with the PIMCQ-2 and perceived sport competence was assessed with a subscale from the BNSSS. The athletes' psychological well-being was measured with the GHQ-12. Results: The results indicate that male athletes experience higher levels of well-being and lower levels of depression/anxiety compared to female athletes. In the first hierarchical regression model with well-being as outcome variable, the overall model explained 33 % of the variance. Gender, a mother-initiated learning/enjoyment climate, and perceived sport competence were positive predictors of well-being. The second hierarchical regression model with depression/anxiety as outcome variable, explained 21 % of the variance. Mother-initiated learning/enjoyment climate and a father-initiated worry-conducive climate positively predicted depression/anxiety, while perceived sport competence negatively predicted depression/anxiety. Conclusions: One result that stands out in the study is that mother-initiated learning/enjoyment climate positively predicted depression/anxiety. This is a result which is not in line with earlier results or theory. Experience of perceived competence is an important protector from feelings of depression and/or anxiety, and has an important role in children's experience of well-being. References: Bois et al., (2005). *J Appl Spo Psy* 17: 273–289 White et al., (2004) *Scand J Med Sci Spo* 14: 57-66

## SWEDISH JUNIOR ATHLETES' PERSONAL PROFILES IN RELATION TO THE DYNAMICS OF ADJUSTMENT IN THE JUNIOR-TO-SENIOR TRANSITION

Franck, A., Stambulova, N.

*University of Halmstad*

According to previous research, the junior-to-senior transition (JST) is decisive for athletes who want to reach the elite/professional sport level, it lasts for 2-4 years, and is known for its high dropout rate. The longitudinal study of the junior-to-senior transition process in Swedish club-based athletes conducted by the authors involved several lines of data analysis with this presentation focusing on the dynamics of athletes' junior-to-senior transition adjustment in relation to their personal characteristics. The study had five measurements conducted every six months using several instruments; these instruments measured the athletes' level of athletic identity, task- and ego orientation, self-esteem and adjustment in the transition process. The latent profile analysis identified three profiles (based on athletes personal characteristics; BIC = 771.11; entropy = 0.87; Parametric Bootstrapped likelihood ratio test = -356.07,  $p < 0.001$ ). In the profile-1, athletes (34 males and 11 females) were characterized by high athletic identity, self-esteem, task orientation, and the JST motivation; they also had moderately high ego orientation. These athletes perceived to be 72 % adjusted at the first measurement, had a positive progression through the transition process, and at the fifth measurement perceived to be 83 % adjusted at the senior level. In the profile-2, athletes (30 males and 7 females) perceived themselves to have high self-esteem and the JST motivation, relatively high athletic identity and task orientation complemented by moderate ego orientation. They perceived themselves to be 66 % adjusted at the first measurement, had a positive progression through the transition process, and at the fifth measurement perceived themselves to be 73% adjusted. In the profile-3 athletes (9 males and 9 females) reported high self-esteem, relatively high task orientation, as well as moderate athletic identity, ego orientation and the JST motivation. These athletes perceived to be 62 % adjusted at the first measurement, had almost no progression through the transition process, and at the fifth measurement perceived themselves to be 64 % adjusted. These findings supported our hypothesis that athletes with different profiles of personal characteristics follow different pathways through the JST process. The JST pathways are going to be explored more in detail with the aim to understand transition variables contributing to the dynamics of perceived adjustment. Further this knowledge can be used in assisting athletes in the JST.

### OP-SH14 Sociology: Sport media

#### GREENING JOURNALISM EDUCATION

Krøvel, R.

*Oslo and Akerhus University College, Norway*

Introduction: This paper intends to reflect on how journalism education can respond to ecological crisis in times of hyper-consumerism. Sports have real and serious environmental consequences. Maxwell and Miller has demonstrated the many ways media contribute to environmental degradation while, at the same time contributing to constructing a vision of new communication technologies as environmentally cost free. However, modern sports and media are entangled in a web of hyper-consumerism and commodification. For instance, when events such as the World Cup, the Euros, and the Champions' League are planned and executed, they leave ruinous ecological costs due to travel and use of electronics as their permanent legacies. As Maxwell and Miller correctly states in "Greening Media Education", this presents media and journalism educations with some serious ethical and pedagogical questions to ponder (Maxwell & Miller, 2015). Methods: The paper draws on existing journalism studies syllabus at Norwegian Journalism Schools to reflect on current teaching on environmental issues. It further draws on existing research on values and norms among journalists and students of journalism in Norway to analyze the role and social responsibility of journalism education (Krøvel, 2015, Forthcoming). Finally, the paper is experienced based in the sense that it makes use of experience gained over seven years of teaching sports journalism to journalism students.

Discussion We find that very little attention is paid to environmental issues in Norwegian journalism education. What is offered, is typically given in courses for students with a "special interest" in environmental issues. Environmental degradation due to sports and mega events, for instance, is hardly mentioned during courses in sports journalism. The compartmentalization of different subjects into sections resembles the differentiation found in newspapers between sections. The paper ends with a discussion employing the concept of a "total view" to discuss "greening journalism education". According to Næss, we should not expect much from specialists. Instead, what is needed is "enlightened generalists" willing to develop "total views" in contrast to the on-going process of ever-greater specialization and reductionism (Næss & Rothenberg, 1989).

### **ATTITUDES TO ENVIRONMENTAL SUSTAINABILITY OF FOOTBALL FANS IN ENGLAND: A CASE STUDY**

Kiernan, A.

*Centre for the Study of Football, Manchester Metropolitan University*

When the issue of sustainability is discussed by English football fans, it tends to be financial and social sustainability that tops the agenda. There are football fans who are politically and culturally aware and have set up clubs and supporters' trusts that they hope will reflect their ideals, but these rarely have anything to do with environmental concerns. The hope for many is that clubs will adopt policies that are inclusive and do not involve pricing people out of attending football matches. There are, however, some examples of environmentally sustainable stadiums in England – Forest Green Rovers' New Lawn is one such example, while Dartford's Princes Park is another. The paper will look at trends in environmentally sustainable stadium design. It will also examine how attitudes of fans and the media to the environmental policies of Forest Green Rovers in particular (the stadium is run on "clean" energy and there is a ban on meat products as these are considered not environmentally friendly) have impacted on the issue of environmental sustainability in English football. Key-words: Media, sustainability, football fandom

### **WHERE THE GRASS IS ALWAYS GREENER': FOOTBALL FANS TALKING - AND NOT TALKING - ABOUT ENVIRONMENTAL ISSUES**

Sandvoss, C.

*Sport Dep*

Football fandom constitutes an important part of the contemporary public sphere, (Sandvoss 2003, 2011, Ruddock 2007) in particular within the distinct spaces of debate through fans' enunciative productivity in online fan fora and on terraces themselves. However, while being an important space of political debate and civic participation, football fandom is no neutral medium of political discourse but shapes debates in two important respects. Firstly, debates among scholars of political communication and football fans follow curiously synchronous lines. While the first group has lamented the popularization and thus trivialisation of politics in which sport has played an important role, the latter has objected to the politicisation of sport. Secondly, participation in the public sphere through the prism of the fandom profoundly shapes the substance and form of political discourses among fans. This paper explores debates about the environmental impact of football and football fandom on football fan fora in two of Europe's top five football markets with different political cultures and propensities to environmentalism: England and German. Studying five online fora in each of these markets, through a mixed methods approach including quantitative content analysis, in-depth interviews and a CASI online survey this paper explores the interplay between discourses of environmentalism, political beliefs and fandom, suggesting that recent work on fan activism (cf. Jenkins 2013) overstates the politically progressive potential of participatory culture in traditional spaces of popular culture such as football.

### **FLATSCREENING FOOTBALL: ECOLOGICAL PERSPECTIVES ON ELECTRONIC SPECTATORSHIP**

Vestberg, N.L., Raundalen, J.

*NTNU Norwegian University of Science and Technology*

Along with the Olympics, major football championships provide important occasions for the electronics industry to market newer, bigger and supposedly better gadgets for screen-based football spectatorship. They are also useful pretexts for digital service providers to persuade their customers to expand bandwidth and cloud capacities. Both of these phenomena add to the ecological footprint of any given international sporting event, by generating more waste hardware, on the one hand, and requiring more waste energy, on the other. This visually-led presentation demonstrates an eco-ethical approach to electronic football spectatorship. It combines statistics on hardware and energy flows with new materialist theory to frame an environmentalist interrogation of a world sport system which is deeply enmeshed in what Richard Giulianotti (2007) has called «the intensified international flows of labour, capital, images and information». Contact email: nina.vestberg@ntnu.no

### **MEDIA COVERAGE OF THE OLYMPIC GAMES – LONDON 2012 IN BRAZIL: A COMPARISON BETWEEN SOCCER AND THE MAIN BRAZILIAN OLYMPIC SPORTS**

Rocco Jr, A.

*Universidade de São Paulo (USP)*

The objective of this research is to demonstrate that, in times of mega events, the Brazilian media behavior is much friendlier to entertainment news and spectacle than restricted to sports apparel. In Brazil, the daily sports media is not used to report facts concerning volleyball, judo and sailing. In time of Olympics Games, as these modalities always get medals for Brazil, the media is required to cover the volleyball, the judo and the sailing competitions. For this, we compare these three sports, which are those in which Brazil has won more medals in Olympic history, with coverage of soccer. Soccer had much success in terms of winning medals. THEORETICAL BACKGROUND The symbolic construction of the sports press is made of professional athletes, especially in time of Olympics, it seeks to turn these athletes into heroes, conquerors made of unusual representative of what the company wants to achieve. The major sports event and athletes are seen as elements of consumption, as a culture, entertainment and spectacle (Van Bottenburg, 2001). One of the strands used by the media to build, in its speech, of legitimizing the sport as spectacle, is the development of the athlete's sporting image, elevation to celebrity status (Amidon, 2012). Guy Debord (1997) calls it "the spectacle society" and Alan Bryman (2004) says that it is the "disneyization of society". METHODOLOGY For 76 days, from July 24 until October 07, 2012, 3 major print media outlets were followed in Brazil - three daily newspapers of national circulation. We selected all the materials that was related to the 2012 Olympics, in general, and also

about soccer, volleyball, judo and sailing. The subjects were classified into five broad categories: a) sports apparel; b) economic fact; c) behavioral fact; d) real show; and, e) political fact and/or national identity. For this classification, we used the method of content analysis developed by Lawrence Bardin. RESULTS AND DISCUSSION During the period considered, 4618 were obtained news about the Olympics in all its aspects. Of this total, only 686 (14.85% of total) had as volleyball, judo and sailing with main subject. According to the news about these three sports, 237 (34.55%) were classified as behavioral fact such as how the athletes lives, their parents's reaction during the games etc. On the other hand, these three sports won 51.85% medals of Brazil's entire history of the Olympics Games. By the way, soccer won only 6.45% medals in this competition. The news is produced more to be sold and less to inform society. It is "the spectacle society" (Debord, 1997) and reveals to us that we are living the "disneyization of society (Alan Bryman, 2004). REFERENCES Amidon, S. (2012). Something like the gods: a cultural history of the athlete from Achilles to LeBron. New York: Rodale/Macmillan Bryman, A. (2004). The Disneyization of Society. London: Sage. Debord, G. (1997). ### OP-PM37 Training & Testing: Endurance I

#### EFFECT OF SOCIO-GEOGRAPHICAL VARIABLES ON SEASONAL PERIODISATION OF TRAINING LOAD IN AUSTRALIAN AND EUROPEAN PROFESSIONAL CYCLISTS

Menaspä, P.1, Martin, D.T.1,2, Abbiss, C.R.1

1: ECU (Perth, Australia), 2: AIS (Canberra, Australia)

**Introduction** The cycling season is divided in three periods: offseason (OFF), preparation (PREP) and competition (COMP) (2). Many variables have been suggested to influence periodization strategies (1). Professional cyclists native of the Southern hemisphere usually spend their OFF and PREP phases on home soil, avoiding the winter in the northern hemisphere. The effect of this socio-geographical variable on training periodization and performance is not well known. The aim of this study was to compare seasonal training volumes and best power outputs (PO) data from professional cyclists who are natives of Southern (SH) and Northern (NH) hemispheres. **Methods** Training and racing of 12 professional cyclists (n: 6 SH; 6 NH) was monitored for 12 months using cycling power meters (SRM). Three seasonal phases were defined: OFF (Oct), PREP (Nov to Jan) and COMP (Feb to Sep). Monthly distance, best PO for 5 sec, 5 min and 20 min were evaluated for both groups. The dependent variables were compared using a two-way ANOVA with repeated measures over time (2 hemispheres x 3 training phases). When a significant F-value was observed, Fisher's LSD test was applied. Critical level of significance was established at  $P < 0.05$ . Results are presented as means  $\pm$  SD. **Results** The seasonal training volume was similar for SH and NH (28774 $\pm$ 4660 and 28648 $\pm$ 2088 km). Monthly distances ridden in PREP and COMP phases were not different in SH (PREP: 2585 $\pm$ 462 and COMP: 2514 $\pm$ 708 km), but significantly different in NH (PREP: 1996 $\pm$ 692 and COMP: 2744 $\pm$ 477 km;  $P < 0.0001$ ). The best 5s PO was significantly different only in NH cyclists between OFF and COMP (OFF: 14.5 $\pm$ 3.3 and COMP: 16.9 $\pm$ 2.1 W/kg;  $P = 0.009$ ). The best 5m PO in PREP and COMP were not different in SH (PREP: 6.3 $\pm$ 0.5 and COMP: 6.2 $\pm$ 0.4 W/kg), but they were significantly different in NH (PREP: 5.7 $\pm$ 0.7 and COMP: 6.5 $\pm$ 0.5 W/kg;  $P < 0.001$ ). Similarly, the best 20m PO in PREP and COMP were not different in SH (PREP: 5.2 $\pm$ 0.4 and COMP: 5.2 $\pm$ 0.8 W/kg), but they were significantly different in NH (PREP: 5.1 $\pm$ 0.7 and COMP: 5.7 $\pm$ 0.8 W/kg;  $P = 0.01$ ). **Discussion** Professional cyclists from the southern hemisphere generally sustain similar training volumes during PREP and COMP whereas their counterparts from the northern hemisphere tend to train less during PREP compared to COMP. In NH cyclists the best power output recorded for duration ranging between 5 sec and 20 min are lower in the OFF or PREP phases when compared to the COMP phase. **In conclusion**, this study highlighted that the seasonal periodization of both volume and intensity differ between cyclists from the SH and NH. **References** 1. #### CADENCES EFFECT ON ENERGY EFFICIENCY DURING SUBMAXIMAL INTENSITY IN ERGOMETER KAYAKING

Pedersen, A., Molbeck, J., Larsen, J., Klitgaard, K., Gam, S., Sloth, M., Olesen, C.

*Health Science and Technology and Mechanical and Manufacturing Engineering*

**Introduction:** Research focusing on physiological performance factors in long duration Flatwater Kayaking is limited, even though long distance kayaking in the form of Marathon kayaking is part of the international Kayak World Cups with more than 87 countries participating. The ability to be energy efficient and economize with stored energy resources to avoid fatigue can be considered a vital part of long distance kayaking. This study focus on energy efficiency for three predetermined cadences and the freely chosen cadence during ergometer kayaking. Based on previous studies on optimal cadences in cycling. It was hypothesized that the freely choosing paddling cadence would be less efficient compared to the most efficient of the three predetermined cadences. **Methods:** 11 male elite Flatwater Kayaking paddlers (age: 19  $\pm$  3, weight: 80  $\pm$  9kg, height: 1.83  $\pm$  0.05m) completed two tests on a Dansprint ergometer. A VO<sub>2</sub>max test was followed by a cadence test, at submaximal intensity of 60% VO<sub>2</sub>max for cadences 65-, 75-, 90 SPM and the freely chosen cadence while measuring energy expenditures. **Results:** A pairwise comparison showed a statistical significant difference between gross efficiency for 65-75 SPM ( $P = 0.0000004$ ) and 65-90 SPM ( $P = 0.016$ ) where 65 SPM was the least efficient. The individual most efficient pre-determined cadence of the three cadences and the freely chosen cadence for each subject showed no statistically significant difference for gross efficiency ( $P = 0.56$ ). **Discussion:** The difference between the cadence 65 SPM and cadences at 75- and 90 SPM could be explained by the efficiency related to contraction velocities of muscle fiber types where low and high cadences has been shown to be less efficient theorizing that 65 SPM in kayaking is primarily driven by the contraction of the less efficient type II fibers. Support to the hypothesis that the freely chosen cadence is not the most energy efficient was not found, but another paradox to which subjects paddling at a freely chosen cadence closely resembling the predetermined cadence 65 SPM, had large disparities in VO<sub>2</sub> and gross efficiency. A possible explanation could be that following a predetermined cadence, leads to an increase in muscle coordination and therefore a higher VO<sub>2</sub> consumption. **References:** Anslay Les. & Patrick Cangle. ### CHRONIC EFFECTS OF SUPERIMPOSED ELECTROMYOSTIMULATION DURING CYCLING ON AEROBIC AND ANAEROBIC CAPACITY

Mathes, S., Link, T., Lehnen, N., Mester, J., Wahl, P.

*German Sport University Cologne*

**Introduction** Electromyostimulation (E) might be a useful tool to intensify endurance training without performing high external workloads. Therefore, the purpose of the present study was to investigate for the first time the chronic effects of superimposed E during cycling on aerobic and anaerobic capacity as well as on markers of muscle damage. **Methods** 21 male subjects (age: 23.4±4.9, mass: 76.3±9.4 kg, rel. VO<sub>2</sub>peak: 57±4.5 ml min<sup>-1</sup> kg<sup>-1</sup>) were randomly assigned to either a cycling (C) or cycling with superimposed E (C+E) intervention group. They performed 14 training sessions over a four-week period. Depending on the group, each training session consisted of 60 min cycling at 60% PPO with or without superimposed E. Before and after training phase, subjects completed 1) a step test to determine VO<sub>2</sub>peak, peak power output (PPOST), power at 2 mmol l<sup>-1</sup> blood lactate (PL<sub>2</sub>), onset of blood lactate accumulation (OBLA), and maximal fat oxidation rate (Fatmax); 2) a 30 sec Wingate anaerobic test to determine PPOW, mean power output (MPOW), and maximal rate of blood lactate accumulation (dLa dtmax-1); 3) a 20-min time-trial to determine MPOTT; and 4) maximal isometric/dynamic strength tests in leg curl and leg extension. Creatine kinase (CK) and lactate dehydrogenase (LDH) were determined over the whole training period. Furthermore, the person's perceived physical state (PEPS) and the perceived physical pain (visual analog scale (VAS)) were recorded. **Results** According to PEPS and VAS, both interventions were equally demanding from the subject's point of view. Only C+E caused significant increases in PL<sub>2</sub> (C+E: +12% vs. C: +7%) and OBLA (C+E: +8% vs. C: +6%), however, no significant differences were found between groups. Nevertheless, Cohen's d revealed small effects between C+E and C (d=0.38; d=0.32). Significant differences between both groups were found for dLa dtmax-1 (C+E: +12% vs. C: +2%). Furthermore, Cohen's d revealed small effects between both interventions (d=0.49). Only C caused significant increases in VO<sub>2</sub>peak (C: +7% vs C+E: 2%; d=0.37). Fatmax was significantly different between groups with higher change after C (C+E: -6% vs C: +12%; d=0.6). PPOST, MPOTT, MPOW and PPOW were significantly increased for both groups, however, C+E did not differ between each other. Effects for maximal strength could not be observed. Furthermore, only C+E caused significant increases in levels of CK and LDH. **Discussion** In conclusion, the results suggest that long-term endurance training with superimposed E affects aerobic and anaerobic capacity less on systemic level, but rather on a local level. Due to increases in PL<sub>2</sub> and OBLA, higher increases in dLa dtmax-1, and no increase in VO<sub>2</sub>peak we presume that C+E improves glycolytic flux and lactate turnover by increased anaerobic and oxidative enzyme activities more than cardiovascular factors. Therefore, it can be speculated that C+E might contribute to improve endurance training efficiency in performance and health particularly by increasing lactate thresholds. ### NORDIC WALKING AND TIRE-PULLING – CONCURRENT AEROBIC AND ENDURANCE STRENGTH TRAINING? A RANDOMISED CONTROLLED STUDY

Mamen, A., Fredriksen, P.M.

*Norwegian School of Health Sciences-Kristiania University College*

**Introduction** Nordic Walking (NW) has become a popular way of doing endurance training. One aim of NW is to increase the working load through arm work. This can be better accomplished when pulling an object, such as a tire. Endurance training can be done as low intensity, long duration training (LD), lactate threshold training with moderate duration, or high intensity interval training with short duration (HIIT), (Seiler and Tønnessen, 2009). The aim of this study was to investigate the feasibility of NW and tire pulling in long distance training and HIIT on the development of endurance strength and aerobic power. **Methods** Students volunteered and were randomised by drawing lots into a Control Group (CG), a Long distance training group (LD) and a High intensity interval training group (HIIT). The results from the 34 students that completed at least 75% of the training sessions are reported. After eight weeks of training, CG consisted of 12 persons, LD of 8 persons and HIIT of 14 persons. Their age spanned from 19 to 49 yr, and almost 2/3 of the subjects were females. The participants completed, prior to and after the intervention period, a lactate threshold test plus a maximal oxygen uptake test. Measurements of arm, leg and core strength, blood pressure, spirometry and anthropometric data were also included. The LD group had 60 minutes supervised training 3 x week. The training intensity was between 70 – 85% of HR<sub>max</sub>. Total training time was 24 hours. The HIIT group had the same training frequency. The sessions had 10 minutes warm-up and 10 times maximum intensity intervals of 20 s with 10 s rest. Total training time was 6 hours. The control group continued with their regular training habits. Group means were compared with one-way ANOVA. A p-value ≤0.05 was considered statistical significant. **Results** The following findings were considered significant: HIIT increased VO<sub>2</sub>max with 5%, Lactate Threshold speed with 6% and Time to exhaustion with 8%. Arm strength increased 25% and Leg strength 24%. LD increased their Leg strength with 37% and Core strength with 22%. CG decreased Time to exhaustion with 4%. Systolic and diastolic blood pressure decreased ~8% in LD and HIIT. Body mass, waist circumference and hip circumference did not change significantly for either of the groups. **Discussion and Conclusion** In the present randomised controlled training study NW with tire pulling has been tested out as a functional training method in endurance as well as strength training with low and high intensity. The results show that the HIIT group increased endurance and strength with a modest training time, 6 h. The LD group improved core stability and leg strength, but needed 24 h training. This study indicates that NW with tire pulling may serve as an effective concurrent training with documented effect on both strength and endurance in young, trained individuals. ### A COMPARISON OF TRAINING LOAD GUIDED VS. CONVENTIONAL ENDURANCE TRAINING IN RECREATIONAL ENDURANCE RUNNERS

Schumann, M.1, Karavirta, L.2, Kinnunen, H.2, Häkkinen, K.1

1: *University of Jyväskylä*

2: Polar Electro Oy, Kempele, Finland **Introduction** Programming endurance (E) training sessions requires instant feedback about the training load and recovery status of an individual athlete (Banister et al. 1980). The Polar Training Load feature aims at continuously monitoring training load based on heart rate recordings throughout each training session and individual physiological variables including age, gender, metabolic thresholds and VO<sub>2</sub>max. This study investigated the effects of E training performed either according to the Polar

Training Load feature or conventionally in recreational E runners. Methods All 24 men ( $34 \pm 7$  yrs,  $77 \pm 8$  kg) performed first 12 wks of similar E training. Thereafter, the subjects were matched by VO<sub>2</sub>max to a training load guided (TL, n=10) or conventional (CT, n=14) group and trained for another 12 wks. In TL, a demanding or easy training session or a rest day was chosen daily based on an estimated recovery status. CT followed a polarized training program with 4-6 sessions per wk of low and high intensity and a pre-defined number of resting days. The training in TL was similar but was performed with modified duration or intensity, if recommended by the recovery status. VO<sub>2</sub>max, time to exhaustion (Tmax) and running velocity at 4 mmol/l blood lactate concentration (OBLA) were assessed by an incremental treadmill test. Results Significant main effects for VO<sub>2</sub>max, Tmax and OBLA were found for time but not interaction. During the first 12 wks of similar training, VO<sub>2</sub>max, Tmax and OBLA increased in TL (5-6%,  $p=0.028-0.004$ ) and CT (4-7%,  $p=0.022-0.009$ ). During wks 13-24, total training time and the number of weekly sessions did not statistically differ between the two groups. The weekly training impulse (TRIMP) was higher in TL than CT ( $375 \pm 47$  vs.  $328 \pm 41$ ,  $p=0.017$ ). VO<sub>2</sub>max, and Tmax significantly increased in CT ( $3 \pm 4\%$ ,  $p=0.034$  and  $3 \pm 3\%$ ,  $p=0.007$ ). During wks 0-24, VO<sub>2</sub>max, Tmax and OBLA increased similarly in both TL (7-9%,  $p=0.013$  to  $<0.001$ ) and CT (6-10%,  $p=0.027-0.001$ ). Discussion This study showed that TL was similarly effective as CT for recreational E runners. Interestingly, while the total training time and the number of weekly training sessions was similar in the two groups, the weekly TRIMP during wks 13-24 was significantly higher in TL compared to CT. Our findings indicate that the Polar Training Load guidance resulted in higher weekly TRIMP leading to no further performance benefits when compared to the present polarized E training. Whether TL is more beneficial than CT in elite E runners with more pronounced needs of higher training intensities and optimized recovery remains to be investigated. ### OP-BN05 Kinematics

#### DOES HEAT STRESS MODIFY THE BIOMECHANICAL MANIFESTATION OF FATIGUE DURING REPEATED RUNNING SPRINTS?

Girard, O., Brocherie, F., Morin, J.B., Racinais, S., Périard, J.D.

*Faculty of Biology and Medicine, University of Lausanne*

Introduction Fatigue substantially alters force production/application characteristics and impact parameters during run-based repeated-sprint exercise. To date, whether hot ambient conditions exaggerate the biomechanical manifestation of fatigue remains undetermined, as description of repeated-sprint running mechanics has hitherto been limited to temperate environments. Therefore, we investigated alterations in running kinetics and kinematics during repeated sprints performed with or without heat stress. Methods Eleven recreational male athletes (team- and racket-sport background) performed three sets of five 5-s sprints with 25-s recovery and 3 min between sets on an instrumented sprint treadmill (ADAL3D-WR) after a ~30-min warm-up. These were randomly conducted in COOL ( $24.9 \pm 0.6^\circ\text{C}$ ,  $45.3 \pm 7.8\%$  RH) and HOT ( $37.6 \pm 2.3^\circ\text{C}$ ,  $21.4 \pm 3.1\%$  RH) ambient conditions. Mechanical data consisted of continuous (step-by-step) measurement of running kinetics and kinematics for each sprint, which were averaged for each set for further analysis. Results Mean skin ( $37.2 \pm 0.7$  vs.  $32.7 \pm 0.8^\circ\text{C}$ ;  $p < 0.001$ ) and rectal ( $38.9 \pm 0.2$  vs.  $38.8 \pm 0.3^\circ\text{C}$ ;  $p < 0.05$ ) temperatures together with thermal sensation ( $6.6 \pm 0.7$  vs.  $4.7 \pm 0.8$ ;  $p < 0.001$ ) and thermal comfort ( $6.3 \pm 0.9$  vs.  $5.0 \pm 0.6$ ;  $p < 0.001$ ) were higher following repeated sprinting in HOT than in COOL. Distance ran in 5 s and propulsive power decreased from set 1 to set 3 (-7.0% and -14.2%;  $p < 0.05$ ), with lower values (-3.5% and -6.8%;  $p < 0.05$ ) in set 2 in HOT vs. COOL. Disregarding the environmental condition, mean vertical (-0.9% and -2.6%;  $P=0.297$  and  $p < 0.01$ ), horizontal (-5.2% and -9.1%; both  $p < 0.001$ ) and resultant ground reaction forces (-1.2% and -3.0%;  $P=0.161$  and  $p < 0.01$ ) decreased in sets 2 and 3 compared to set 1. Contact and swing times increased from the first to the third set (+9.6% and +4.8%;  $P < 0.001$ ), but averaged values for the three sets were higher in HOT compared to COOL (+3.2% and +2.4%;  $p < 0.001$ ), while flight time and stride length remained constant. From set 1 to set 2, larger reductions in stride frequency occurred in HOT (-4.8%) compared to COOL (-2.7%;  $p < 0.05$ ), stride frequencies being 3.4% and 3.0% slower in set 2 and set 3 in the heat ( $p < 0.001$ ), with no additional alterations between sets 2 and 3. Discussion We confirm that kinetics and kinematics deteriorate substantially during multi-set repeated sprinting. In the heat, higher whole-body temperature and perceptual strain are associated with slightly larger alterations in running kinematics (mostly visible in set 2), but not kinetics. #### BIOMECHANICAL ANALYSIS OF ELITE SPRINT KAYAKER USING FIXED AND SWIVEL SEAT: A PILOT STUDY

Lok, Y.L., Smith, R., Sinclair, P.

*The University of Sydney*

BIOMECHANICAL ANALYSIS OF ELITE SPRINT KAYAKER USING FIXED AND SWIVEL SEAT: A PILOT STUDY Introduction Sprint kayaking race became more competitive since the introduction of 200 metre event in the 2012 Olympic Games. A more intense application of an effective and powerful paddling execution is needed. The present study aimed to investigate the effect on kinematics and kinetics variables between the fixed and swivel seat in 200 metre and 1000 metre simulated race. Methods The test was conducted using a modified kayak simulator system in laboratory setting. The subject was an elite flat water sprint kayaker, started the session with a self-paced warm up. The type of seat was randomly assigned and the subject was required to perform an all-out kayak simulation test (i.e. 40 seconds for 200 m event and 3 minutes 30 seconds for 1000 m event) on two separate testing days. Ten left and right strokes with the highest paddle peak force value in both events were selected for statistical analysis. Results Only the paddle force and foot force showed significant difference ( $p < 0.01$ ) during the 200 m test using the swivel seat. All the variables, which consisted of paddle force, foot force, stroke time and stroke rate in 1000 m were statistically different ( $p < 0.01$ ) across seat conditions. Correlation value of more than -0.9;  $p < 0.01$  was obtained in the stroke time and stroke rate in both events and seat conditions. Strong correlations of value more than 0.9;  $p < 0.01$  were also found between foot force with the opposite side of paddle force in all conditions. Discussion Varied outcomes were found in both simulated races with more obvious changes observed in 1000 m test using the swivel seat. Such differences observed here might be helpful as a guideline for the coaches in the preparation of specific training in the relevant race distance. High correlations of the foot force causing the contralateral force generation on the opposite side of the paddle force played an important role as a chain of relation in power transfer with the use of lower limbs pedalling motion. Such motion is effective by utilising the larger muscle groups and not depending solely on arm strength alone, especially beneficial for long distance race. As suggested by McDonnell, Hume and Nolte

(2013), a decrease in stroke time will improve the stroke rate which had a high relation with kayak velocity. The results presented is limited to this single subject study and based only on the ten selected strokes which will require a bigger pool of subjects in the future for a more in depth findings. References McDonnell, L. K., Hume, P. A., & Nolte, V. (2013). A deterministic model based on evidence for the associations between kinematic variables and sprint kayak performance. *Sports Biomechanics*, 12(3), 205-220. ### **VALIDATION OF MEASURING ROWERS' CENTRE OF MASS ACCELERATION IN ROWING DIRECTION WITH INERTIAL SENSORS**

Lintmeijer, L.L., Hofmijster, M.J., Schulte Fishedick, G.A., Zijlstra, P.J., Kruk, H.R., Faber, G.S.

*Vrije Universiteit Amsterdam*

**Introduction** Rowing performance depends on maximization of mechanical power delivered by the rower(s) and minimization of power losses during a stroke cycle (Hofmijster et al., 2008). In many cases, a rower's mechanical power has been calculated by multiplying the moment of the oar with oar angular velocity (e.g. Baudouin&Hawkins, 2004). However, due to the boat speed being unsteady (Hofmijster et al., 2008; Baudouin&Hawkins, 2004), a secondary power term -related to the rower's centre of mass (CoM) acceleration- needs to be incorporated. In this study we evaluated whether horizontal CoM acceleration of the rower during ergometer rowing could be estimated by using a magneto-inertial suit. **Methods** Ten participants (5 male and 5 female) rowed 7 trials on an ergometer placed on two force plates. For each trial, stroke rate per minute (15, 25, 35, ascending stroke rate) or technique (early leg extension, early back extension, stroke to recovery ratio 2:1) was manipulated. The rower's CoM acceleration in rowing direction was calculated (100 Hz) from the weighted average (Hof, 1989) of the accelerations of 17 inertial sensors of an Xsens MVN motion capture suit (Roetenberg et al, 2013), each strapped to a separate body segment. Validating the accuracy of this calculation, this CoM acceleration was compared to the rower's CoM acceleration as determined by the force plates, namely the recorded inertial force divided by the mass of the rower. **Results** For every trial, 10 strokes in the middle of the trial were selected. Statistics showed that the rower's CoM acceleration in rowing direction determined with inertial sensors ( $0.52 \text{ m/s}^2 \leq M \leq 5.53 \text{ m/s}^2$ ) was strongly correlated with the rower's CoM determined with the force plates ( $0.49 \text{ m/s}^2 \leq M \leq 5.87 \text{ m/s}^2$ ) for every participant in every trial ( $0.98 \leq r \leq 1.00$ ,  $0.09 \text{ m/s}^2 \leq \text{SEE} \leq 0.95 \text{ m/s}^2$ ). **Discussion** This study shows that a rower's CoM acceleration in rowing direction can be calculated accurately by means of an inertial magnetic suit. This suggests that this technology could be used to measure the secondary mechanical power term related to the rower's CoM acceleration. On-water studies will be conducted to test the magnitude of this power term. **References** Baudouin, A., & Hawkins, D. (2004). *J Biomech*, 37 (7), 969-976. Hof, A.L. (1989). *J. ### **QUANTITATIVE COMPARISON OF ROWING BIOMECHANICS CAPTURED ON WATER AND ON A DYNAMIC ERGOMETER**

Harfield, P., Halkon, B., Phillips, I.

*Loughborough University*

**Introduction** Ergometers are widely used for fitness training in rowing (land). However, they are not considered appropriate for skill acquisition training. When comparing rower biomechanics during water and land Elliott et al. (2002) suggest similar technique is achieved while Fleming et al. (2014) show significantly different upper leg muscle recruitment patterns. We present a novel parameterisation of rowing biomechanics applicable in both environments. **Method** Sigrist et al. (2013) demonstrate the application of augmented feedback during land rowing. To justify such a coaching intervention it is necessary to quantitatively compare the biomechanics of the two modalities with specific reference to the component of the rowing skill being trained. In this study sub-elite rowers performed step rating tests in a single scull and on an instrumented ergometer. Boats carried an accelerometer; the ergometer recorded rower forces applied at the foot stretcher and handle. Rowers' biomechanical parameters for the drive, recovery and front reversal phases were calculated and statistically compared for every stroke. **Discussion** The efficacy of applying augmented feedback during water rowing is not yet fully understood. Concurrent feedback is promoted at low stroke rates to influence handle force profiles and hull dynamics (Altenburg et al., 2012). This is offset by: difficulty in isolating skills of individuals during crew rowing, increased complexity of the water environment, reliably relaying information to the rower and interrupting normal training. We hypothesise that indoor rowing is a more appropriate environment to deliver concurrent feedback providing the differences between the two environments are understood. Extending the work by Baca et al. (2006) that compared rower forces applied on land and water, we parameterise the resultant force of the rower and undertake novel quantitative comparison. The efficacy of performing concurrent feedback training on a dynamic ergometer is determined. **References** Altenburg, D. et al. ### **DETECTING FATIGUE IN RESISTANCE TRAINING USING ACCELEROMETRY AND PCA**

Brown, N., Bichler, S., Fiedler, M., Alt, W.

*University Stuttgart*

**Introduction** Detection of objective fatigue in resistance training is difficult, due to missing criterion measures and complex fatigue characteristics. Thus a variety of methods is used to determine fatigue, including electromyography (Rogers & MacIsaac, 2013), kinematics (Sánchez-Medina & González-Badillo, 2011) or perception (Day et al., 2004). However, recent research indicates a beneficial fatigue detection if multifactorial parameters are used. Principal component analysis (PCA) has previously been used to detect fatigue in sports (Witte et al., 2011). The aim of this study was to use PCA on a multifactorial dataset based on kinematic measurements to determine fatigue. **Methods** Twenty subjects (60% male, resistance training experience) were tested for 12-repetition maximum (RM). In a second session, 3 sets of 3 exercises were executed with 50 (12 repetitions), 75 (12 repetitions) and 100% of individual 12 RM (RM). Data were collected with a 3D-accelerometer and analyzed by a newly developed algorithm (Brown, Bichler, & Alt, 2014) to get time features and range of motion for each repetition. A PCA with six variables was carried out on the results. The loadings of the variables on the first component were then used to calculate a fatigue factor. ROC-Curves were used to define a threshold between fatigued and non fatigued

exercises. One-way ANOVA with Bonferroni post-hoc analysis was calculated to test for differences between the intensity levels. Results The first component explained 57% of total variance. All six input variables had high loadings on the first component. The ROC-Curves revealed a fatigue score value of 0.56 to distinguish between fatiguing and non-fatiguing exercises. 95% of the non-fatiguing exercises were below threshold. The ANOVA showed a significant difference between intensities ( $p < 0.001$ ). Post-hoc analysis revealed a difference between 100% and the lower intensities ( $p < 0.05$ ) and no difference between 50 and 75%-12RM. Discussion Based on the results of this study, it is possible to distinguish between fatigued and non-fatigued sets of resistance training based on acceleration data with a single parameter calculated by a linear combination of set-specific features gained from PCA. ### OP-BN08 Balance & Stability, Coordination

#### PREDICTING THE ROLE OF KNEE JOINT MUSCLES IN JOINT STABILIZATION FROM EXTERNAL MOMENTS

Flaxman, T.E., Alkjaer, T., Simonsen, E.B., Krogsgaard, M.R., Benoit, D.L.

*University of Ottawa*

Due to their anatomical orientation, major muscles crossing the knee are categorized as flexors or extensors, and can efficiently oppose loads in the sagittal plane. Yet, knee loads are not limited to a single axis. Cocontraction of the flexors and extensors are suggested to support frontal and transverse plane loads since their moment arms too possess varus-valgus and rotational moment arm components [1]. The purpose of this study was to determine the influence of knee joint moments on the activation of knee joint muscles. A force matching protocol [2] evaluated muscle activation patterns of 23 healthy young adults. Subjects stood with leg of interest fixed to a force platform and modulated ground reaction forces (GRFs). Surface EMG, kinetics and kinematics were recorded while subjects generated 30, 45 and 60% of their maximal GRF in 12 different directions to elicit various combinations of flexion-extension, ab-adduction, and rotational knee moments. While controlling for GRF direction and effort level, multiple stepwise linear regressions was used to assess the ability of knee moments to the predict levels of muscle activation. Significant contributions to the model were determined when input variables yielded  $R^2$  Change  $> 0.05$ . The model was a weak predictor of the mono-articular vastii muscles ( $R^2 < 0.21$ ), meaning their activation is not load dependent. We have previously described roles of muscles as it relates to joint stability [2] and based on the current results, we classify the mono-articular vastii as general joint stabilizers. In contrast, strong model correlations, indicating load dependency, were observed in the other bi-articular muscles ( $R^2 = 0.51-0.81$ ). Differences in the roles mono- and bi-articular muscles play in lower limb force control has been described by [3]: mono-articular muscles provide a general gross force while the bi-articular muscles “fine tune” the distribution of net joint moments across adjacent joints. Beta indicates the number of stDev that muscle activation would change with 1 stDev change in a moment. Rectus femoris (RF) was best predicted by its extensor function ( $\beta = 0.52$ ). The greatest predictor of medial (MH) and lateral hamstrings (LH) were internal rotation ( $\beta = 0.36$ ) and adduction moments ( $\beta = 0.39$ ), respectively. Flexion was the second significant predictor of MH and LH activation ( $\beta = 0.33 \& 0.17$ ). We classify RF as a movement facilitator, and hamstrings as specific joint stabilizers, indicating the hamstrings have a more complex role in knee joint stability, beyond that of generating flexion moments. Further investigation into muscular support for frontal and transverse knee loads is warranted. References: [1] Lloyd, 2001. J Biomech 34, 1257-67 [2] Flaxman, 2012. #### SQUAT VARIATION FOR PREFERENTIAL UNILATERAL QUADRICEPS LOADING

Jean, L.M.Y., von Gaza, G.L., Panariello, R., Chiu, L.Z.F.

*University of Alberta*

Introduction Persons with anterior cruciate ligament (ACL) injury have unilateral quadriceps weakness. To date, no rehabilitative approach, including single- and multi-joint unilateral and bilateral exercises, satisfactorily restores quadriceps strength in the involved limb [3]. The purpose of this research was to examine if squat exercise could be modified to preferentially load the quadriceps in one limb. We hypothesized that squats with one limb on an elevated surface would increase knee extensor net joint moment (NJM) and quadriceps EMG activity in the contralateral limb. Methods Five men and 5 women performed 2 sets of 5 repetitions each of plate squats [2] under normal, left limb elevated and right limb elevated conditions. For limb elevated conditions the foot was placed on a 5cm platform. Motion analysis was performed with 7 optoelectronic cameras and two force platforms. Vastus lateralis (VL), vastus medialis (VM) and rectus femoris (RF) activity were recorded with bipolar electrodes. Inverse dynamics was used to calculate knee NJM. EMG data were filtered and processed using a 100ms window root mean square. For all data, the average value was calculated for 15 degree knee flexion intervals during eccentric and concentric phases [1]. Results With the right limb elevated, left knee extensor NJM increased resulting in greater contra- versus ipsilateral knee extensor NJM. VL and VM EMG increased in the contra- and decreased in the ipsilateral limbs. With the left limb elevated, right knee extensor NJM was greater than left when knee flexion was less than 90 degrees. Contralateral VL, VM and RF EMG increased while ipsilateral VL and VM EMG decreased at some squat depths. Regardless of condition, knee extensor NJM and quadriceps EMG were largest at high knee flexion angles. Discussion Elevating a single limb appears to increase quadriceps loading in the contralateral limb while decreasing quadriceps loading in the ipsilateral limb. Therefore, this squat variation may be useful to target unilateral quadriceps weakness, such as in ACL injured persons, by elevating the non-involved limb. However, these findings were most robust with the right limb elevated, whereas left limb elevated trials showed effects only at shallow knee flexion angles. Further examination of this squat variation with ACL injured persons is warranted. Regardless of the variation, full squat exercise may be required to increase quadriceps strength – including in ACL injured – as quadriceps loading is highest when knee flexion is greater than 105 degrees. ## UNSTABLE FOOTWEAR DECREASES COMPLEXITY OF POSTURAL CONTROL

Buchecker, M., Müller, E.

*University of Salzburg*

**Introduction** Although the effects of unstable shoes (US) on pain relief and on promoting strength, stability or proprioception abilities are well acknowledged (Nigg et al., 2012), the basic motor mechanisms involved have not yet been fully understood. Therefore, the aim of the current study was to upgrade the framework of US by investigating the complexity of centre of pressure (COP) patterns through tools assessing the structure of corresponding fluctuations. **Methods** Twenty-nine healthy men conducted three bipedal standing trials using US (M-Walk, MBT) or flat footwear (Vellum 2, Puma) in a counter-balanced within-subject design. Simultaneously, kinetic signals were captured for 30 seconds by a six-component AMTI force platform, sampling data at 100 Hz. After reconstructing medio-lateral (COPx) and anterior-posterior (COPy) COP trajectories each coordinate was low-pass filtered and normalised to unit variance. For quantifying the complexity of COP profiles, fractal- and entropy-based indices derived from detrended fluctuation analysis (DFA) and multi-scale entropy (MSE) calculations (Duarte & Stenard, 2008) were computed and statistically processed employing a two-way repeated measures ANOVA (shoe x direction) – with Alpha fixed at 0.05. **Results** Compared to the control condition DFA and MSE outcomes revealed higher scaling exponents and a decrease in sample entropy estimates of the overall COP sway when wearing US (shoe: all  $P < 0.001$ ; all  $f > 0.40$ ); however, these changes were consistently greater in COPx than in COPy time series (shoe-by-direction: all  $P < 0.05$ ; all  $f > 0.40$ ). **Discussion** US caused system responses which were more closely related to the dynamics of a random walk, meaning that COP deviations occurred along fewer time-scales and demonstrated a more predictable sequence. Consequently, participants performed numerous, active postural adjustments – via recruiting hip muscles as well – for combating the requirements of US. This type of compensatory strategy generally suggests a fixation of independent degrees of freedom in control space since an intensified coupling of functional units governing a steady-state position can be expected (Duarte & Stenard, 2008; Hong et al., 2008). If true, the resultant loss of physiological complexity following an US intervention would again point towards a certain potential of the underlying construction concept to serve as an extrinsic constraint applicable in every-day settings (Stöggel et al., 2010). **References** Duarte M, Stenard D (2008). *Exp Brain Res*, 191(3), 265-276. ## STATIC POSTURAL CONTROL DOES NOT STRONGLY PREDICT DYNAMIC GAIT STABILITY RECOVERY FOLLOWING A TRIP IN ADULTS WITH AND WITHOUT VESTIBULAR DYSFUNCTION

McCrum, C.1,2, Eysel-Gosepath, K.3, Epro, G.2, Meijer, K.1, Savelberg, H.1, Brüggemann, G.P.2, Karamanidis, K.2

*1: Maastricht University, The Netherlands, 2: German Sport University Cologne, Germany, 3: Heinrich Heine University of Düsseldorf, Germany*

**Introduction** Unilateral peripheral vestibular disorder (UPVD) disrupts vestibular sensory feedback information, negatively affecting upper and lower body motor performance (Raptis et al., 2007; McCrum et al., 2014), but postural control during quiet stance in UPVD patients has not been directly compared with dynamic stability control after an unexpected perturbation during locomotion. Therefore, we analysed centre of pressure (COP) characteristics during static posturography in UPVD patients and healthy controls and compared this with performance of a trip recovery task. **Methods** 17 UPVD patients and 17 healthy matched controls were unexpectedly tripped during the swing phase of the right leg while walking on a treadmill. The margin of stability (MoS) was calculated at touchdown (TD) of the perturbed step and the first six recovery steps to analyse recovery and dynamic stability control (Süptitz et al., 2013). Posturography was used to assess postural stability during 30 seconds of quiet standing with eyes open and closed using a force plate. Pearson correlations between the trip recovery task and posturography outcome measurements were conducted. **Results** The unexpected trip reduced the MoS of the perturbed leg ( $p < 0.05$ ) with no significant differences in MoS between the groups. Controls returned to MoS baseline level in five steps and patients did not return within the six analysed steps. UPVD patients showed a significantly greater total COP sway path excursion (closed eyes only), anterior-posterior range of COP distance and a more posterior COP position in relation to the posterior boundary of the base of support (COPpmin). There were no significant correlations between COP sway path excursion and MoS values. Significant correlations were found only between the COPpmin and the MoS at TD of the second to fourth steps post-perturbation ( $0.4 < r < 0.57$ ;  $p < 0.05$ ). **Conclusion** We concluded that UPVD patients have a diminished ability to control and recovery dynamic gait stability after an unexpected trip and lower static postural stability control compared to healthy matched controls. As no consistently significant relationship between task performances was found, it appears that trip recovery and static postural control rely on different control mechanisms. Therefore, static posturography may be of limited use in predicting dynamic stability during perturbed walking. **References** Raptis et al. *J Neurophysiol*, 2007; 97: 4069-78 McCrum et al. *Physiol Rep*, 2014; 2(12): e12222 Süptitz et al. *Hum Mov Sci*, 2013; 32: 1404-14 Contact chris.mccrum@maastrichtuniversity.nl

## THE EFFECT OF AN 8-WEEK CORE-STABILITY PROGRAM ON COORDINATION DYNAMICS AND KICKING SPEED IN FEMALE SOCCER PLAYERS.

Serrien, B., Steiner, V., Clijse, R., Baeyens, J.P.

*Vrije Universiteit Brussel*

**Introduction.** In this study we wanted to analyze the effect of core-stability (CS) training on ball speed (BS) and coordination dynamics (CD) in a penalty kick from a single-subject point-of-view. The constraints model (organismic-task-environment) and the self-organization principle offer a useful framework to study CD. In this study, we focused on the effects of altered neuromuscular constraints after an 8-week CS intervention. **Methods.** Twenty-five female soccer players (median age 16) from the Austrian 2nd league participated in this study. After subjects were age- and anthropometrically matched, they were randomized between an intervention (I4) and control group (CON, 11) who followed their normal soccer training. The intervention group received a CS exercise program for 8 weeks, 2 times a week for 30 minutes beside their normal soccer training. CD in 12 penalty kicks was analyzed with self-organizing maps (SOM) for every subject separately with the method described by Lamb et al. with as input vector 20 kinematic time series (joint angles and – velocities of pelvis, trunk and kicking leg) during the penalty kick. We hypothesized that the CON subjects would have their local minima of the coordination potential on the same nodes of the SOM and that the local minima of the intervention subjects would be shifted. Analysis of BS was done for every subject with a paired t-test. **Results.** In the intervention group, 1 subject showed a significantly increased BS and 3 subjects showed a sig. decreased BS. In the CON, 3 subjects showed a sig. increase and 1 subject a sig. decrease. The results of the CD analysis

with the SOM's showed that most players exhibited a mono-stable coordination potential on both sessions. The hypothesis could not be confirmed: from both groups, subjects had altered coordination patterns. These shifts in coordination are thus probably only day-to-day variability and no systematic alteration. Discussion. The results indicate that the intervention program focusing on CS was not effective in improving BS or altering the CD because of altered organismic constraints. Various reasons contribute to this result, including low adherence to the training regimen of some subjects and a very heterogeneous group on several other not controlled factors such as CS experience and soccer experience. Organismic constraints are much more difficult to alter on a systematic basis. Further research with a simpler motion and more experimental control will be necessary to study the effect of organismic constraints on CD. ### **THE EFFECT OF FORCE-CONTROLLED BITING ON MOTOR CONTROL – EXPERIMENTAL STUDIES UNDER LABORATORY AND FIELD CONDITIONS**

Ringhof, S.1, Hellmann, D.2, Schindler, H.J.2, Potthast, W.3, Meier, F.1, Etz, E.2, Stein, T.1

1: Karlsruhe Institute of Technology; 2: University of Heidelberg; 3: German Sport University Cologne

**Introduction** Human motor control is based on complex sensorimotor processes, including diverse sensory systems. Trigeminal connections to several structures involved in motor control (Buisseret-Delmas et al., 1999) further imply that human movements could be influenced by the input of the craniomandibular system (CMS). Recent studies showed that changes of the CMS, like jaw motor tasks and oral devices, did not only enhance postural stability (Hellmann et al., 2011), but also improve performance in high level shooters (Gangloff et al., 2000). The aim of our study was, therefore, to investigate whether oral motor tasks likewise influence (A) postural control in more challenging situations, and (B) performance in coordinative demanding full-body motor tasks, as golf shots. **Methods** In experiment A twelve healthy subjects performed force-controlled (FB) and non-biting while balancing in unipedal and bipedal narrow stance. Postural stability and joint kinematics were evaluated by means of center of pressure (COP) displacements detected by use of a force plate, and biomechanical motion analysis, respectively. In addition, electromyographic activity of six postural muscles was recorded. Field study B investigated the effect of FB on shot precision (60 m, 160 m) and shot length (Drive) in 14 professional golfers; with golf performance being quantified by means of a radar based system. The bite forces in both studies were visualized as real-time feedback. **Results** In study A, COP displacements were significantly reduced during FB, accompanied by smaller ranges of motion and lower mean angular velocities in hip, knee and ankle joints in both frontal and sagittal planes. Furthermore, muscular co-contraction variability in five of six muscle pairs was significantly reduced during FB. In study B, however, oral motor tasks did not systematically affect any performance variable under investigation. **Discussion** The results of study A showed that biting at a submaximum level also improved postural control in more demanding situations, and thereby reinforced the impact of the CMS on human motor control. Joint kinematics and co-contraction variability, moreover, revealed that neuromuscular control strategies might be more precise under FB. Notwithstanding this, study B indicates that the stabilizing (study A) and performance enhancing effects (Gangloff et al., 2000) apparently are not transferable to coordinative demanding full-body movements. The empirical and clinical relevance of the functional impact of the CMS, thus, needs to be investigated in further studies. **References** Buisseret-Delmas C, Compoin C, Delfini C, Buisseret P (1999). #### **GIVING THE ATHLETE A VOICE: PRELIMINARY FINDINGS OF THE MY SPORTING JOURNEY QUESTIONNAIRE.**

Juanita, W., Warmenhoven, J., Medlicott, R., Gulbin, J.P.

*Australian Institute of Sport*

Within the Australian Sporting system, the operational framework of FTEM (Foundation, Talent, Elite & Mastery) (Bergeron et al 2015, Gulbin et al 2013,) in complement with the conceptual model of 3D-AD (3D-Athlete Development, Gulbin & Weissensteiner 2013) provides a practical and best practice approach for guiding sporting stakeholders across the span of the development pathway. Such an approach is assisting in aligning athlete and coaching educational initiatives, promoting innovative and ecological development practices and fostering the progressive and reactive, interdisciplinary case management of athletes. Central to informing this strategy, is engaging the 'athlete's voice' –regarding the relative impact of intrinsic and extrinsic factors (environmental, system, chance) on their development, progression, transition and performance (Weissensteiner, 2015). The My Sporting Journey Questionnaire, sought to give contemporary Australian Olympic, Paralympic and Professional athletes a voice regarding their developmental experiences both positive and negative. **Method:**The My Sporting Journey questionnaire captures and chronicles holistically, the developmental history of each athlete from their early foundational experiences to their highest level of competition and development according to the FTEM framework. The questionnaire was administered online to over 800 athletes from numerous Olympic, Paralympic and Professional sports and included over 280 elite and mastery level athletes. **Results:**Preliminary findings revealed inter alia differences between the male and female developmental experience; unique characteristics of Mastery level athletes; common foundational catalysts preceding expertise; the high influence of peers, mentors and role models on development; critical transition points in the pathway and aligned barriers and facilitators; and the impact and breadth of high performance stressors. **Discussion:** Collectively, the findings provide strong evidence to guide and refine current practice and the support of athletes across the entire development pathway, at a gender and sport-specific level. Utilising an evidence-informed approach informed by the athlete voice ensures that ensuing strategies supporting the athlete are grounded, relevant and effective. **RELATIVE AGE EFFECT AND PHYSICAL GROWTH ON PHYSICAL EDUCATION ATTAINMENT**

Dalen, T., Roaas, T.V., Pedersen, A.V., Ingvaldsen, R.P., Steen, I., Aune, T.K.

*Nord-Troendelag University College*

Introduction: Physical education (PE) is perhaps the school subject that is most susceptible to the relative age effect (RAE). Though being less competitive and selective than sports, students' attainments rest on their physical performance rather than on academic or cognitive variables as in most other subjects. Like in sports (see for example Musch & Grondin, 2001), physical maturity might give students in physical education an advantage, and this could be mistaken for superior ability. The aim of the present study was to investigate the extent to which the physical growth and RAE reflects the attainment in Norwegian PE. Method: To investigate the influence of date of birth and physical growth measured as body height on physical education attainment we used a questionnaire for pupils in the three last year of secondary school (13 - 16 year). In total 2978 pupils participated in the study representing a large comprehensive area of schools situated in the middle of Norway. Results: In total the correlations between height and mark in PE were  $r = 0.14$ ,  $r = 0.32$  and  $r = 0.29$  for boys in 8th, 9th and 10th grade, ( $p < 0.001$ ) and  $r = 0.11$ ,  $r = 0.33$  and  $r = 0.21$ , for girls in 8th, 9th and 10th grade ( $p < 0.001$ ). The most obvious effect of differences in height was observed when the groups were split into students with high and low attainment. Both boys and girls with high attainment were in average 10 cm higher than students with low attainment. The distribution of the number of top marks per quarter show that it is advantageous to be born early in the year. 114 out of 179 top marks were given to pupils born the first half year. Discussion: Norwegian physical education curriculum emphasizes participation over performance (Norwegian Ministry of Education and Research, 2012), and children's physical capacity and maturation should not directly contribute to their end year attainments, and should neither be monitored according to the curriculum. However, as attitudes and motivation are not so easily measured, there might be used more traditional ratings of sport performance, including physical fitness testing (Cale & Harris, 2009). Such assessments have been proven to be biased and affected by children's relative age and physical maturity. References: Cale, L., & Harris, J. (2009). Fitness testing in physical education - a misdirected effort in promoting healthy lifestyles and physical activity? *Physical Education & Sport Pedagogy*, 14(1), 89-108. Musch, J., & Grondin, S. **THE EFFECTIVENESS OF INTER-PROFESSIONAL SIMULATED-PATIENT BASED SIMULATION IN DEVELOPING EXERCISE PHYSIOLOGY STUDENT INDUSTRY READINESS**

Reeves, N., Waite, M., Bialocerkowski, A., Tuttle, N.

*Griffith University*

Introduction Clinical educators and students alike indicate that additional exposure to a wide variety of 'practice' clinical experiences better equips them to effectively manage patients and initiate inter-professional care models when undertaking clinical practicum. This study reports on the impact this style of simulation had on Exercise Physiology student's industry readiness with respect to inter-professional care. Methods This investigation includes the responses to pre- and post- simulation questionnaires from Exercise Physiology students ( $n=14$ ) completing a Graduate Diploma in Exercise Science at Griffith University, Australia. Students completed three inter-professional simulation modules (two with Nutrition & Dietetics students, one with Pharmacy student) covering topics including inter-professional management of a Type 2 Diabetic Patient, Cardiorespiratory Patient, and Cancer-End of Life Care Patient. The simulation modules were facilitated by experienced and accredited practitioners from the respective professions and included pre-reading, briefing, simulation using simulated patients, and debriefing components. Exercise Physiology students were paired with a student from the other profession and the simulation modules were delivered on campus or remotely, via telehealth, to those students embedded in practicum rotations across the state. The pre- and post-simulation questionnaires were designed to elicit quantitative and qualitative information on the reaction, learning and behaviour levels of the Kirkpatrick model. Quantitative data were analysed descriptively and using the Wilcoxon Signed-Ranks Test to investigate changes in students' confidence following the simulations. Themes were derived from open-ended responses. Results Post simulation Intrinsic Motivation Inventory scores indicated high levels of interest, competence, and confidence, and moderate levels of tension (means ranged 5.4 - 6.6, and 2.5 - 4.1 respectively on a 7-point scale). Scores indicated very high levels of perceived impact on skills in communication, assessment, management and the ability to collaborate with other health professionals (means ranged 6.0 - 6.82). Wilcoxon Signed Ranks Test scores indicated significant increases in confidence in communication, patient assessment, management and inter-professional collaboration ( $p < 0.05$ ). Qualitative information supported the quantitative data with students appreciating the opportunity to receive feedback from the simulated patients and facilitators. They identified being able to observe how the other professions' approached the management of the patient and the inter-professional collaboration in developing a treatment plan of significant benefit. Discussion The positive response to the simulation modules and impact on students' learning demonstrates the influence of inter-professional simulated learning on developing Exercise Physiology student industry readiness.

**LYING IN BETWEEN. ABOUT THE CONTINGENCY OF CROSSING.**

Roscher, M.

*Johannes Gutenberg University Mainz*

Existing research currently focuses on practical abilities as the means to enhance performance. Techniques are polished, tactics are improved, and in some cases, mental training is incorporated. What is missing is the understanding of how inner principles such as aesthetics affect sports performance. The oral presentation explores the interplay between aesthetics, sensual awareness, practical abilities, and sports performance. Drawing from ongoing discussions in aesthetic philosophy around the question of sensory perception as an activity, sport philosophers and educators should ask themselves whether sensory perception is based solely on an ability to create sensual understanding, as Baumgarten would put the subject of aesthetics. Herder has proposed the existence of an inner principle beyond the influence of a certain subject. These views set the foundation for explorations of an inner force within aesthetics. If we do read the formation of aesthetics as being a progression resulting from an inner principle without conscious reference to itself, then this inner principle cannot be normative and as a result cannot be a practical ability. The practical ability of an athlete originates from physical exercises. However, this exercising interrupts the aesthetic play. The functioning of the aesthetic is indifferent to the exercise of the practical ability, on the contrary it is necessary for effective exercising: Aesthetic play frees physical activity from standards, laws and purposes. In doing so, it expresses the difference between aesthetic force and practical ability, and furthermore it grasps the human as difference. Within sports we experience a specific mediality of aesthetic practice: the human body itself. The sportsman's activities arise from both, conscious ability as well as ecstatically freed force. And he is not simply using one or the other, but he is the crossing from one to the

other. Practical ability and inner force flow into each other. Thus, enhancing the performance requires more than increasing the practical abilities. It requires the ability to exceed it. Assuming a contingency of crossing exists forces us to examine the physical expertise anew.

### **WHO PARTICIPATE AND WHY?: YOUTH PARTICIPATION IN SWEDISH CLUB SPORTS**

Theidin Jakobsson, B.

*The Swedish School of Sports and Health Sciences*

The main aim of this study is to increase knowledge of what characterizes club sport participation during childhood and youth, and what distinguishes young participators who continue club sport in their late teens and to understand why they continue. An important premise for this study is that sport is one of the most widespread leisure activities among youth. Many young people in Sweden stop participating in club sport during their teens, but some continue. Rather than concentrating on those who drop out of club sports the focus of this study is on the ones who continue with club sports during teenager years. Aaron Antonovsky's salutogenic theory and sense of coherence model (SOC) has inspired the analysis of what it is that seems to be comprehensible, manageable and meaningful when participating in club sport. Furthermore, Pierre Bourdieu's key concept habitus and capital have been used as research tools when analyzing the relationship between sports participation and social position among teenagers. The study is longitudinal where the same 585 pupils born 1991 have answered a questionnaire at 10, 13, 16 and 19 years of age. The results show that club sports are successful in getting large numbers of children to attend and participate, but there seem to be many who just participate for a short time and only about one third stay on in their late teens. Very few start after the age of 13. Teenagers who are active participants appear to have started early, have taken part in different sports and do not mind taking part in competitions. Furthermore, they seem to possess specific dispositions (and certain assets) in terms of a habitus with a taste for sport and a specific cultural capital in terms of academic success. Moreover, it looks as if doing club sport is a social space where the teenagers can experience meaningfulness based on learning, developing physical ability, experiencing a feeling of belonging, and being challenged but few had elite ambitions. The conclusion is that sports clubs should try to organize activities emphasizing development with numerous opportunities and challenges for motor and social learning with less focus on competitions as the only focal point. By asking questions about and taking into account what teens need to understand, cope with, and what they perceive as meaningful in sports, it is possible that more young people want to participate longer. ##### **TOO MUCH PRESSURE ON THE PUMP?**

Whyte, G., Roberts, W.

*Liverpool John Moores University*

Regular physical activity is good for health and heart. The marathon is popular in the running community with nearly 3,600 races around the world and over a half million finishes in the USA and 1.6 million finishes worldwide in 2012. This session will look at cardiovascular changes associated with long term endurance training at the bench and diagnostic imaging level and the latest in road race medicine to save lives on the street during races. Like medications, there is likely an optimal exercise "dose" for health that may differ for marathon participation. This session will look at the cardiovascular risks and changes associated with marathon participation on race day and the potential heart changes over the course of long term training. The session at heart related changes associated with long term endurance training including coronary artery calcification, myofibrosis, and conduction system changes (atrial fibrillation). In additions we will also discuss the risk of sudden cardiac arrest and current race related strategies to reduce sudden cardiac death during races.

##### **DYING ON THE STREETS?**

Roberts, W., Whyte, G.

*University of Minnesota*

Regular physical activity is good for health and heart. The marathon is popular in the running community with nearly 3,600 races around the world and over a half million finishes in the USA and 1.6 million finishes worldwide in 2012. There is much discussion surrounding the effects of marathon running on the heart; both acute and chronic. Are marathon runners dying in unexpected numbers during training and race participation? Are your highly active patients at increased risk for cardiac dysfunction or death? This session will look at cardiovascular changes associated with long term endurance training at the bench and diagnostic imaging level and the latest in road race medicine to save lives on the street during races. Like medications, there is likely an optimal exercise "dose" for health that may differ for marathon participation. This session will look at the cardiovascular risks and changes associated with marathon participation on race day and the potential heart changes over the course of long term training. There is concern that long term endurance training and marathon running may "overdose" the heart and lead to pathological coronary artery calcification levels, myofibrosis, and conduction system changes (atrial fibrillation). There is also the risk of exercise associated collapse with sudden cardiac arrest, and the session will address current race related strategies to reduce sudden cardiac death during races.

## Invited symposia

**IS-PM04 EFFECTS OF EXERCISE ON BRAIN FUNCTION, LEARNING AND MEMORY****NEURAL EFFECTS OF EXERCISE ON LEARNING AND PROBLEM SOLVING IN THE INTACT AND BRAIN INJURED INDIVIDUAL**

Mogensen, J.

*University of Copenhagen*

Cognitively enhancing effects within such domains as learning, memory and problem solving have been found in intact individuals as well as after traumatic and vascular brain injury. Such effects have been demonstrated in humans as well as in animal models – although the vast majority of well documented results have been obtained using experimental animals. Within animal models addressing effects of physical exercise on cognitive recovery after brain injury focus has been on: (A) Identifying the neural mechanisms mediating such clinically relevant effects and (B) identification of the optimal parameters for obtaining therapeutic effects. Exercise influences a vast spectrum of neural processes. But increased production of neurotrophins appears to play a central role in recovery-promoting processes. Especially increased transcription of Brain Derived Neurotrophic Factor (BDNF) has been shown to be at least one of these mechanisms. Attempting to identify the optimal parameters for enhancement of posttraumatic cognitive recovery the focus has primarily been on: (1) The timing of initiation of exercise – soon/immediately after infliction of injury or at a later time-point? (2) The optimal intensity of exercise. And (3) whether the exercise should be voluntary or forced – relatively stress-free or associated with stressful processes? Within all of these research areas results remain contradictory. This lack of a cohesive understanding may primarily be due to methodological issues. For instance, the literature contains inconsistencies regarding factors such as the type of injury as well as the cognitive parameters used to evaluate potential cognitive enhancing effects.

**EPIDEMIOLOGICAL STUDIES OF THE IMPORTANCE OF CARDIOVASCULAR FITNESS FOR COGNITIVE ABILITY AND NEUROPROTECTION.**

Aberg, M.

*Institute for Neuroscience and Physiology*

Background: Cardiovascular fitness is associated with positive effects on multiple aspects of brain function and cognition. Studies report benefits of long-term, regular physical activity on later cognition and brain health. However, several of these studies have relatively short follow-up times or lack objective measures by relying on self-reported questionnaires. Objectives: To determine whether physical exercise at 18 years of age, as indexed by cardiovascular fitness, is associated with cognitive performance; to determine whether cardiovascular fitness at 18 years of age predicts future cognitive achievements and future risk of mental illness, epilepsy, stroke and early-onset dementia. Material/Methods: We performed a population-based, cohort study of over 1.1 million Swedish male conscripts who were followed for up to 42 years. Data on cardiovascular fitness and cognitive performance were collected during conscription exams and linked with the Swedish Twin Register, national databases for information on school achievement, socioeconomic status and hospital registers to calculate later risk of mental illness, epilepsy, stroke and early-onset dementia using Cox proportional hazards models controlling for several confounders. Results: We have shown in twin models that physical fitness and cognitive ability at 18 years of age are positively correlated and that the association is not determined by genetic factors (Åberg et al., 2009). Our data also demonstrate that poorer physical fitness at 18 years of age leads to an increased risk of depression, suicide, epilepsy, stroke and dementia later in life (Åberg et al., 2012, Åberg et al., 2014, Nyberg et al., 2013, Nyberg et al., 2014). The highest risks were observed for individuals with a combination of low cardiovascular fitness and cognitive performance. Conclusion: These findings indicate the importance of cardiovascular exercise during adolescence for cognitive capabilities and future brain health. From a public health perspective and from a lifetime perspective the issues of how physical activity, fitness and IQ are related over time to cognition and neuroprotection are central to obtain answers for, so that we can have a good basis for future prevention and intervention.

**EFFECTS OF EXERCISE INTERVENTIONS ON HUMAN MOTOR LEARNING, COGNITIVE FUNCTIONS AND MEMORY**

Lundbye-Jensen, J.

*University of Copenhagen*

The positive effects which cardiovascular exercise may have on several aspects of cognitive functioning are well established. During the recent years, there has been an increasing focus on neuroplasticity and on the processes that support memory formation and learning and several studies documented positive interactions between exercise, memory and learning. However, the mechanisms underlying the effects of exercise on human memory and learning remain controversial. Several studies have attempted to identify potential modulators that could explain the divergent responses to cardiovascular exercise in improving both declarative and nondeclarative memory as seen in motor learning. For example, there has been an emerging interest in understanding how specific parameters of exercise such as intensity might influence the effects on memory. One important but commonly neglected parameter that is essential for memory formation processes is the timing of exercise. I present data supporting the hypothesis that the effects of cardiovascular exercise on memory are not only intensity but also time-dependent. The results encompass studies focusing primarily on the effects of acute exercise on mechanisms involved in motor learning but results from longitudinal studies are also presented. In addition to effects of exercise on memory, the longitudinal studies also include effects of exercise on cognitive functions and academic performance e.g. in children. We argue that strategically scheduled exercise performed in close proximity to learning sessions may promote the effects of exercise on learning and memory in part through an effect on consolidation. **IS-PM03 FEMALE SEX HORMONES AND SKELETAL MUSCLE \*****HORMONE REPLACEMENT THERAPY – EFFECT ON MUSCLE MASS AND MUSCLE FUNCTION**

Sipilä, S.1, Finni, T.2, Pöllänen, E.1, Kovanen, V.1

*University of Jyväskylä*

**Introduction** Cross-sectional studies suggest that the accelerated decline in neuromuscular function with aging occurs earlier in women than in men (Phillips et al 1993). Hormonal changes during menopausal transition may be among the underlying factor for this early decline in women. Hormone replacement therapy (HRT) has successfully been used to treat symptoms which are unquestionably caused by estrogen deficiency. Knowledge on the role of estrogen deficiency and the effects of HRT on neuromuscular system in peri- and post-menopausal women is, however, inconsistent. The purpose of this presentation is to summarize the results of our studies investigating the role of HRT on neuromuscular function in women at their early postmenopausal years. **Methods** A year-long randomized controlled trial included 80 women aged 50–57 yrs randomized in 4 study groups; HRT (estradiol 2mg and norethisterone acetate 1mg), exercise (EX), HRT+EX and control (CO). A twin study included 15 MZ 54–62-year-old twin pairs discordant for HRT for on average of 7 yrs. Muscle mass and composition (CT scanning) and neuromuscular function (muscle force, twitch torque, power, walking and running speed) were measured (Finni et al 2011, Ronkainen et al 2011, Sipilä et al 2001). Gene expression of IGF-1 signaling pathway was assessed from muscle biopsies using microarray data (Illumina Inc., San Diego, CA) (Pöllänen et al 2010, Ronkainen et al 2010). **Results** Both studies showed that HRT is beneficial for neuromuscular function. We observed 14-16% greater muscle power, 32% greater plantar flexion twitch torque and 2-7% greater running and maximal walking speed in HRT users compared to non-users. No difference between the twin sisters was observed in habitual walking speed or voluntary isometric force. HRT had favourable effects on muscle mass and composition. Twin sister on HRT had 28% greater expression of IGF-1 receptor than their co-twins not on HRT. HRT significantly upregulated expression of IGF-1, IGF-1Ec, androgen receptor, FOXO3 and mTOR and down regulated AKT1 compared to CO. **Discussion** HRT has beneficial effects on neuromuscular system and function in women during their early postmenopausal years, especially in activities with higher contraction velocity. IGF-1 signaling pathway is among the biological mechanisms underlying beneficial effects of HRT in skeletal muscle. **References** Finni et al. (2011). *Muscle Nerve*, 44(5),769-75. **ORAL CONTRACEPTIVES – EFFECT ON SKELETAL MUSCLE AND TENDON PROTEIN TURNOVER AND BIOMECHANICAL PROPERTIES**

Hansen, M.

*Aarhus University*

**Introduction** Use of oral contraceptives (OC) is wide-spread especially among young women. Nevertheless, the knowledge regarding the effect of OC on skeletal muscle is sparse. In this presentation the recent literature on the effect of OC on skeletal muscle and tendon will be presented. The focus will be on muscle and tendon protein turnover, muscle mass, tendon structure and tendon biomechanical properties. Furthermore, the association between OC use and injury risk will be discussed. **References** Hansen M & Kjaer M. (2014). *Exerc Sport Sci Rev*, 42(4), 183-92 Hansen M, et al. **ESTROGEN REPLACEMENT AND SKELETAL MUSCLE: MECHANISMS AND POPULATION HEALTH**

Tiidus, P.

*Wilfrid Laurier University*

**Introduction** Using an ovariectomized rodent model we have demonstrated that as well as enhancing antioxidant and anti-inflammatory properties, estrogen replacement will augment post-exercise muscle satellite cell activation and proliferation. This effect may explain some of the ability of estrogen replacement in post-menopausal women to maintain and enhance muscle mass and function. Our more recent research has also demonstrated the influence of muscle estrogen receptors and the PI3K-Akt signalling pathway as physiological mechanisms by which estrogen will induce this augmentation of muscle satellite cell responses to exercise. In addition, we will present new data on the influence of estrogen on muscle Heat shock protein expression as well as the negative effects of a post-ovariectomy delay in estrogen replacement on post-exercise muscle satellite cell proliferation using our rodent model. Implications of these effects for muscle function in older human females will be also discussed. Finally, some of the health issues associated with hormone replacement therapy in post-menopausal women will be noted. **References** Mangan G. et al. ### OP-PM16 Physiology: Fatigue

#### PACING DIFFERS BETWEEN TIME- AND DISTANCE-BASED TRIALS

Abbiss, C.R., Thompson, K.G., Lipski, M., Meyer, T., Skorski, S.

*Edith Cowan University*

**Introduction:** An important aspect of pacing is the ability of an individual to make prospective judgments about the demands of a task (Chinnasamy et al. 2013) and momentary (De Koning 2011) or anticipated physiological/metabolic stress (Tucker et al. 2004). Both time- and distance-based time trials (TT) are often implemented to assess pacing and performance. One's ability to judge time and distance is likely to influence anticipated task demands and thus pacing (Chinnasamy et al. 2013). The purpose of this study was to compare pacing and performance between distance- and duration-based trials of short (~6 min) and long (~30 min) duration. **Methods:** On separate occasions and in a randomised semi-balanced order, 13 trained cyclists (4 female, 9 male; mass:  $74 \pm 9$  kg,  $VO_{2max}$ :  $55.1 \pm 3.9$  ml/kg/min) completed four self-paced cycling time trials (TT; 4 km, 20 km, 6 min and 30 min). Duration and distance of TTs was chosen to approximately match the total work during short (4 km and 6 min) and long (20 km and 30 km) TTs. Participants were instructed to complete each time trial with the highest sustainable power output. Distance/duration covered was the only feedback provided. **Results:** Average power output was not different between the 4 km and 6 min TTs ( $324 \pm 46$  vs  $325 \pm 45$  W;  $P=0.96$ ), nor the 20 km and 30 min TTs ( $271 \pm 44$  vs  $267 \pm 38$  W;  $P=0.24$ ). Exercise time was lower during the 4 km TT (min:s;  $5:40 \pm 0:18$ ) compared with the 6 min TT ( $P=0.01$ ) but not different between the 20 km ( $29:51 \pm 1:45$ ) and 30 min trial ( $P=0.77$ ). There was also no significant trial by split interaction for the short or the long TTs ( $P=0.74$  and  $0.15$ , respectively). The rate of decline in power output over the first 40% of the trial was not different between the 4 km and the 6 min TT ( $P=0.13$ ), but was greater in the 20 km TT compared with the 30 min TT ( $P=0.01$ ). **Discussion:** Pacing within short trials was similar however, athletes commenced a longer distance-based TT at relatively higher power outputs when compared with a similar time-based trial. This contrasts findings in children where lower running speeds have been observed in the final stage of a time- compared with distance-based task (Chinnasamy et al. 2013). These findings indicate that pacing differs between prolonged distance- and time-based tasks which may be related to the athletes' anticipation of task demands. **References:** Chinnasamy C, St Clair Gibson A, Micklewright D (2013). *Med Sci Sport Exerc.* 45(2), 395-402. #### THE EFFECT OF A SLEEP HYGIENE PROTOCOL ON PHYSICAL RECOVERY FOLLOWING A LATE-NIGHT MATCH IN FOOTBALL PLAYERS

Fullagar, H.H.K.1, Skorski, S.1, Duffield, R.2, Meyer, T.1

*(1) Saarland University, Germany (2) University of Technology Sydney, Australia*

**Introduction** Late-night matches are a common occurrence for elite footballers and can result in sleep disruption, which is often highlighted as a cause of slower recovery (Meyer et al. 2014). Sleep hygiene protocols (SHP) have been suggested to aid sleep quantity/quality (Duffield et al. 2014) and therefore may assist ensuing recovery from late-night finishes. However, the effectiveness of SHP to improve recovery following these matches remains unknown. Therefore, this study aimed to investigate the effects of a SHP on physical recovery following late-night matches in football players. **Methods** In a randomised cross-over trial, 20 male ( $179 \pm 6$  cm;  $75.6 \pm 7.4$  kg;  $25 \pm 4$  y) well-trained football players from 2 teams played two friendly matches against one another with late-night kick-offs (20:45), seven days apart. Following each match, players either completed a SHP (Duffield et al. 2014) with bed time before 12:00am or remained awake without sleep protocols (NSHP) until 02:00 (objective sleep data collected). Players were awoken at 07:30 the next morning. Post-match recovery measures (Counter-movement jump (CMJ) and YoYoIR2 (YYIR2) tests were obtained 12 h and 36 h post-match. **Results** Mean±SD time of sleep for SHP and NSHP was  $12:22am \pm 26$  min and  $02:30am \pm 13$  min, respectively. Sleep duration was significantly greater ( $P < 0.01$ ) in the SHP group ( $372 \pm 46$  min) compared to the NSHP condition ( $266 \pm 27$  min). No significant differences were found between conditions for CMJ for 12 h (NSHP:  $35.3 \pm 3.9$  cm; SHP:  $35.9 \pm 3.8$  cm) and 36 h (NSHP:  $35.2 \pm 3.9$  cm; SHP:  $34.8 \pm 3.6$  cm) post-match ( $P=0.13$  and  $0.33$ , respectively). Further, no significant differences were found between conditions for YYIR2 for 12 h (NSHP:  $627 \pm 153$  m; SHP:  $606 \pm 131$  m) and 36 h (NSHP:  $630 \pm 152$  m; SHP:  $600 \pm 155$  m) post-match ( $P=0.13$  and  $0.44$ ). **Discussion** Whilst SHP improved sleep quantity by around 2 h following a late-night football match, there were no improvements in acute physical recovery. The lack of an effect on recovery may be possibly due to not having a large enough absolute sleep difference between conditions, albeit the bedtime in the NSHP condition is similar to reported match bedtimes in professional players. Further, our matches were friendlies limiting the inference of our results to competitive matches (different physical/psychological loads). Thus, future research may be directed towards whether a larger differential in sleep duration can improve the recovery timeline. In addition, evidence concerning responses to sleep interventions following actual competitive matches in professional players is required. **References** Meyer T, et al. *Sport Orthop Traumatol.* 2014;30:112-8. #### EFFECT OF PROGRESSIVE NORMOBARIC HYPOXIA ON DYNAMIC CEREBRAL AUTOREGULATION

Horiuchi, M., Endo, J., Dobashi, S., Kiuchi, M., Koyama, K., Subudhi, A.W.

*Mt. Fuji Research Institute*

**Introduction** Previous studies have shown impairments in dynamic cerebral autoregulation (CA) during acute periods (~10) of severe, but not moderate, hypoxia (1). These findings have led to speculation that a threshold level of hypoxia must be exceeded before CA is impaired. We sought to determine the threshold of hypoxia necessary to impair CA. **Methods** Six healthy young men with a mean age of  $22 \pm 3$  years (mean ±SD), height of  $175 \pm 5$  cm, and body weight  $64 \pm 4$  kg, were studied at an elevation of 3000 m ( $P_{bar} = 735$  mmHg). Subjects were exposed to progressive levels of normobaric hypoxia (30 min stages inspiring 21, 18, 15, and 12% O<sub>2</sub>). At each level of hypoxia, dynamic CA was evaluated twice (?) using the classic thigh-cuff inflation (3 min at 220 mmHg) / rapid deflation technique to induce a transient drop in arterial blood pressure. Common carotid artery (CCA) blood flow and beat-by-beat blood pressure were measured throughout the study. Rate of regulation (RoR) as an indicator of dynamic CA was calculated from the slope of CCA conductance (CCA blood flow/blood pressure) from 1.0~4.0 s after thigh cuff-release, relative to the drop in mean arterial pressure (MAP);  $RoR = (\Delta CCA$

conductance / delta t) / delta MAP. Results RoR was unchanged from 21 % to 18 % O<sub>2</sub> (include RoR values respectively, P>0.05), but was impaired at 15 % and 12 % O<sub>2</sub> (include RoR values, respectively) when compared against 21 % and 18 % O<sub>2</sub> (P<0.05). Progressive hypoxia from 15 to 12 % O<sub>2</sub> did not further reduce RoR (P>0.05). Discussion Our results indicate that the hypoxic threshold for impairment in dynamic CA occurs at ~15 % O<sub>2</sub> (PIO<sub>2</sub> of 560 mmHg). Our findings are in agreement with a previous study, which utilized shorter periods of hypoxia (~10 min) and transfer function analysis to assess CA. These studies suggest that dynamic CA impairment may be seen at elevations where the PIO<sub>2</sub> is similar. Future field studies are necessary to confirm these findings and study the implications of impaired CA at higher elevations. References 1. Iwasaki et al. ## ENDURANCE EXERCISE INCREASES PLASMA KYNURENIC ACID IN HUMANS

Schlittler, M.

*Karolinska Institutet*

**INTRODUCTION** The kynurenine pathway of tryptophan degradation generates several neuroactive metabolites, such as quinolinic acid (QUIN; a glutamate agonist) and kynurenic acid (KYNA; a glutamate antagonist). Induction of the neurotoxic branch, leading to excess of QUIN has been associated with depression (1). Exercise training may protect from depression by an increased expression of skeletal muscle kynurenine amino-transferases (KATs), which convert plasma kynurenine to KYNA and thus prevent metabolism towards QUIN (2). The aim of this study was to analyse plasma KYNA in humans at rest and following different types of exercise. **METHODS** Blood samples were drawn from athletes before and after (1h and 24h) aerobic endurance exercise (150 km road cycling or 21.1 km running). Results were compared to another group of athletes performing high-intensity eccentric exercise (100 drop-jump) as well as to a group of inactive subjects (non-athletes). In all samples, plasma was analysed for KYNA by high-performance liquid chromatography with fluorescence detection. **RESULTS** In the athletes performing endurance exercise, KYNA concentration increased significantly 1 hour after endurance exercise compared to baseline. The concentration of KYNA returned to baseline 24 hours after exercise. Plasma concentration of KYNA was not affected by the high-intensity eccentric exercise. Plasma KYNA concentrations of inactive subjects were similar to those of the athletes before exercise. **DISCUSSION** Our data indicate that plasma KYNA concentration increases following endurance exercise but not after high-intensity eccentric exercise. Endurance exercise may thus cause a peripheral shift in the kynurenine pathway that could be protective against depression. In high-intensity eccentric exercise, which causes muscle damage and severe fatigue but is less metabolically challenging than the endurance exercise, plasma KYNA did not increase. This suggests that activation of the kynurenine pathway in exercise is linked to metabolic demand. **REFERENCES** 1 Claes, S. et al. ## EFFECTS OF ACUTE DIGOXIN INTAKE ON SKELETAL MUSCLE NA<sup>+</sup>,K<sup>+</sup>-ATPASE CONTENT, PLASMA K<sup>+</sup> REGULATION AND FATIGUE DURING INTENSE EXERCISE IN HEALTHY YOUNG ADULTS

Atanasovska, T., Smith, R., Wong, C., Petersen, A.C., Krum, H., McKenna, M.J.

*Victoria University, Melbourne, Victoria, Australia*

Potassium (K<sup>+</sup>) disturbances during intense exercise have been linked with fatigue. We investigated the effects of acute administration of digoxin, a specific Na<sup>+</sup>,K<sup>+</sup>-ATPase (NKA) inhibitor, on K<sup>+</sup> regulation, exercise performance and skeletal muscle NKA content and isoform abundance, in 10 healthy adults, in a randomised, crossover, double-blind, counterbalanced design study. Participants were orally administered 50 mg digoxin (DIG) or placebo (PLAC) and then 60 min later commenced cycling for 1 minute at 60% and 95%VO<sub>2peak</sub>; then to volitional fatigue at 95%VO<sub>2peak</sub>. Radial arterial plasma [K<sup>+</sup>]<sub>a</sub> was measured at rest, during exercise, for up to 60 min in recovery. A vastus lateralis muscle biopsy was performed at rest and immediately post-exercise and analysed for NKA content via [3H]-ouabain binding, without and with digoxin antibody DigiF(ab)<sup>®</sup> to detect the fraction of NKA bound by digoxin; and for NKA isoform protein abundance. Serum digoxin concentration prior to exercise was 3.36±0.80 nM in DIG (below 0.2 nM detection limit in PLAC). Time to fatigue at 95%VO<sub>2peak</sub> was 6.4% less during DIG than PLAC (233.7±46.0 vs 249.8±53.3, respectively, P=0.029). Muscle NKA content as determined by [3H]-ouabain binding was unchanged with DIG; but separate [3H]-ouabain binding analysis after removal of bound digoxin with DigiF(ab)<sup>®</sup> antibodies revealed a 7.8% digoxin occupancy compared to PLAC (P=0.003), indicating a 7.8% increase in actual muscle NKA content after DIG. The NKA α-1 and β-2 isoform protein abundances were unchanged with digoxin. Plasma [K<sup>+</sup>]<sub>a</sub> increased during exercise and fell immediately in recovery, being lower than baseline at 10 min post-exercise (P=0.025). Plasma [K<sup>+</sup>]<sub>a</sub> was greater in DIG than PLAC across all times (4.93±0.18 vs. 4.88±0.20, respectively, P=0.035). Thus acute digoxin treatment increased the number of apparently functional NKA complexes, as detectable by the 7.8% increase in [3H] ouabain binding after DigiF(ab)<sup>®</sup> pre-treatment, which occurred in the absence of any increase in α or β isoform abundances. This may indicate that acute digoxin-inhibition of NKA stimulated increased assembly of existing α and β subunits. This would act to rapidly recover the number of available NKA, thus preserving muscle NKA capacity in the face of acute NKA inhibition and consequent potential deleterious effects. Despite this, DIG perturbed arterial K<sup>+</sup> regulation and impaired muscle performance, with increased fatigability during intense exercise.

## Invited symposia

### IS-BN02 SPORT EXPERTISE: PUTTING BRAIN, BODY, AND ENVIRONMENT TOGETHER AGAIN

#### EXPERTS EXPLOIT NEUROBIOLOGICAL DEGENERACY IN MULTI-ARTICULAR SKILLS

Seifert, L.

*University of Rouen*

This talk identifies key properties of expertise in sport predicated on the performer-environment relationship. Weaknesses of traditional approaches to expert performance, which uniquely focus on the performer and the environment separately, are highlighted by an ecological dynamics perspective. Key properties of expert movement systems include degeneracy, multi- and meta-stability, adaptive varia-

bility and the attunement to affordances (Seifert et al., 2013). Empirical research on these expert system properties indicates that skill acquisition does not emerge from the internal representation of declarative and procedural knowledge, or the imitation of expert behaviours to linearly reduce a perceived 'gap' separating movements of beginners and a putative expert model. Rather expert performance corresponds with the ongoing co-adaptation of an individual's behaviours to dynamically changing, interacting constraints, individually perceived and encountered. The functional role of adaptive movement variability is essential to expert performance in many different sports, showing how many coordinative structures can achieve the same function (i.e., performance outcome), which is known as degeneracy property (Edelman and Gally, 2001; Friston and Price, 2003). This key property signifies that, in sport performance, although basic movement patterns need to be acquired by developing athletes, there exists no ideal movement template towards which all learners should aspire, since relatively unique functional movement solutions emerge from the interaction of key constraints (Davids et al., 2015). In this talk, a special focus on degeneracy property is provided to highlight how expert functionally explore and interact with their environment in climbing (Seifert et al., 2014). ### **ACTION ANTICIPATION AND ACTION PLANNING IN ELITE ATHLETES: EVIDENCES FROM PSYCHOPHYSICS AND TRANSCRANIAL STIMULATIONS STUDIES**

Cesari, P.

*University of Verona*

Although behavioral studies suggest that professional athletes have better sensory and motor skills than novices, very little is known about the neural underpinnings of these superior perceptuo-motor abilities. Elite sports performance not only involves the ability to execute complex actions such as, for example, shooting a ball into a basket, but also the ability to predict and anticipate the behavior of other players. Thus, observing others' actions may imply a covert simulation of the very same action, a process likely crucial in both imitative and non-imitative motor learning. One may wonder whether the modulation of resonant action systems has any specific role in the superior perceptual abilities exhibited by athletes engaging in sports activity. Here we present several experiments showing the exceptional ability that basketball and soccer players along with professional dancers have in pre-programming and in anticipating the actions in which they excel.

### **AN ECOLOGICAL DYNAMICS VIEW OF SOCIAL COORDINATION: GOING BEYOND A TEAM OF EXPERTS TOWARDS AN EXPERT TEAM**

Araujo, D.

*University of Lisbon*

Previous research has proposed that team coordination is based on shared knowledge of the performance context, responsible for linking teammates' mental representations for collective, internalized action solutions. However, we argue that the traditional shared knowledge assumption is predicated on "knowledge about" the environment, which can be used to share knowledge and influence intentions of others prior to competition. Rather, during competitive performance, the control of action by perceiving surrounding informational constraints is expressed in "knowledge of" the environment. This crucial distinction emphasizes perception of shared affordances (for others and of others) as the main communication channel between team members during team coordination tasks. From this perspective, the emergence of coordinated behaviours in sports teams is based on the formation of interpersonal synergies between players resulting from collective actions predicated on shared affordances. We highlight innovative measurement tools which might be used in research and practice to capture such interpersonal synergies. These tools are suitable to reveal the idiosyncratic collective behaviours of sports teams, particularly their coordination of effort and the more frequent patterns of communication and interactions between team players. More to the point, we will address three properties of synergies and the tools that could measure each of them. For example, dimensional compression could be measured by cluster phase; Sharing patterns could be measured by dominant regions; and reciprocal compensation could be measured by social complex networks.

## **Invited symposia**

### **IS-BN03 THE WORKPLACE AS ARENA FOR HEALTH ENHANCING PHYSICAL ACTIVITY INTERVENTIONS. QUANTIFICATION AND HOW TO REACH THOSE MOST IN NEED**

#### **DESIGNING WORKPLACE PHYSICAL EXERCISE TRAINING INTERVENTIONS TAILORED TO OCCUPATIONAL EXPOSURE.**

Søgaard, K.

*Institute of Sports Science and Clinical Biomechanics*

Introduction Physical exercise at the workplace is a key factor in managing musculoskeletal pain, improving health and decreasing risk factors for lifestyle diseases. Many studies have focused on the effect of physical exercise among office workers, while the evidence for employees with physically heavy work is more scarce. This is an interesting paradox since the latter sectors presents with the largest prevalence of musculoskeletal pain and life style diseases in general. The employees in these sectors are thus most in need of and have the largest potential to benefit from physical exercise programs. The emerging interest in sedentary lifestyle, including inactivity in working time, as a risk factor has logically also increased focus on physical exercise as the general tool that can be used to counteract lifestyle diseases and the work place as the setting. However, in many occupational sectors the employees still have a relatively high physical workload, which in contrast to leisure time physical activity may not be health enhancing. Rather, occupational physical activity consists of many different elements, some of them, but not all, usually considered risk factors for mechanical, metabolic and cardiorespiratory

overload. Thus high static loads such as in frequent lifting may constitute a risk factor while dynamic work involving walking or standing to some degree may maintain aerobic fitness. This involves a special challenge when introducing health enhancing physical activity among workers with physically heavy work. The challenge may be met by a thorough analysis of the work exposure as well as the capacity of the workers. This will form the basis for a sound exercise profile tailored to different occupational sectors and combining optimal ergonomics adjustment of the working conditions with physical exercise training. The same basic principles may apply both in sedentary and physically heavy jobs as the relation between the exposure and the effect forms a U-shape with an optimum exposure for obtaining the largest physiological benefit in terms of tissue growth, strength and general function. The concept of "Intelligent Physical Exercise Training" has been developed to tailor exercise to individual capacities and disorders, balancing capacity relatively to occupational exposure. For successful implementation, the concept strives to allow for flexibility in time scheme and location as well as to consider preferences of the participant to keep motivation high and in addition be as cost-effective for the company as possible. In this presentation an overview will be given of a number of recent Danish interventions involving more than 2000 employees and targeting both job sectors with physically heavy and more sedentary jobs.

#### **'OCCUPATIONAL PHYSICAL ACTIVITY – QUANTITY AND ROLE IN A HEALTH PERSPECTIVE**

Ainsworth, B.

*Arizona State University*

Physical activity at work is difficult to quantify but it represents an important part of the total daily energy expenditure. Thus, precise measures of occupational physical activity are needed to estimate the contribution of work behaviors to health and the risks of a number of life style diseases. Historically, epidemiologists have used job titles and job classification systems as a proxy for differences in occupational physical activity demands. They have compared those classifications with health outcomes. An improved estimation of occupational demands can be provided by assigning MET values to job tasks and classification systems. This method provides an inexpensive and feasible approach for quantification of occupational physical activity by intensity and estimation of work-related energy expenditure. Yet, as job demands and job titles change over time and increased emphasis is placed on the impact of sedentary behaviors on health, the MET classifications and occupational PA assessment methods must be updated to cover the content of today's occupations. This contribution will describe the methods and rationale for assigning MET estimates to occupational classification systems. Population estimates are presented for intensities of occupational activity to illustrate the use of the MET classification of occupational physical activity and thereby to quantify the relative contribution of this fraction to total physical activity, which may be of importance in a public health perspective.

#### **WORKPLACE PHYSICAL ACTIVITY INTERVENTIONS IN A COST-EFFECTIVENESS PERSPECTIVE.**

van der Beek, A.J., van Mechelen, W.

*EMGO Institute for Health and Care Research, VU University Medical Center*

From a number of perspectives, worksite health promotion programs seem to be relevant and might be even more effective than usual care regarding typical health risk factors, such as reductions in musculoskeletal disorders, body weight, cholesterol level, and cardiovascular disease risks. However, if the company should take a serious interest in such costly health enhancing initiatives, they should also be informed about side-effects on productivity, sick leave, and the overall economical aspect of a sustainable work force. Hence, the financial benefits related to these issues should be included in scientific evaluations, and the costs of the program should be minimized. This presentation will not only cover the aspect of the general benefit of the society related to primary prevention, but will also take the perspective of specific interest of the companies for such work-related health enhancing programs. Starting from the systematic review of J.M. van Dongen et al. (*Obes Rev* 2011;12:1031-49), an overview will be given of the scientific evidence that has been published since then, about the financial return of worksite health promotion programs aimed at improving nutrition and/or increasing physical activity.

### **Invited symposia**

#### **IS-SH04 RELATIVE AGE EFFECTS IN YOUTH SPORT: INSIGHTS FROM PHYSIOLOGICAL, PSYCHOLOGICAL, AND SOCIOLOGICAL PERSPECTIVES**

##### **RELATIVE AGE EFFECTS - A PSYCHOLOGICAL PERSPECTIVE**

Cobley, S.

*Sydney University*

In childhood and youth sport, discrepancies between the relatively older and younger participating on school, local, regional representative, and national sport teams can often vary between ratios of 1.5 to > 9 – 1. But as an outcome, these RAE effect sizes likely occur as a result of numerous interacting factors and social processes that span from the broad developmental system to the individual. For instance, RAEs likely relate to cognitive bias, whereby sports systems and practitioners apply errorful heuristics of 'availability, representativeness, escalation, and attribute substitution'. In contexts espousing and enacting a social-cultural focus upon 'domination and winning', essentially emulating the adult-elite sporting world, the conditions are set to identify and select players who can achieve those immediate outcomes (i.e., the relatively older and more physically mature). In this sense, practitioners are selecting appropriately, but in another sense they - and the system - are either not aware or consciously considering the dynamics of growth and development from a longer-term performance standpoint. Likewise, the potential psycho-social, skill, and health benefits from sport participation are being undermined. To change these values and ideologies in youth sport systems (i.e., replacing heuristics with analysis, rationality, and logic) the presentation also highlights recent intervention work seeking to reduce and remove RAEs from evaluation and selection processes.

**THE RELATIVE AGE EFFECT FROM THE PHYSIOLOGICAL AND PERFORMANCE PERSPECTIVE**

Gil, S.M.

*University of the Basque Country (UPV/EHU)*

Most sports systems group athletes according to their chronological age. Thus, a selected date of birth, known as the cut-off-date, is used to group children into age-specific teams. This particular date of birth is the 1st of January in most European countries, but it may be a different one (i.e. 1st September). Thus, a child born soon after this cut-off-date will be almost 12 months older than another one born at the end of the same year. Nevertheless, they will play sports together. The term relative age refers to a person's age relative to that of their peers within the same annual group. This characteristic depends on the date of birth relative to the selection data used to place a child in a specific age group. The variations in age within an annual age group have been referred to as relative age differences, and its consequence as the relative age effect (RAE). As a result of the RAE, there is an overrepresentation of the participants born in the first months after the cut-off-date in many sports, particularly in soccer and hockey. But it has also been observed in basketball, handball, tennis, winter sports, rugby league, swimming and cricket. Moreover, it has been reported not only in Europe, but also in Brazil, Japan, America and Australia. It is well documented that the RAE is more relevant in high level sport, particularly in male squads. In this respect, 36-50% of highly selected and international male soccer players had been born within the first three months of the year. On the other hand, not only skill level, but also age seems to be important in the RAE. In fact, RAE appears to progressively increase with age from childhood to adolescence. Besides, in school sports the differences are not so large; however, it depends on the sport. Physical and physiological growth and maturation have been hypothesized several times as the underlying cause for the RAE. In order to clarify it, some studies have compared performance and fitness of youngsters and adolescents of the general population born in the different months of the year, demonstrating controversial results. On the other hand, it has been observed that some sports participants born in the beginning of the year are taller, heavier and they also perform better compared to those born towards the end of the year. In contrast, in highly selected squads the differences become smaller. The importance of this issue is relevant for two reasons: on one side, children born at the end of the year will not have the same opportunities to be selected to participate in higher level sports; on the other, from a more competitive point of view, there will be an inevitable loss of talent.

**RELATIVE AGE EFFECT FROM A SOCIOLOGICAL PERSPECTIVE**

Pettersson, T.

*Dep. of Sport Sciences*

The sports movements in the Scandinavian countries have, in an historical perspective, been comparatively well supported by the State. State support for youth leisure activities has been directed to different youth organizations, particularly sports clubs. Government grants to sport are given primarily because it fulfills through its various activities a number of goals which do not necessarily have to do with sports, but which society considers important to achieve by means of government funding. The resources are to be used to reach out to people and activate those who want to take part in organized sports or choose to do physical exercise for their own well-being. For sports clubs, however, fostering top athletes is an essential part of their pursuit. Selection systems believed to produce top athletes exists at all levels within the sports movements – local, regional and national. And selection systems cannot be used without the appearance of Relative Age Effects. RAEs have been suggested as representing a form of bias, irrationality, and are counter-productive to longer-term attainment and the motives of the State to support youth sport. In the long run this could lead to the public acceptance of a generous tax-paid support to youth sport being jeopardized. Therefore we argue for the research community to engage with sport organizations and sport governing bodies to more strongly support child and youth longer-term development. We also believe in the importance of doing this using a multidisciplinary approach.

**Invited symposia****IS-SH09 SPORTS LABOUR MOBILITY AND THE POLITICS OF PRECARIY**

---

**GLOBALIZATION, SPORTS AND THE PRECARIY OF MASCULINITY**

Besnier, N.

*University of Amsterdam*

Through the lens of multi-sited comparative ethnographic research on the hopes of young man in the Global South and the migratory actions that derive from them, the ERC-funded "Globalization, Sports and the Precarity of Masculinity" (2012–17) project seeks to shed light on a number of fundamental theoretical problems in the contemporary world: How masculinity articulates with the body, consumption, and the global condition; how it operates as a guide for social action in contexts in which poverty and marginality have seriously undermined the ability to hope; and how nationalism, citizenship, and belonging operate in a field in which global dynamics have seriously disrupted their taken-for-granted nature, while they simultaneously remain at the forefront of public debates. The project analyses the global condition through an understanding of gendered bodily practices, thus reversing common approaches that begin with large-scale processes as the frame for understanding sports labour migration. Furthermore, the project provides a critical and hitherto unexplored angle on themes that are of immediate concern to not only societies teetering on the edge of the global, but also to industrial societies that must engage with the Global South: "the predicament of youth," "the precarity of masculinity," and "the crisis" tout court.

**THE CIRCULATION OF BRAZILIAN FOOTBALL PLAYERS**

Rial, C.

*Federal University of Santa Catarina*

The dissemination of Brazilian football players abroad, even if not recent, has heightened in the 21st century, presenting a large symbolic impact given its strong presence in the global media and the colonization of masculine imaginations exercised by football. In addition to the player-celebrities at global clubs in Europe, there is also a numerically significant flow of non-famous players who look for work in countries that are unlikely destinations for other Brazilian emigrants such as Russia, China, India, Korea and Morocco. There is also a

nearly invisible flow of Brazilian women football players who seek the United States and northern Europe countries to practice the sport in which they have been historically discriminated against in Brazil, as indicated by the closing of the women's football department at Santos, which had traditionally been Brazil's leading women's football club. Based on multi-site ethnographic research conducted since 2003 about the careers and lifestyles of Brazilian players living in more than 10 countries, I argue that categories such as frontier, migration, immigrant/emigrant and transnationalism do not apply to the mobilities of male and female football players. In the same way that in other professional trajectories, such as those of diplomats or intellectuals, these displacements are constituted in circulations beyond state borders, with periodic returns to the country of origin. I show that life abroad takes place in protected bubbles, where the relations of the protagonists are more translocal than transnational and that in recent years there has been a more accentuated return. o not insert authors here

### PRECARIOUS ISSUES IN WOMEN'S FOOTBALL MIGRATION

Agergaard, S.

*Aarhus University*

The career of an international athlete is often characterized by short-term contracts and career uncertainties illuminating central aspects of contemporary labour migration and neo-liberal employment practices. The British economist, Guy Standing, has examined the process of becoming part of the 'precariat' combining the concepts precarious and proletariat. The defining characteristic of precariats is the unstable and short-term nature of their employment underpinned by a low probability of building a career. This presentation will be based on a critical case study of African female athletes' migration into and away from Scandinavian football clubs. First of all, the case study points to precarious issues relating to the processes through which athletes obtain labour mobility by moving to Europe and between European sports clubs. Secondly, precarious issues are found in relation to labour conditions and accommodation of migrant athletes in Scandinavia, and thirdly the case study points to precarious issues relating to life after the professional athletic career. Even if Scandinavian clubs and audiences employ and consume an increasing numbers of transnational athletes, there is no policy framework set up to ensure support to their dual career development and post-career transition. In other words, even if migrating female athletes certainly belong to the elite, there are many aspects of the market, profession and their job that may suggest comparing their options for upward mobility or secured existence with those of blue collar workers: giving your (physical) skills fully into the sports industry. However, the sports industry, its show business and, above all, the enactment of the game, also provide several options of self-realization and agency to their main social actors; the transnationally mobile player. The players themselves state that their primary motivation for moving is "the love of the game", which may be interpreted partly as a joy of being fully engaged in a game (that also is your main leisure interest) and, partly as an expression of the risks following with engaging yourself in the global labour market of sports. The presentation will address weaknesses in current policy provision that needs future societal and scientific attention.

## Oral presentations

### OP-PM38 Training & Testing: Endurance II

#### CORRELATION BETWEEN OXYGEN CONSUMPTION AND ACCELEROMETER COUNTS AT DIFFERENT PLACEMENTS DURING RUNNING

Poulsen, M.K., Larsen, R.G., Franch, J.

*Aalborg University*

Background - Measuring energy expenditure (EE) during free-living activities has received increasing interest from the research community (1). However, validity of EE measurements during exercise of higher intensities has proven difficult (2). Measuring EE using direct calorimetry (i.e., oxygen consumption; VO<sub>2</sub>) is the more accurate method but can be challenging to implement during free-living conditions (2). Therefore, triaxial accelerometers counts have been employed to quantify physical activity intensities and EE (3). Based on correlation analyses between accelerometer counts and EE, previous studies have shown that accelerometer counts underestimate EE during running at higher speeds (4, 5). Therefore, the purpose of this study was to investigate the correlations between vector magnitude (VM) counts and EE using alternative accelerometer placements during running. Methods - VO<sub>2</sub> (Oxycon Pro, Jaeger) was measured during progressive treadmill running starting at 8km/h with 2km/h increase every fourth minute until 18km/h with 30s brakes between each step. VM counts were measured with accelerometers (GT3X, ActiGraph) at 4 different sites (wrist, hip, thigh and ankle). VO<sub>2</sub> and VM counts from the last minute during each speed were analyzed. The subjects (N=14) were competitive triathletes/runners (1 female, 13 males) with an age (Mean±SD) of 28±8.2yr, mass 69.9±7.5kg and height 1.77±0.078m. Results - During progressive running, VM counts from the hand, ankle and thigh was strongly correlated with VO<sub>2</sub>/kg/min (wrist, thigh and ankle r<sup>2</sup> = 0.99), whereas VM counts from the hip-placed accelerometer showed poor correlation (hip r<sup>2</sup> = 0.02). Discussion - The current results confirm that VM counts underestimate EE during higher speeds of running using hip-placed accelerometers. In contrast, accelerometers placed on thigh, wrist and ankle all show excellent agreement between VM counts and EE. Previously, the plateau of VM counts reached during running at higher speeds using hip-placed accelerometers have been proposed to be a consequence of bandpass filtration (4). This explanation seems plausible, but it is unclear why this phenomenon was not present when accelerometers were placed at other sites. Further, equations is being constructed to predict EE from VM counts at the different accelerometer placements so future studies could investigate EE during free-living activities at various accelerometer placements. 1. #### TEST PROTOCOL OPTIMIZATION OF THE HEART RATE-BASED LACTATE MINIMUM TEST

Perret, C., Kurzen, J.

*Swiss Paraplegic Centre and ETH Zurich*

Introduction: The knowledge of the maximal lactate-steady-state (MLSS) is useful to steer and monitor the training process of athletes. Unfortunately, the exact determination of MLSS needs several tests, which is not feasible for daily practice. A promising approach to accurately predict MLSS based on one single exercise test might be the use of the lactate minimum testing concept. Some years ago, the

so-called heart rate-based lactate minimum test (LMT-HR) developed at our institute (Strupler et al., 2009) revealed a high correlation between lactate minimum (LM) and MLSS (Perret et al., 2012). However, despite this high correlation, MLSS was systematically underestimated by LM. Thus, the aim of the present study was to modify the existing protocol in order to improve the results of the original LMT-HR protocol. Methods: 14 healthy non-smoking endurance-trained male athletes (age: 39.7y (SD: 8.2); height: 181cm (6); body mass: 79kg (7); VO<sub>2</sub>peak: 54ml/min/kg (5) randomly performed four different LMT-HR, i.e. the original test protocol plus three new test protocols. The new test protocols were modified by changing the starting workload, duration and/or the size of the workload increment during the second part of the LMT-HR. In addition, athletes performed several endurance tests in order to assess their individual MLSS. Heart rate (HR), workload, lactate concentrations and oxygen uptake at LM of the different test protocols were compared to corresponding MLSS data. Results: As expected LM of the original LMT-HR protocol significantly underestimated MLSS concerning HR (154bpm (8) vs. 165bpm (7), workload (208W (31) vs. 224W (19), blood lactate concentration (3.4mmol/l (1.2) vs. 4.6mmol/l (1.3) and oxygen uptake (39ml/min/kg (4) vs. 42ml/min/kg (3)), whereas two of three of the modified new LMT-HR protocols showed no statistically significant differences for all measured parameters comparing LM (HR: 162bpm (7) and 162bpm (8); workload: 228W (23) and 234W (30); lactate: 4.7mmol/l (1.7) and 5.3mmol/l (2.2); oxygen uptake: 41ml/min/kg (4) and 41ml/min/kg (4)) with MLSS data. Conclusions: It can be concluded that LM directly corresponds to MLSS in two of our modified new LMT-HR protocols; thus, these new protocols can be used in practice to accurately and easily predict MLSS based on one single exercise test. ## PREDICTION OF ELITE TRIATHLON PERFORMANCE BY MULTIPLE LINEAR REGRESSION MODELS

Hoffmann, M.1, Moeller, T.2, Seidel, I.2, Stein, T.1

1: Karlsruhe Institute of Technology (KIT, Karlsruhe, Germany), 2: Institute of Applied Training Science (IAT, Leipzig, Germany)

Introduction: The physical characteristics of triathletes were investigated in several studies, mostly with recreational athletes (Van Schuylenberg et al., 2004; Schabert et al., 2000). Only a few studies focused on the relationship between individual parameters and race performance (Schabert et al., 2000). Accordingly, the aim of the current study was to analyze whether Olympic distance triathlon performance of elite athletes might be predicted by multiple-linear regression models using specific parameters from performance diagnostics. Methods: The dataset combines anthropometric and physiological performance parameters of 25 laboratory tests of eleven male elite triathletes (20-32 years), collected at the IAT between 2008 and 2012. Initially, an exploratory factor analysis was used to preselect relevant parameters. Eleven anthropometric (e.g. body height, pelvis width and body fat) and twelve physiological parameters (e.g. blood lactate concentration (La), pace and respiratory rate during treadmill running (peak/per interval)) were considered. Two multiple linear regression analyses were used to determine appropriate parameters to predict overall race time [s] in Olympic distance, separated in one anthropometric and one physiological model ( $p < 0.05$ ). Results: Multiple linear regression model using anthropometric parameters explained 40 % ( $p < 0.01$ ) of the variance in overall race time. Pelvis width ( $\beta = -0.674$ ) and shoulder width ( $\beta = 0.434$ ) had a significant influence. Predicted race time could partially ( $R^2 = 0.405$ ,  $SEE = 155.14s$ ) be calculated by equation  $7643.56 - 80.889 \times (\text{pelvis width [cm]}) + 37.388 \times (\text{shoulder width [cm]})$ . Multiple linear regression model using physiological parameters explained 67 % ( $p < 0.01$ ) of the variance in overall race time. Running pace at 3-mmol/l La ( $\beta = -0.474$ ), maximum La ( $\beta = -0.450$ ) and maximum respiratory rate RR ( $\beta = 0.505$ ) had a significant influence. Predicted race time could partially ( $R^2 = 0.665$ ,  $SEE = 117.27s$ ) be calculated by equation  $8521.03 + 8.556 \times (\text{RR [breaths/min]}) - 332.80 \times (\text{running pace [m/s]}) - 61.658 \times (\text{max La [mmol/l]})$ . Discussion: The best predictors in the multiple linear regression model of overall race time in Olympic distance triathlon using anthropometric parameters were pelvis width and shoulder width. The multiple linear regression model based on physiological parameters included running pace at 3-mmol/l La, maximum La and maximum respiratory rate. In a next step a mixed model with anthropometric and physiological parameters as well as a non-linear approach will be calculated. Information about previous races (overall/split times) and training indicators could lead to a better prediction of the performance (Gilinsky, 2014). References: Gilinsky N et al. (2014). *J Sci Med Sport*, 17, 300-305. Schabert EJ et al. (2000). *Med Sci Sports Exerc*, 32 (4), 844-849. Van Schuylenbergh R et al. (2004). *Eur J Appl Physiol*, 91 (1), 94-99. ## VALIDATION OF MODIFIED D-MAX METHOD FOR CALCULATING INDIVIDUAL ANAEROBIC THRESHOLD IN WELL TRAINED MALE CYCLISTS

Flockhart, M., Mattsson, C.M.

The Swedish School of Sport and Health Sciences

Introduction To predict endurance performance and evaluate adaption to training in endurance athletes a laboratory test for retrieving the anaerobic lactate threshold is often used. The maximal rate of oxidative metabolism that can be sustained during prolonged exercise indicates preserved homeostasis and thereby sets the upper limit for long term endurance. Exercise intensities above the anaerobic threshold require an additional input from anaerobic energy sources resulting in blood lactate accumulation and reduced time to fatigue. The threshold is therefore a reliable and powerful predictor of performance in aerobic exercise lasting approximately 40-60 min. The work rate that elicits a blood lactate of 4 mmol/l (e.g. LT4) is widely used to determine the threshold, but by using a fixed lactate concentration, flexibility to account for inter- and intra-individual differences in aerobic and anaerobic metabolism is lost. Our hypothesis was that our modified D-max method (D-maxmod) would provide a more accurate performance related value by calculating the individual anaerobic threshold (IAT). Methods 20 males cyclists age  $36 \pm 5$  years, weight  $79.7 \pm 5.8$  kg, VO<sub>2</sub>max  $4.4 \pm 0.4$  l/min performed an incremental test on a cycle ergometer for calculation of LT (D-maxmod, and LT4) at two occasions separated by 8 weeks. The test consisted of 5 minutes long stages separated by 1 min of rest where lactate was sampled. The increase in work rate was 30 W/stage starting at 100 W and ended above LT4. Short after, an incremental test to fatigue (start at LT4 power, increase 20 W/min) was performed for assessment of VO<sub>2</sub>max, calculation of maximal aerobic power (MAP) and maximal power achieved in the test (Wmax). On a separate day a 40 minutes time-trial (TT40) was performed for assessment of aerobic endurance performance. IAT D-maxmod was defined as the derivate to the exponential curve created from exponentially lactate increase, including maximal lactate concentration plotted at MAP. The increase in lactate relative to power was defined as the increase in blood lactate from the point where the exponential curve crossed the lactate baseline (See also Cheng et al. 1992 and Zhou & Weston 1997). Results IAT D-maxmod was calculated to  $5.0 \pm 0.8$  mmol/l. Both D-maxmod and LT4 were highly significantly correlated with both TT40 and Wmax. Coefficients of determination were higher for D-maxmod compared to LT4 for both TT40 ( $r^2 = 0.78$  vs  $0.69$ ) and Wmax ( $r^2 = 0.89$  vs  $0.64$ ). Conclusion The calculated D-maxmod correlated better with performance than LT4 for parameters highly linked to performance in road- and mountain bike competitions. ### CONVENTIONAL CRITICAL POWER TEST PREDICTS 16.1 KM ROAD TIME TRIAL PERFORMANCE

Morgan, P.T., Durant, J.H., Black, M.I., Bailey, S.J., Jones, A.M., Vanhatalo, A.

*University of Exeter*

**Introduction** Critical power (CP) and 'functional threshold power' (FTP) are indices of aerobic fitness and strong predictors of endurance performance (Smith et al., 1999). Completion time (T<sub>lim</sub>) during a cycling time trial (TT) can be predicted on the basis of the CP (asymptote) and W' (curvature constant) parameters of the power-duration relationship according to the equation  $T_{lim} = (W - W')/CP$ , where W indicates total work done during the TT. However, the accuracy of this performance prediction when CP and W' are estimated by on-bike power meters is unclear. The FTP test is a popular fitness test for cyclists but its agreement with CP is also yet to be determined (Gavin et al. 2012). Therefore, the aims of this study were to test the hypotheses that: 1) 16.1 km TT performance on the road would be accurately predicted from laboratory-based estimates of CP and W' using on-bike power meters; and 2) FTP would be significantly correlated with CP. **Methods** Following ethical approval, 13 competitive male cyclists (VO<sub>2</sub> peak of  $63.48 \pm 6.54$  ml•kg<sup>-1</sup>•min<sup>-1</sup>) completed 4-5 TT exercise bouts for the estimation of CP and W', and a 20 min TT (FTP test). These trials were completed in the laboratory with the participant's individual competition bike loaded onto a static trainer for rear wheel power output measurement (PowerTap, CycleOps). Subjects also performed a 16.1 km TT on the road on one occasion with the same power measuring device. 16.1 km TT performance was predicted using the equation  $T_{lim} = (W - W')/CP$ . Results CP and W' derived from the power-time relationship were estimated at  $277 \pm 42$  W and  $19.5$  kJ  $\pm$  6.5 kJ, respectively, while FTP was  $278 \pm 42$  W. FTP and CP were not significantly different ( $P > 0.05$ ) and these variables were significantly correlated ( $r = 0.96$ ,  $P < 0.05$ ). Predicted 16.1 km TT performance ( $27.32 \pm 3.29$  min) was within 4.4% of, and not significantly different to, actual TT performance ( $26.66 \pm 2.17$  min,  $P > 0.05$ ). **Discussion** Our findings suggest that CP and W', as derived from mobile power meters in the laboratory, may be used to accurately predict 16.1 km cycling TT performance on the road. In addition, we observed a close agreement between FTP and CP, suggesting that the FTP may provide a time efficient, single-test estimate of the CP. These observations may help inform, and improve the accessibility of, testing procedures that can be employed to predict TT performance in competitive cyclists. **References** Gavin, T.P., Van Meter, J.B., Brophy, P.M., Dubis, G.S., Potts, K.N., and Hickner, R.C. ### RELATIONSHIP OF PHYSIOLOGICAL FACTOR CHANGES IN JAPANESE UNIVERSITY DISTANCE RUNNERS

Tanji, F., Shirai, Y., Enomoto, Y., Nabekura, Y.

*University of Tsukuba*

**Introduction** Maximal oxygen uptake (VO<sub>2</sub>max) and running economy (RE) are important factors for long distance runners. The presence of good indicators results in great running performance. A positive relationship between VO<sub>2</sub>max and RE has been reported (Fletcher et al. 2009). However, it is unclear how the change in one indicator affects the change in the other indicator in each runner. Japanese athletes have two race seasons. These generally take place between April and June and between September and November, with the periods from December to March and from July to August acting as preparation seasons. The main training in the competitive phase is tapered for the race, which differs from preparation phase training. Physiological factors might change according to the phase. Therefore, the aim of the present study was to measure VO<sub>2</sub>max and RE three times throughout year to clarify the relationship of physiological factor changes. **Method** Sixteen male university long-distance runners who completed the same training were studied. Measurements of VO<sub>2</sub>max and RE were taken in July, December and the following March. Participants ran in a multi-stage incremental load test for 3 min at 230, 250, 270, 290 and 310 m/min. RE was evaluated as the running cost (kcal/kg/km) using the method described by Kyröläinen et al. (2001). vVO<sub>2</sub>max was evaluated as a performance factor. **Result** A positive significant relationship was observed changes in the VO<sub>2</sub>max value and changes in the RE value above LT intensity running among runners ( $P < 0.05$ ). Many improving performance runners were plotted under the VO<sub>2</sub>max-RE regression line area. In addition, in each runner, a positive significant relationship was observed between VO<sub>2</sub>max and RE. VO<sub>2</sub>max tended to increase from July to December ( $P = 0.11$ ), but it did not change significantly throughout the year ( $70.5 \pm 5.7$ ,  $73.3 \pm 5.9$  and  $70.6 \pm 5.9$  ml/kg/min). Further, RE at all velocity and vVO<sub>2</sub>max did not change significantly throughout the year. **Discussion** Results of the present study indicated that RE decreased when VO<sub>2</sub>max increased by training. Improvement in either factor limited the reduction in the other factor because a positive relationship between VO<sub>2</sub>max and RE in each runner. Therefore, the balance between high VO<sub>2</sub>max and RE was important. On the other hand, relationships between these factors and performance changes were not observed by season. Further investigation is needed to determine how training lead to the change in the factors. **Reference** Fletcher JR, Esau SP, MacIntosh BR. ### OP-PM70 Molecular Biology and Biochemistry: Epigenetics

#### APOE GENE VARIANTS AND CONCUSSION SEVERITY

September, A.V., Abrahams, S., Mc Fie, S., Patricios, J., Suter, J., Posthumus, M.

*University of Cape Town*

**Introduction:** Concussion is the transmission of biomechanical forces to the head resulting in neurological deficits, stimulating elevated release of brain tissue damage markers and promoting neural cell death. Apolipoprotein E is involved in nerve tissue integrity and encoded by the APOE gene. The ε4 allelic variant of the APOE gene was associated with greater severity for brain injury in boxers. Therefore, this study's aim was to investigate the association between APOE variants and concussion profile in rugby players. **Materials and Methods:** In this case-control genetic association study, 198 previously concussed cases and 129 non-concussed, sport-matched controls (age: 15 – 39 years old) were recruited from rugby playing schools and clubs. Participants were genotyped for rs405509 (G/T), rs429358 (ε3/ε4) and rs7412 (ε2/ε3) variants within the APOE gene. Sport, concussion and medical history were recorded. Inferred haplotype analyses were conducted. **Results:** No significant genotype or allele frequency differences were noted between cases and controls ( $>P = 0.149$ ) and for concussion symptom duration in cases ( $>P = 0.253$ ). However, the frequencies of the age-adjusted inferred G-ε4-ε3 (28% vs. 24%;

$P < 0.001$ ) and G- $\epsilon$ 3- $\epsilon$ 2 (25% vs. 19%;  $P = 0.001$ ) haplotypes, of the APOE variants (rs405509-rs429358-rs7412), were significantly greater among cases compared to controls respectively. Conclusion: Although the independent APOE genotype frequencies were not associated with concussion susceptibility or severity, the combined effect of the three APOE variants implicates APOE in concussion susceptibility. Further exploration is needed to understand the complex role of APOE in susceptibility.

### GENDER DIFFERENCES IN MAXIMAL MITOCHONDRIAL RESPIRATORY CAPACITY IN ADIPOSE TISSUE BUT NOT IN MUSCLE AFTER INTENSIVE LIFESTYLE INTERVENTION

Dandanell, S.1,2, Larsen, S.1, Dela, F.1, Helge, J.W.1

1) University of Copenhagen, 2) Metropolitan University College Copenhagen

Introduction Weight loss and increased maximal oxygen uptake (VO<sub>2</sub>max) is the purpose of most intensive lifestyle interventions (ILI). Maximal mitochondrial respiratory capacity (MMRC) in skeletal muscle (SM) increases with aerobic training (AT) in both women (W) and men (M), but it is uncertain how a concomitant WL will influence the adaptation to ILI. In addition W have more subcutaneous adipose tissue (SAT) than M (1), but whether there are gender differences in the MMRC of the SAT is unclear. We hypothesized that MMRC would increase more in SM than in SAT after an ILI and that W would have a higher MMRC in the SAT than M. Methods 41 obese W and 21 obese M (BMI: 36.9  $\pm$  0.2, 39.0  $\pm$  0.2; Fat %: 44.9  $\pm$  1.3, 38.2  $\pm$  0.9) attended 11 weeks of ILI consisting of AT (1-3 hours/day) and hypo-caloric healthy diet (~ -500 Kcal/day). Biopsies from m. vastus lateralis and the abdominal SAT were obtained before and after the ILI. MMRC was determined using high-resolution respirometry (Oxygraph-2k, Austria). VO<sub>2</sub>max was measured on a graded cycle test (Cosmed Quark CPET, Italy) and body composition was measured by bio-impedance (Quantum X, USA). Results W and M lost body weight (W: 102  $\pm$  4 to 93  $\pm$  3; M: 126  $\pm$  5 to 114  $\pm$  4 kg,  $p < 0.001$ ) and increased VO<sub>2</sub>max (W: 2554  $\pm$  85 to 2701  $\pm$  86; M: 3113  $\pm$  100 to 3629  $\pm$  119 ml O<sub>2</sub>/min,  $p < 0.01$ ) after the ILI, respectively. M were heavier and had a higher VO<sub>2</sub>max than W ( $p < 0.001$ ), but W had a higher whole body fat % ( $p < 0.001$ ). Coupled and uncoupled MMRC increased in SM after the ILI in both W and M, respectively, (W: 53  $\pm$  3 to 62  $\pm$  2, 66  $\pm$  3 to 74  $\pm$  2; M: 52  $\pm$  2 to 64  $\pm$  2, 67  $\pm$  3 to 76  $\pm$  3 pmol/mg/s,  $p < 0.001$ ) but no effect of the ILI was found in the SAT (W: 1.1  $\pm$  0.1 to 1.1  $\pm$  0.1, 1.3  $\pm$  0.1 to 1.3  $\pm$  0.1 kg, M: 1.0  $\pm$  0.1 to 1.0  $\pm$  0.1, 1.2  $\pm$  0.1 to 1.2  $\pm$  0.1 pmol/mg/s). However, there was a trend towards higher coupled and uncoupled MMRC in SAT in W than in M ( $p = 0.09$ ,  $p = 0.06$ ). Discussion The main finding was that the MMRC increased after the ILI for both genders in SM, but not in SAT. Furthermore, in SAT there was a trend towards a gender difference, which was unrelated to the ILI. The findings imply that the ILI affects the metabolism in SM but not in SAT, and that W may have a higher metabolic rate in SAT than M. In line with that W also have a higher lipolytic sensitivity in abdominal SAT than M (1). Thus, the molecular differences related to MMRC and lipolytic sensitivity of SAT in W and M, respectively, may contribute to elucidation of why W are less prone to develop ectopic fat storage in non-adipose tissues than M. ### THE INDIVIDUAL AND COMBINED ASSOCIATION BETWEEN MULTIPLE GENE POLYMORPHISMS AND ELITE ENDURANCE ATHLETE STATUS

Lockey, S.J., Erskine, R.M., Pedlar, C., Kipps, C.W.G., Heffernan, S.M., Herbert, A.J., Stebbings, G.K., Williams, A.G., Day, S.H.

MMU Sports Genomics Laboratory, Manchester Metropolitan University, Crewe, UK.

A complex phenotype is required for endurance performance. Therefore, it is likely that 'elite status' is polygenic. We investigated individually, and in combination, eight gene polymorphisms (ACE rs1799752, ACTN3 rs1815739, AGT rs699, HIF1A rs11549465, PPARGC1A rs8192678, UCP2 rs659336, UCP2 rs660339 and UCP3 rs1800849) and elite endurance athlete status in male and female marathon runners. Marathon runners (272 Caucasians) were stratified by personal best (PB) into elite (men <2 h 30 min, women <3 h) and sub-elite (men <2 h 45 min, women <3 h 15 min) and compared to 528 Caucasian controls. There were initially some differences in AGT and PPARGC1A genotype and allele frequency between the stratified groups. However, after correction for multiple testing using the Holm-Bonferroni method, no significant differences in genotype or allele frequency remained between those groups. When considering PB, in women the PPARGC1A CC genotypes ran the marathon approximately 5 min 38 s faster than other genotypes ( $P = 0.046$ ), which is generally consistent with previous literature. The combined impact of all eight polymorphisms was assessed, with athletes classified according to the number of endurance alleles they possessed and a Total Genotype Score (TGS) generated. There was no significant correlation between TGS and PB ( $P = 0.871$ ), nor any differences between the TGS of athletes and controls as a combined cohort or when stratified by sex ( $P \geq 0.365$ ). An unexpected finding was that male elite athletes had a TGS approximately 8% lower than controls (36.5 vs 39.3,  $P = 0.042$ ). In summary, these results suggest that PPARGC1A should be considered a favourable genetic marker in elite marathon running and emphasises the role of this gene and its expression in oxidative metabolism. However, a lack of association between marathon PB and any other individual polymorphism studied, combined with the TGS unexpectedly being lower in elite athletes despite the variants and endurance alleles being selected from previous literature, demonstrates the need to apply hypothesis-free approaches in large cohorts of well-defined athlete groups if substantial genotype-phenotype associations are to be identified successfully.

### ENDURANCE TRAINING-STIMULATED FNDC5/IRISIN INDUCES BEIGE ADIPOSE-LIKE PHENOTYPE IN VISCERAL ADIPOSE TISSUE OF OBESE RATS

Rocha-Rodrigues, S.

Faculty of Sport- University of Porto

Introduction Exercise stimulates muscle-derived cytokines production that have pleiotropic effects in multiple tissues, including adipose tissue. The recently discovered FNDC5/irisin, an exercise-induced PGC-1 $\alpha$ -dependent myokine, is secreted into circulation and has the ability to brown adipose tissue, which is associated with greater whole-body energy expenditure and protects against obesity-related metabolic disorders. Therefore, we aimed to analyze whether voluntary physical activity and endurance training induces beige adipose-like phenotype in visceral adipose tissue from obese rats. Methods Male rats were assigned into sedentary (S), voluntary physical activity (VPA) and endurance training (ET) groups fed with two isocaloric diets, standard (STD) and HFD (35% or 70% fat-derived Kcal, respectively) as follows: S35, VPA35, ET35, S70, VPA70 and ET70 during 17 wks. VPA-animals had free access to running wheel throughout the entire protocol. After 9-wk of HFD, ET-animals performed 8-wks of endurance training on treadmill while maintained dietary treatments. Fibronectin type III domain-containing protein 5 (FNDC5) was determined in gastrocnemius muscle, uncoupling protein (UCP1), adiponectin and leptin in epididymal adipose tissue (EPI), peroxisome proliferator-activated receptor- $\gamma$ coactivator (PGC-1 $\alpha$ ) in both tissues by Western Blot. Results HFD significantly increased body weight (BW) and visceral adiposity index (VAI). In muscle tissue, HFD augmented PGC-1 $\alpha$  (S70 vs. S35) although no alterations were observed in FNDC5 protein levels. In EPI fat depot, UCP1 and PGC-1 $\alpha$  protein levels were reduced in

HFD-fed animals but adiponectin and leptin protein levels were unchanged. VPA decreased BW and VAI compared to sedentary counterparts (VPA35 vs.S35; VPA70 vs.S70). EPI adiponectin, leptin, PGC-1 $\alpha$ , UCP1 and muscle FNDC5 levels remained unchanged in VPA animals. ET significantly decreased BW, VAI and EPI leptin levels in both diets however had no effect on adiponectin. A pronounced ET effect was observed by increases in heart/body weight ratio and muscle citrate synthase. ET increased muscle FNDC5 protein levels accompanied by an increase in EPI UCP1 and PGC-1 $\alpha$  in both diets compared to sedentary counterparts. A significant positive correlation between leptin and VAI and a negative correlation between leptin and FNDC5 and UCP1 were found. Discussion Our results suggest that ET-related increases in skeletal muscle FNDC5 protein levels contributed, at least in part, to induce beige adipose-like phenotype in visceral adipose tissue of obese rats. ### OP-PM42 Training & Testing: Strength III

#### ASSESSMENT OF ISOKINETIC KNEE STRENGTH AND ITS RELATIONSHIP WITH VERTICAL JUMP AND POWER IN YOUTH BASKETBALL PLAYERS

Michaelides, M., Parpa, K.

*UCLAN Cyprus*

**Introduction** The purpose of the study was to measure the isokinetic concentric strength of the knee muscle groups, and their relationship with the vertical jump performance in youth male basketball players. **Methods** Thirty six youth male basketball players (age =15  $\pm$  1.5 years) performed a countermovement jump, and an isokinetic knee test using the Humac Norm dynamometer. The maximal isokinetic peak torque of the knee extensor and flexor muscles was recorded at two angular velocities (60°s<sup>-1</sup>, 300°s<sup>-1</sup>) for both the dominant and non-dominant legs. **Results** There was no significant difference between dominant and non-dominant leg at both angular velocities (both  $p > 0.05$ ). Moderate significant positive correlations (all  $p < 0.05$ ) were detected between the isokinetic measures of the knee extensors and flexors and the vertical jump height for both angular velocities with the strongest ones measured at 60°s<sup>-1</sup>. Furthermore, when power calculated from vertical jump used to determine the relationship with the two angular velocities the results demonstrated strong significant positive correlations (all  $p < 0.0001$ ). The hamstrings to quadriceps (H/Q) ratio at 60° s<sup>-1</sup> for both right and left knee had no significant correlation with vertical jump performance again with the strongest ones measured at 60°s<sup>-1</sup>. **Conclusion** The results demonstrated that moderate relationship could be obtained between isokinetic knee extensors and flexors strength and vertical jump height. Interestingly, the stronger relationships occurred when vertical jump was used to calculate the power in youth male basketball players. Caution should be taken when using vertical jump alone to determine the optimal isokinetic speed in this group of sportsmen.

#### VALIDATION OF ISOMETRIC STRENGTH-TESTING DEVICES FOR DIFFERENT ANKLE MOVEMENTS

Bavdek, R., Dolenc, A.

*University of Ljubljana*

**Introduction** Ankle joint is one of the main joints of lower limb with the purpose to support and move the body (Sarrafian, 2011). Most important ankle movements are plantar flexion, dorsiflexion, ankle eversion and inversion. Knowledge of the muscle strength which implements above-mentioned ankle movements is important for athletes, seniors and everyone who is in a process of ankle rehabilitation. For this purpose we had developed two strength testing devices for measuring isometric contraction in vertical and in horizontal direction. The aim of this research was to determine whether the results of the isometric devices are accurate and repeatable. **Methods** The research included 14 students (20,3  $\pm$  0.4 years, 171.5  $\pm$  5,2 cm, 70,6  $\pm$  9.2 kg). Participants were performing four different isometric contractions in the ankle joint: plantar flexion (PF), dorsiflexion (DF), ankle eversion and inversion, all in seated position. PF and DF were performed in isometric strength-testing device, which measured torque in vertical direction, while ankle eversion and inversion were measured with a device which measured torque in a horizontal direction. Plantar surface of the foot was horizontally placed on the ground. Within the 4 weeks period participants performed multiple measurements, and we tracked the development of the torque. In the analysis, we observed results between the four measuring days for all ankle tasks and between two repetitions that were performed on the same day for one ankle task. To identify the differences between two repetitions for single task in one day and to identify the differences between four measuring days for four tasks we used the intraclass correlation coefficient – ICC (Field, 2009). **Results** The results showed very high correlation of ICC ( $r > 0.9$ ) for first and second repetition for each task. Comparisons among the best repetition for each measuring day showed a very high correlation in inversion ( $r = 0,913$ ) and DF ( $r = 0,966$ ), high correlation in PF ( $r = 0,706$ ) but average correlation in eversion ( $r = 0,680$ ). Value of ICC, when compared first and fourth repetition at ankle eversion, was extremely low ( $r = 0,198$ ). **Discussion** Among four measuring days is a very high correlation in inversion, DF and high in PF. This means that these two strength-testing devices measure reliably and that the results of the measurements are repeatable. We notice medium correlation between all four repetitions of measuring day in ankle eversion, but no correlation between first and fourth day of measurement. Therefore we can conclude that when measuring ankle eversion learning process has a large impact on this measurement. **References** Sarrafian S., Kelikian, A., S. (2011). #### SEX DIFFERENCES IN MEASURES OF POWER AND VELOCITY DURING DEADLIFTING

Jones, M.T.1, Carr, P.J.1, Martin, J.1, Oliver, J.M.2

*1George Mason University, 2Texas Christian University*

**Introduction** Men have more muscle mass than women, which results in greater force and power when comparing Olympic lift and squat performance at the same relative intensity. However, whether these differences exist when normalized to fat free mass (FFM) is unknown. This study sought to determine if sex differences existed in power and barbell velocity at various loads in the conventional deadlift (CDL) when normalized to FFM. **Methods** Women (n=9, mean  $\pm$  SEM: 29  $\pm$  2yrs, 162.3  $\pm$  1.8cm, 62  $\pm$  2.4kg) and men (n=9, 29  $\pm$  3yrs, 175.6  $\pm$  1.8cm, 85.5  $\pm$  1.4kg) with  $\geq 1$  year of CDL experience participated in four testing sessions. Session 1 consisted of body composition assessment ([BodyPod] women: 23.3  $\pm$  3.2% body fat (BF), men: 14.8  $\pm$  2.4%BF) and a maximal (1RM) CDL test. In sessions 2-4,

which were separated by 7 days each, subjects completed a supervised warm-up followed by three CDL repetitions separated by 2-min rest at each of three randomly assigned workloads (30%, 60%, 90% of 1RM). Average velocity (AV), peak velocity (PV), average power (AP), and peak power (PP) were measured by the Tendo® Analyzer (Tendo Sport Machines, Slovak Republic), which was attached inside the sleeve of the barbell. A 2 x 3 repeated measures ANOVA was used to analyze AV, PV, AP, and PP ( $\alpha$ :  $p < 0.05$ ). Results Men had a greater CDL 1RM ( $197 \pm 16$  vs.  $100 \pm 6$  kg;  $p < 0.001$ ), which contributed to greater overall AP when collapsed across loads ( $698 \pm 36$  vs.  $336 \pm 36$  W;  $p = 0.001$ ). AP and PP were greatest at 60% in all subjects, with men producing greater PP at all loads ( $p < 0.001$ ). AV was higher for men at 30% ( $p < 0.001$ ), while PV was higher at 30% and 60% ( $p < 0.05$ ). All subjects generated the greatest AV and PV at 30% ( $p < 0.001$ ). When normalized to FFM, similar observations were made in both AP and PP with men being greater. However, post hoc analysis on the sex effect showed that, when collapsed across loads, women produced higher AV ( $0.014 \pm 0.001$  m•s<sup>-1</sup> • kg FFM<sup>-1</sup>) and PV ( $0.021 \pm 0.001$  m•s<sup>-1</sup> • kg FFM<sup>-1</sup>) than men (AV:  $0.010 \pm 0.001$  m•s<sup>-1</sup> • kg FFM<sup>-1</sup>; PV:  $0.015 \pm 0.001$  m•s<sup>-1</sup> • kg FFM<sup>-1</sup>) ( $p < 0.05$ ). Discussion A paucity of research exists in regard to sex differences in power and velocity during the CDL. Current results are in agreement with previous findings that showed men produce greater power across a range of loads. However, this study demonstrates that at higher intensities (60% and 90%), greater power is driven solely by force production, as AV did not differ at 60% or 90% of 1RM. Further, when normalized to FFM, women produce significantly higher velocities. In conclusion, the CDL may be used to improve power in women. ## HEAVY STRENGTH TRAINING DOES NOT AFFECT PERFORMANCE IN JUNIOR FEMALE CROSS-COUNTRY SKIERS

Losnegard, T., Skattebo, Ø., Rønnestad, B.R., Hallén, J.

*Norwegian school of sport science*

Introduction Performance in cross-country (XC) skiing is highly related to the maximal aerobic power. However, during sprint- and mass start events the ability to perform supra-maximal workloads is important and maximal strength training has therefore gained interest as a training model. Gender differences in performance increases with increasing involvement of the upper body (Sandbakk et al., 2014). Hence, improved upper-body strength can potentially improve double poling (DP) performance in female XC skiers. Methods Sixteen well-trained females skiers ( $17 \pm 1$  yrs,  $60 \pm 6$  kg,  $169 \pm 6$  cm, maximal oxygen uptake running:  $60 \pm 5$  mL • kg<sup>-1</sup> • min<sup>-1</sup>) were assigned either to an intervention group (INT;  $n=9$ ) or a control group (CON;  $n=7$ ). INT completed two weekly sessions of upper-body heavy strength training for 10 weeks in addition to their normal endurance training, while CON continued their normal endurance training. The skiers were tested for 1 repetition maximum (1RM) in seated pull-down exercise, submaximal and maximal O<sub>2</sub>-uptake and two performances test in a DP ergometer (3-min all out in rested- and fatigued state). Results Body weight increased significantly in both INT (mean  $\pm$  90% CI) ( $2.5 \pm 1.2\%$ ;  $p < 0.01$ ) and in CON ( $2.6 \pm 1.9\%$ ;  $p < 0.05$ ). 1RM increased significantly more in INT ( $24 \pm 5\%$ ;  $p < 0.01$ ) than in CON ( $8 \pm 7\%$ ;  $p < 0.05$ ), with a group difference of  $15 \pm 8\%$  ( $p < 0.01$ ; ES: 0.90). No significant changes were seen in sub-maximal O<sub>2</sub>-cost from pre- to post-test in either INT or CON. VO<sub>2</sub>max relative to body mass decline significantly in INT ( $-3.7 \pm 2.2$ ;  $p < 0.05$ ) and was unchanged in CON ( $0.0 \pm 2.8\%$ ). DP performance in rested- and fatigued state increased in both groups ( $\sim 16\%$ , all  $p < 0.05$ ) with no group differences in either pre-values, post-values or change score (ES: 0.04-0.07). Discussion Adding heavy strength training to high volume endurance training increased muscle strength but had no effect on performance in DP. Sub-maximal O<sub>2</sub>-cost did not change after adding strength training, a finding that is in agreement with recent studies in XC skiing (Losnegard et al., 2011; Rønnestad et al., 2012). These results together with previous studies indicate that heavy strength has trivial impact on performance in young XC-skiers and that endurance- and technique training should be prioritized. ## STRETCH INDUCED MUSCLE HYPERTROPHY IN THE HUMAN TRICEPS SURAE OF YOUNG MALES

Simpson, C.L., Kim, B.D.H., Jakobi, J.M.

*University of British Columbia Okanagan*

Introduction Muscle hypertrophy attributable to chronic stretching was previously shown in animal studies (Holly et al., 1980, Sola et al., 1973), however there is little evidence of this in humans. The purpose of this study was to examine whether 6-weeks of chronic stretch training induces adaptations in force and muscle architecture of the gastrocnemius Achilles tendon unit indicative of muscle hypertrophy. Methods Five days/week for 6-weeks the non-dominant ankle of 11 males (age  $22 \pm 3$  years) was rotated to maximal dorsiflexion and passively stretched against a load (20–60% MVC) for 3 minutes. Muscle strength, body composition (Hologic Discovery DXA), muscle fibre length, pennation angle, muscle cross-section and tendon length (B1500 E9 GE Ultrasound) of the triceps surae and Achilles tendon of both legs were measured at zero, three, six and one week after the conclusion of stretch training at week seven. Data were compared to the contralateral leg, and 10 non-exercised controls (age= $21 \pm 2$  years). Results Muscle cross-section area at 3 (11%) and 6 weeks (8%) was significantly larger from week zero ( $p < 0.05$ ). Muscle fibres at the junction of the gastrocnemius medialis and Achilles tendon were longer at 3 (25% increase), 6 (21% increase) and 7 weeks (19% increase) compared to week zero ( $p < 0.05$ ). Total body composition did not change, but force decreased at 3 (6.58%), 6 (7.80%) and 7 weeks (7.12%) compared to zero ( $p < 0.05$ ). All changes were significant from the contralateral leg, and control group ( $p < 0.05$ ). Discussion Six weeks of loaded chronic stretch training increased gastrocnemius cross-section and lengthened the fibres at the muscle tendon junction. Static stretching stimulated an increase in size and length of muscle fibres, but body composition did not change, and force decreased suggesting that hypertrophic adaptations to stretch lessen force production. References Holly, R.G., Barnett, J.G., Ashmore, C.R., Taylor, R.G., Mole, P.A. (1980). ## CONTRIBUTION OF LEG MUSCLE FORCES TO PADDLE STROKE FORCE AND KAYAK SPEED DURING MAXIMAL EFFORT FLAT-WATER PADDLING AMONG ELITE KAYAKERS

Rosdahl, H.1, Nilsson, J.1,2

*1 Swedish School of Sport and Health Sciences (GIH) Stockholm Sweden 2 Dalarna University, Falun Sweden*

Introduction: In flat-water sprint kayaking the paddling technique among elite kayakers has changed and is presently characterized by a more prominent use of the trunk and leg muscles than before (Michael et al 2009). The importance of trunk rotation with leg movements

has support in notational analysis research (Brown et al 2011) but the contribution of leg muscle forces to paddle force and kayak speed has not been carefully investigated. Begon and co-workers (2010) has used a kinematic simulation to analyze the contribution of the lower limbs to ergometer kayaking performance but the leg produced forces during ecological conditions in flat-water sprint kayaking has not yet been investigated. Methods: Five male elite kayakers performed, after a warm up, a sequence of perceived-maximal-speed paddling starting from zero and to remain at maximal speed for about 10 s. This was done with normal leg work and after a short rest with restricted leg work i.e. when the knee joints were kept in a locked position. The leg forces were recorded on the foot-bar with a new and recently described device (Nilsson and Rosdahl 2014) while the paddle stroke forces were recorded by moveable strain-gauge-based sensors. These data was stored together with data from a GPS and an electrogoniometer in a portable custom-built data-acquisition system placed in the kayak. Results and Discussion: The mean paddle stroke force was reduced by 21% and kayak speed by 16% with restricted leg action which highlights the importance of the leg muscle generated forces. A greater contribution from leg muscle contractions and larger paddle force, results in a higher speed and shorter water thrust phase duration, which in turn will increase the paddle cycle rate. The large gain in speed with normal leg action indicates the possibility to emphasize the leg action among kayakers to optimize performance. Accordingly, future research and training may focus on which is the best way to synchronize the leg action phase with respect to the paddle water phase and to perform these phases to best transfer forces from leg muscles to the propulsion of the kayak. ### OP-PM23 Physiology: Energy metabolism

#### GREATER FAT UTILISATION DURING ECCENTRIC CYCLING THAN CONCENTRIC CYCLING

Posthumus, M., Thompson, J., Capostagno, B., Goedecke, J., Lipski, M., Abbiss, C.R., Nosaka, K., van der Merwe, W.

*University of Cape Town*

Purpose It has been previously shown that fat utilisation is greater during and after eccentric cycling when compared with concentric cycling at the same power output [1]. However, it is unknown if differences in fat oxidation occur when exercising at the same oxygen consumption, and whether this relationship may change with exercise intensity. As such, this study compared substrate oxidation, energy expenditure, power output, mechanical work, efficiency, and heart rate between eccentric and concentric cycling matched for oxygen consumption and perceived exertion (RPE; 6-20 scale). Methods Sixteen recreationally active men ( $24 \pm 2$  y) performed a bout of 30 min concentric and a bout of 30 min eccentric cycling one week apart. Each bout consisted of 15 min of cycling at 50% VO<sub>2</sub>max and 15 min of cycling at various RPEs; (i.e. 8, 13, 16), with a 10-min passive rest between the two. Fat and carbohydrate oxidation, energy expenditure, relative VO<sub>2</sub>, relative power output, mechanical work and efficiency, relative heart rate and respiratory exchange ratio were assessed during each cycling bout. Results Fat oxidation was greater during eccentric compared with concentric cycling at 50% VO<sub>2</sub>max ( $p=.002$ ) and at an RPE of 13 ( $p=.008$ ) and 16 ( $p<.001$ ). Conversely, carbohydrate oxidation was greater during concentric compared with eccentric cycling at 50% VO<sub>2</sub>max and at an RPE of 13 and 16 (all  $p<.001$ ). Total energy expenditure was greater during concentric compared with eccentric cycling at 50% VO<sub>2</sub>max and at an RPE of 13 and 16 (all  $p<.001$ ). VO<sub>2</sub> was greater during concentric compared with eccentric cycling at an RPE of 8, 13 and 16 (all  $p<.001$ ). Power output was greater during eccentric compared with concentric cycling at 50% VO<sub>2</sub>max during the first, second and third 5 min as well as at the same perceived exertion as concentric cycling (both  $p<.001$ ). Efficiency was greater during eccentric compared with concentric cycling at 50% VO<sub>2</sub>max and at all RPEs (both  $p<.001$ ). Heart rate was greater during eccentric cycling at 50% VO<sub>2</sub>max ( $p=.002$ ) but greater during concentric cycling at RPE of 13 and 16 (both  $p<.001$ ). Discussion and Conclusion This study indicates that fat oxidation is greater during eccentric compared with concentric cycling at the same oxygen consumption and the same RPE, and fat oxidation increases with increasing intensity during eccentric cycling. #### ULTRA ENDURANCE EXERCISE AND CHANGES IN LEAN MASS

Furber, M.J.W., Anton-Solanas, A.

*GlaxoSmithKline*

Introduction In ultra endurance events the ability to maintain body mass is often compromised due to a restricted energy intake and high energy expenditure. The following case report details the body composition changes of 6 athletes competing in 4 different ultra endurance events. Methods The athletes observed took part in 4 different ultra endurance events. Three male athletes ( $39.4 \pm 7.1$  years) participated in the 2014 Marathon des Sables (running 251 km in 6 days); one female athlete (38.1 years) participated in the 2014 solo Race Across America (cycling 2,150km and withdrew after 9 days due to injury); one male athlete (36.4 years) skied from the coast of Antarctica to the South Pole (1,150 km in 29.8 days); and one male athlete (36.1 years) skied from the Antarctic coast to the South Pole and back (2,888 km in 105 days). Each athlete received comprehensive, structured nutrition and physiology support. Body composition was measured as close as possible pre and post each event (11.6 $\pm$ 12.1 and 8.1 $\pm$ 5.7 days, respectively) using dual energy x-ray absorptiometry. Results No significant difference was detected in total body mass (BM) between pre and post event (84.43 $\pm$ 10.72 vs. 81.93 $\pm$ 10.44 kg) across all challenges, however in the events lasting >10 days (>10 d) a mean BM loss of 5.65 $\pm$ 1.91 kg was observed compared to 0.93 $\pm$ 0.88 kg in <10 days (<10 d) events. Total lean mass (LM) increased significantly post event (64.07 $\pm$ 11.58 to 65.00 $\pm$ 11.99 kg); the trunk region exhibited the greatest increase (29.43 $\pm$ 4.83 to 30.93 $\pm$ 5.45 kg). In events lasting >10 d trunk LM increased by 2.68 $\pm$ 0.73 kg compared to 0.92 $\pm$ 0.73 kg in events lasting <10 d. Limb LM demonstrated a greater decrease in >10 d events (-1.69 $\pm$ 0.28 vs. -0.02 $\pm$ 0.58 kg). In the weight bearing challenges, bone mineral density (BMD) significantly decreased (1.393 $\pm$ 0.17 to 1.380 $\pm$ 0.169 mg/cm<sup>2</sup>); no changes were observed in the cyclist. Discussion The data presented demonstrate that multi-day exercise can result in increases in lean mass, the trunk exhibiting the greatest increase. In the two >10 d events the athletes were pulling a sled (>60 kg weight) resulting in a heavy isometric load on the trunk and a repetitive low resistance load on the limbs. This unique combination of exercise potentially led to the observed increases in trunk LM and decreases in limb LM. Similar but lower magnitude body composition changes were observed in <10 d events,

highlighting the impact exercise duration has on body composition change. It is well established that impact exercise can support gains in BMD; however the current data demonstrate a significant decrease in BMD in the high impact challenges. These findings suggest research is required to better understand body composition changes during ultra endurance.

### DIETARY COUNSELING INTERVENTION DECREASED CARDIOMETABOLIC RISK IN MALE HEAVYWEIGHT JUDO ATHLETES

Murata, H., Oshima, S., Torii, S., Taguchi, M., Higuchi, M.

*Waseda University*

**Introduction** Male heavyweight athletes have excessive body fat which may increase cardiometabolic risk including insulin resistance, dyslipidemia and hypertension (Borchers et al., 2009). Abdominal fat especially visceral fat (VF) accumulation has been shown to play crucial roles in the development of metabolic syndrome (Matsuura et al., 1998). Therefore, the purpose of this study was to examine whether a dietary counseling intervention (DCI) can effectively decrease cardiometabolic risk of male heavyweight Judo athletes without reducing their performance. **Methods** Seventeen male Judo athletes who belonged to an over 100kg class participated in this study. They were divided into 2 groups such as DCI group (n=9; age 20.1±1.0 years, body weight (BW) 127.0±12.6 kg, %body fat (%BF) 28.1±3.6%, VF 119±32 cm<sup>2</sup>) and Control group (n=8; age 20.9±1.2 years, BW 124.2±2.4 kg, %BF 28.9±5.8%, VF 129±33 cm<sup>2</sup>). DCI group completed a 10-week dietary counseling using e-mail and personal interview by the certified Sports Dietitian which instructs them to have a well-balanced diet with proper caloric intake. VF was measured by magnetic resonance imaging and body composition was assessed by dual energy X-ray absorptiometry. Physical fitness including cardiorespiratory endurance and muscle strength were also examined. The statistical difference of before and after the DCI was examined by the paired t- test. **Results** After the intervention, both BW and VF significantly decreased by 4.2kg (3.3 %) and 10cm<sup>2</sup> (7.8 %) in DCI group, respectively, whereas fat-free mass or subcutaneous fat area did not change. Triglyceride (from 163±129 to 113±80 mg/dL, p<0.05), HOMA-IR (from 2.2±1.3 to 1.2±0.7, p<0.01), and systolic blood pressure (from 135±10 to 122±11 mmHg, p<0.01) were also significantly decreased. On the other hand, muscular strength including handgrip, back and leg strength as well as cardiorespiratory endurance level of both groups were maintained even after the weight loss. **Discussion** It was found that the 10-week DCI significantly lowered cardiometabolic risk without reduction of FFM, muscle strength as well as the cardiorespiratory endurance even after the weight loss. The previous study reported that a DCI including caloric restriction with exercise effectively decreased visceral fat and cardiometabolic risk in obese individuals (Straznicki et al., 2012). Therefore, proper dietary intervention may be effective to lower cardiometabolic risk even with small reduction of VF for heavyweight athletes. **Conclusion** This study suggests that DCI can effectively reduce cardiometabolic risk with reducing visceral fat for male heavyweight Judo athletes without influencing their physical performance. **References** Borchers JR, Borchers, JR, Clem, K L et al. ### THE ACUTE EFFECTS OF BEETROOT JUICE ON SUB-MAXIMAL EXERCISE EFFICIENCY AND SKELETAL MUSCLE METABOLISM IN RECREATIONALLY ACTIVE MALES

Betteridge, S.I., Bescós, R.I., Stathis, C.I., Martorell, M.2, Pons, A.2, McConell, G.1

*(1) Victoria University, Melbourne, Australia (2) University of Balearic Islands, Palma de Mallorca, Spain*

**Introduction** Beetroot juice rich in inorganic nitrates (NO<sub>3</sub>) have been shown in some studies to decrease oxygen consumption (VO<sub>2</sub>) for a given workload i.e. increases efficiency. It has generally been assumed that the exercise efficiency effect of nitrates is due to an increased availability of nitric oxide (NO) since NO<sub>3</sub> can be reduced to nitrite (NO<sub>2</sub>) and then NO, especially under acidic and hypoxic conditions. In this pathway oral bacteria play a key role, and the use of antibacterial mouthwash has been shown to reduce some effects related with NO<sub>3</sub> such as a decrease in blood pressure. However this has not been examined in regards to exercise efficiency. Additionally, there is a lack of studies investigating the effects of NO<sub>3</sub> on important aspects of exercise metabolism such as glucose kinetics or muscle glycogen utilisation. Therefore, the main goal of this study was to investigate the effects of nitrates on skeletal muscle metabolism. **Method** Eight participants (age: 27 ± 4 yr, VO<sub>2peak</sub>: 46.3 ± 8.1 ml/kg/min) performed 3 trials; Placebo, Beetroot juice (BR) (~8mmol NO<sub>3</sub>), or BR + mouthwash (BR+MW) following a randomised cross over design. Two and a half hours after treatment participants exercised for 60 minutes on a cycling ergometer at 65% of VO<sub>2peak</sub>. Respiratory parameters (VO<sub>2</sub>, VCO<sub>2</sub> and RER) were analysed during exercise from 10-15 and 45-50 minutes. The stable isotope glucose tracer [6,6-2H] glucose was infused to determine glucose kinetics. Muscle biopsies were obtained prior to and immediately after exercise and analysed for glycogen, lactate, adenosine triphosphate (ATP), phosphocreatine (PCr) and creatine (Cr). Blood samples were obtained prior to, and during exercise and analysed for lactate, glucose, non-esterified fatty acids (NEFA), glucose isotope enrichment, and NO<sub>2</sub>. **Results** Plasma nitrite [NO<sub>2</sub>] increased significantly after the ingestion of BR, and the increase was attenuated with mouthwash. Despite this, there was no significant (p>0.05) effect of BR or BR+MW on oxygen consumption during exercise. There was also no difference in plasma glucose, glucose kinetics, lactate, NEFA, muscle glycogen utilisation, ATP, PCr and Cr between trials. **Conclusion** Despite a significant increase in plasma nitrite concentration after the ingestion of BR there was no effect on exercise VO<sub>2</sub>, glucose kinetics or muscle metabolites. Further research is required to clarify the importance of nitrate on exercise in humans.

### ONE WEEK OF BED-REST SUBSTANTIALLY REDUCES MUSCLE MASS AND INDUCES INSULIN RESISTANCE IN HEALTHY MALES

Dirks, M.L., Wall, B.T., van de Valk, B., Goossens, G.H., van Loon, L.J.C.

*Maastricht University Medical Centre + (MUMC+)*

**Background:** The recovery from illness or injury is generally accompanied by short periods (<1 week) of bed-rest. Whereas the functional and metabolic consequences of prolonged (> 1 month) bed-rest have been well-established, the impact of short-term bed-rest remains largely unexplored. The present study assessed the effects of one week of bed-rest on skeletal muscle mass, leg strength, and whole-body insulin sensitivity. **Methods:** Ten healthy males (23±1 y) were subjected to 7 days of strict bed-rest. Prior to and immediately following bed-rest, a DEXA scan, CT scan of the upper leg, and a hyperinsulinemic-euglycemic clamp were performed to assess lean body mass, quadriceps cross sectional area (CSA) and peripheral insulin sensitivity, respectively. Additionally, prior to and after bed-rest, an incremental cycle ergometer test and a 1-Repetition Maximum (1RM) test were carried out to determine VO<sub>2peak</sub> and maximal leg strength. **Results:** One week of bed-rest resulted in 1.4±0.2 kg loss of lean tissue mass (P<0.01) and a 3.2±1.0% loss of quadriceps CSA (P<0.01). Glucose infusion rates decreased from 62±6 to 42±3 μmol•kg FFM<sup>-1</sup>•min<sup>-1</sup>, representing a 29±5% decline in peripheral insulin sensitivity

( $P < 0.01$ ). Following bed-rest,  $VO_2$  peak and 1RM had declined by  $6.4 \pm 2.3\%$  ( $P < 0.05$ ) and  $6.9 \pm 1.4\%$  ( $P < 0.01$ ), respectively. Conclusion: One week of bed-rest substantially reduces muscle mass, leg strength, whole-body oxygen uptake capacity, and peripheral insulin sensitivity. Effective strategies should be designed to attenuate the loss of muscle mass and decline in metabolic health during short periods of muscle disuse.

### THE INFLUENCE OF BLOOD DONATION ON ENERGY CONTRIBUTION AND PACING DURING MIDDLE DISTANCE CYCLING

Lawler, N.G.1,3, Abbiss, C.R.2, Raman, A.1, Fairchild, T.F.1, Maker, G.L.3, Trengove, R.D.3, Peiffer, J.J.1

1: School of Psychology and Exercise Science, Murdoch University; 2: School of Exercise and Health Science, Edith Cowan University; 3: Separation Science and Metabolomics, Murdoch University

Purpose Delivery of oxygen to the working muscles is vital for aerobic metabolism and when reduced, it has been observed to impair performance. However, its effect on pacing during middle distance self-paced events is unknown. The primary aim of this study was to investigate the effect of oxygen delivery on pacing and middle distance performance. Methods On six separate occasions, seven male cyclists ( $32.0 \pm 8.9$  y) completed an incremental cycling test followed 20 min by a four-minute self-paced cycling time trial (4MMP). The initial two sessions acted as a familiarisation and baseline testing after which 470 ml of blood was removed. The remaining tests were performed 24 h, 7 d, 21 d and 42 d following blood removal. During all 4MMP trials, power output, oxygen consumption ( $VO_2$ ), and aerobic and anaerobic energy contribution were determined. Results  $VO_{2max}$  measured during the incremental test decreased by  $7.03 \pm 4.71\%$  during the first 24 h following blood removal ( $P < 0.05$ ) but was not different from baseline in subsequent tests. Compared with baseline, PPO measured during the incremental test decreased by  $6.86 \pm 3.72$ ,  $4.61 \pm 1.62$ , and  $3.40 \pm 3.47\%$  at 24 h, 7 d and 21 d following blood removal, respectively ( $P < 0.01$ ). Average power output in 4MMP trial decreased by  $7.19 \pm 5.60$ ,  $6.01 \pm 8.36$  and  $4.15 \pm 6.31\%$  at 24 h, 7 d and 21 d following blood removal, respectively ( $P < 0.01$ ). Aerobic contribution during the 4MMP was  $4.70 \pm 4.14$ ,  $3.95 \pm 5.17$ , and  $4.27 \pm 10.06\%$  lower than baseline at 24 h, 7 d and 21 d, respectively ( $P < 0.01$ ). Anaerobic contribution was not different across any of the 4MMP trials ( $P = 0.91$ ). There was no difference in pacing observed across the 4MMP trials ( $P = 1.00$ ). Conclusion The results indicate that the removal of 470 ml of blood reduces aerobic energy contribution and decreases performance during self-paced exercise but does not alter pacing pattern. These findings support previous literature indicating that variation in pacing during middle distance events may be largely influenced by the distribution of anaerobic resources.

### OP-BN10 Motor learning, Coordination

#### POSTURAL THREAT INFLUENCES NEURAL CONTROL OF UPRIGHT STANDING IN YOUNG AND ELDERLY ADULTS

Johannsson, J., Duchateau, J., Baudry, S.

Université Libre de Bruxelles

Introduction: Postural control is associated with modulation of peripheral and descending drive converging onto soleus motor neurones (2). Most studies have shown, in young adults, a decrease of the Hoffmann (H) reflex amplitude when standing at the edge of an elevated platform compared with standing on the ground (1). This decrease in reflex loop excitability may reflect a shift to supraspinal control balance when increasing the height of the standing surface or the postural threat associated with standing at the edge of a platform. The suggested decrease in capacity of elderly adults to modulate spinal reflex (3) might place them in an unsafe situation when standing at the top of a stair. This study therefore investigated the influence of height and postural threat on spinal and corticospinal excitability in young and elderly adults. Methods: 12 young ( $25 \pm 1$  yrs) and 9 elderly ( $70 \pm 5$  yrs) adults participated in the study. Surface electromyogram (EMG) was recorded from soleus, gastrocnemius medialis and tibialis anterior. The H reflex was evoked in the soleus by stimulating the fibular nerve. The motor evoked potential (MEP) was recorded in the same muscle in response to transcranial magnetic stimulation elicited at an intensity of 120% of the active motor threshold. Three upright standing conditions were investigated consisting of standing downstairs, upstairs backing stairs and upstairs facing stairs. In addition to height, the latter condition was aimed at increasing postural threat by limiting stepping response strategy. Results: Age did not influence ( $p > 0.05$ ) the modulation of EMG, H-reflex and MEP between standing conditions described hereafter. Compared with downstairs, maximal H-reflex amplitude decreased when subjects stood upstairs facing stairs ( $-8.7\%$ ;  $p < 0.01$ ) but did not change when standing upstairs backing stairs ( $p = 0.31$ ). The MEP amplitude varies by less than 1% across standing conditions ( $p > 0.05$ ). Background EMG did not differ between standing conditions. Discussion: The decrease in H-reflex amplitude in absence of change in background EMG when standing upstairs facing stairs suggests an increase in presynaptic inhibition of muscle spindle pathway to decrease reflex activity that may impair balance in presence of postural threat (1). These results also indicate that elderly adults can still modulate muscle spindle pathway depending on standing conditions. The lack of change in MEP amplitude, however, does not support an increase in corticospinal contribution to control upright standing when postural threat is increased. References 1) Sibley et al. #### CONTRIBUTION OF VISUAL AND PROPRIOCEPTIVE INFORMATION IN POSTURAL CONTROL DIFFERS WITH AGE

Penzer, F., Duchateau, J., Baudry, S.

Université Libre de Bruxelles

Introduction Previous work revealed the importance of sensory inputs to control balance, with different contribution of vestibular, visual and proprioceptive information (Peterka 2002). Accordingly, the decline in the integrity of the sensory systems with ageing alters balance capacity (Maki et al. 1996). But the effects on the respective contribution of sensory information to control upright standing remain to be determined. To investigate the effect of age on the contribution of visual and proprioceptive information in the control of postural balance, young and elderly adults were compared while standing with different visual conditions before and after prolonged bilateral Achilles tendon vibration aimed at altering the proprioceptive information from leg muscles. Methods Fifteen young ( $22.9 \pm 1.6$  yrs) and fourteen elderly adults ( $70.1 \pm 7.6$  yrs) participated in this study. Prior to and immediately after 1 hour of Achilles tendon vibration (1-mm amplitude,

80Hz), subjects were asked to stand on a force platform with eyes open (REO) and closed (REC) and with a visual feedback (VFB) of their centre of pressure (CoP). CoP path length (CoPpath) was measured during 40-s trials in each visual condition. The Hoffmann reflex confirmed the efficacy of vibration in altering muscle spindle afferents in both groups. Results Before Achilles tendon vibration, CoPpath did not differ between age groups in REO ( $p=0.41$ ). It increased significantly in REC in both age groups, but to a greater extent in elderly (+25%,  $p=0.001$ ) than in young adults (+17%,  $p<0.001$ ). Compared with REO, CoPpath did not change significantly with VFB in young adults whereas it increased (+18%,  $p=0.007$ ) in elderly adults. After vibration, CoPpath increased in REO (+14%,  $p=0.029$ ) and REC (+18%,  $p=0.001$ ) whereas it did not vary with VFB ( $p=0.37$ ) in young adults. In contrast, Achilles tendon vibration did not influence CoPpath in any of the visual conditions in elderly adults. Discussion In agreement with previous work, elderly adults experienced more difficulties to stand stable without vision. In addition, this study indicates that visual feedback of CoP impairs balance stability only in elderly adults, whereas long-duration tendon vibration altered the control of upright standing solely in young adults. These results suggest that age-related impairments of the somatosensory system (Shaffer and Harrison 2007) decrease dependence to muscle spindle afferents and induce a shift toward a greater reliance on visual information to control balance in elderly adults. ### THE INFLUENCE OF AN EXTERNAL FOCUS OF ATTENTION VERSUS INTERNAL FOCUS OF ATTENTION WITH REGARD TO MOTOR LEARNING AND SKILL ACQUISITION FOR ANTERIOR CRUCIATE LIGAMENT INJURY PREVENTION.

Pantano, K.

*Cleveland State University*

Introduction: Exercise programs aimed at preventing ACL injury may decrease injurious mechanics. Wulf suggests that motor task learning is maximized when an external focus of attention (EFA) versus internal focus of attention (IFA) is provided during skill acquisition. The effect of IFA and EFA instruction during ACL injury prevention programs has not been adequately studied. Objective: To compare the effect of EFA vs. IFA instruction on the change in magnitude of muscle activity during a 6-week neuromuscular exercise program designed to prevent ACL injury. It is hypothesized that subjects receiving EFA instruction would exhibit more desirable muscle activity patterns in muscles protective of the ACL compared to those receiving IFA instruction. Design: Pre-Post-test group comparisons. Setting: Research laboratory. Subjects: A convenience sample of 31 female recreational athletes ( $24.5 \pm 1.8$  years) with no history of knee injury/LE surgery were randomly assigned to 2 subject groups. Interventions: Subjects performed a series of exercises including neuromuscular trunk and lower strengthening, balance, plyometric, agility and jump training (Hewitt, Silvers) in 8 rotating stations 2x/week for 6 weeks. Groups 1 and 2 received IFA and EFA instruction, respectively, during implementation of the exercise program. Pretraining and posttraining muscle activity for the right vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), biceps femoris (BF), gastrocnemius (GS), gluteus medius (Gmed), and gluteus maximus (Gmax) were monitored with surface electromyography (EMG) during weight acceptance of a forward jump from a platform, and a right-cut maneuver. A linear envelope filtered at 10 Hz, normalized to % MVIC, determined magnitude of muscle activity for an average of 3 trials. Main Outcome Measures: Pre-post-training changes in integrated and peak EMG muscle activity (LEEMG) during weight acceptance of a forward jump and right-cut maneuver were analyzed between groups. One-tailed independent sample t-tests were performed with  $P<0.05$  set a priori. Results: There were no significant differences between groups for the forward jump. For the right cut, pre-post change in peak RF ( $6927 \pm 1.66$ ;  $-8686 \pm 1.17$  % MVIC;  $P<0.007$ ) was significantly less in Group 2 than Group 1. Changes in integrated RF ( $0.0767 \pm .151$ ,  $-0.053 \pm .141$  % MVIC,  $P<0.017$ ) and GS ( $1.22 \pm .22$ ,  $-0.0129 \pm .110$  % MVIC,  $P<0.03$ ), and peak VMO ( $1.23 \pm 4.26 - 1.08 \pm 2.33$  % MVIC,  $P<0.05$ ) and GS ( $1.01 \pm 2.06$ ,  $-2.79 \pm 1.45$  % MVIC,  $P<0.04$ ) during the right cut were significantly greater in Group 1 than Group 2. Conclusions: EFA instruction vs. traditional cues (IFA) may provide some benefit when implementing an ACL injury prevention program but may not be generalizable across all ages, motor tasks and muscles. Future research should examine whether a specific type of instruction affects motor learning, as well as motor skill retention.

### GENERALISED JOINT HYPERMOBILITY IN ELITE LEVEL ADOLESCENT ATHLETES – BENEFICIAL OR PROBLEMATIC IN RELATION TO INJURY, PAIN, PHYSICAL FUNCTIONING AND QUALITY OF LIFE?

Schmidt, H., Lykke Pedersen, T., Nicholson, L., Engelbert, R.H.H., Juul-Kristensen, B.

*University of Southern Denmark*

Introduction Generalised Joint hypermobility (GJH) affects injury frequency, pain, physical functioning and health related quality of life (HRQoL) in the general population, but such relations are unknown in adolescent elite level athletes. The aim was to investigate whether adolescent elite level athletes with GJH had higher injury and pain frequency, and lower physical functioning and HRQoL than non-GJH (NGJH). Methods Totally 132 adolescents (36 males; 96 females), aged 14.01 (0.88) years, participated ( $n=22$  ballet dancers,  $n=57$  team gymnasts,  $n=53$  team handball players). GJH was defined by the Beighton score (BS) (GJH4:  $BS \geq 4/9$ , GJH5:  $BS \geq 5/9$ , GJH6:  $BS \geq 6/9$ ). Two questionnaires were used, comprising injuries during latest month, and lower extremity related physical limitations and HRQoL (RAOS-Child questionnaire). Dynamic and static motor competence was tested with one-leg hop for distance (OLHD), three consecutive cross-over hops (COH), and four postural sway tests (bilateral and unilateral stance with open (1OE, 2OE) and closed eyes (2CE, 1CE)) measured as sway length, Center of Pressure Path Length (COPL), from December 2013-March 2014. Results Prevalence of GJH4, GJH5 and GJH6 was 27.3%, 15.9% and 6.8%, respectively, with the highest prevalence in ballet and team gym. There was no significant difference between GJH and NGJH in injury frequency, pain and HRQoL. However, in GJH5, RAOS symptom score was lower ( $p=0.027$ ), and hop length (OLHD) shorter ( $p=0.032$ ). COPL in bilateral stance was increased in all GJH groups (2OE; GJH4:  $p<0.001$ ; GJH5:  $p<0.001$ ; GJH6:  $p=0.015$ . 2CE; GJH4:  $p<0.001$ ; GJH5:  $p<0.001$ ; GJH6:  $p=0.014$ ). In unilateral stance, only GJH4 had increased COPL (1OE; GJH4:  $p=0.022$ ), and GJH5 had fewer completed trials (1CE;  $p=0.006$ ) than NGJH. Conclusion GJH was most prevalent in ballet dancers. Elite level adolescents with GJH were not more prone to injury, pain or decreased HRQoL than NGJH. In GJH symptoms related to lower limb function were more prevalent. Those with GJH demonstrated increased sway in bilateral stance and completed fewer unilateral sway trials. Further studies of the longitudinal consequence of GJH are indicated. ## NEITHER VOLUNTARY MUSCLE ACTIVATION NOR STRETCH TOLERANCE IS A LIMITING FACTOR TO ANKLE JOINT RANGE OF MOTION

Yoshikawa, A.1, Inami, T.2, Wakabayashi, H.3, Osuga, T.4, Kawakami, Y.2

1,2: Waseda University, 3,4: Aoki Memorial Hospital

**Introduction** Joint range of motion (ROM) is a multi-factorial attribute of flexibility, including extensibility of soft tissues that cross and/or cover the joint. Previous studies proposed significant impact of muscle activity triggered upon passive stretch (Osternig et al., 1987), and the "stretch tolerance" (Magnusson et al., 1996a ; 1996b) as major limiting factors of ROM. However, direct evidence is scarce for these factors. The aim of this study was to examine these contributions by comparing the conscious and anaesthetized conditions. **Methods** Five Subjects (four males, one female) who had orthopaedic surgery operation of upper extremities participated in this study. Before operation (conscious) and under mask anaesthesia (fully unconscious with muscle relaxant) conditions, ankle joint angle, medial longitudinal arch angle, and elongation of the muscle belly of the gastrocnemius medialis (dMus) during maximally tolerable passive dorsiflexion (matched for the two conditions by the force applied to the ankle joint into dorsiflexion) were measured, and Achilles tendon elongation (dTen) was estimated (based on the formula by Grieve et al., 1978). **Results** There were no significant differences between conscious and unconscious conditions for ankle joint angle and elongation of dMus and dTen. The medial longitudinal arch angle reached a significant level toward decrease in unconscious compared to conscious condition (116 vs. 123 deg,  $p < 0.05$ ). Although not significant, in four out of five subjects, ankle joint ROM was smaller in unconscious than in conscious condition. **Discussion** Our finding is in sharp contrast to the notion that the joint range of motion is largely affected by the amount of voluntary activation of the muscles under stretch (Magnusson et al., 1996b). Our finding also does not support the idea that we avoid injuries by actively resisting excessive joint loading into the ROM limit (Alter, 2004). The present study discards voluntary muscle activation and stretch tolerance from the major candidates limiting ankle joint flexibility. **References** Alter. (2004) Science of flexibility. #### INQUIRY BASED LEARNING AS PEDAGOGICAL APPROACH TO ENHANCE REFLECTIVE PRACTICE IN PHYSICAL EDUCATION TEACHER EDUCATION

Østergaard, L.D.

Aalborg University

**Introduction:** During the last decades, reflections have gained attention as a tool for teachers to improve and qualify physical education (PE) teaching (Standal & Moe, 2013). However, research has shown that reflective practice in PETE as well as in PE is experienced as a difficult process (ibid.). In this project inquiry based learning (IBL) is proposed as a pedagogical approach to promote students' reflective practice in PETE. **Methods:** IBL was implemented over a period of 10 weeks in a PETE training program where 32 students were given challenges related to the PE curriculum in secondary school. Data were collected in the form of audio and video recordings of students' reflections and actions during the unit. Further, the students' written reflections on the challenges were collected. The data were analyzed by interpretative phenomenological analysis (Palmer, Larkin, de Visser, & Fadden, 2010) in order to identify and extract common themes and patterns. **Results:** The analysis of the data revealed that during the IBL approach the students reflected on both the inquiry approach as a methodology, the current challenges they were given, and their own practice as coming PE teachers. Second order critical reflections were seen mostly in the phases of hypothesizing and evaluation. **Discussion:** In this project IBL seems to work as the students during the unit showed signs of questioning, critical thinking and problem solving. These results are similar to results from other projects introducing IBL (Padraig & McLoughlin, 2009). Critical reflections were mostly seen as students' thinking about their coming practice as PE teachers. In general the IBL approach stimulated the students to use interpersonal reflections as transformative, challenging-the-exciting, and critical forms of 2nd order reflections (Wackerhausen, 2009), which are important skills to acquire as the students in their future practice as PE teachers need to be critical and reflective to optimize, plan and design motivating PE courses. **References:** - Padraig, M., & McLoughlin, M. #### 'THERE ARE NO RIGHT OR WRONG WAYS' - PE TEACHERS USING EXPRESSIVE DANCE AS A LEARNING TOOL WITHIN PHYSICAL EDUCATION.

Mattsson, T.

Faculty of Education and Society, Malmö University

**Introduction** It is argued that the use of expressive dance can question gender stereotypes in physical education (PE). Dance has been a part of the PE curriculum in several countries for a long time. In spite of this, studies demonstrate that teaching dance in PE is rare and aesthetic perspectives on moving bodies are absent. Therefore, the purpose of this research is to investigate PE teachers' experiences of using expressive dance as a learning tool and to explore whether dance can help broaden understandings of potential and possibilities within PE. **Method** Pre and post semi structured interviews have been used to 'give voice' to PE teachers' experiences in combination with videotaped observations during a dance theme in PE. Data collection focused on teachers' actions and narratives, while also taking the whole didactic system into account; the knowledge intended to be learned, teachers' strategies and the context (Amade-Escot 2006). The empirical material consisted of eight interviews with four PE teachers and 24 observed PE lessons. **Results** PE teachers described a

feeling of freedom and that teaching expressive dance has broadened their perceptions of what and how students learn. Rather than imitating movements the focus changed to the students themselves, who created and reflected on their movements. Teachers 'discovered' new students, other than those who tended to dominate the sport teaching. Teachers also recognized that boys and girls can and do co-operate and that girls take as much physical space as boys do. Discussion Underscoring Dewey's (1934/2005) thoughts of bodies in transaction in social, cultural and physical context, feminist theory (Sullivan 2001) is used to expand the thinking about the gendered body, such as the role of habit and meaning. Expressive dance as non-competitive and without predetermined movements can challenge a masculine-coded subject. Such a discussion can add new dimensions to debates on the nature and purposes of a sustainable PE for now and in the future. References Amade-Escot, C. (2006). ## PHYSICAL LITERACY THROUGH DANCE EDUCATION

Cheung, S.T.J.

*The Chinese University of Hong Kong*

This study is an action research to investigate the inclusion of dance education in the PE curriculum of a female secondary school in Hong Kong, in order to maximize students' learning outcomes through PE lessons. Teaching dance is regarded as a child-centered context for learning (Brown, 2014). It facilitates the integration of developing our mind and body (Brown, 2014), and fosters creative and rational thinking (Byeon, 2012). Numerous studies also elaborate the values of dance education in school curriculum. Participants of this action research are from the junior and senior forms of a female secondary school in Hong Kong. The PE teacher conducts dance lessons in two intervention cycles. The teaching approach is adopted as structured, open and reflective as Henley (2014) suggested. Participants are asked to complete the Intrinsic Motivation Inventory (IMI), developed by Ryan (1982) and his colleagues from the Rochester Motivation Research Group (McAuley, Duncan & Tammen, 1989), in both the first and second intervention cycles to determine the levels of intrinsic motivation in terms of interest-enjoyment, perceived competence, effort and tension throughout the dance lessons. Moreover, interviews with PE teacher and participants are organized to collect the qualitative data on students' enjoyment and social aspects in dance lessons. When designing PE curriculum, physical educators would consider its scope, sequence and balance of the teaching contents, therefore this action research is served as an example for including dance education in the PE curriculum to maximize students' all-round development through the participation in dance activities in PE lessons. Further studies are suggested to examine dance education in male schools or coeducational schools. Brown, A.K. (2014). ## CHALLENGES FOR INTERVENTION RESEARCH IN HEALTH AND LIFESTYLE RESEARCH – A SYSTEMATIC META-LITERATURE REVIEW

Kristén, L., Ivarsson, A., Parker, J., Ziegert, K.

*School of Health and Welfare Sciences*

Introduction Health and well-being are two concepts that are widely discussed within today's society. A major perspective in health and lifestyle research is to investigate what determinants are associated with health. When it comes to the delivery of health interventions several different approaches have been suggested. Methods The meta-synthesis was chosen for synthesis of research studies using a health and lifestyle the review format and analyse meta-questions. The process included the following five phases: 1. Literature search for articles. 2. Selection of relevant articles after repeated reading and appraisal of the articles. 3. Extraction of data from each article and creating a list of findings as key phrases, ideas and concepts for each individual study. 4. Determining how the findings of the selected studies are related and translating findings into one another. 5. Synthesizing the translations to produce a new theoretical interpretation. Results The search yielded a total of 561 unique citations and finally 24 citations remained. Of those 11 studies focused on health determinants, while 13 focused on interventions for health promotion. The meta-synthesis led to four recommendations for the design of future intervention studies. (1) scientific disciplines should collaborate in the design, implementation and evaluation of the study. (2) to use theoretical frameworks that focus on health determinants and to apply longitudinal studies with a repeated measures design. (3) involve behavioral interventions. (4) to design face-to-face intervention studies. Discussion Determinants was related to a physical active lifestyle, more specifically high quality school programs for physical education. It could be a starting point for a nationwide approach of daily physical activity in whole society. In all intervention studies physical activity behaviors were included as outcome or intervention program. It is therefore speculated that physical activity behavior could be discussed as one mediator between health determinants and health outcomes. References Bailey, R. (2006). ## THE EFFECTS OF PHYSICAL ACTIVITY IN PRIMARY SCHOOLS ON ACADEMIC PERFORMANCE

Collard, D., Boutkan, S.1, Grimberg, L.2, Lucassen, J.1, Breedveld, K.1

*(1) Mulier institute (Utrecht, the Netherlands) (2) Dutch Ministry of Education, Culture and Science (The Hague, the Netherlands)*

Introduction Increasingly, articles and policy documents are suggesting that sport and physical activity have an effect on academic performance. At the request of the Dutch Ministry of Education, Culture and Science insight was provided in the direction of this relationship

(positive, negative or neutral), but also whether there is a causal effect. It is also relevant to look at the body of evidence for this relationship (number of studies). Therefore we did a survey into the scientific literature on the relationship between sport and physical activity and (determinants of) academic performance. Methods To ensure that the most important literature is included in the summary, three methods were used. Firstly, known literature was consulted and an additional research was done in electronic literature databases (Pubmed, Psychinfo). Secondly, Dutch experts in this field were asked to supply input. They were asked to name the most important literature on the relationship between sport and physical activity at school and the determinants of academic performance. In addition, the literature references of important included articles have been verified. The research focused on the relationship between sport and physical activity and academic performance of primary school children. In addition, also the relationship between sport and physical activity and the determinants of academic performance were included, such as brain structure and executive functions (attention, concentration), motor skills, fitness and social behaviour. Results Results show that it is not (yet) clear whether there is a positive causal relationship between sport and physical activity at school and academic performance. Results are inconclusive and better quality and long-term studies are needed. What is clear is that sport and physical activity at school has no negative effect on academic performance. It should be noted that sport and physical activity clearly has positive effects on motor skills and complex movement skills, fitness, brain structure and executive functions. Evidence for the other relationships is still light or weak. Discussion Results show that there are some limitations in the research on the causal relationship between sport and physical activity and academic performance are described below. Firstly, there is insufficient understanding of the mechanism that explains the relationship between sport and physical activity and academic performance. Besides that, there is also insufficient understanding of the frequency, duration, intensity and type of sport or physical activity at school that contribute to improving academic performance Contact: d.collard@mulierinstituut.nl

### PS-PL03 EXERCISE, ENERGY INTAKE, BRAIN HEALTH AND WELL BEING

#### ENERGY INTAKE AND EXERCISE AS DETERMINANTS OF BRAIN HEALTH AND VULNERABILITY TO INJURY AND DISEASE

Mattson, M.

*Johns Hopkins University School of Medicine*

Humans evolved in environments where food was not continuously available, and so possess robust adaptive physiological and behavioral responses to periods of food scarcity. Emerging research in this Laboratory and elsewhere has shown that intermittent energy restriction (IER; for example fasting for a period of 24 hours several times each week) and vigorous exercise can increase numbers and strength of synapses and can enhance brain function (cognitive and sensory – motor performance) and mood. We find that the general mechanism by which IER and exercise benefit neurons is by challenging them by increasing their activation state and energy demand, which results in a coordinated engagement of signaling pathways that promote neuroplasticity and cellular stress resistance. The pathways activated by exercise and IF include those involving brain-derived neurotrophic factor (BDNF), mitochondrial biogenesis, DNA repair and removal of oxidatively damaged proteins and organelles (autophagy). Peripheral changes in energy metabolism that occur during fasting and exercise may also contribute to their beneficial effects on the brain. In this regard, the depletion of glycogen stores in the liver triggers the mobilization of fatty acids from fat cells and the production of ketone bodies. Ketone bodies such as beta-hydroxybutyrate provide an alternative energy source for neurons and may also activate signaling pathways that enhance the ability of the brain to cope with stress. Our studies in animal models of chronic neurodegenerative disorders (Alzheimer's and Parkinson's diseases) and acute brain injury (stroke and severe epileptic seizures) demonstrate robust neuroprotective and neurorestorative effects of IER. IER protects the brain by bolstering antioxidant defenses and protein chaperone levels, and by suppressing inflammation. The implications of these findings for strategies for optimizing brain function and reducing the risk of neurodegenerative disorders will be described. Acknowledgement: Supported by the intramural research program of the National Institute on Aging.

#### CAN EXERCISE AND PHYSICAL ACTIVITY OPTIMISE THE WELLBEING OF POPULATIONS?

Thompson, J.L.

*The University of Birmingham*

Existing evidence suggests that engagement in structured exercise programmes or lifestyle physical activity is associated with better physical and mental health. Much of the evidence to date has focused on examining the effects of exercise and physical activity on physical and cognitive function, and psychological disorders such as depression and anxiety. Studies have predominantly assessed a range of psychological and wellbeing measures in relatively small groups of individuals within settings such as worksites, education, clinical populations, or within specific age groups (e.g. older adults). There is a very limited body of evidence examining the role of exercise and physical activity in optimising community- or population-level health. This presentation will provide an overview of the current evidence, and will examine the complexities and challenges inherent in this area of research, including the: 1) multitude of outcome measures used to represent 'wellbeing'; 2) difficulty in controlling for the plethora of personal, social, economic, and environmental factors that can strongly influence wellbeing; and 3) lack of methodological approaches capable of elucidating physiological and psychological mechanisms explaining changes in wellbeing. In addition, examples of funded initiatives working to integrate multi-disciplinary and multi-level approaches to optimising the wellbeing of populations will be discussed.

## MO-PM37 Training and Testing: Fatigue and neuromuscular physiology

**BRAIN OXYGENATION, CARDIOVASCULAR RESPONSES AND RUNNING PERFORMANCE WEARING A COMPRESSION GARMENT**

Leoz-Abaurrea, I., Santos-Concejero, J., Grobler, L., Engelbrecht, L., Aguado-Jiménez, R.

*Public University of Navarre*

**Introduction** The effectiveness of wearing CGs during exercise has been questioned in the majority of studies, not finding differences in cardiorespiratory, thermoregulatory or metabolic during submaximal and maximal exercises (1). Despite previous physiological factors, there is an amount of evidences supporting that the central nervous system (CNS) is the limiting factor of exercise performance (2). Whole body exercise provokes central fatigue or the inability of the CNS to recruit the muscles involved in the exercise, and this is thought to be due to perturbations of metabolism and cerebral oxygenation (3). The latter, has never been studied wearing an upper body compression garment (UBCG), which could give to authors a better physiological vision on the use of CGs in the future. Hence, the aim of the present study was to analyse the physiological and performance responses of wearing an UBCG during a running performance test until exhaustion. Further, we would like to add novel data regarding the haemodynamic responses of the brain for a better understanding of the effects of CGs during exercise. **Methods** Ten recreational male runners (mean  $\pm$  SD: age  $23 \pm 3$  yrs;  $VO_{2max}$   $56 \pm 5$  ml  $\cdot$  kg $^{-1}$   $\cdot$  ml $^{-1}$ ) completed two identical sessions wearing either an UBCG (1-3 mmHg) or conventional running T-shirt (CON) in an ambient temperature of  $20 \pm 1$  °C and  $54 \pm 7\%$  rh. Testing consisted of running 45 min at 60% of peak treadmill speed (PTS) followed by a time to exhaustion (TTE) at 80% of PTS and 10 min recovery. Core temperature (Tcore), cardiorespiratory responses and brain oxygenation were measured during the test. **Results** Wearing the UBCG resulted in an impaired running performance ( $P=0.045$ ) probably due to a significantly higher ( $P=0.01$ ) respiratory exchange ratio (RER), a meaningfully higher plasma lactate ( $9.1 \pm 1.7$  vs.  $7.8 \pm 2.1$  mmol $\cdot$ L $^{-1}$ ) and a significantly lower ( $P=0.014$ ) cerebral blood flow (CBF) expressed in normalised total haemoglobin index (nTHI) at TTE. Conversely, a significantly lower Tcore was observed wearing the UBCG at TTE ( $P=0.041$ ). During recovery higher ( $P < 0.05$ ) heart rate, lactate and respiratory frequency values were recorded in the UBCG, whereas Tcore remained lower ( $P=0.002$ ). **Discussion** Although wearing a heat dissipating UBCG reduced Tcore during a running performance test, it incremented the ventilatory mechanical workload (expressed in RER) and plasma lactate concentrations, and reduced the CBF (expressed in brain nTHI) resulting in a decline in performance in comparison to CON. Further, these physiological differences were accentuated during recovery between garments. Thus, wearing an UBCG increased cardiovascular and respiratory responses and affected running performance. **References** 1. MacRae BA et al. **EXERCISE-INDUCED MUSCLE DAMAGE MARKERS DURING A FAMILIARIZATION PROTOCOL TO ECCENTRIC CYCLING**

Tornaghi, M.1, Bosio, A.1, Ferioli, D.1, Morelli, A.1, Martin, D.T.2, Menaspà, P.2,3, Fell, J.4, Rampinini, E.1

*1:Mapei Sport (Olgiate Olona, Italy), 2:AIS (Canberra, Australia), 3:ECU (Perth, Australia), 4:UTAS (Tasmania, Australia)*

**INTRODUCTION** Subjects unaccustomed to eccentric (ECC) exercise can experience muscle damage (MD) and related side effects (decreased resistance and endurance performance) the days following exercises involving ECC contractions. Aim of this study was to measure delayed onset muscle soreness (DOMS), creatine kinase (CK), maximal voluntary contraction (MVC), voluntary activation (VA) and neuromuscular functions (NMF) of the quadriceps during a familiarization period to ECC cycling. **METHODS** Eight amateur cyclists completed 11 sessions (2/week) of ECC. Each session consisted in alternating low (40%) and high intensity ECC (50-120% of aerobic PPO) on a custom-built cycle ergometer. The workload increased weekly and the last week was for tapering. At each session heart rate (HR) and RPE were measured. DOMS (0-10) asked at 24 and 48 hours post sessions. Once a week CK, MVC, VA and NMF were measured Pre and Post session. **RESULTS** Average HR during ECC was different ( $p=0.012$ ) throughout the familiarization period and a strong trend was seen for RPE ( $p=0.058$ ). These variables tended to match the weekly increase of the workload. CK was stable on normal values during the period. Average DOMS<sub>24</sub> ( $2.9 \pm 2.0$  week1 and  $0.1 \pm 0.4$  week6) was higher (m.e. of Time  $p=0.002$ ) than DOMS<sub>48</sub> ( $1.6 \pm 1.8$  week1 and  $0.1 \pm 0.4$  week6) and overall tended to decrease (m.e. of Weeks  $p=0.098$ ) during the familiarization. Baseline MVC and VA did not vary throughout the familiarization period and a similar pattern was found for Pre-Post ECC % changes. However, after the session examined, a strong trend ( $p=0.053$ ) towards a MVC reduction at Post vs Pre was present. Only baseline Peak Twitches (PT) at 1Hz tended to be higher during the last 3 sessions of the familiarization compared to the earlier session. PT % decrements on the last session were lower compared to the previous sessions at 1, 10, 100 Hz. PT % decrement was found lower on session 2 compared to 1 for stimulation at 1Hz. **DISCUSSION** Evidence from the present study suggests that the criteria used during the 6 weeks of familiarization to ECC seem appropriate to decrease the main markers of muscle damage. It is interesting to emphasize that none decrease of baseline MVC and NMF (the most likely cause of performance decline in presence of MD) was present in spite of a continuous increase of the ECC workload throughout the familiarization. A decrease of DOMS (the most annoying sign of MD) towards its complete absence might be an advantage also from a perceptual point of view. **REFERENCES:** Warren GL et al. (1999). ## EFFECTS OF DIFFERENT RECOVERY INTERVENTIONS FOLLOWING A HALF MARATHON ON MARKERS OF FATIGUE AND RECOVERY IN RECREATIONAL RUNNERS

Wiewelhove, T., Raeder, C., Ferrauti, A.

*Faculty of Sports Science, Ruhr-University Bochum*

**Introduction** Following half-marathon running an acute state of fatigue will occur, reflected by mechanisms from the central nervous system (e.g. impaired central motor drive) to the muscle cell itself (e.g. muscle damage and systemic inflammation) (Ament & Verkerke, 2009). Athletes, therefore, use different recovery interventions in an effort to speed recovery and to resume their normal training schedule in the shortest possible time (Hauswirth & Mujika, 2013). However, research on the efficiency of recovery interventions following endurance events is inconsistent and limited. Therefore, the aim of this investigation was to assess the effects of active recovery, cold-water immersion and massage after a half-marathon on markers of fatigue and recovery in runners. **Methods** 46 well-trained male athletes (age:  $30.0 \pm 10.9$  years) completed a half-marathon, followed by one of four 15 min recovery interventions. For the assignment to either active recovery, cold-water immersion, massage or passive recovery, runners were matched according to age and performance. Creatine kinase (CK), C-reactive protein (CRP), countermovement jump ability (CMJ), and delayed onset muscle soreness (DOMS) were evaluated before the half-marathon (pre), after the recovery intervention (postrec) and 24 h after the half-marathon (post24). Results Except for CMJ, no significant intervention x time interaction was found for markers of fatigue and recovery. After the half-marathon, runners in all groups showed increased serum CK (pre:  $248 \pm 194$  U•l<sup>-1</sup>; postrec:  $383 \pm 178$  U•l<sup>-1</sup>; post24:  $701 \pm 443$  U•l<sup>-1</sup>) and CRP concentrations (pre:  $1.18 \pm 2.19$  mg•l<sup>-1</sup>; post24:  $3.94 \pm 2.46$  mg•l<sup>-1</sup>) as well as DOMS (pre:  $1.0 \pm 1.4$ ; postrec:  $4.6 \pm 2.3$ ; post24:  $4.4 \pm 2.7$ ). In addition, cold-water immersion led to an acute decrease in CMJ postrec ( $-5.4 \pm 2.5$  cm). **Discussion** The main findings of the study were that a half-marathon induces muscle damage and a systemic inflammatory response. This is in line with previous research showing sustained inflammatory responses and muscular stress following endurance exercises (Byrne, Twist & Eston, 2004). Furthermore, the results suggest that none of the recovery interventions as applied in our study is able to contribute to a faster recovery during the first 24 hours following a half-marathon compared to passive rest. In addition, when using recovery interventions between subsequent events at the same day, coaches and athletes must be aware that cold-water immersion leads to an acute decline in performance. **References** Ament, W. & Verkerke, G.J. ## METABOLIC PROFILE OF BODY MASS-BASED SQUAT EXERCISE IN HEALTHY YOUNG MEN.

Haramura, M., Takai, Y., Yoshimoto, T., Yamamoto, M., Kanehisa, H.

*National Institute of Fitness and Sports in Kanoya*

**Purpose:** Training modality with body mass-based exercise is known to be effective for enhancing muscular strength in children, middle-aged and elderly individuals (Yoshitake et al., 2011; Takai et al., 2013), and muscular activities during the body mass-based exercise depend on the strength-capacity of the participant (Fujita et al., 2011). However, there is little information concerning aerobic metabolic profile of physiological response for the body mass-based exercise. Thus, the present study aimed to quantify the aerobic metabolism during body mass-based squat exercise. **Method:** Eight healthy young men ( $23.5 \pm 4.4$  years,  $171.7 \pm 4.8$  cm,  $69.2 \pm 7.9$  kg) participated in this study. The subjects performed body-mass based parallel squat exercise 200 times at a pace of once every 3 s. During the exercise, blood lactate (fingertip), electromyograms (EMGs) from vastus lateralis (VL), rectus femoris (RF), vastus medialis (VM), biceps femoris (BF), and gluteus maximus (GM) muscles, oxygen uptake (breath-by-breath), and heart rate (ECG) were measured. The EMG amplitudes during the body mass-based squat exercise were normalized to those during maximal voluntary contraction (EMGmax), and expressed as % EMGmax. All data were analyzed, and averaged over once every 10 times (N10-N200). **Results:** Oxygen uptake was higher in N20 than in N10, and in N30 than in N20, but no significant differences were found in the other combinations. Mean heart rate was lower in N10 than in N30 and N40. Blood lactate at the 10th trial was lower than at the 40th trial. After the 40th trial, no significant difference was found in each of oxygen uptake, mean heart rate and blood lactate. There were no significant differences in the % EMGmax across times and muscles. Heart rate was highly related to the blood lactate concentration ( $r = 0.974$ ,  $p < 0.05$ ) and oxygen uptake ( $r = 0.933$ ,  $p < 0.05$ ) during body-mass based squat exercise. Oxygen uptake was highly related to blood lactate concentration ( $r = 0.941$ ,  $p < 0.05$ ). These results suggest that the execution of the body-mass based parallel squat exercise depends on aerobic metabolism if it is continued for 2 minutes and over (> 40 times). In addition, the metabolic equivalent during the exercise after 2 minutes corresponded to 6.3 METs. **Conclusion:** The current results indicate that body mass-based squat exercise at a pace of once every 3 s may be steady state in oxygen uptake, heart rate and blood lactate after the 40th trial. **Reference:** Yoshitake et al (2011) *Int J Sports Med*. 2011, 32 (12):924-8 Takai et al (2013) *J Sports Sci Med*. 2013 12 (1):60-65. ## PHYSIOLOGICAL RESPONSES TO TWO CONSECUTIVE SIMULATED TAEWONDO MATCHES <4X1.5 MIN> IN ELITE YOUNG ATHLETES

Nikolaidis, P.1, Tasiopoulos, I.1, Kostoulas, I.1, Tziolas, D.I.2, Meletakos, P.3, Torres-Luque, G.4, Padulo, J.5

*1: Hellenic Army Academy (Athens, Greece), 2: University of Peloponnese (Sparta, Greece), 3: University of Athens (Greece), 4: University of Jaen (Spain), 5: University e-Campus (Novedrate, Italy)*

**Introduction** The aim of the present study was to examine the physiological impact of two consecutive simulated taekwondo matches, each consisting of four 1.5-min rounds, with 1 min break among rounds and 30 min break between matches, in elite young athletes. **Methods** Fourteen national level taekwondo athletes (four girls, age 13.1 yrs, height 157 cm, body fat 15.1%) participated in the present study. They performed two simulated matches; countermovement jump (CMJ, Optojump, Italy) and the sum of right and left handgrip muscle strength (Takei, Japan) were recorded before (PRE) and after the first match (POST1), and after the second match (POST2). Rate of perceived exertion (RPE) was recorded with the 6-20 Borg scale and lactate was measured 3-5 min after each match. Heart rate was monitored continuously, and mean HR (HRmean) and peak HR (HRpeak) were recorded. **Results** A one-way repeated measures ANOVA revealed significant differences in CMJ ( $p=0.003$ ,  $\eta^2=0.44$ ) among PRE, POST1 and POST2 (28.2, 30.4 and 30.1 cm, respectively), but not in handgrip strength (59.6, 56.4 and 58.6 kg,  $p=0.135$ ,  $\eta^2=0.15$ ). A paired-samples t-test did not show any difference between the two matches in lactate (7.9 vs. 7.4 mmol.L<sup>-1</sup>, respectively), RPE (13.1 vs. 13.4), HRmean (182 vs. 182 bpm) and HRpeak (199 vs. 199 bpm). **Conclusions** Based on these findings, it was concluded that 30 min break between two simulated matches (4x1.5 min) allowed participants to fully recover as the three indices of exercise intensity (lactate, RPE and HR) indicated similar workload for the two matches. **COMPARISON OF METHODS TO IDENTIFY THE ANAEROBIC THRESHOLD ON A BICYCLE ERGOMETER**

Kovářová, L., Pánek, D.

*Charles University, Faculty of Physical Education and Sport*

The aim of this study was to compare five current different AT estimations on a bicycle ergometer. Ten trained triathletes participated in this study (age  $35.89 \pm 7.94$  years, body height  $181.83 \pm 6.52$  cm, body weight  $80.65 \pm 6.53$  kg). We calculated five AT using different proposed methods: AT1 - intensity corresponds to ventilatory threshold (V-slope method), AT2 - intensity corresponds to a first lactate rise (Free Freiburg (Simon) threshold), AT3 - Conconi test, AT4 - intensity corresponds to 95% of 20 min of the time trial test, AT5 - theoretical calculation. ANOVA with repeated measures at the level of statistical significance of  $p < 0.05$  was used to compare HR and power in the different methods. The mean  $\pm$  values of HR and power output AT were AT1 ( $156 \pm 11$  beat.min<sup>-1</sup>,  $233 \pm 27$  W) AT2 ( $157 \pm 6$  beat.min<sup>-1</sup>,  $235 \pm 27$  W), AT3 ( $173 \pm 14$  beat.min<sup>-1</sup>,  $313 \pm 75$  W), AT4 ( $162 \pm 11$  beat.min<sup>-1</sup>,  $234 \pm 27$  W) and AT5 ( $165 \pm 7$  beat.min<sup>-1</sup>). We found statistically significant differences between both compared values ( $p = 0.000$ ). By pairwise comparison were found significant differences between AT3 and AT2 ( $p = 0.037$ ) as well as between AT2 and AT5 ( $p = 0.039$ ) at HR values. At power output values significant differences were found by pairwise comparison between AT3 and AT4 ( $p = 0.039$ ), AT3 and AT2 ( $p = 0.013$ ), AT3 and AT1 ( $p = 0.039$ ). AT3 method couldn't be used with good accuracy, conversely a noninvasive field test AT4 meets the requirements for practical needs by coaches and athletes.

**UNIQUE ACTIVATION OF THE QUADRICEPS FEMORIS DURING MULTI-JOINT EXERCISE: IMPLICATION FOR TRAINING-SPECIFICITY OF INDIVIDUAL MUSCLES**

Ema, R., Kawakami, Y.

*Waseda University*

Introduction Activation of the biarticular rectus femoris is lower than the monoarticular vasti (lateralis, medialis, and intermedius) during leg extension exercise (simultaneous extensions of knee and hip joints) (Ploutz-Snyder et al. 1995). This fact may underlie the lack of rectus femoris hypertrophy by leg extension training that causes significant hypertrophy of the vasti (Ema et al. 2014). However, previous studies did not provide detailed data of the magnitude of difference in activation among the muscles, and there is shortage of knowledge as to why inter-muscular differences exist in hypertrophic responses. Our recent data (Ema et al. 2014) also suggest inter-muscle differences in muscle activations over fatiguing contractions during repetitive leg extension exercises. This study examined this possibility. Methods Fifteen healthy men performed knee extension and leg press exercises at an intensity of 20, 40, 60 and 80% of one repetition maximum (1RM) load (experiment 1). In the experiment 2, 14 healthy men conducted leg press at 40 and 80% of 1RM load until exhaustion. Muscle activation during the exercises was measured for the vastus lateralis, vastus medialis and rectus femoris by using surface electromyography and root mean square (RMS-EMG) values were determined. Results and Discussion In the experiment 1, there were no differences in RMS-EMGs of the vastus lateralis and vastus medialis between knee extension and leg press at any intensities. The RMS-EMG of the rectus femoris was significantly higher during knee extension than leg press. In addition, there was no statistical difference in RMS-EMG of the rectus femoris between leg press at 80% of 1RM load and knee extension at 20% of 1RM load. The results of experiment 2 showed significant increases in RMS-EMGs of the vastus lateralis and vastus medialis in both intensities. The RMS-EMG of the rectus femoris did not change at 80% but increased at 40% of 1RM load, although at the point of muscular failure at 40% of 1RM load rectus femoris RMS-EMG was only 24% of the 1RM knee extension. The results show that muscle activation of the biarticular rectus femoris is substantially low and does not increase following fatiguing leg extension exercise even at high intensity, unlike the monoarticular vasti. These may be related to the significant hypertrophy of the vasti but not of the rectus femoris following chronic leg extension exercise (Ema et al. 2014). **MUSCLE SYNERGIES OF LOWER LIMBS DURING VERTICAL JUMP**

Takagi, H.I, Hagio, S.I, Kouzaki, M.I

*1: Kyoto University*

Introduction In human vertical jump, multiple muscles are activated in a timely way and in a moment, in order to generate hip joint torque and knee joint torque ankle joint torque. Hence, very complicated and precise control is required in human vertical jump. In the study of motor control, muscle synergy, neural control mechanism activating multiple muscles coordinately was suggested (Tresch et al., 1999; Ting and Macpherson, 2005; d'Avella et al., 2003). Human vertical jump may be low-dimensionally achieved by muscle synergies. Therefore, the purpose of this study is to clarify how the CNS control human vertical jump based on muscle synergy. Methods Subjects performed different types of maximum jump, i.e., squat and countermovement jumps with and without arms swing. There were 5 trials with a sufficient rest for removing fatigue between each type of jump. During tasks, the vertical and horizontal ground reaction forces, the three-dimensional position coordinate of locations of the 29 anatomical landmarks and electromyogram (EMGs) of 24 muscles in right side were measured. The EMGs were divided by standard deviation of each muscle and were combined into matrix. The nonnegative matrix factorization was applied to extract individual muscle synergies and their activation coefficients of muscle synergies (Lee and Seung, 1999; Tresch et al., 1999). Results Muscle synergies and their activation coefficients were extracted from all subjects for each task. In countermovement jump, the peaks of activation coefficients come at the similar timing and rhythm for all subjects. Muscle weighting of synergies activated in the second phase from the last were similar for all subjects ( $r = 0.42 - 0.74$ ). Muscle synergies in other phases were differ among subjects, but there are similar synergies activated in different timing. Discussion The significance finding was that 4 or 5 muscle synergies were extracted from EMGs of 24 muscles in countermovement jump to sufficiently reconstruct the original EMG. That suggests that human vertical jump is low-dimensionally achieved by muscle synergies. The peaks of activation coefficients occur at the similar timing and rhythm for all subjects, while muscle synergies activated in the same timing were differ among subjects. In human jump, the CNS inherently utilizes similar muscle synergies and timing of activation of muscle synergies has similarity, but how order the CNS activates the muscle synergies are different among individuals. ### MO-PM35 Training and Testing: Strength

#### TRAINING OUTPUT MONITORING SCALE IN SOCCER

Muñoz-Lopez, A., Naranjo Orellana, J., De la Cruz Torres, B.

*Univeristy Pablo de Olavide*

**Introduction** Although some subjective (1, 2) and objective (3) methods have been proposed to quantify training loads in soccer, there is still a lack on the calculations to obtain estimated training loads values. The purpose of this study was to validate a new method to monitor the training output in soccer (TOM Scale). **Methods** 26 male professional football players from the same National European Association team participated on this study. External load variables (ELV) (total distance (TD), accelerations (ACC), decelerations (DCC), sprints, impacts, impacts over 7G and work-rest ratio) with a multiple sensor device (Wimu, Realtrack Systems, Spain) and internal load variables (ILV) (relative heart rate (HR), time spent on different HR zones, Edwards and Banister TRIMPS) with a HR monitor (GARMIN HRM, Garmin, USA) were recorded from 22 training sessions and 2 friendly official matches for each player. The Borg Scale 6-20 was modified following the lactate curve in order to fit an exponential curve of the values used to estimate the session loads. Session loads were calculated multiplying the new subjective estimated values by the effective volume of each session (TOM Scale). The Session-RPE was also used for each session. Correlation analysis assessed the relationships between TOM Scale and Session-RPE with ELV and ILV. Multiple linear regression analysis was also performed to find the fitness measures that better explained the new scale. Results Large to nearly perfect significant correlations ( $p < 0.001$ ) were found between TOM Scale and all the ELV. These correlations were higher in all variables comparing with Session-RPE, although smaller for ACC and DCC. Moderate to nearly perfect correlations ( $p < 0.001$ ) were also found between TOM Scale and all the ILV. With ILV, Session-RPE only correlated with Edwards and Banister TRIMPS with the same strength (nearly perfect). Multiple lineal regression revealed that TD, DCC, sprints and impacts over 7G were the variables that better explained the new loads ( $r = 0.976$ ). **Conclusion** Understanding the load as an exponential curve (TOM Scale) results in a better method than a linear load increment (Session-RPE) to quantify training and match play loads in soccer. **References** 1. #### SPRINT KINETICS AND KINEMATICS ON A NON-MOTORISED TREADMILL ARE UNIQUE TO POSITION IN RUGBY ATHLETES

Brown, S.R., Cross, M.R.

*Auckland University of Technology*

**INTRODUCTION** Unique positional characteristics are an accepted part of rugby union. Ruling structures indirectly govern athletes to specific actions that result in distinct mechanical stresses specific to position. While variables such as horizontal force (FH) have been highlighted as fundamental to sprint performance in rugby (Cross et al., 2014), kinetics and kinematics specific to position have not been investigated. We assessed rugby athletes on a non-motorised treadmill (NMT) to illuminate if position-specific sprint profiles exist. **METHODS** Thirty male academy rugby athletes, separated into forwards and backs ( $n = 15/15$ ), performed maximal 6s sprints on a NMT. Comparison of kinetic and kinematic variables were made between positions during initial acceleration (steps 1-2), acceleration (steps 3-12) and maximal velocity (steps 13-22) phases using effect sizes (ES). **RESULTS** Backs produced higher absolute and relative FH at initial acceleration ( $ES = 1.07$  and  $ES = 1.6$  respectively) but lower absolute FH at acceleration ( $-0.78$ ) and maximal velocity ( $ES = -1.0$ ) compared to forwards. Backs displayed faster split times at 2m ( $ES = -1.03$ ), 5m ( $ES = -0.82$ ), 10m ( $ES = -0.63$ ) and 15m ( $ES = -0.50$ ) but achieved a lower peak velocity ( $ES = -0.54$ ) compared to forwards. **DISCUSSION** During NMT sprinting, backs generated greater levels of FH during initial acceleration, resulting in faster short-distance split times, whereas forwards produced greater levels of FH during acceleration and maximum velocity. While backs typically reach greater peak velocities during over-ground sprinting (Cross et al., 2014), forwards displayed higher peak velocities on the NMT; seeming contradictory to moderate correlations between NMT and over-ground sprinting (Highton et al., 2012). Given forwards are heavier and possess greater posterior-chain strength (Brown et al., 2014), the superior levels of absolute force and peak velocities exhibited by this position supports the notion that NMT sprinting favours these characteristics. The high intrinsic resistance of the NMT, requiring greater levels of FH, reinforces the contention that the lighter and weaker backs were disadvantaged in maintaining faster split times with increasing distance and reaching peak velocity. The relationship between over-ground and NMT sprint performance may be weakened in sporting codes featuring position-subsets with differing mechanical profiles. Practitioners wishing to profile and compare sprint mechanics using NMTs are advised to separate athletes by position. **REFERENCES** Brown SR, Brughelli M, Griffiths PC, Cronin JB. #### MONITORING OF TRAINING LOAD AND FATIGUE IN YOUTH CYCLISTS

Kilian, Y.1,2, Wahl, P.1,2, Mester, J.1,2

*German Sport University Cologne*

**Introduction** The physiological responses of athletes are basically due to the training stimulus during different training phases. Especially during periods of high training load, as in training camps, there is an increased risk of overreaching (Meeusen et al. 2013). Several markers were suggested to monitor training load, however, data on stress reactions in children and youth are rare. Therefore, the aim of the present study was to investigate the stress reactions and fatigue using minimally invasive "point-of-care-testing" (POCT) devices and other non-invasive parameters in youth cyclists to high loads of endurance training. **Methods** Six well-trained youth male cyclists (age:  $15.0 \pm 1.3$  years; height:  $177.2 \pm 8.8$  cm; weight:  $58.5 \pm 6.9$  kg; relative  $VO_{2peak}$ :  $59.7 \pm 7.0$  mL/kg/min) performed a 7-day pre-season training camp (517 km, 5820 m of altitude difference). The cycling training consisted of two training blocks, each lasting three days, separated by one day of recovery. During the camp a set of biomarkers (albumin, bilirubin, creatine kinase (CK), urea, aspartate aminotransferase

(AST), alanine aminotransferase (ALT)) and non-invasive parameters (person's perceived physical state (PEPS), resting heart rate, heart rate variability, questionnaires on muscle soreness (visual analog scale, VAS)) were collected every morning. Two days before and after the training camp, subjects performed an incremental step test and a Wingate anaerobic test to determine performance/fatigue. Results Performance did not change significantly. Albumin significantly decreased in the second training block. Bilirubin significantly increased in the first training block. CK and urea were significantly increased over both training blocks. VAS significantly increased only at recovery days. No significant changes were observed for AST and ALT. Perceived physical energy and health significantly decreased in the second training block. Perceived physical fitness and flexibility did not change over time. Resting heart rate and measures of heart rate variability (meanRR, RMSSD, SDNN) did not change significantly over time. Discussion Both, the blood parameters as well as the non-invasive markers showed a load-dependent rise or fall during the 7-day training camp, respectively. However, performance was not impaired despite the high training load. Since no single marker can be used as an indicator of the training stress of an athlete, a specific monitoring from a combination of performance tests, physiological, biochemical, immunological and psychological variables, especially in periods of high training loads, might be the best strategy to determine the athletes strain. The minimal invasive character of POCT might be one way to establish biochemical, besides psychological, monitoring also in elite youth athletes. References Meeusen, R. et al. (2013). *Med Sci Sports Exerc*, 14 (1), 186–205 Contact y.kilian@dshs-koeln.de

### **INCREASED HAIR CORTISOL LEVELS IN FEMALE ENDURANCE ATHLETES THROUGH ALTITUDE TRAINING: A USEFUL DIAGNOSTIC TOOL FOR OVERTRAINING**

Bamba, A.1, Okamoto, M.1, Ochi, G.1, Hyodo, K.1, Okazaki, K.2, Enomoto, Y.1, Soya, H.1

1: *University of Tsukuba (Tsukuba, Japan)*, 2: *Osaka City University (Osaka, Japan)*

**Introduction** Altitude training (AT) effectively enhances endurance performance, probably due to a positive adaptation to chronic stress caused by hypobaric-hypoxia; however, the chronic stress of excessive training without sufficient rest can lead to the physical and psychological impairment of ability called overtraining. Therefore, monitoring chronic stress is necessary for assessing the success or failure of AT. However, a diagnostic tool that monitors chronic stress has yet to be developed. Recently, hair cortisol has been increasingly gaining attention as a novel biomarker of chronic stress (Davenport et al., 2006), and our laboratory previously found that higher hair cortisol levels are related to lower POMS scores for vigor, which is an overtraining symptom among long-distance runners (Soya et al., 2013). Therefore, we hypothesized that hair cortisol levels increase after AT and that elevated hair cortisol might be associated with training effects. To test this, we monitored longitudinal cortisol levels in hair together with several physiological parameters related to endurance capacity in female endurance athletes during and after one-month AT at an altitude of 1,800 m. **Methods** Seven female long-distance runners (age:  $20 \pm 3.8$  years, height:  $159 \pm 4.2$  cm, weight:  $47 \pm 1.2$  kg) trained at an altitude of 1,800 m for one month in Albuquerque, USA. Before and after the AT, cortisol levels in hair, blood and urine, and total blood volume, total hemoglobin mass (THb), red blood cell volume (RCV) at rest together with VO<sub>2</sub>max on the treadmill were measured. Hair cortisol was methanol extracted and measured in the most proximal 1 cm of hair by ELISA. Results VO<sub>2</sub>max was significantly increased after AT. However, RCV and THb together with total blood volume did not change. Hair cortisol, but not blood and urine cortisol, was significantly increased after AT, and was negatively correlated with  $\Delta$ THb and  $\Delta$ RCV. **Discussion** In this study, most athletes had increased VO<sub>2</sub>max post-training, but did not have any endurance parameters, such as increased THb and total blood volume that would imply positive endurance capacity. Indeed, we found for the first time that while blood and urine cortisol levels did not increase, hair cortisol levels did increase after AT, and the hair cortisol levels accumulated during AT had a negative correlation with changes in THb and RCV levels among the endurance parameters. Thus, the higher chronic stress of AT may reach the ceiling by depressing production of these parameters. These findings suggest that hair cortisol could be a useful biomarker of chronic stress caused by AT, which may in turn be a diagnostic tool for detecting overtraining.

### **BILATERAL SQUAT SYMMETRY PRE AND POST A 7 WEEK TRAINING PROGRAM FOR SURFING ATHLETES**

Lundgren, L.

*Computing, Health and Science*

**Introduction** Surfing involves asymmetrical positions, which may cause bilateral differences among competitive surfing athletes. Previous studies have found that an imbalance of approximately 6% exists in the ground reaction force among college athletes' squat pattern (Newton et al., 2006). Furthermore, it has been reported that bilateral squat asymmetry can be corrected using feedback systems (McGough et al., 2010). The purpose of this study investigated whether a seven-week training program incorporating strength and gymnastics could decrease the asymmetry between the left and right side. **Methods** Seven junior competitive surfing athletes (6 males and 1 female) participated in the study (age:  $16.4 \pm 0.67$  y, weight:  $67.3 \pm 7.7$  kg, height:  $1.74 \pm 0.06$  m) and were tested pre- and post-training on symmetry during bilateral squats. Using a split stance between two force plates (Fitness Technology, Adelaide) recording at 600 Hz, the athletes performed 10 repetitions, first without any external load (BW) and secondly with an external load (EL) corresponding to 25% of their BW. From the average force of the left and right side of the six mid repetitions, symmetry index (SI) was calculated (McGough et al., 2010). The seven-week training program consisted of two sessions per week of gymnastics and lower body strength exercises. Paired non-parametric statistical tests (Wilcoxon) were used to evaluate differences from pre- to post-training, with significance criteria set at  $p < 0.05$ , and effect size  $r > 0.5$  considered large. Results A decrease in SI was found for the BW bilateral squat task ( $p = 0.01$ ,  $r = 0.59$ ), however not for the EL bilateral squat task ( $p = 0.15$ ,  $r = 0.19$ ). The mean pre- to post-training SI for the BW squat changed from  $8.3 \pm 11.1$  to  $4.2 \pm 5.2$ , and from  $7.8 \pm 8.2$  to  $6.3 \pm 7.4$  for the EL squat, with a large individual variation. **Discussion** Although the number of athletes that participated in this study was low, there seems to be a trend showing that asymmetry can be reduced with lower body strength and gymnastics training in seven weeks. The role of a symmetrical squatting pattern for surfing athletes remains unknown, and should be investigated further. Previous studies have proposed that there may be a relation between lower extremity asymmetry and injury risk for athletes (Brumitt et al., 2013), which stresses the need to implement a bilateral screening tool and lower body strength program for athletes. ### ELBOW ANGLE CHANGES DURING THE UNDERWATER STROKE PHASE IN SPRINT-ASSISTED TRAINING FOR COMPETITIVE SWIMMERS

Tanaka, T., Hoshino, R., Yoshimura, Y., Yasukawa, M., Oishi, K.

*Chuo University*

**Introduction:** As the outcome of a swimming race is decided by only a fraction of a second, many different training methods have been developed to improve performance. One such training method is sprint-assisted training, which is commonly used by coaches and competitive swimmers to improve the swimmer's ability to apply force over a greater distance. However, the most appropriate assist velocity is unknown. **Purpose:** To investigate the effects of changes in the assist velocity on freestyle swimmers' form, with a focus on their elbow movement during the underwater stroke phase. **Methods:** This study evaluated 7 male Japanese competitive collegiate swimmers. A pulling assist system with a velocity meter (Maglischo, 2003), which includes a wire line to pull the subjects, was used. This system precisely recorded the intracyclic velocity variations during 25 m of maximum effort freestyle swimming, with assist velocities of 0 m/sec (baseline), 2.0 m/sec, 2.2 m/sec, and 2.4 m/sec, respectively. In addition, an underwater video analysis system was used to monitor the subjects' elbow movements from in front of the subjects. Using the video data, the elbow angles (degrees of elbow flexion at end of the first half during underwater stroke phase) were determined for each subject. **Results:** The mean  $\pm$  standard deviation of the elbow angles for the 7 subjects was  $130.0 \pm 14.8$  degrees at baseline. The changes in the elbow angles at 2.0 m/sec, 2.2 m/sec, and 2.4 m/sec (vs. baseline) were  $6.0 \pm 4.1$  degrees,  $7.4 \pm 6.1$  degrees, and  $14.0 \pm 4.6$  degrees, respectively (Jonckheere-Terpstra test,  $P = 0.006$ ). Thus, the incremental changes in the elbow angles (relative to baseline) became larger as the mean assist velocity increased. **Conclusion:** Underwater stroke pattern was changed by incremental increases in the assist velocity, and this finding may help in developing optimum assist conditions for training competitive swimmers. **Reference:** Maglischo, E. W. (2003) *Swimming Fastest*. Human Kinetics.

### EFFECTS OF 8 WEEKS OF ISOKINETIC TRAINING ON POWER, GOLF KINEMATICS, AND CLUB HEAD SPEED IN ELITE GOLFERS

Parker, J.M.1,2, Lagerhem, C.1, Olsson, M.C.1

*1 Halmstad University, Sweden. 2 Scandinavian School of Golf, Gothenburg, Sweden*

**Introduction:** Elite competitive golfers commonly use physical conditioning as a way of improving playing results. Multiple studies have investigated the use of different training methods for improving performance but few studies have investigated the use of isokinetic power training as a way of improving swing kinematics and/or club head speed (CHS). The specific objective of the study was to investigate if eight weeks of isokinetic power training was more effective than traditional power training in improving swing kinematics and CHS. **Methods:** 20 competitive elite golfers (handicap better than -3.1), 13 men and 7 women, (age  $22 \pm 2$  years) were tested for lower body power (countermovement jump and loaded vertical squat jump 20,40 & 60kg), rotational power (seated upper body rotational power at 10% of body weight; bw) and golf swing kinematics (pelvis, thorax and lead arm peak rotational velocities using electromagnetic motion capture system; Polhemus Inc. USA ) and club head speed (doppler-radar launch monitor system; FlightScope, South Africa). Participants were split into a control (CTL) group ( $n=10$ ) who continued with the regular strength and power training and an intervention (IK) group ( $n=10$ ) performing isokinetic power training in the isokinetic 1080Quantum system (1080Motion, Sweden) during 8 weeks. The intervention focused on barbell squat (22kg at 0.5 ms<sup>-1</sup>) and standing rotation (10% body weight at 1 ms<sup>-1</sup>). **Statistical analysis:** a 2 (between; groups) x 2 (within; time) ANOVA assessed any differences in power, club and swing kinematics. **Results:** Statistically significant improvements were observed in both the IK and CTL group for rotational power ( $p < 0.001$ ), CHS ( $p = 0.025$ ), and peak arm speed ( $p = 0.001$ ). There were no significant differences in countermovement jump height, peak power during squats, peak pelvis speed, or peak thorax speed following the intervention period. **Discussion:** After 8 weeks of power training, both rotational power and peak arm speed improved as did the performance measure of CHS in both the IK and CTL group. However no significant changes were found between the two groups. **In conclusion,** there was no evidence suggesting that isokinetic training, as performed in this study, is neither detrimental, nor more effective, than traditional strength training when it comes to increasing CHS in golf performance.

### THE EFFECTS OF 8 WEEKS OF PLYOMETRIC TRAINING ON SPRINT AND JUMP PERFORMANCE IN FEMALE HIGH SCHOOL BASKETBALL PLAYERS

Benis, R.1,3, Rossi, R.1, Russo, L.2,3, La Torre, A.1

*milan*

**Do not insert authors here Aim:** Many studies of match-analysis have recorded a great number of jumps, sprints and change of direction during a basketball competitions (Ben Abdelkrim et al., 2007; McInnes et al., 1995). Although these high intensity activities represent a small portion of the total game time, causing 42% of the energy expenditure, they are believed to be very important for the result of a match. The aim of this study is evaluate the influence of plyometric program on sprint and jump performance in female basketball players. **Methods:** Twenty-four young female basketball players ( $15.9 \pm 0.8$  y-o;  $170.7 \pm 7$  cm;  $61.5 \pm 8.2$  kg) were involved in a 8-wks protocol consisting of 2 session/week with 6/7 exercises in accordance with NSCA plyometric guideline. All subjects were divided in two groups: 12 in a Training Group (TG) and 12 in a Control Group (CG) that performed the normal training routine of technical basketball drills. Subjects were tested at baseline (BL) and at week 8 (W8). Vertical jump performance (height) was measured by using the Optojump system (Microgate, Italy) and sprint over 20 meters was measured using Polifemo Photocell system (Microgate, Italy). **Results:** All participants completed the 8 weeks program. A paired T-test and a unpaired T-test were used respectively to assess pre-post differences within groups and between groups. Results were expressed as mean  $\pm$  SD. Significant differences were found at  $p < 0.05$ . The experimental group at W8 showed significant improvements in vertical jump height for both CMJ test and Stiffness test, whereas no significant result were founded in sprint performance (ES 0.2). The control group did not show any significant difference at W8 compared to BL. No significant difference between groups with unpaired T-test although very positive effect sizes for all variables in post-training differences. **Conclusion:** The study shows how a simple and short program of plyometric exercises has a significant influence on the vertical jump height in young female basketball players. **References:** Ben Abdelkrim et al. ### EFFECTIVENESS OF 4-WEEK LOADED MOVEMENT OR BODYWEIGHT TRAINING IN IMPROVING THE THICKNESSES OF THE DEEP AND SUPERFICIAL ABDOMINAL MUSCLES IN COLLEGIATE STUDENTS

Izumi, S.1, Kaneko, Y.2, Kondo, H.3, Kinoshita, N.1, Hiura, M.1

1: Hosei University, 2: Kuretake Gakuen, 3: Tsukuba University of Technology

**Introduction:** Loaded movement training (LMT) is defined as a multidirectional, task-oriented resistance exercise in which external resistance is applied to the body. LMT is performed widely in the United States and Japan for functional training. LMT may improve body composition, increase energy expenditure, muscle strength, and motor function. However, evidence from direct scientific research to support these claims is lacking. The purpose of this study was to investigate the effects of the thicknesses of the deep and superficial abdominal muscles, muscle endurance, and muscle power on 4-week LMT or body weight training (BWT). **Methods:** Nineteen collegiate students (age,  $20.5 \pm 0.7$  years; height,  $164.3 \pm 9.1$  cm; body mass,  $56.0 \pm 8.3$  kg) were allocated randomly into either a LMT or a BWT group. Baseline testing involved a 30-sec sit-up test (number of times) of muscle endurance, 10-sec incremental bike test of peak power, impedance measurements of body weight and body fat rate, and measurements of abdominal circumference and thicknesses of the deep and superficial abdominal muscles. The thicknesses of the rectus abdominis, external oblique, internal oblique, and transversus abdominis muscles were measured on ultrasonographic images. After baseline testing, the participants were allocated between the LMT and BWT intervention groups, which they performed 12 times over 4 weeks ( $3 \times 4$  weeks). The subjects performed 15 min of intermittent training (20-s work, 10-s rest) per session. The LMT group used a 4-kg ViPR weight in every training session. A rating of perceived exertion (RPE) was used to evaluate the intensity of the LMT and BWT in each session. **Results:** RPE did not differ between the two groups. The impedance measurements of body weight and body fat rate did not differ between before and after the intervention in both groups. LMT significantly decreased abdominal circumference (before vs. after the intervention:  $73.1 \pm 6.5$  vs.  $70.7 \pm 6.4$  cm,  $p < 0.05$ ), and the transversus abdominis thickness significantly increased in LMT ( $0.57 \pm 0.13$  vs.  $0.73 \pm 0.12$  cm,  $p < 0.01$ ). BWT significantly increased the 30-s sit-up test score ( $30.8 \pm 4.3$  vs.  $32.5 \pm 4.5$  times,  $p < 0.001$ ) and peak power ( $586.7 \pm 153.9$  vs.  $621.5 \pm 178.3$  W,  $p < 0.05$ ). The rectus abdominis thickness significantly increased in BWT ( $1.08 \pm 0.29$  vs.  $1.15 \pm 0.25$  cm,  $p < 0.05$ ). **Discussion:** Results demonstrated that LMT using the 4-kg ViPR weight improved the thickness of the deep abdominal muscles (transversus abdominis) and decreased abdominal circumference. BWT improved the thickness of the superficial abdominal muscles (rectus abdominis), and muscle endurance and peak power. Therefore, LMT can improve body composition. **References:** Yamashita N, Ito R, Nakano M, Matsumoto T. (2015). JSCR, 29(1), 116–125. Ota M, Ikezoe T, Kaneoka K, Ichihashi N. (2012). ### ACUTE EFFECTS OF ONE-LEGGED STRETCHING ON REGIONAL ARTERIAL STIFFNESS IN HEALTHY YOUNG MEN

Yamato, Y.1,2, Hasegawa, N.1, Sato, K.1, Ogoh, S.3, Iemitsu, M.1

1)Ritsumeikan University, 2)Aino University, 3)Toyo University

**BACKGROUND:** Acute aerobic exercise induces decrease in arterial stiffness, and chronic aerobic exercise training also reduces arterial stiffness. Additionally, recent studies reported that chronic stretching exercise reduced blood pressure and improved arterial function (Cortez-Cooper MY, et al., 2008, Wong A and Figueroa A., 2014). However, the effect of arterial stiffness on acute stretching exercise remains unclear. We hypothesized that arterial stiffness was transiently reduced in stretched region. **PURPOSE:** The purpose of this study was to clarify whether regional arterial stiffness was reduced by acute passive one-legged calf stretching in healthy young adults. **METHODS:** Fourteen healthy young men ( $21 \pm 1$  years,  $172 \pm 2$  cm,  $65 \pm 2$  kg) volunteered for the study. Subjects were performed passive one-legged calf stretching exercise (6 repetitions of 30 seconds with a 10-second recovery). Femoral-ankle (faPWV), as an index of arterial stiffness, and systolic blood pressure (SBP) and diastolic blood pressure (DBP) in both lower legs were measured before and immediately after and 15, 30 min after stretching exercise. Carotid-femoral pulse wave velocity (cfPWV) as an index of central arterial stiffness and heart rate (HR) were also measured. **RESULTS:** faPWV in the stretched leg was decreased immediately ( $p < 0.01$ ) and 15 min ( $p < 0.05$ ) after passive stretching exercise compared with before stretching exercise. This acute reduction of faPWV was returned to the basal levels at 30 min after stretching exercise. On the contrary, faPWV in the unstretched control leg was not changed by stretching exercise. Additionally, the passive one-legged stretching exercise did not alter SBP and DBP in both legs, and cfPWV and HR was not changed by stretching exercise. **CONCLUSION:** These results suggest that regional arterial stiffness in the stretching leg was reduced by acute passive one-legged calf stretching in healthy young adults. Supported by Grants-in-Aid for Scientific Research (#23680071 and #25560378, M. Iemitsu). **References:** Cortez-Cooper MY, et al. (2008). Eur J Cardiovasc Prev Rehabil 15: 149-155. #### RELATIONSHIP BETWEEN HEIGHT, BODY MASS AND RUNNING SPEED PERFORMANCES IN YOUTH MALE SOCCER PLAYERS

Mathisen, G., Pettersen, S.A.

University of Tromsø

Do not insert authors here **Introduction** In adolescence, different growth- and maturity-related factors influence running speed, and body mass and height have found to be determinants of the performances. In youth male soccer, the knowledge of performance related to chronological age, especially around the growth spurt is important, because physically taller and heavier player, tend to be selected. The aim of the current study was to investigate the relationship between anthropometric (height / body mass), and running speed and agility. **Methods** In total, 132 young male soccer players, aged 10-16 years, were tested (Brower Timing System) in straight-line speed, 20-m with 10-m split time, and in agility performance. The participants were divided in three age groups; 10-11 (mean  $10.8 \pm 0.50$ ) years, 13-14 (mean  $13.9 \pm 0.50$ ) years and 15-16 (mean  $15.5 \pm 0.24$ ) years. Relationship between anthropometrics (height and body mass) and results of speed and agility performance were determined using Pearson correlation (r) analyses. Two way ANOVA was used to test between subject effects. **Results** Body mass was correlated with 10-m ( $r = 0.40$ ,  $p < 0.05$ ), and 20-m ( $r = 0.33$ ,  $p < 0.05$ ) straight-line sprint in the

13-14 year-old group, and in 20-m ( $r = 0.34$ ,  $p < 0.05$ ) and 10 to 20-m ( $r = 0.35$ ,  $p < 0.05$ ) straight-line speed in the 15-16-year-old group. Body height was correlated with 20-m sprint ( $r = 0.55$ ,  $p < 0.01$ ), 10 to 20-m sprint ( $r = 0.53$ ,  $p < 0.01$ ), in the 13-14-year-old group, and in 20-m sprint ( $r = 0.42$ ,  $p < 0.01$ ), and 10 to 20-m sprint ( $r = 0.48$ ,  $p < 0.01$ ) in the 15-16-year-old group. Agility correlated only with body height in the 13-14-year-old group. ( $r = 0.32$ ,  $p < 0.05$ ). In 10-11-year-old age, there was no significant relationship between anthropometrics and speed and agility performance. Discussion This study has demonstrated that body height and body mass influence straight-line sprint up to 20-m, in 13 to 16 year-old male soccer players. In this age group, taller and heavier participants was better in straight-line speed, however, in the 10-11 year-old group there was no significant relationship. The result is attributable to their maturation status, with huge difference in height and body mass following the growth spurt. However, the agility performance was significant better for the taller and heavier participants only in the 13-14 year old group. Selecting based on anthropometry (height and body mass), leads to advantage for taller and heavier players, and may lead to selection bias and drop-outs in youth soccer. ## DEVELOPMENT AND RELIABILITY OF THE COLORADO COLLEGE ANAEROBIC CAPACITY TEST

Bull, A., Vandersluis, K., Herron, R., Doernhoefer, E.

*Colorado College, Colorado Springs, CO, USA*

Field based sports such as football (soccer) involve repeated high intensity, short duration sprints which rely on a high rate of cellular ATP production, ability to recover quickly, and a large anaerobic capacity to do work. Various field tests are used by coaches to assess anaerobic fitness; however, many tests are pass/no-pass and do not provide a graded level of anaerobic capacity, or involve sprints that are much longer than are found in game situations. Therefore, the purpose of this study was to develop a field test for anaerobic capacity that would be easy to administer, provide reliable results with field-based athletes, and provide coaches with useful information about athletes' anaerobic fitness. The Colorado College Anaerobic Capacity Test (CAT) was developed after multiple testing sessions of various protocols with local field-based athletes serving as participants. In its final version the CAT consists of repeated 40 meter sprints (the width of the penalty area on a standard NCAA soccer field, 40.23-m/44-yds) at maximal speed. Athletes have 7 second to sprint the 40 meters, with 13 seconds of active recovery in between sprints. Athletes continue sprints back and forth every 20 seconds until they can no longer cover the 40 meters in 7 seconds, and their number of attempted sprints is recorded. The Colorado College Women's soccer team (NCAA D-I) performed the CAT twice within a 7-day period to evaluate the test's reliability, with 14 athletes completing both trials. The mean (SD) number of sprints attempted by the athletes in the two CAT trials was 8.0 (2.8) and 7.14 (3.0), respectively. A dependent t-test revealed that there was a significant difference ( $p=0.012$ ) between the number of sprints completed in the two trials, indicating that this test was not reliable. However, this poor reliability may be due to the fact that the soccer team had a practice on the morning that the second test was administered, but not the first. This unexpected practice may have affected the results in the second trial because the athletes were fatigued from a high-intensity practice. Continued testing is planned to evaluate the reliability and validity of the CAT with more subjects and with greater control over the amount of exercise done 24 hours prior to administering the test. Additional results may be available for presentation at the congress.

## VALUATION OF FOOTBALL PLAYERS LEVEL BY LOWER LIMBS STRENGTH USING CMJ 2.1

Rossi, A., Boccolini, G., Alberti, G.

*Università degli studi di Milano*

Introduction The football players (FP) need high level of lower limbs strength during matches such as during headshots (Reilly and Korkusuz, 2008). Testing the vertical jump height is widely used to determine the lower limbs strength. The aim of this study was to determine if the new functional test Countermovement Jump 2.1 (CMJ2.1) (Alberti et al., 2015) was able to characterize the level of athletes. Methods 49 FP (age:  $21.0 \pm 7.0$  yrs; height:  $178.1 \pm 6.0$  cm; weight:  $73.6 \pm 5.3$  kg) were recruited from local high and low level football teams (HL:  $n=26$  and LL:  $n=23$ , respectively). The participants were tested on bipodalic countermovement jump height landing on two legs (CMJbip), landing on right leg (CMJ2.1R) and landing on left one (CMJ2.1L). The FP were also tested on right and left monopodalic countermovement jump height (CMJR and CMJL, respectively). In accordance to Shapiro-Wilks' normality test, Unpaired t-test or Mann-Whitney U test and Paired t-test or Wilcoxon test were performed using Aabel (versione 3.0.3; Gigawiz Ltd. Co., Tulsa, OK, USA). A p value lower than 0.05 was considered statistically significant. Results No statistical difference was detected in CMJbip between HL and LL ( $38.2 \pm 5.4$  cm and  $35.9 \pm 4.7$  cm, respectively). However, statistical differences were detected in CMJR ( $p < 0.001$ ) and CMJL ( $p < 0.001$ ) between HL and LL. Furthermore, a statistical difference was found in CMJ2.1R ( $p < 0.05$ : HL:  $33.5 \pm 5.5$  cm; LL:  $30.4 \pm 4.2$  cm), but no statistical difference was found in CMJ2.1L (HL:  $33.3 \pm 4.9$  cm; LL:  $31.1 \pm 4.4$  cm). In both groups, no statistical differences were detected between CMJ2.1R and CMJ2.1L. Greater statistical differences between CMJbip and CMJ2.1 were found in LL (CMJbip vs CMJ2.1R =  $p < 0.001$ ; CMJbip vs CMJ2.1L =  $p < 0.001$ ) than in HL (CMJbip vs CMJ2.1R =  $p < 0.01$ ; CMJbip vs CMJ2.1L =  $p < 0.01$ ). Discussion No statistical difference found in CMJbip between HL and LL could be explain by lower contribution of coordination skill and unspecific dynamic sport movement during this test as compared to monopodalic CMJ test. Indeed, the HL FP reached higher CMJR and CMJL than LL because of different strength level performed using one leg. Lower values recorded during CMJ2.1 as compared to CMJbip are due to unconsciously neuromuscular mechanism that permit to reduce the impact on the ground after jumps (Withrow et al., 2006). The differences detected in LL between CMJbip and CMJ2.1, in both right and left legs, are higher than HL. The smaller is the difference in vertical jump height between CMJ2.1 and CMJbip, the higher is the FP level. References Alberti G, Boccolini G, Rossi A (2015). ## FACTORS AFFECTING SLEEP BEHAVIOURS IN PROFESSIONAL AUSTRALIAN FOOTBALL PLAYERS

Coutts, A.J., Sullivan, C.J., Cianciosi, M., Hocking, J., Bilsborough, J.C.

*University of Technology, Sydney (UTS), Carlton Football Club*

Introduction Due to its physiological and psychological restorative effects, sleep is widely considered to be a critical component of recovery in high performance athletes (Fullagar et al., 2015). However, at present, relatively little is known about the moderating factors that influence sleep behaviours in elite team sport athletes (Lastella et al., 2015; Robey et al., 2015). The aims of this study were to investigate

the sleep/wake behaviour of professional Australian Football (AF) players, and examine the influence of training, playing level, the use of caffeine and technology on sleep/wake behaviours. Methods Twenty three professional AF players from the same professional club participated in this study. Sleep/wake behaviour was assessed using self-report sleep diaries and wrist actigraphy monitors for a minimum of 14 nights (range: 14-18) over a 21 day period during the competition season. Training dose, player wellness, caffeine intake, sleep location, technology use prior to sleep and playing level were also recorded. Results Players fell asleep at 22:57±1:06 h:min and slept for 530±91 min. Two players demonstrated signs of poor sleep. Whilst, there were no significant effects of training on sleep/wake behaviours, the number of awakenings, sleep efficiency, perceived sleep quality were reduced on the night prior to matches (all  $p < 0.05$ ) and time in bed, sleep time and perceived sleep quality were reduced on the night following matches (all  $p < 0.05$ ). Higher level players spent significantly less time in bed (~38 min) and time asleep (~30 min) than lower level players. Caffeine consumption during the day resulted in more awakenings and shorter sleep ( $d = 0.33$ ). Similarly, players who used technology prior to sleep spent less time in bed (~34 min), less time asleep (~31 min), although sleep quality was not affected. Perceived sleep quality showed moderate relationships with time in bed ( $r = 0.40$ ), sleep time ( $r = 0.33$ ) and number of awakenings ( $r = 0.30$ , all  $p < 0.05$ ). There were small relationships between self-reported soreness with sleep latency, efficiency, sleep time and number of awakenings ( $r = 0.20-0.36$ ). Discussion Whilst these data show that almost all players achieve adequate sleep, sleep/wake behaviours are reduced prior to, and following games. These perturbations in sleep around competition are likely due to increase anxiety, travel and social factors. The negative influence of caffeine and technology use prior to sleep provides empirical support to recent sleep hygiene suggestions to avoid caffeine/stimulant and technology immediately prior to going to bed. These data also provide some support to the construct validity of likert scale questionnaires as a non-invasive method for quantifying sleep in team sport athletes. ### INTENSITY AND ENERGY EXPENDITURE OF EXERTIONS AND RATE OF PERCEIVED EXERTION AFTER FUTSAL TOURNAMENT MATCHES

Wolański, P., Goliński, D., Muracki, J., Ciałowicz-Murawska, E.

*University of Physical Education in Wrocław*

Introduction: Futsal is a very dynamic team sport. Futsal players perform similar moving actions like in outdoor football – sprints, running with high, medium and low intensity, gait, standing and specific actions with the ball – shooting, passing, tackling, heading, defending. Futsal players change the type of motion on average in every 3,38 [s] and the average time of sprint is 1,95 [s] separated with 80 [s] active resting periods (1). The substitutions are made during the match in order to give the players a possibility to reconstitute. The aim of the study was the assessment of the intensity, energy expenditure (EE) of the exertions and the rate of perceived exertion (RPE) during following matches of futsal tournament. Methods: Participants of the study were futsal players of the academic team. Heart Rate (HR) was registered during four following matches: 1st (A), 2nd (B), 3rd (C) and 4th (D). HR registration was continuous starting from the warm up of the players before the match and ending 5 minutes after the end of the match by Polar Team 2 system. Results: The highest intensity of exertion was observed in match A and equaled on average  $90,22 \pm 4,90$  %HRmax. Overall EE made by the players during four matches was on average  $395,11 \pm 118,70$  kcal/match. Average EE of single effort was  $16,33 \pm 5,36$  kcal/min. The highest EE was observed in match A – on average  $17,31 \pm 4,71$  kcal/min during single on the pitch period. It was value significantly higher comparing to three other matches. The RPE analysis did not show significant differences between matches, thus match C was characterized by the players as the most tiring (RPE  $15,1 \pm 1,52$ ). In matches A,B and D the average RPE was  $\leq 14 \pm 2,11$ . Discussion: The highest average intensity of effort was registered during the first match (A), it equaled  $90,22 \pm 4,90$  % HRmax which is higher than the value  $86,4 \pm 3,8$  % HR max observed in the first Brazilian league futsal players who participated in Rodriguez study (3). Intensity observed in our study is very high and what is more is considerably higher comparing to the intensity of 11-players football (2). In our study the EE values ranging from  $360,57 \pm 99,39$  to  $443,12 \pm 113,58$  [kcal/match] was considerably higher than in other official futsal matches with the value of  $313 \pm 9,3$  [kcal/match] observed by Rodriguez et al. (3). References: 1. Castanga C, et al. (2009). *Journal of Science and Medicine in Sport*, 12, 490-494. 2. Stølen T et al. (2005) *Sports Medicine*, 35(6), 501-36. 3. Rodrigues VM et al. (2011). *Journal of Strength and Conditioning*. 25 (9), 2482-7.

### YOUTH SOCCER PLAYERS WHO ENTER, CONTINUE AND -OUT A PROFESSIONAL YOUTH ACADEMY

Bidaurragana-Letona, I.I, Lekue, J.A.2, Gil, S.M.1

*1Department of Physiology, University of the Basque Country (UPV/EHU), Spain 2Medical Services, Athletic Club Bilbao, Basque Country, Spain*

Acknowledgements This study was supported by grants from the Basque Government (BF12010-35 and IT700-13) INTRODUCTION Elite adolescent soccer players are often relatively homogeneous in training history, functional capacity and sport-specific skills. This homogeneity makes it even more difficult for training staff to evaluate which factors influence the progression of the young players. As such, the purpose of the present study was to identify the factors that determine player's potential to progress to higher levels within an elite youth soccer academy. METHODS The sample included 50 players ( $12,27 \pm 0,18$  years) of the professional soccer club Athletic Club (Spanish, La Liga). Data was collected at the beginning and at the end of a competitive-season, with new players joining the club at the beginning of the season (Enter players=EP), players progressing to the next age category within the club (Club players=CP) and players leaving the club at the end of the season (Drop-out players=DP). The following measurements were undertaken: complete anthropometry, velocity 15-m, Barrow's modified agility test, Yo-Yo intermittent recovery test level 1 (Yo-Yo IR1) and counter-movement jump test (CMJ). Also, chronological age and age at peak height velocity were calculated. A two way repeated measures analysis of variance was performed to determine if significant differences existed between groups (CP vs. DP firstly, and CP vs. EP secondly) and testing. RESULTS CP vs. DP: Both groups became heavier and larger during the season ( $p < 0.001$ ). However, at the end of the season CP were significantly taller and heavier ( $p < 0.05$ ). Also, although performance improvements were observed during the season in both groups, improvements were larger in CP (velocity and agility,  $p < 0.001$ ; Yo-Yo IR1,  $p < 0.05$ ; CMJ,  $p < 0.01$ ). No interaction (group x time) was observed in anthropometry, performance or maturation. CP vs. EP: No anthropometrical changes were observed in EP. However, the analysis revealed that CP were significantly lighter and shorter ( $p < 0.05$ ). Regarding performance, significant improvements were observed in both groups ( $p < 0.05-0.001$ ). Also, EP appeared to be significantly closer to their maturity offset than CP. No interaction (group x time) was observed in anthropometry, performance or maturation. CONCLUSION Results indicated that anthropometrical and physical performance characteristics can differentiate between players who are selected from those who are not. Whereas improvements in performance during the season appeared to be the main reason to pass to the next category within the academy, maturation and body size appeared to be the reason for being selected to play in the club. Thus, different indicators seem to be important for coaches when selecting or promoting players.

### COMPARISON OF THE ENERGETIC PROFILE, TIME-MOTION AND TECHNICAL ACTIONS BETWEEN SMALL VS. LARGE-SIDED SOCCER GAMES

Oh, S., Hartmann, U.

*Institute of Movement and Training Science*

Introduction Smaller (e.g. 1vs1) and larger game formats (e.g. 6vs6) are recommended for the anaerobic- and aerobic training, respectively, based on the responses of heart rate and blood lactate (Hill-Haas et al., 2009). Only by using heart rate and blood lactate, however, it is not possible to calculate the relative energy contributions from the aerobic and anaerobic energy system. Therefore, the aim of this study is to compare the energetic profile between smaller and larger game formats in relation of time-motion and technical actions. Methods Eleven U-16 elite junior soccer players (15.8±1.0 yrs, 66.3±8.2 kg, 1.75±0.1 m) participated in this study during in-season period. 2vs2 and 6vs6 were chosen as smaller and larger format, played with 2 and 4 min of one bout, respectively. The energy profiles were calculated based on the accumulated oxygen uptake above rest (aerobic, [Aer]), fast component of the post-exercise oxygen uptake (anaerobic lactic, [AnAla]), maximum net accumulation of blood lactate (anaerobic lactic, [AnLa]) (Beneke et al., 2004) using portable spirometry (MetaMax 3B, GER) and lactate determination (BIOSEN S\_line, GER). Time-motion analysis was completed (SPI Pro 5 Hz, AUS) and all game sessions were recorded using a video camera to obtain the number of technical actions. Paired sample t-test was used to compare the differences in each variable between two game formats. Results The Aer share for 2vs2 (69.5±5.8%) was significantly lower than that for 6vs6 (87.6±2.4%, p<0.001), while the share of both AnAla and AnLa for 2vs2 (21.1±3.8% / 9.4±4.8%, respectively) was significantly higher than those for 6vs6 (10.1±2.6% / 2.3±1.0%, respectively, p<0.001). There was no significant difference in the sprint distance (>18km/h) between 2vs2 and 6vs6 (11.5±4.1m / 20.9±7.4m, respectively). There were no significant differences in the number of ball contacts between 2vs2 and 6vs6 (12.1±4.3 / 7.7±4.4, respectively). Discussion The AnAla and AnLa shares were recruited in a higher percentage during 2vs2 than during 6vs6, confirmed by no differences in the sprint distance covered and the number of ball contacts during 2vs2 despite the shorter duration of 2min. However, even when smaller game format (2vs2) and short times (2min) are used in training the aerobic share is still dominant and gives only a stimuli of secondary importance to the anaerobic-lactic system. ### AGE-RELATED DIFFERENCES IN COUNTERMOVEMENT VERTICAL JUMP IN BASKETBALL PLAYERS 13-18 YEARS OLD: COMPARISON WITH ELITE BASKETBALL PLAYERS.

Koulla, P.1, Michaelides, M.1

*Uclan University of Cyprus*

Introduction The aim of this study was to examine the effect of age on leg muscle strength and power in youth basketball players and compare them with elite basketball players. Methods Fifty two basketball players, all members of competitive basketball clubs and classified into 4 age groups (G1=13-14, n=15; G2=15-16, n=15; G3=17-18, n=6; G4pros=20-33, n=16, years of age) participated in this study. They were examined for anthropometric characteristics, and performed a free arm counter movement jump and an isokinetic knee test using the Humac Norm dynamometer. They were examined for anthropometric characteristics, and performed the arm-swing counter-movement vertical jump (CVJ) as a measure of leg muscle power. The maximal isokinetic peak torque of the knee extensor and flexor muscles was recorded at two angular velocities (60°s<sup>-1</sup>, 300°s<sup>-1</sup>) for both the dominant and non-dominant legs. Results A one-way analysis of variance revealed significant differences between age groups with respect to CVJ (F<sub>3,51</sub> = 19.57, p < 0.001, η<sup>2</sup> = 0.55). The findings indicated significant increase of CVJ with age except between G2 and G3 (e.g., 39±5.92 cm in G1, 41.52±3.48 cm in G2, 41.50±1.98 and in G4pros 54.43 ±8.96). There was no significant difference between dominant and non-dominant leg at both angular velocities (both p > 0.05) for all age groups. With respect to the isokinetic measurements professional basketball players exhibited significantly higher values in both angular speeds versus the rest of the groups (p<0.05). Significant positive correlations (all p < 0.0001) were detected between the isokinetic measures of the knee extensors and flexors and the CVJ for both angular velocities. Discussion It is reasonable to suggest that there are large increases in fat free mass with development in basketball players and consecutively increases in leg muscle power, even though these differences are minimized in groups that have small age differences. These gains are accompanied by large increase on performance measured with the isokinetic device and the CVJ. The findings of this study could be useful in the context of talent identification and training optimization. Contact Koulla Parpa kparpa@uclan.ac.uk

### WARM-UP FOR TEAM SPORTS: A DESCRIPTIVE REVIEW OF STUDIES AND PROCEDURES

Peña, J.1, Moreno, D.2, García-Ramos, F.1, Buscà, B.3, Casals, M.4

1: University of Vic (Spain), 2: Club Joventut Badalona (Spain), 3: FPCEE Blanquerna. Ramon Llull University (Spain), 4: CIBERESP (Spain)

Introduction Several attempts have been carried out in the last years to establish a methodology and a set of actions that may be implemented in team sports warm-up, increasing athletes' performance and avoiding injuries. Well-structured protocols have been proven effective to enhance power and prevent injuries in sports like basketball, handball, volleyball and soccer. Nevertheless, further studies should be reviewed to improve and generalize this effectiveness to some other disciplines. Methods Twenty-five research articles were analyzed to study warm-up effects and procedures for team sports. For inclusion, studies were required to be (i) intervention studies or meta-analysis; (ii) include a quantitative outcome assessment; (iii) be published later than December 2004. Results Sixteen percent of the studies evaluated warm-up duration with agreement on an activity length between 10 and 20 minutes and a pre-match recovery of 5 to 10 minutes. Forty-four percent of the studies considered dynamic stretching activities in their routines, with all of them finding a benefit over static stretching exercises in power, jump and agility and noticing suitability in young athletes. Equipment use was observed in 28% of the studies, with benefits in the adoption of vibration plates, weights and muscular belts in subsequent explosive actions despite not noticing clear benefits on the use in expert athletes. Six studies assessed the injury reduction derived from the use of warm-up protocols with 60% finding positive interaction with long-term injury reduction, especially in muscles and tendons. Warm-up routines prove not clear decrease in post-exercise muscle soreness up until now. Discussion Team sports are activities with high demands of power actions such as jumping, throwing and hitting. Most of them have strenuous actions with contact. The use of warm-up activities with a length over 10 minutes, incorporating dynamic stretching (Behm and Chaouachi, 2011) and equipment to improve postactivation potentiation and

neuromuscular demands (Bazzett-Jones et al., 2008) seems capital to improve performance (McMillian et al., 2006) and to reduce injuries (Steffen et al., 2013). Further experimental studies should be conducted to observe if any cumulative effect is produced by the use of all these strategies together. References Bazzett-Jones DM, Finch HW, Dugan EL. ### MO-PM39 Training and Testing: Team Sports II

#### THE EFFECTS OF RECOVERY TIME ON REPEATED SPRINT ABILITY IN SOCCER PLAYERS

Padulo, J.1,2, Nikolaidis, P.T.3, Gevat, C.4, Zagatto, A.5, Ardigo, L.P.6

1: *eCampus (Italy)*, 2: *CNMSS (Tunisia)*, 3: *Army Academy (Greece)*, 4: *Ovidius (Romania)*, 5: *UNESP (Brazil)*, 6: *Verona (Italy)*

**Introduction** In the last few years, Repeated Sprint Ability protocols (RSA) have frequently been used for both team sports specific testing and training (Impellizzeri et al., 2008). The aim of this study was to assess the influence of different recovery times on RSA and muscular performances (Bosco et al., 1982). **Methods** Seventeen male soccer players (age 16±0 yrs; mass: 66±10 kg; height: 1.81±0.06 m; BMI: 20.1±2.0 kg•m<sup>-2</sup>) participated in this study and performed three RSA protocols (6×(20+20-m) with 180° change of direction with three different recovery times: 15/20/25-sec) on three different days (four days in-between). Before and after each RSA test blood lactate concentration (BLa) and counter movement jump (CMJ) were assessed. The reliability (Hopkins et al., 2000) of the measures was assessed by re-testing ten days later and calculating the intra-class correlation coefficient (ICC). ANOVA with repeated measures was applied to assess the effect of recovery times on all investigated variables. **Results** Good reliability (ICC) was found for the first sprint time (ICC=0.851) and CMJ height (ICC=0.860). 25-sec recovery improved test (-3% total time from 15-sec to 25-sec recovery, p=0.0013) and CMJ (+7% post-test height from 15-sec to 25-sec recovery, p=0.038) performances, while decreased BLa accumulation (-33% post-test from 15-sec to 25-sec recovery, p<0.0001). **Conclusions** This study contributes to tune RSA procedures recovery duration starting from usually field-chosen durations (~20 sec) and already literature-investigated durations (from 2-3 to 120 sec). By investigating performance, metabolic-anaerobic demand and muscular stretch-shortening performance variables in ecological conditions, it was found that the optimal recovery duration is 25 sec in order to practically maximize performance and contain metabolic-anaerobic power involvement and muscular stretch-shortening performance deterioration. In comparison with shorter recovery duration RSA tests, a 25-sec recovery one is featured by better overall performance and post-test muscular stretch shortening performance with lower anaerobic demand in young soccer players. **References** Bosco C, Ito A, Komi PV, Luhtanen P, Rahlkila P, Rusko H, Viitasalo JT. #### ANALYSIS OF INTENSITY OF EXERCISE LOAD OF BASKETBALL PLAYERS IN A CHAMPIONSHIP MATCH IN THE CADETS CATEGORY – CASE STUDY

Vala, R., Litschmannová, M., Valová, M., Cipryan, L.

*University of Ostrava*

**Introduction** The focus of this study is the analysis of the exercise intensity in a championship match in the Cadets category (U-16) of the top league. This is the crucial point for prescribing the effective training program since the relationship between the match and training exercise intensity is considered the key training problems of sport games including basketball (Kelly and Coutts, 2010). The aim of this case study was to monitor and analyze the progress of the exercise intensity during the championship match. in the Extra-league team of Cadets (U-16) **Methods** The heart rate of players (n=5; starting lineup only) was monitored using the Polar TEAM 2 system. The average HR is calculated only from the sections of the match where the players were actively involved in the game and the game clock was running (the so-called "live time") according to Abdelkrim et al. (2007). **Results** For starting lineup players, the average HR value was calculated as 176.1 ± 5.8 heart beats per minute, which corresponded to 90.6 ± 2.9 % of HRmax determined during the graded exercise test in the laboratory conditions. There was a significant decrease in the heart rate in the first vs. last quarter of the match comparison (5% significance level). **Discussion** The presented results showed very high exercise intensity (90.6 ± 2.9 % HRmax) during the real situations in the championship basketball match in U16 category. Similar results (91 % HRmax) have been published previously for 19-year-old basketball players (Abdelkrim et al., 2007) which may indicate non-dependence of the exercise intensity during the match on age category. There are, however, the important factors which have to be taken into account before relating these results to a certain individual. The performance in sport games can be influenced by a number of factors, such as a different player position or different role of each player performs in the team (Vala and Litschmannová, 2012). The training process in basketball, as well as in any sport, must be in accordance with the typical load requirements for the real championship match corresponding to a certain performance level. The obtained information about exercise loads in the championship match should be the basis for the subsequent creation of a training plan and selection of appropriate methodological and organizational types of practice of the same age and skill category (Kelly and Coutts, 2010). **References** Abdelkrim NB, El Faza S, El Ati J. #### THE INFLUENCE OF SMALL SIDED GAMES PITCH SIZE ON INTERNAL AND EXTERNAL LOAD

Malone, S.1, Collins, K.1, McRobert, A.P.2, Doran, D.A.2

1: *ITTD (Dublin, Ireland)*, 2: *LJMU (Liverpool, England)*

**Introduction:** Small-sided games (SSG) enable coaches replicate tactical and technical skill production in game type situations (Hodgson, et al., 2014). The aim of the current study was to identify the impact of SSG pitch dimension on the external and internal load placed on

hurling players. Methods: Twenty-four male hurling players were monitored during training games using heart rate monitors (Suunto, Finland) and 4 hz global positioning satellite systems (VX Sport, New Zealand). Players participated in 4v4 SSG of varying pitch dimensions 40x20m, 60x20m, 80x20m (n=990). Percentage of heart rate maximum (%HRmax), total distance (m), high speed (>17 km.hr-1) distance (m), peak speeds (km.hr-1) and the number of accelerations were considered. A multiple analysis of variance was used to analyse pitch size differences across internal and external load metrics with statistical significance set a  $p \leq 0.05$ . A least significance difference post hoc test was used to identify differences between pitch dimensions. Data is reported as mean  $\pm$  sd. Results Percentage of heart rate maximum were significantly higher (80x20m -  $98 \pm 8\%$ ; 60x20m -  $96 \pm 7\%$ ; 40x20m -  $82 \pm 11\%$ ;  $p = .003$ ) in the 80x20m playing area. The total distance covered was significantly higher in the larger playing area (80x20m -  $729 \pm 185$ m; 60x20m -  $509 \pm 145$ m; 40x20m -  $298 \pm 89$ m;  $p < .001$ ). Similar trends were seen across high speed ( $\geq 17$ km.hr-1) distance (80x20m -  $298 \pm 127$ m; 60x20m -  $198 \pm 93$ m; 40x20m -  $76 \pm 25$ m;  $p = .002$ ). Peak speeds were significantly higher in the 80x20m playing area (80x20m -  $29.1 \pm 3.6$  km.hr-1; 60x20m -  $26.1 \pm 3.3$  km.hr-1; 40x20m -  $22.5 \pm 2.4$  km.hr-1;  $p = .004$ ). The larger pitch dimensions resulted in a greater number of accelerations being completed (80x20m -  $44 \pm 10$ ; 60x20m -  $30 \pm 10$ ; 40x20m -  $15 \pm 3$ ;  $p = .002$ ). Conclusion The findings of the current study indicate a manipulation of pitch dimensions in hurling SSG can be used to change the internal and external load placed on players. The current data may be utilised to guide coaches who use SSG as a training methodology. References Hodgson C, Akenhead R, Thomas K. (2014). *Human Mov Sci*, 33, 25-32 Contact: shane.malone@mymail.ittdublin.ie

### EARLY PREDICTION OF MAXIMAL HEART RATE DURING INCREMENTAL TESTING IN YOUNG SOCCER PLAYERS

Di Michele, R., Merni, F.

*University of Bologna*

Introduction The maximal heart rate (HRmax) is commonly used for monitoring training intensity in soccer. HRmax is typically measured by means of tests requiring an exhaustive effort. Age-based predictions are also used, but such approach tends to have substantial prediction errors. In a recent study (Baralis et al., 2013), it was shown that parameters associated to maximum effort during an incremental cycle ergometer test can be early predicted by the HR and ventilatory responses to the initial submaximal stages of the test. Thus, the purpose of this study was to evaluate the effectiveness of estimating HRmax from HR responses measured during the first phase of a graded running test. Methods 29 young soccer players (mean (SD) age: 16 (0.3) yrs, height: 174.2 (6.2) cm, weight 62.9 (5.6) kg) completed an incremental running test on an oval track, with speed set at 8.5 km/h and increased by 0.5 km/h every minute until exhaustion (Leger et al., 1988). Beat-by-beat HR was assessed throughout the test. HRmax was calculated as the peak HR value of 5-s segments. For each of the players, the slope and intercept of the HR vs. time relationship were estimated using HR data measured from the third to the sixth minute of the test, and used to predict HRmax with a linear regression. Results The mean HRmax and test duration were 202.1 (7.3) bpm (range: 187 to 216), and 809 (100) s (range: 625 to 1020). The linear model with (HR vs. time) slope and intercept as predictors explained 65% of variance in HRmax. The mean residual between the actual and predicted HRmax was 0 (3.8) bpm (range: -9.2 to 10.3). Discussion The present findings show that HRmax can be predicted with a reasonably little error (< 5%) using HR vs. time relationship determined in the early stages of an incremental test (up to a 11 km/h running speed) in young soccer players. The approach of estimating maximal parameters from responses to non-exhaustive incremental exercises seems a promising tool for testing competitive athletes without requiring a maximal effort. ### PERFORMANCE CHANGES IN WOMEN'S HANDBALL PLAYERS FOLLOWING TWO DIFFERENT TRAINING PERIODIZATION MODELS

Manchado, C., Tortosa-Marfinez, J., Cortell-Tormo, J., Caus-Peretegaz, N.

*UNIVERSIDAD DE ALICANTE*

Purpose This study was undertaken to compare training-induced changes in selected physiological, body composition and handball key performance factors following two training periodization models: traditional versus block periodization. Methods Eleven women's HB players from a first league team were assessed four times during a training cycle over two consecutive seasons. On each occasion, subjects completed a 20m maximal sprint test, a treadmill incremental test to exhaustion to determine  $VO_{2max}$ . Maximal dynamic strength 1-repetition maximum (1RM) for upper bench press and lower half-squat body, maximal isometric hand grip force, as well as explosive strength test for upper (throwing velocity) and lower extremities (countermovement and squat jumps) were assessed. Anthropometric measurements including height, body mass and body mass index were also obtained. Results Both, Traditional and Block Periodization cycles resulted in gains in lower extremities explosive strength, maximal dynamic strength and 20m sprint test, but following Block Periodization players experienced significant larger gains. Additionally, meaningful improvement were found in throwing velocity in all modalities only in the Block model. Conclusions These findings suggest that Block Periodization may be more effective than Traditional Periodization for improving the most important Handball performance factors in a Spanish first league women's Handball team.

### MEASURING GAME INSIGHT SKILLS OF ELITE YOUNG FOOTBALL PLAYERS

Savelsbergh, G.

*Vrije University*

The aim of the study is to examine the game insight of talented young elite soccer players using a video temporal occlusion technique paradigm (1). Focussing on their performance in 4-vs-4 (2) and 11-vs-11 (3) football games and cognitive functioning (4) by the Attention Networking Test (ANT). Eight coaches judged independently several 4 by 4 games and were asked to rank players according to their game insight abilities. This rating is novel compared to other studies and will validate all other variables used. In the video occlusion task the players had to anticipate the trajectory of an oncoming ball. During the task the visual information is temporal occluded at 80 ms before ball contact (-80 ms), at ball contact (0 ms) or 80 ms after ball contact (+80ms). Two groups were created based on the coaches ratings: one with a high level of game insight (HL; n=5) versus one with a lower level of game insight (LL, n=6). For the video task a significant interaction is found for group by occlusion ( $F(2, 11.8) = 5.26$ ,  $p = 0.034$ ). The HL group scored significantly better in the 0 and +80 ms contact conditions. In addition HL group performed significantly better in the 4-4 games ( $t(5.8) = 6.86$ ) as well in the 11-11 games ( $t(8.3) = 4.5$ ). No differences between groups were found with respect to the cognitive tests. The findings indicate that the video occlusion task proved to be a valid differentiator for measuring game insight in young football players.

**COMPLEX STAGE TESTING IN YOUNG SOCCER PLAYERS**

Berdnikova, A., Zakharova, A.

*Ural Federal University*

COMPLEX STAGE TESTING IN YOUNG SOCCER PLAYERS Introduction Successful training of the athlete is provided by qualitative stage control for informative and reliable indicators about athlete current conditioning. Because of early sport career beginning, increase in competitive and training loads at the initial stage of sport training regular control of young athletes is of great importance. The aim of the research was to estimate a physical fitness level of young football players and to give coach recommendations about training program design. Methods A group (n = 29) of young football players with 3 years of sport experience (age 9 – 10) was examined. The multifrequency bioimpedance segmental body composition monitor "Tanita MC-980" was used for full body composition analysis. The impedance cardiography was held for an express assessment of athletes cardiohemodynamics. The quality of regulation of athlete organism was estimated with active ortho- and clinostatic tests. Jumping testing allowed to estimate feet power and jumping technique. Running high intensity interval testing (Tabata Protocol) was held to analyze the development of speed and power abilities and specific endurance. Heart rate monitoring with GPS (Forrunner 310XT) was used to measure the distance length covered in each intensive bout in outdoor activity. Results 20,6% examined athletes have low body fat, 35% have insufficient body weight and 41% of football players have significant deficiency of body weight. The majority of cardiohemodynamic indicators are inside age norm frames. Increased heart and breathing rate at rest, hypovolemia  $-57 \pm 18,9\%$  (hypovolemia is a state of decreased blood volume in blood vessels; in healthy children closely connected with dehydration) and increased cardio contractility function ( $52 \pm 18,7$ ) are revealed. All young athletes have a good tolerance of functional tests. There are unequal level of speed and speed endurance among the football players of 9-10 years and mistakes in running technique. Discussion It is necessary to enlarge water and nutrition intake according to the nature of physical activity of football players and its intensity. For improvement of aerobic capabilities it is recommended to increase a number of low intensive (HR=  $120 \pm 10$  bpm) aerobic trainings, power training without accelerations paying more attention to a complete recovery and relax exercises for recovery. The majority of running technique mistakes are connected with lack of strength in corresponding muscles groups. That is why strength enhancement is recommended individually. For development of the main soccer skills and feet explosive force foot exercises for ligaments and tendons should be included in training process. It is also recommended to include hopping (jumping) part with emphasis on high-quality performance of each element and the position of foot during jumps. Contact sport\_tsp@mail.ru

**Mini-Orals****MO-PM40 Training and Testing: Endurance****ACCURACY OF PREDICTIVE MAXIMAL HEART RATE EQUATIONS IN FEMALE ATHLETES**

Reilly, E., Esco, M., Williford, H., Bishop, P.

*Auburn University at Montgomery & The University of Alabama*

Introduction: Athletes often use maximal heart rate (HRmax) as a guide to developing their training and conditioning programs. There are a number of published HR (heart rate) equations in the literature, but few have been validated on female athletes. The purpose of this study was to determine the accuracy of three general and two female-specific age-predicted HRmax prediction equations in female collegiate athletes. Methods: Thirty female collegiate athletes (age =  $21.5 \pm 1.9$  years, height =  $164.7 \pm 6.6$  cm, weight =  $61.3 \pm 8.2$  kg) participated. HRmax was determined by a maximal treadmill graded exercise test (Bruce protocol). Expired gas fractions were evaluated with a metabolic cart (ParvoMedics TrueOne® 2400, Sandy, UT). The test was terminated when the participant reached at least two of the criteria for maximal oxygen consumption (VO<sub>2</sub>max) as follows: a plateau in VO<sub>2</sub> ( $\pm 2$  ml.kg<sup>-1</sup>.min<sup>-1</sup>) with increasing work rate; respiratory exchange ratio > 1.10; Ratings of Perceived Exertion of at least an 8 out of 10; or volitional fatigue. Predictions were evaluated with three general equations (Fox et al., Astrand, and Tanaka et al.) and two female specific equations (Fairbairn et al. and Gulati et al.). Means and standard deviations were determined for the observed and predicted HRmax values, which were compared with repeated measures analysis of variance followed up with paired T-tests. A Bonferroni adjusted p-value was applied to reduce the chances of obtaining a type I error when multiple pairwise tests were performed, which resulted in an adjusted alpha level for significance of  $p < 0.01$ . Results: There was no significant difference between observed HRmax ( $185.9 \pm 5.0$  beats.min<sup>-1</sup>) and the Fairbairn ( $187.5 \pm 1.2$  beats.min<sup>-1</sup>) and Gulati ( $187.1 \pm 1.7$  beats.min<sup>-1</sup>) equations ( $p = 0.11$  and  $0.23$ , respectively). The Fox ( $198.5 \pm 1.9$  beats.min<sup>-1</sup>), Astrand ( $198.1 \pm 1.6$  beats.min<sup>-1</sup>), and Tanaka ( $193.0 \pm 1.4$  beats.min<sup>-1</sup>) equations provided significantly higher estimates compared to observed HRmax ( $p < 0.001$  for each). The standard error of the estimate was similar for all the prediction equations (between 5.0 and 5.4 beats.min<sup>-1</sup>), but the total error was smallest for Fairbairn and Gulati (5.3 beats.min<sup>-1</sup> for each) and largest for Fox and Astrand (13.9 beats.min<sup>-1</sup> and 13.3 beats.min<sup>-1</sup>, respectively). The 95% limits of agreement of the mean error were similar for all of the prediction equations with values varying between 9.9 and 10.5 beats.min<sup>-1</sup>. Conclusions: The female-specific HRmax equations of Fairbairn et al. and Gulati et al. provided the most accurate mean values. However, all of the equations that were analyzed in the study provided large limits of agreement and showed tendencies to over-predict HRmax especially among the participants with lower observed values. Due to the wide limits of agreement displayed by each equation, the use of age-predicted methods for estimating HRmax in collegiate female athletes should be used with caution when using HRmax prediction equations.

**RELATIONSHIP BETWEEN AEROBIC FITNESS AND MATCH ACTIVITY PROFILES OF JAPANESE YOUNG SOCCER REFEREES**

Yoshihiko, I., Hisashi, N., Akihiro, S., Hayao, O., Masafumi, Y.

*Juntendo university*

INTRODUCTION: Previous studies have demonstrated that, in experienced Italian elite-level referees, both maximal oxygen uptake (VO<sub>2</sub>max) and running speed at blood lactate concentration of 4 mmol/L (onset of blood lactate accumulation; OBLA) were correlated with the total distance covered, with VO<sub>2</sub>max being slightly a better predictor of the total distance than was OBLA 1), 2). Whereas, neither VO<sub>2</sub>max nor the speed at OBLA (s-OBLA) were correlated with the distance covered at high intensity running (HIR:  $\geq 15$  km/h). In these studies, however, video images were used to calculate running speeds, with which the accuracy may be limited. Moreover, the definition of HIR differed from what has been accepted in recent studies (HIR:  $\geq 18.1$  vs.  $15.0$  km/h) 3). Therefore, further investigations for the corre-

lation between the aerobic fitness parameters (VO<sub>2</sub>max and s-OBLA) and the match activity profiles may be warranted. Moreover, compared with the quantity of information for elite-older referees, there is paucity of data for young referees. Thus, this study was aimed to investigate the relationship between aerobic fitness parameters and match activity profiles of Japanese young soccer referees. METHODS: Fourteen Japanese male referees (26 ± 3 year-old) completed a submaximal incremental treadmill test to determine the running speed at the onset of blood lactate accumulation (s-OBLA) and to estimate VO<sub>2</sub>max from the heart rate. Match activity profiles (total distance, HIR and distances from fouls) were calculated during competitive matches using data recorded from a GPS device and a video camera. RESULTS: Total distance covered during a match was 11.3 ± 0.6 km, 1.9 ± 0.4 km was covered at HIR, and the mean distance from fouls was 14.4 ± 1.0 m. The s-OBLA ranged between 12.6–16.3 (14.5 ± 1.0) km/h, which was correlated positively with the distance covered at HIR ( $r = 0.77$ ;  $p < 0.05$ ) and negatively with the mean distance from fouls ( $r = -0.62$ ;  $p < 0.05$ ). However the estimated VO<sub>2</sub>max was not related to these variables ( $p > 0.05$ ). DISCUSSION: A high frequent occurrence of HIR during a match 4) may necessitate the ability to counter fatigue development. The submaximal aerobic parameters such as s-OBLA may better reflect this type of ability, compared to VO<sub>2</sub>max; an index of maximal aerobic power at fast speed but for a limited duration. Thus, OBLA assessment may provide good indices of fit young referees who can cover longer distances at high intensity speed and judge closer to a foul play. 1). Castagna C, D'Ottavio S. (2001) J. ## COMPARISON OF OXYGEN UPTAKE KINETICS DURING LABORATORY AND FIELD CYCLING AT HIGH-INTENSITY EXERCISE

Prinz, B., Haselsberger, K., Nimmerichter, A.

*University of Applied Sciences, Wiener Neustadt, Austria*

Introduction The primary response of oxygen uptake to a step increase to a high-intensity work rate is typically investigated in a laboratory setting. Despite the high ecological validity of field tests only a few studies examined oxygen uptake kinetics in field conditions. The aim of this study was to compare the primary response of oxygen uptake between laboratory and field conditions. Methods Thirteen competitive male cyclists (age: 23 ± 4.7 y; stature: 178.5 ± 5.2 cm; body mass: 69.0 ± 7.8 kg; VO<sub>2</sub>max: 68.2 ± 4.7 mL/min/kg) performed an incremental graded exercise test to determine the ventilatory threshold (VT) and Pmax. On two separate days participants performed two trials of 6 min duration at the intensity corresponding to 70% between VT and Pmax (Delta70%) at two cadences (60 and 90 rpm) in field and laboratory conditions. Breath by breath ventilation and oxygen uptake was measured with a portable gas analyser (MetaMax3B, CORTEX, Germany) and power output was measured with a SRM mobile power crank (Schoberer Rad-Messtechnik, Juelich, Germany) mounted on a 26-inch mountain bike. The time constant and the amplitude of the exponential primary response were resolved by least square regression. A factorial ANOVA with cadence and condition as model factors was used for statistical analyses. Results The amplitude was significantly affected by cadence (F<sub>1,12</sub> = 10.9, P = 0.006; 60 rpm: 2488 ± 394 mL, 90 rpm: 2697 ± 306 mL) and condition (F<sub>1,12</sub> = 19.2, P = 0.001; field: 2730 ± 408 mL, laboratory: 2455 ± 286 mL). The time constant was not significantly affected by cadence (F<sub>1,12</sub> = 0.2, P = 0.702; 60 rpm: 22.3 ± 4.6 sec, 90 rpm: 22.8 ± 2.4 sec) and condition (F<sub>1,12</sub> = 3.2, P = 0.1; field: 24.0 ± 4.4 sec, laboratory: 21.1 ± 3.8 sec). The end-exercise oxygen uptake was significantly affected by cadence (F<sub>1,12</sub> = 29.7, P < 0.001; 60 rpm: 4094 ± 466 mL, 90 rpm: 4383 ± 471 mL). No significant difference was observed between field (4246 ± 526 mL) and laboratory conditions (4232 ± 427 mL) (F<sub>1,12</sub> = 0.03, P = 0.859). Discussion In accordance with previous studies in trained athletes, a higher cadence has no effect on the time constant despite a higher amplitude and end-exercise oxygen uptake. The higher amplitude and the tendency to a slower (i.e. higher) time constant, indicate a higher energy demand and an impaired primary response of oxygen uptake in field compared to laboratory conditions. Whether or not these findings affect exercise tolerance or time-trial performance in field or laboratory conditions remains to be shown. Contact bernhardbp@gmx.at

## THE D-MAX METHOD IS A VALID LACTATE THRESHOLD MEASUREMENT FOR PREDICTING 5-KM TREADMILL RUNNING PERFORMANCE IN VETERAN ATHLETES

Forsyth, J.

*Staffordshire University*

Introduction Measuring lactate threshold to predict endurance performance is difficult among veteran athletes, due to an age-related decline in type 2 muscle fibres. Using absolute values of blood lactate to determine lactate threshold, such as the 4 mmol/L method or onset of blood lactate accumulation (OBLA), are not appropriate, especially if net lactate concentration is too low for a threshold to be accurately detected. The purpose of this study was to determine whether the lactate threshold, as assessed using the maximal deviation method (Dmax) (Cheng et al., 1992), which is not dependent on absolute values of lactate, could be used as a valid measure of 5-km running performance. Methods A total of 36 veteran runners (18 male and 18 female) (mean±SD, age 47.3±6.7 years) performed an incremental exercise test to establish mean treadmill velocity and mean heart rate at Dmax, and on a separate occasion, completed a 5-km time trial. Results Mean treadmill velocity and heart rate at Dmax were 12.2±1.8 km/h and 157±12 beats/min, respectively, not being significantly different to values (12.1±1.8 km/h and 159±11 beats/min, respectively) attained during the 5-km time trial (t(35)=-1.06, p=.30 and t(35)=.78, p=.44, respectively). Mean treadmill velocity at Dmax and during the 5-km time trial were significantly correlated ( $r = .92$ ,  $p < .001$ ), as were mean heart rate ( $r = .57$ ,  $p < .001$ ). Limits of agreement were -1.61 to 1.35 km/h, and -20.6 to 23.5 beats/min. In contrast, when an absolute value of 4 mmol/L of blood lactate was used, differences were significant for both velocity (t(35)=-4.49,  $p < .001$ ) and heart rate (t(35)=-1.89,  $p = 0.01$ ), limits of agreement were wider (e.g., -6.1 to 5.5 km/h), and correlation was lower (e.g.,  $r = .47$  for heart rate). Discussion Mean treadmill velocity and heart rate at Dmax for determining lactate threshold is useful for predicting 5-km running performance among male and female veteran athletes. This finding is in agreement with that of Fell (2007), who suggested that the Dmax method was a good predictor of endurance performance in well-trained, veteran cyclists, and with Machado et al. (2011), who found that the Dmax method correlated more strongly with 10-km road race performance among recreational, female, veteran runners, than did OBLA. The Dmax method can therefore, be used for predicting 5-km performance time among veteran runners. References Cheng B, Kuipers H, Snyder AC, Keizer HA, Jeukendrup A, Hesselink, M. **INTERVAL SPRINT TRAINING INCREASES AEROBIC CAPACITY IN PRIMARY SCHOOL CHILDREN**

Kappenstein, J., Ferrauti, A.

*Ruhr-University Bochum*

Introduction Intensive interval endurance training is a natural exercise for children and increases their aerobic fitness (Bailey et al. 1995; Baquet et al. 2003). Additionally, compared to continuous endurance training methods, it is time saving, and therefore of special interest for physical education in primary school. The aim of the present study was to compare the effects of playful interval sprint training and continuous endurance training on aerobic fitness, sprint performance and body composition as well as exercise tolerance and acceptance in primary school children. Methods During a 10-week intervention the effects of playful interval sprint training (INT, n=16) and continuous endurance training (CT, n=16) compared to a non-training control group (CON, n=10) were examined in 42 children (9.5±1.1 yrs; Tanner Stage <2). Each participant completed a paediatric examination as well as a pre- and post-diagnostic to determine anthropometry, aerobic fitness (e.g. peak oxygen uptake (VO<sub>2peak</sub>) and sprint performance (20 m). INT consisted of 30 min intensive interval sprint and game forms (5-15 sec bouts). CT consisted of 50 min extensive continuous run and game forms. The participants rated their acceptance of each training session by a scale of marks from 1 (very good) to 5 (poor). During two training sessions maximum blood lactate concentrations (LA) and mean heart rates (HR) were determined. Results Each participant of the training groups completed 19 (of maximum 20) training sessions. LA was significantly higher and HR significantly lower during INT (LA 2.6±0.8 mmol/l, HR 145±14 bpm) compared to CT (LA 1.3±0.4 mmol/l, HR 158±137 bpm). Acceptance was significantly higher in INT (1.3±0.3) compared to CT (1.8±0.8). VO<sub>2peak</sub> was significantly improved after INT (20%) and CT (19%), but not in CON (4%). Body mass showed a significantly lower increase after INT (3.5%) and CT (3.1%) compared to CON (6.5%) (p<0.05). Sprint performance remained unchanged in all groups (p>0.05). Discussion Playful interval sprint training shows equal results in aerobic fitness as continuous endurance training does, both without individual intensity control. Moreover, improvement in VO<sub>2peak</sub> exceeds the results of previous studies (Baquet et al., 2010; Matos and Winsley, 2007). Time saving of about 40% and high compliance offer new perspectives for fitness- und health related endurance training in school sport. **A SPECIFIC REPEATED SPRINT ABILITY TEST FOR YOUNG TENNIS PLAYERS: VALIDITY AND VENTILATORY CHANGES**

Martínez-Cantó, A., Hernández-Davó, J.L., García-Valverde, A., Mateo-Cubo, F., Marc-Hernández, A., Sánchez-Martos, M.A., Sarabia, J.M., Guillén, S., Fernandez-Fernandez, J., Moya, M.

*MIGUEL HERNÁNDEZ UNIVERSITY OF ELICHE*

INTRODUCTION: The ability to repeat high-intensity specific efforts or sports movements during a match (repeated sprint ability, RSA), is defined by the ability to perform maximal or near-maximal efforts <10 sec, with incomplete rest intervals (Girard, Mendez-Villanueva, & Bishop, 2011). Most used tests consist of 6-15 rep of 30-40 m with 25 sec rest (Chaouachi et al., 2010). Aiming to give validity to RSA tests, several studies have used the category/ranking as a construct (Wilkinson, McCord, & Winter, 2010), but participants in those studies were largely heterogenous. Therefore, in this study, a specific and reliable test for young tennis players has been used to provide the construct validity of the RSA. METHODS: 14 males tennis players were divided into two groups based on their result in the RSA test (high performance; low performance; n=7, each). The RSA test was V-shaped and consisted of 20 m with 3 changes of directions (COD) (two of 180° and one of 90°). Each participant carried out 6 reps of a RSA circuit initiated every 20 seconds. Total time (TT) of RSA ( $\sum$  of 6 repetitions), time required to change of direction (CODA),  $\sum$  of both 180° COD, fatigue index (FI) and the VO<sub>2</sub> during the test were analyzed. In addition, the evolution of lactate concentration (Lac) in capillary blood was analyzed at the end of the RSA test, an anthropometry was used to determine fat mass, and a 20m test, as well as a maximal oxygen uptake test were also performed. RESULTS: Bivariate correlations were made for all the data, and a paired t-test was used to find differences between both groups. Significant correlations were found between TT and: a) velocity in 20m (r = 0.765); b) CODA (r = 0.638); and c) Lac at 3 (r = -0.599) and 7 min (r = -0.540) post-RSA. However, TT did not correlate with VO<sub>2max</sub> or VO<sub>2</sub> during the test, neither with % fat mass, nor ranking. The FI did not correlate with any other variable. A significant difference was found in TT (p = 0.004) and in CODA (p = 0.024) between groups. CONCLUSIONS: The 20m sprint (Pyne, Saunders, Montgomery, & Hewitt, 2008) and CODA seem to be the most important validity variables. Nevertheless, ranking or VO<sub>2max</sub> were not good validity criteria. REFERENCES: Chaouachi, A., et al. (2010). *The Journal of Strength & Conditioning Research*, 24(10), 2663-2669. **EFFECT OF DIFFERENT TIME-AVERAGING INTERVALS ON THE VALID DETERMINATION OF VO<sub>2</sub>PEAK IN CHILDREN AND ADOLESCENTS WITH CHRONIC KIDNEY DISEASE**

Herhaus, B.1, Thys, S.1, Potreck, H.1, Schaar, B.2

*1: GSU (Cologne, Germany), 2: UFAF (Munich, Germany)*

Introduction: The oxygen uptake applies in sports medicine to an important gross criterion for the evaluation in physical capacity of individuals. Children and adolescents with chronic kidney disease have a lower oxygen uptake compared to healthy subjects and indicate in cardiopulmonary exercise tests (CPETs) a shorter exposure time. They cannot reach maximum oxygen uptake with plateau formation on the basis of the renal disease, therefore subjective exhaustion is selected (VO<sub>2peak</sub>). Point in time, there is no standard in the determination of VO<sub>2peak</sub> given, in regard to the time-averaging interval of data. Because of the lack of standard, the aim of this study was to determine VO<sub>2peak</sub> by modified time-averaging intervals at CPETs of children and adolescents with chronic kidney disease. Methods: In this study, 28 CPETs of chronic kidney diseased children and adolescents (sex: m=23, f=5; age: X= 15.0±15.3 years; body weight: X= 49.3±15.6 kg; body height: X= 158.5±18.5 cm) were evaluated. The test protocol was adapted to the performance of the children, the Godfrey protocol was chosen. In the analysis of CPET three different time-averaging intervals were selected: 10 sec, 20 sec and 30 sec without data smoothing. Results: There were significant differences between the averaging interval 10 sec (X = 1.241±0.380 l/min) 20 sec (X = 1.152±0.343 l/min) and 30 sec (X = 1.124±0.331 l/min). Discussion: For this patients a modified time-averaging interval of 10 seconds in a one-minute test protocol is recommended. Longer time-averaging intervals cannot validly determine the oxygen uptake. Reasons are no plateau in oxygen uptake and the time-limited VO<sub>2peak</sub>. Exercise physiologists need to verify this data-processing from maximal and peak oxygen uptake in this patients. ### IS HEART RATE A VALID MEASURE TO MONITOR EXERCISE INTENSITY DURING TRAIL RUNNING IN UNDULATING TERRAIN?

Born, D.P.1, Stöggl, T.2,3, Swären, M.2, Sperlich, B.1, Björklund, G.2

1 University of Wuerzburg, Germany; 2 Mid Sweden University, Sweden; 3 University of Salzburg, Austria

**Introduction** During incremental lab tests, heart rate linearly increases and correlates with oxygen uptake and energy expenditure (Saltin et al. 1968, *Circulation*). Therefore heart rate is commonly used by athletes and coaches to control and evaluate exercise intensities in training and competition. During trail running however, the metabolic demand of the working muscle quickly changes due to steep up- and downhill sections and different surface conditions (i.e. forest tracks, dirt roads, gravel, rocks, wood and various other obstacles) (Jensen et al. 1999, *J Sports Sci*). It remains unclear, whether heart rate adequately reflects exercise intensities during high intensity trail running in challenging undulating terrain. **Methods** After the determination of running economy and maximal oxygen uptake (VO<sub>2</sub>max) in an incremental lab test, nine competitive runners (3 women: 31.3±8.5 yrs, 61.7±3.7 kg, 21.3±5.1%fat, 207±12 mL O<sub>2</sub>/kg/km, 53±3 mL/kg/min; 6 men: 28.9±4.1 yrs, 71.6±6.1 kg, 12.8±3.2%fat, 208±7 mL O<sub>2</sub>/kg/km, 65±5 mL/kg/min) performed a trail run time trial on an outdoor cross-country track consisting of two laps with 3 steep up- and 3 steep downhill sections each and variations in track surface (total distance: ~7km, total change in altitude: ~850m). Cardio-respiratory and global positioning data (MetaMax3B\_R2, Cortex, Leipzig, GER) were measured with a portable breath-by-breath gas analyzer and a chest belt (Polar Electro OY, Kempele, FIN) to assure time alignment of all data. **Results** Comparing lap times of the trail run, the first lap (20:11±01:58 min:s) was completed faster than the second one (21:30±01:57 min:s; p<0.01). In the up- and downhill sections, the athletes ran with 79±2% and 72±4% of VO<sub>2</sub>max while heart rate was about 93±2% and 92±2% of HRmax, respectively. ANOVA with repeated measure revealed a significant difference between the up- and downhill sections in the first and second lap respectively for oxygen uptake (both p<0.01), energy expenditure (p=0.04, p=0.03), oxygen pulse (both p=0.02) and running velocity (both p<0.01). In contrast, heart rate (p=0.32, p=0.27), ventilation (p=0.26, p=0.24) and breathing frequency (p=0.67, p=0.61) remained unaffected by running up- and downhill. **Discussion & Conclusion** While oxygen uptake and energy expenditure varied widely with each up- and downhill section, heart rate did not reflect the changing metabolic demand. Therefore, heart rate during trail running does not seem to provide an adequate measure to describe exercise intensities in undulating terrain and with variations in track surface.

#### VALIDATION OF A SINGLE BLOOD LACTATE MEASURE AS A PRACTICAL ALTERNATIVE TO FIXED BLOOD LACTATE THRESHOLDS IN ATHLETES

Garcia-Tabar, I., Asiain, X., Setuain, I., Gorostiaga, E.M.

Government of Navarre

**Introduction** Duggan and Tebbutt (1990) proposed a submaximal running test to assess aerobic capacity by a single blood lactate concentration (BLC) value measured at a fixed running speed of 12 km/h (BLC12) as a practical alternative to fixed blood lactate concentration (FBLC) determination in soldiers. To date, there are no other published data about the validity of this test. The majority of the recreational athletes do not have the opportunity to determine their FBLC thresholds (Denadai et al., 2005). It was therefore deemed necessary to further explore the appropriateness of a single BLC measure to monitor aerobic capacity in athletes. **Methods** One hundred amateur Basque-ball and thirty six professional team-sport players performed a submaximal discontinuous incremental running test. BLC was measured after every exercise stage and running speeds at FBLC of 3 mmol/L (S3mM) and 4 mmol/L (S4mM) were calculated. Regressions equations to predict S3mM and S4mM from BLC12 were determined. Eighty athletes were tested again after two months of intensified training to verify whether regression equations were valid for longitudinal monitoring of aerobic capacity. A subset of 30 subjects was tested again at least one year apart, and these data was used for external validation of the regression equations. **Results** BLC12 was significantly (p < 0.001) and inversely related to S3mM (r = 0.94) and S4mM (r = 0.98). Relationships were maintained over the longitudinal testing. Furthermore, training-induced changes in FBLC were related to changes in BLC12 (r = -0.68 to -0.83; p < 0.001). In the cross-validation study sample, estimated and measured FBLC thresholds did not differ (p > 0.05), were robustly correlated (r = 0.91-0.99; p < 0.001) and showed good agreement by Bland and Altman plots. **Discussion** BLC12 during a submaximal incremental running test in the field was strongly related to FBLC thresholds in 136 athletes. External validation of the regression equations and the maintenance of the relationships over the time despite improvements in aerobic conditioning further corroborated these results. The current study extends earlier findings (Duggan and Tebbutt, 1990) and gives empirical support to use a single BLC measure during a submaximal test of no longer than 13 min as a simple, low-cost and practical alternative to FBLC thresholds in amateur and professional athletes. This information would be of particular interest to athletes and coaches with limited resources. **References** Denadai BS, Gomide EB, Greco CC (2005). *J Strength Cond Res*, 19, 364-368 Duggan A, Tebbutt SD (1990). *Int J Sports Med*, 11, 111-115 Contact ibai.garcia.tabar@gmail.com

#### PHYSIOLOGICAL CHARACTERISTICS AND PERFORMANCE ANALYSIS OF MONZA-RESEGONE NIGHT-RUN ATHLETES

Zaccaria, D., Casonato, S.

\*University of Pavia, #Science of Cycling

**OBJECTIVE** Monza-Resegone night run consists in a distance of around 42 km and takes place in all weather conditions. The race is timed and the winner is the team (3 athletes) that runs in the shortest time ever. The start is in the city of Monza (162m). Competitors challenge along the flat asphalt of Monza-Brianza province until Calolziocorte where they find the first steep steps. At Erve the road ends and the run continues on uneven and dark footpath. Athletes reach the finish line (1173m) on Resegone Mount. **METHODS** The objective of this study is to describe the physiological characteristics of runners in order to assess the performance and to quantify the metabolic energy contributions in this kind of competition. Three, well-trained, male runners (58,7±6,2 kg, 167±2,2 cm, 38±4 years of age) completed an

incremental VO<sub>2</sub>max test (13 km/h 0.5% gradient start + 1.5 km/h each minute) on a treadmill. Ventilatory Threshold has been calculated using V-Slope graph (Cosmed @ Quark B2) The performance of the three men's team was investigated during the 53rd race edition, using a Garmin GPS device, with post-hoc analysis developed using Trainingpeaks Software @ with dedicated tools. RPE data has been reordered according to 0-10 Borg Scale. RESULTS VO<sub>2</sub>max (75.7±2.1 ml/min/kg) and Threshold Speed (19,0±0,6 Km/h) was comparable with medium-high level non professional runners. The first section with little elevation gain (36,3 km with 200 m of altitude gain) have the best, steady, aerobic decoupling (pace vs heart rate) with an average pace of 3:52 min/km, 15,49 km/h of average speed. In the uphill section, about 5,7 Km long, the runners average 593m of total ascent with non-linear pace and several interval efforts on steady ramps walking on hard slopes in the final part of the ascent. The mean normalized grade pace of the trail run was 7:39 min/km, corresponding to 7,8 km/h, with a running pace that shows large differences caused by different slopes and terrains. There was not a significant difference in RPE when comparing participants, with a very hard perception of the final effort at night (5.5±1 in the linear road section vs 9.2±0.5 in the uphill off-road section). CONCLUSION It's evident that Monza-Resegone is a demanding event; the performance is characterized by night running, continuum between the marathon and trail sections and the steep arrival at the top of Resegone Mount. More studies are needed to determine the impact of different aspects on this unique event, such as muscular and biomechanical aspects of the first and last part of the race and strategies for energy supplies. ### DOES SELF-STRUCTURED RUNNING IMPROVE RUNNING ECONOMY AND VO<sub>2</sub>MAX IN NOVICE RUNNERS; A 31-WEEK PROSPECTIVE STUDY.

Rokkedal-Lausch, T.

*Aalborg University*

The purpose of the study was to investigate if training volume and intensity were associated with changes in running economy (RE) and change in maximal oxygen uptake (VO<sub>2</sub>max) following self-structured running. A sample of 48 novice runners (20 females/28 males, 32.2 ±SD 7.9 years, BMI 24.2 ±SD 2.8 Kg / m<sup>2</sup>) were included in a prospective study with a 31-week follow-up. During follow-up, all subjects quantified their running volume and intensity by GPS. To examine the associations between cumulative running volume or intensity of training and changes in RE and VO<sub>2</sub>max, crude and adjusted regression analyses were performed on subjects dichotomized into low- and high-training groups. The results of the study show that the high-volume group (mean weekly running of 4.7km) had a significant improvement of 4.1% (95% CI: [1.7%; 6.3%], p=0.002) in VO<sub>2</sub>max while no change was found in the low-volume group. There was no association between intensity in training and the development in VO<sub>2</sub>max. In addition, no associations between running volume or running intensity and the development in RE were found. In conclusion novice runners with a high volume had a mean improvement in VO<sub>2</sub>max of 4.1% following a self-structured 31-week running regimen. In contrast, no change in RE was found.

### A NEW TREADMILL TEST TO EVALUATE AEROBIC INDICES FROM UPHILL RUNNING

de Lucas, R., Matos, B.K., Souza, K.M., Guglielmo, L.G.A., Denadai, B.S.

*Federal University of Santa Catarina*

**Introduction** Although the popularity of uphill running and orienteering events is growing, the testing procedures applied to uphill running is limited to incremental tests at selected inclines. A clear limitation relevant to these protocols is that the runner always performs an incremental speed test against a fixed incline (Paavolainen et al., 2000; Pringle et al., 2002; Carter & Deckerle 2013). Thus, the aim of this study was to determine the aerobic functional indices from an incline-incremented treadmill test, and compare this to the indices derived from a traditional speed-incremented running test. **Methods** Thirteen endurance-trained runners took part in this study. Firstly, they performed an incremental test at 1% incline on a treadmill. This test started at 10 km/h and every 3 min the speed was increased by 1 km/h. A second incremental test was performed and the speed was set at a constant of 50% of the peak speed obtained during the first test. Additionally, the inclination started at 3 % and was incremented by 2% every 3 min. Cardiorespiratory variables were recorded during the entire testing. Blood lactate was measured after each stage. From the first test the external load (i.e. intensity) was described by speed (km/h), whilst from the latter the intensity was described by grade (%). **Results** The mean peak speed reached during the speed-based test was 17.9 ± 1.6 km/h and the peak inclination obtained during the incline-based test was 17.6 ± 1.2%. The VO<sub>2</sub>max was not significantly different between the tests. However, the maximal heart rate (HRmax) was significantly higher in the speed-based (185 bpm) than the incline-based test (181 bpm). The same was observed for heart rate at lactate turnpoints. **Discussion** The current uphill protocol seems to present greater ecological validity compared to the other protocols (Pokan et al., 1995; Paavolainen et al., 2000; Pringle et al., 2002), given that running up steep hills the speed becomes relatively slower. This situation is replicated in the present uphill test allowing runners to achieve their maximal possible inclination. The lower HRmax observed during incline-based treadmill test should be considered to prescribe uphill training according to the current protocol. This test may provide a specific basis for assessment and prescription for uphill training in orienteers and endurance runners. **References** Carter H, Deckerle J. ### CARDIOVASCULAR AND METABOLIC RESPONSES DURING ON-WATER UPWIND SAILING IN OPTIMIST SAILORS

Capelli, C.1,3, Lopez, S.1, Bourgois, J.2, Tam, E.1

1: *DNMS, UNIVR (Verona, Italy)*; 2: *DMSS Ghent University (Ghent, Belgium)*; 3: *DPP, NSSS (Oslo, Norway)*

**Introduction** Physiological responses during upwind dinghy sailing have been extensively investigated in adults during simulated/on-water sailing. However, they have been only occasionally evaluated in young subjects (Callewaert et al. 2014, Rodio et al. 1999). We aimed to investigate cardiac output (CO), blood pressure and oxygen uptake (VO<sub>2</sub>) during actual on-water upwind sailing in highly trained Optimist sailors to describe cardiovascular and metabolic responses in ecological conditions. **Methods** We studied 10 highly trained male and female optimist sailors (12.7 ±0.8; 153 cm±9; 41 kg±6; sailing career: 6.2±1). In a laboratory session, VO<sub>2</sub>, cardiac output (CO), mean blood pressure (MAP) and heart rate (HR) were measured at 4 submaximal steady state workloads and at maximal level (VO<sub>2</sub>peak) on a bicycle ergometer. During on-water upwind sailing with constant course over water (C) and with tacks (T) (Lago di Garda, Italy, 20-24 °C), CO, MAP and HR were measured for 15 minutes together with boat speed and wind intensity (WI). Indirect estimation of VO<sub>2</sub>, based on HR measurements on the water and use of the individual HR-VO<sub>2</sub>ss relationship preliminarily obtained during the

laboratory session, was used. Results WI ranged between 4.6 and 13.4 m/s.  $\dot{V}O_2$  increased linearly with WI from 0.50 L/min $\pm$ 0.05 to 1.20 L/min $\pm$ 0.19. No significant difference was found between C and T.  $\dot{V}O_2$  corresponded to 48 $\pm$ 15 % $\dot{V}O_{2peak}$  at the highest WI. CO linearly increased with WI from 6.3 L/min $\pm$ 0.9 to 10 L/min $\pm$ 1.3, implying an increase of the arterial-venous O<sub>2</sub> difference by about 70 % from rest to extreme sailing conditions. MAP during sailing was a linear function of WI, ranging from 90 to about 110 mm Hg, whereas it did not change during cycling exercise. Total peripheral vascular resistances (TPR=MAP/CO) significantly decreased with WI. However, covariance analysis showed that TPR during on-water sailing was 23 % (P<0.001) larger than during cycling. Triple product of the heart (TPH = MAP \* CO) increased significantly with WI and it was about 60 % larger (P<0.001) during on-water sailing than during cycling. Discussion Optimist sailing may elicit cardiovascular and metabolic responses that may overload the heart of these young athletes. Increase of MAP and a high cardiac load may be the consequences of an increased afterload due to the (quasi-) isometric nature of prolonged hiking applied to create a counteracting up-righting moment to optimize boat speed and to prevent the boat from capsizing at the highest wind intensities. ### CRITICAL VELOCITY DOES NOT REFLECT STEADY STATE EXERCISE IN LONG TRACK SPEED SKATING

Mulder, R., Noordhof, D., van der Zee, W., van der Hauw, C., Veeger, H., de Koning, J.

*VU University Amsterdam*

**Introduction** The concept of critical power (CP) or critical velocity (CV) is well investigated in cycling, running and swimming, and may be used in practice to prescribe training. Exercise performed below CP/CV generally results in steady state exercise, while exercise above CP/CV results in non-steady state conditions (1). Assessment of CV requires at least three to five individual time trials, with at least five minutes between the shortest and the longest trial (1). A common event in long track speed skating is an allround tournament, 4 different time trials ranging from 500 m to 5 or 10 km, which may be used to determine CV and circumvent extensive testing. Therefore, the purpose of the current study was to determine CV and assess the physiological interpretation of the concept of CV in long track speed skating. **Methods** CV was determined from the results of an allround tournament (4 individual time trials) in 11 trained competitive speed skaters (6 male, 5 female). CV was determined using a linear model, where CV is represented by the y-intercept of the relation between  $\dot{V}O_2$  and the inverse of time to exhaustion. Subjects skated two constant velocity trials to exhaustion or 12 min, one at their individually determined CV (CV<sub>trial</sub>) and one below CV (CV-10%<sub>trial</sub>). In both constant velocity trials respiratory parameters were measured. Results Only 18% (2 out of 11) of the subjects sustained skating 12 min at CV. 7 subjects completed the CV-10%<sub>trial</sub> (64%), but did not reach steady state. RER and minute ventilation of the 7 subjects that completed the CV-10%<sub>trial</sub> increased with 11.6% and 20.3% from minute 4 to 11, respectively. Average sustainability of the CV<sub>trial</sub> and CV-10%<sub>trial</sub> were 9.3  $\pm$  2.4 min (range 5.0 min – 12 min) and 11.6  $\pm$  0.7 min (range 10.2 min – 12 min). **Discussion** Skating at CV, as calculated according to procedures described in literature, does not result in steady state exercise. It seems that even in longer skating trials the anaerobic contribution is substantial (2). This may be explained by the restricted blood flow to the upper leg muscles as a result of the characteristic crouched skating posture (3). Therefore, it is concluded that speed skating at CV does not represent the velocity that can be sustained for a considerable time and does not result in steady state exercise. **Literature** 1. ### IDENTIFYING TRAINING THAT IMPROVED PERFORMANCE: ANALYSIS OF LARGE GPS TRAINING DATASETS IN WELL-TRAINED RUNNERS

Passfield, L.I, Kosmidis, I.2

1: *Endurance Research Group, (University of Kent, UK)* 2: *University College London (UK)*

**Introduction** It is clear that the individual response to standardised training programmes is highly variable for reasons that remain unclear. An innovative approach to this problem is to examine which training gave rise to observed performance improvements. Technological developments such as portable GPS make it possible to record endurance runners' training in great detail. Consequently, the aim of the present study was to investigate which training speeds were associated with enhanced performance by examining a large training dataset of a group of runners. **Methods** All the training data from a group of 14 highly trained male endurance runners were gathered using portable GPS watches in a 1-year study by Galbraith et al. (2014). In total running speed and distance in 3,469 training sessions, accounting for 3,239 training hours were recorded by GPS with an average data resolution of less than 5 s per data point. Changes in performance were assessed with field-based trials of 1,200m, 2,400m and 3,600m conducted on an athletics track five times during the study. Runners'  $\dot{V}O_{2max}$ , OBLA, and running economy were also measured five times during the year. To analyse the 2.5 million training observations we constructed a "training distribution profile" for each session. Using the "training distribution profile" we identified the running speeds in training that were significantly associated with improvements in the runners' field based performance trials. Results Time spent training at running speeds between 5.3 and 5.7 m/s was associated significantly with increases in running performance. By constructing a model of endurance performance separate significant contributions for runners' height, OBLA and running economy to performance were also identified. A model to predict the effects on performance of time spent training at certain speeds was also developed. **Discussion** This study introduces the "training distribution profile" as a method for sports scientists to present and analyse large training datasets. The "training distribution profile" can be used to summarise continuous training data such as training speed, power output or physiological measurements such as heart rate. From an analysis of their large training dataset it was possible to determine that time spent training at 5.3 to 5.7 m/s was associated with significant improvements in running performance. For this group of runners, the identified running speeds did not correspond with velocity at  $\dot{V}O_{2max}$  or OBLA and were therefore unlikely to be identified or prescribed on the basis of current training theory. Consistent with previous studies we found that endurance running performance was associated with short stature, a high velocity at OBLA, and a high running economy. A model to predict the effect of any proposed endurance training programme on performance was also developed. Reference Galbraith, A., Hopker, J. G., Cardinale, M., Cunniffe, B., & Passfield, L. ## INTERINDIVIDUAL VARIATION IN THE RELATIONSHIP OF DIFFERENT INTENSITY MARKERS – A CHALLENGE FOR TARGETED TRAINING PRESCRIPTIONS

Hecksteden, A.

Saarland University

Introduction Training intensities are generally prescribed as relative intensities based on a unique reference value (e.g. VO<sub>2</sub>max) (1). However, exercise-induced physical strain is multifaceted (e.g. cardiopulmonary and metabolic) and large interindividual variability in intensity markers has been reported for constant load exercise with standardized relative intensity (2). Importantly, limited accuracy in the reference value (VO<sub>2</sub>max (2)) may contribute to variation in other intensity markers. Moreover, differences in the load dependent courses of the respective relationships are unstudied so far despite the importance of interpolated „performance curves“ for the prediction of other indicators based on the reference. This trial aims to address the above challenges in order to estimate the potential value of individualized, multivariate approaches for the prescription of exercise intensity. Methods 15 trained cyclists (VO<sub>2</sub>peak 67 ± 7 ml·kg<sup>-1</sup>·min<sup>-1</sup>) completed a stepwise incremental cycling test followed by 5 constant load tests (60 min) with the absolute workloads from the incremental test in randomized order. The highest of these workloads which yielded a lactate (BLa) steady state was repeated. From constant load tests, the courses of BLa relative to the respective reference value (e.g. %VO<sub>2</sub>peak) were interpolated by polynomial regression analogously to the lactate performance curve. Variability between individual regression curves was analyzed by mixed modeling. Due to the non-linear behavior of the BLa performance curve a polynomial (quadratic) model was employed for this dependent variable. Results The proportion of total variation in the course of BLa relative to the respective reference parameter accounted for by subject ID was 36% for %VO<sub>2</sub>peak, 51 % for %VO<sub>2</sub>reserve, 40 % for %HFmax, 44 % for HFreserve and 36 % for % of individual anaerobic threshold (IAS). The proportion of interindividual variation in the relationship of %HFmax and %VO<sub>2</sub>peak was 25 % (57 % for % of reserves). Discussion In our data, the load dependent relationship of intensity markers differs considerably between individuals. This corroborates previous reports and calls for a multivariable, individualized approach to intensity prescriptions if the aim is accurately targeting perturbations of homeostasis. However, the potential increase in accuracy and ultimately in training efficacy remains to be demonstrated. References 1. Mann T, et al. ## HEADACHE RESPONSE TO SPECIFIC STRENGTH TRAINING FOR TENSION-TYPE HEADACHE PATIENTS IN A RANDOMIZED CONTROLLED STUDY

Madsen, B.K., Søgaard, K., Andersen, L.L., Skotte, J.H., Jensen, R.H.

Danish Headache Center

Introduction Specific strength training has shown effect in reducing musculoskeletal pain in the neck. As neck pain is highly prevalent in Tension-type Headache (TTH) patients, specific strength training of the upper shoulder muscles may also be effective in TTH patients. A concern may be that high-intensity strength training worsens TTH immediately and more prolonged after training. The aim of this study was therefore to investigate the acute effect of strength training on headache intensity in the hours immediately after training. Methods 60 TTH patients were included after completion of one month headache diary, to ensure fulfillment of the ICHD2 criteria for TTH occurring ≥8 days per month. TTH patients were randomized into training and control group. The specific strength training group trained upper shoulder muscles for 10 weeks with progressive strength training 3 times weekly, using rubber bands. They also completed a 10 week training diary with TTH intensity on a numeric rating scale from 0 to 10 before, immediately after and 2 hours after training. The control group was instructed in ergonomics and posture correction. During the 10 week intervention period, and 12 weeks follow up frequency, and duration of headache were recorded in a diary. Mean values and SD are presented. Results 23 patients completed strength training, and 21 completed the control group. Specific strength training resulted in significantly lower headache duration (hours) at follow-up (227(166) compared to baseline 252(153) (p<0.05). Significantly lower frequency (days/month) at follow-up (17(10) compared to baseline 19(9) (p<0.05). Control group had also significantly lower headache duration at follow-up 144(117) compared to baseline 198(138), (p<0.05), and frequency was lower at follow-up 13(7) compared to baseline 17(7) (p<0.01). The 23 strength training patients TTH reported pain intensity before training session as 2.81(2.32), and immediately after training and 2 hours after not significantly different as 2.89 (2.26) (p= 0.07) and 2.96 (2.33) (p= 0.16), respectively. Discussion This randomized controlled trial showed significantly lower TTH duration and frequency after both strength training of upper shoulder muscles, and by the ergonomics and posture control intervention. Strength training was not superior as treatment, but was well tolerated by the TTH patients with no significant intensity increase of TTH after, or 2 hours after strength exercise. ## IS THE EKBLOM-BAK TEST A VALID SCREENING TOOL FOR VO<sub>2</sub>PEAK IN HIGHLY ACTIVE INDIVIDUALS?

Cardinale, D.1,2, Boushel, R.1, Ekblom-Bak, E.1

1: The Swedish School of Sport and Health Sciences (Göteborg, SWE); 2: Elite Performance Centre, Bosön - Swedish Sports Confederation (Lidingö, SWE)

Introduction Maximal oxygen consumption testing is suggested to be regularly included between training blocks of athletes in order to monitor changes in fitness throughout the season. However, despite the good reliability and validity of this physiological test, an expensive metabolic chart, and expert personnel are needed. Further, the maximal effort needed by the athlete makes this test difficult to be performed routinely. Therefore, it is important to develop valid tools that are also feasible for the estimation of the maximal oxygen consumption. The aim of this study was to validate the Ekblom-Bak test (EBT) (Ekblom-Bak et al., 2014) against an incremental test measuring peak VO<sub>2</sub> by gas exchange on a cycle ergometer in well-trained individuals. Methods 33 highly active individuals aged 34.5±6.6yrs (mean ± standard deviation (SD)) body mass 74.5±12kg, and height; 178± 9.3m) participated in the study. The EBT test was performed prior to the incremental exercise test to peak effort on a cycle ergometer for VO<sub>2</sub>peak assessment. Oxygen uptake was determined by an automated measuring system for oxygen uptake with a mixing chamber (OxygenPro, Jaeger GmbH, Germany) validated against the Douglas bag method resulting in a typical error of 2%. The mean difference and standard deviation of the differences between the EBT and measured VO<sub>2</sub>peak was calculated with Bland-Altman analysis. Results The measured mean and SD VO<sub>2</sub>peak was 4.1±0.8 L·min<sup>-1</sup> for the whole group (male 4.4±0.6 L·min<sup>-1</sup> and female 2.9±0.5 L·min<sup>-1</sup>). The mean differences between measured and estimated (EBT) VO<sub>2</sub>peak was 0.05 L·min<sup>-1</sup> (95% CI: -0.15 to 0.25). CV was 13.2% in the whole group with no significant differences between sexes. For individuals with a VO<sub>2</sub>peak within the valid range of the EBT (VO<sub>2</sub>max 1.56 to 4.49 L·min<sup>-1</sup>, n=23), the mean differences between meas-

ured and estimate  $\text{VO}_2\text{peak}$  was  $-0.22 \text{ L}\cdot\text{min}^{-1}$  (95% CI;  $-0.36$  to  $-0.08$ ), resulting in a CV of 8.2%. For individuals above the valid limit ( $n=10$ ), the mean difference was  $0.68 \text{ L}\cdot\text{min}^{-1}$  (95% CI;  $0.47$  to  $0.98$ ) with a CV of 6.9%. Discussion The Ekblom-Bak test is an easily applied and inexpensive screening tool for a population of highly active individuals within the current validity range, and may be used routinely in monitoring fitness. ### VALIDATION OF TWO SUBMAXIMAL EXERCISE TESTS IN BREAST CANCER PATIENTS UNDERGOING CHEMOTHERAPY TREATMENT

Mijwel, S., Cardinale, D., Ekblom-Bak, E., Sundberg, C.J., Wengström, Y., Rundqvist, H.  
*Karolinska Institutet*

Introduction The use of cardiopulmonary exercise testing is becoming increasingly important in disease management and in rehabilitation settings. Breast cancer patients have considerable impairments in cardiorespiratory fitness that in part have been linked to the toxic effects of anticancer therapy. Physical exercise as a means of rehabilitation of cancer patients is an emerging area of research, emphasising the need for accurate and feasible physical capacity measurements in this group. The purpose of this study was to evaluate the validity of the predicted  $\text{VO}_2\text{peak}$  from the Ekblom-Bak test (EBT) (Ekblom-Bak et al., 2014) and the Åstrand prediction model (ÅT) (Åstrand, 1960). Methods Six patients with breast cancer stage I-IIIa undergoing chemotherapy treatment (mean  $\pm$  standard deviation body mass, height, and age;  $70.68 \pm 10.25 \text{ kg}$ ;  $1.64 \pm 0.09 \text{ m}$ ; and  $51 \pm 11 \text{ yrs}$  respectively) participated in the study. Oxygen uptake was determined with a metabolic chart (OxygenPro, Jaeger GmbH, Germany) validated against the Douglas bag method (typical error=2%). EBT was performed prior to a 20 Watt incremental exercise test to peak effort on a cycle ergometer (Monark 839E, Vansbro, Sweden) for  $\text{VO}_2\text{peak}$  assessment. ÅT was used to estimate  $\text{VO}_2\text{max}$  when pedalling at 60 rpm. The mean difference and standard deviation of the differences between the EBT and ÅT and measured  $\text{VO}_2\text{peak}$  respectively was calculated with Bland-Altman analysis. Results The mean measured  $\text{VO}_2\text{peak}$  was  $1.78 \pm 0.16 \text{ L}\cdot\text{min}^{-1}$ . The predicted  $\text{VO}_2\text{peak}$  resulting from EBT led to an overestimation of  $\text{VO}_2\text{peak}$  with  $0.89 \text{ L}\cdot\text{min}^{-1}$  and a coefficient of variation of 23% while the predicted  $\text{VO}_2\text{peak}$  resulting from the ÅT led to an underestimation of  $0.41 \text{ L}\cdot\text{min}^{-1}$  with a coefficient of variation of 8% compared to the incremental exercise test to  $\text{VO}_2\text{peak}$ . Discussion The predicted  $\text{VO}_2\text{peak}$  from the Ekblom-Bak test, resulted in an overestimation of the cardiovascular fitness of the patients, suggesting that the use of this  $\text{VO}_2\text{peak}$  prediction model based on difference in heart rate between a low and high work load seems to be inappropriate in breast cancer patients undergoing chemotherapy treatment. This may be due to chemotherapy itself or medication received in combination with chemotherapy affecting the heart rate. However, from these findings, the Åstrand model resulted in a fairly good prediction of  $\text{VO}_2\text{peak}$ . This may in part be due to the fact that Åstrand prediction model is based on heart rate from one work load only. Exploration of a new correction factor may be key to improve the accuracy of submaximal testing in this population. References Astrand, I. (1960). Acta Physiol Scand Suppl, 49(169), 1-92. ## Mini-Orals

### MO-PM42 Training and Testing: Interval training, Time trial

#### A NOVEL APPROACH TO THE PRESCRIPTION OF HIGH-INTENSITY INTERVAL TRAINING USING THE CRITICAL VELOCITY ON A YOYOIRT

Collins, K., Malone, S., Doran, D.  
*ITT Dublin*

Introduction High intensity interval training (HIIT) has been shown to develop maximal oxygen uptake and enhance a players ability to undertake repeated high intensity efforts (Dupont et al., 2004). The aim of the present study was to determine the effect of YoYo IRTL1 critical velocity prescribed HIIT on performance characteristics. Methods Thirty-one sub-elite hurling players (Age:  $22 \pm 4 \text{ yrs}$ ; Height:  $178 \pm 9 \text{ cm}$ ; Weight:  $79.3 \pm 10.9 \text{ kg}$ ) participated in the study. Counter movement jump (CMJ), sprint speed (5-, 10-, 20 m), YoYo IRTL1 distance, YoYo IRTL2 distance and repeat anaerobic sprint test (RAST) performance were identified. The critical velocity on the final stage of the YoYo IRTL1 was used to calculate the distance of each players high-intensity effort. Over an eight-week period with two sessions a week a standardised step load progression (100-140%) based on the YoYo IRTL1 critical velocity was used to prescribe training. During each session multiple linear 15 seconds of effort with 15 seconds of recovery were completed. A one-way ANOVA with used to identify variation in performance characteristics with statistical significance set a  $p \leq 0.05$ . Results The CMJ, 10- and 20 m sprint performance showed little variation. The 5 m sprint performance changed significantly over the intervention period (5 m:  $1.17 \pm .08 \text{ s} - 1.04 \pm .09 \text{ s}$ ;  $p < .001$ ). Results have shown that YoYo IRTL1 distance increased by 46% ( $1424 \pm 368 \text{ m} - 2276 \pm 590 \text{ m}$ ;  $p < .001$ ) and YoYo IRTL2 distance increased by 54% ( $599 \pm 244 \text{ m} - 1045 \pm 385 \text{ m}$ ;  $p < .001$ ) respectively. The RAST performance improved over the intervention period, the change was non significant ( $p = .077$ ). Discussion The current study demonstrates that individualized HIIT induces significant improvements in 5 m, YoYoIRT L1 and L2 performance. Further research is required to identify the benefits of the current mode of exercise prescription in elite hurling players. References Dupont G, Akapo K, Berthoin S. (2004). #### ACUTE EFFECTS OF A TRAINING SESSION ON IGF-I AND IGFBP3 CONCENTRATIONS OF JIU-JITSU FIGHTERS

Tourinho Filho, H., Puggina, E.F., Moraes, C., Oliveira, L.P., Martinelli Júnior, C.E.  
*University of São Paulo*

INTRODUCTION In the last few years, the literature has shown some ambiguous informations regarding the behavior of the GH/IGF-I axis during the physical effort, with some studies showing increased levels of these hormones (NEMET et al., 2012), studies failing to identify these effects (NEMET et al., 2003) and studies that found decreased levels of GH/IGF-I after training sessions (PILZ-BURSTEIN et al., 2010). On the other hand, there are few studies investigating the hormonal responses associated with the sports training in combat sports (PILZ-BURSTEIN et al., 2010). This study aimed to investigate the effects of a Jiu-Jitsu training session on the IGF-I and IGFBP-3 concentrations. METHODS Nine male jiu-jitsu fighters participated in the study, they represent the national elite in the sport in Brazil, with  $5.4 \pm 2.7$  years of practice and  $25 \pm 4.7$  years old. Blood samples were collected in the beginning of the training session (30minutes rest) and immediately

after the end of the training. Seric concentrations of IGF-1 and IGFBP3 were performed by immunocolorimetric assays (ELISA) using commercial kits (DSL, Diagnostic Systems Laboratories, USA). Wilcoxon test was used to analyze the data obtained with p values set at 0,05. RESULTS No difference was observed regarding IGF-1 ( $p= 0.57$ ) and IGFBP-3 ( $p= 0.73$ ) levels before and after the Jiu-Jitsu training session. DISCUSSION A jiu-jitsu training session composed by six fights of 7.5 minutes with perception of effort between "hard" and "very hard" did not change the IGF and IGFBP-3 concentrations. On the opposite way, the study of Nemet et al. (2002), investigating wrestling fighters before and after a training session, found reductions in total IGF-1 total ( $-11,2 \pm 2,3\%$ ) and IGF-1 bound ( $-11,2 \pm 2,4\%$ ). A possible explanation for the absence of reduced values of IGF-1 and IGFBP-3 in the second measurement in this study would be the training status of the jiu-jitsu fighters, who were in their maximum level of performance in the season. ## DETERMINATION OF ANAEROBIC THRESHOLD'S CORRECTION FACTORS IN DIFFERENT INTERMITTENT TRAINING SETS IN SWIMMING

Gobbi, R.B.1, Campos, E.Z.1, Kalva-Filho, C.A.2, Barbieri, R.A.1, Castro, F.A.S.3, Gobatto, C.A.4, Papoti, M.2

1: UNESP (Rio Claro, Brazil), 2: USP (Ribeirão Preto, Brazil), 3: UFRGS (Porto Alegre, Brazil), 4: UNICAMP (Limeira, Brazil).

The aim of the present study was to establish correction factors and kinematic parameters in intermittent swimming bouts on maximal lactate steady state intensity. Participated in the present study, 14 swimmers affiliated to São Paulo State Aquatic Federation, with at least 3 years of competitive swimming. Intermittent swimming sessions with approximately 3000m were divided in 50, 100 and 200m bouts with 30 seconds between each bout. Lactate minimum test was used to determine anaerobic threshold intensity and performed once at each 4 weeks. The training sessions were recorded and kinematic parameters were determined in clean swimming. Normality of the data were tested through Shapiro-Wilk's test and ANOVA one-way for repeated measurements and Tukey's post-hoc was used. For the training sessions consisted of 60 bouts of 50m, 30 bouts of 100m and 14 bouts of 200m, the correction factors were  $118.11\% \pm 0.49$ ;  $105.75\% \pm 0.57$  and  $104.27\% \pm 0.62$  of the anaerobic threshold intensity and blood lactate concentrations were  $4.49 \pm 0.36$ ;  $4.01 \pm 0.37$  e  $3.32 \pm 0.53$  mM, respectively. The stroke length, stroke rate and stroke index for the 60 bouts of 50m were  $1.02 \pm 0.03$  m,  $1.24 \pm 0.05$  Hz e  $1.34 \pm 0.07$  m<sup>2</sup>/s; 30 bouts of 100m were  $0.98 \pm 0.02$  m,  $1.18 \pm 0.03$  Hz e  $1.14 \pm 0.05$  m<sup>2</sup>/s and 14 bouts of 200m were  $1.09 \pm 0.03$  m,  $1.11 \pm 0.03$  Hz e  $1.31 \pm 0.05$  m<sup>2</sup>/s, respectively, and all of them presented significant difference with the same parameters observed at anaerobic threshold intensity. Stroke length and rate presented a deflection and an inflection near each correction factor. In conclusion, intermittent training in which the objective is to improve aerobic capacity with sets of 60 bouts of 50m, 30 bouts of 100m and 14 bouts of 200m with intervals of 30 seconds, the suggested correction factors are 4.3%; 5.7% and 18% of the anaerobic threshold intensity determined by lactate minimum protocol.

## HIGH INTENSITY INTERVAL TESTING IN SPORT

Zakharova, A., Tarbeeva, N.

*Urals Federal University*

Introduction To design the training program for experienced athlete or to improve it we need to evaluate athlete. As a rule it takes a whole training session or more to obtain the complex athlete test information. Earlier we investigated the diagnostic possibilities of high-intensity interval training (HIIT) for the assessment of skiers special readiness [Shishkina et al., 2014] and were satisfied with the experimental results. The aim of new experiment was to adapt HIITesting to other kinds of sport (football, volleyball, ice hockey, etc) and to fulfill the test in field (not in laboratory) conditions. Methods Athletes performed HIITraining (Tabata Protocol) of 8 sets of 20-second interval with an "all-out" effort separated by 10 seconds of passive recovery [Tabata et al., 1996]. Heart rate (HR) monitoring with GPS (Forunner 310XT) was used to measure the distance length covered in each intensive bout in case of outdoor activity. Blood lactate and HR recovery were measured after test. For selection of HIITest activity for experienced athletes we take into account the essential competitive activity, so football players and middle distance runners did run whereas hockey players used shuttle skating. Results For analyzing the athlete conditioning we use following indicators: the best result among 8 intervals, the lowest one, the amount of 8 results as well as the speed of results decreasing in the early beginning and in the middle of the test. For example, the following distance results were obtained in hockey: 146-130-111-120-121-116-109-107. Discussion The comparison and ranking of the first distance results of all athletes of one kind of sport reveal the winner in speed and/or power while champion in 8 distances amount shows the desirable level of specific endurance. The bar chart of HIITest results assists to determine the athletes' weaknesses and motivate athlete to work harder for speed endurance in case of dramatically decrease in the first three results or to improve aerobic workability in case of uneven last three results. HR monitoring allows to determine the cardio related reasons of low athletes' results in HIITest and evaluate the cardiac "cost" of intensive physical load. Lactate measuring also help us with assessing how well-conditioned athlete is at a specific point in time or how intensive was his work during test. Thus, HIITest can be used as a specific strength and conditioning test for experienced athletes in order to lead them to an optimal performance. Test may be informative in many kinds of sport. ## MONITORING FATIGUE AND RECOVERY DURING HEAVY STRENGTH TRAINING

Raeder, C., Wiewelhove, T., Simola, R.A.P., Meyer, T., Ferrauti, A.

*Ruhr-University Bochum*

Introduction Lengthy periods of intensified strength training accompanied by insufficient recovery may lead to an increase of the incidence of overtraining symptoms (i.e., prolonged decline in sport-specific performance). To avoid mistakes in program design and to prevent maladaptation and underperformance, it is of great practical necessity to identify sensitive and non-extra fatigue inducing markers indicative for fatigue and recovery at an early stage. Therefore, this study aimed to investigate the sensitivity of jump tests and tensiomyography (TMG) markers of muscle contractility for monitoring fatigue and recovery. Methods Twenty-three male and female strength-power athletes ( $24.7 \pm 2.0$  yrs) completed an intensive strength training micro-cycle (STM) reflected by significant changes in discipline-

specific performance (i.e., maximal dynamic strength (1RM)). The STM comprised two straining sessions per day, morning and afternoon, and consisted of high-resistance (i.e., 85% RM) combined with maximal eccentric (i.e., 100% RM) strength exercises, both for upper and lower limbs. 1RM, countermovement jump height (CMJ), multiple rebound jump height (MRJ), reactive strength index (RSI), as well as electrostimulated (via TMG) maximal radial displacement of the muscle belly (Dm) and muscle contraction velocity (V90) were measured before (Pre), after six days of training (Post 1=fatigue) and after four days of recovery (Post 2=recovery). Magnitude-based inferences were used to determine practical significance. Results Changes in 1 RM were possibly (71.2%) decreased between Pre and Post 1 (~8%), and displayed a likely trivial (89.2%) increase between Post 1 and Post 2 (~5%). Changes in CMJ, MRJ, RSI, Dm, and V90 very likely (>95%) decreased between Pre and Post 1 (~7 to 16%), whereas only changes in CMJ and MRJ demonstrated a very likely (96.1%) or likely (80%) increase between Post 1 and Post 2 (~6%). Discussion The changes in 1RM after STM indicate a state of fatigue at Post 1 and a not fully recovered state at Post 2. The analyzed markers CMJ, MRJ, RSI, Dm, and V90 were capable to sensitively capture this fatigue at Post 1, whereby only CMJ and MRJ were eligible to sensitively monitor recovery at Post 2. In conclusion, the aforementioned markers are highly recommended to use in the field of strength training in order to improve strength training prescription, as all of these constitute to be practical and appropriate for the regular assessment of athletes' performance capacities. References Meeusen et al. (2013). *Med Sci Sports Exerc*, 45 (1), 186-205. Urhausen, A. & Kindermann, W. (2002). *Sports Med*, 32 (2), 95-102.

### PACING ACCURACY DURING AN INCREMENTAL STEP TEST IN ADOLESCENT SWIMMERS

Scruton, A., Baker, J., Roberts, J., Basevitch, I., Gordon, D.

*Anglia Ruskin University*

Introduction: Pacing strategies are attributed to optimising a balance between artefacts of fatigue and regulation of metabolism and are a function of biologically and cognitively orchestrated afferent signals. The homeostatically orientated responses are manifest to prevent a depletion of the finite anaerobic capacity. Children have an inability to modulate pace which is associated with the stage of cognitive development and lack of a perceptual template. During incremental swimming step tests the swimmer is required to exercise at pre-determined speeds thus an uncontrolled pacing strategy, would yield unreliable blood lactate (BLa) scores. Therefore the purpose of this study was to assess pacing accuracy in a group of adolescent swimmers during an incremental step test in a pool. Method: Fifteen well-trained swimmers (age  $15 \pm 1.5$ yr; height  $170.2 \pm 8.8$ cm; mass  $60.2 \pm 6.6$ kg), naïve to step testing completed two 7 x 200m tests (TR-1) and (TR-2), separated by ~72-h. They were instructed to swim to a pre-determined incrementally increasing pace based on their personal-best (PB) for 200 m per step. 5 s was added to the PB to take into account a push start, with this time equating to stage 7. All preceding stages were 5 s slower than the previous. For all swims the participants were instructed to swim an even pace, thus as swim pace increased recovery duration increased. Upon completion of each step RPE, heart rate (HR) and BLa were recorded. Results: Significant differences were observed for TR-1 between actual and prescribed swim time for step-1 ( $P=0.003$ ), step-2 ( $P=0.001$ ), step-3 ( $P=0.007$ ) and step-7 ( $P=0.002$ ) and TR-2 for step-1 ( $P=0.001$ ), step-2 ( $P=0.006$ ), step-3 ( $P=0.007$ ), step-4 ( $P=0.007$ ), step-5 ( $P=0.023$ ) and step-7 ( $P=0.02$ ). In all cases the participants swam too fast against pace in the early steps and to slow in the latter steps. Additionally significant differences were observed between the 1st and 2nd 100-m of each step in TR-1 for step 1 ( $P=0.001$ ), step 2 ( $P=0.0001$ ), step 4 ( $P=0.0001$ ), step 5 ( $P=0.005$ ), step 6 ( $P=0.0001$ ) and step 7 ( $P=0.0001$ ). Similar responses were witnessed for TR-2 ( $p<0.05$ ). Only significant difference observed between TR-1 and TR-2 for actual swim time for step 4 ( $P=0.001$ ) and step 5 ( $P=0.03$ ). Discussion: These findings suggest that the participants engaged the finite anaerobic capacity sooner than would anticipated, as a function of an inability to regulate pace. This is proposed to be a consequence of the volume of exposure to the biological and psychological sensations and cognitive developmental status. Caution should therefore be applied when using such tests with adolescent athletes and alternate means of modulating pace be investigated.

### PACING STRATEGY, MOOD AND HORMONAL RESPONSE IN YOUTH ATHLETES DURING OFFICIAL TRIATHLON AND DUATHLON COMPETITIONS

Piacentini, M.F.1, Comotto, S.1, Cibelli, G.2, Di Castro, A.3

*1University of Rome-Foro Italico, 2 University of Foggia, 3 Italian triathlon federation*

Introduction: Given the recent introduction of the Youth Olympic games which include the sprint triathlon distance, the aim of this study was to analyze pacing, perception of effort (RPE) mood and changes in salivary cortisol (sC), and amylase (sAA) during duathlon (DUA) and triathlon (TRI) youth official competitions. Methods: Nine Youth athletes (age  $15 \pm 1$  yrs) participated in both DUA (1.8km run, 8km bike and 1km run) and TRI (300m swim, 8km bike and 2km run) national championships. A wearable GPS was used to analyse pacing. Mood, sC and sAA were measured before and after competition, and RPE, pre, post and after each segment of the race. A 2 way ANOVA was utilized to verify differences between races and on the parameter time course ( $p<0.05$ ) Results: TRI lasted  $27:17 \pm 02:17$  min:s and DUA  $27:41 \pm 01:49$  min:s. TRI showed higher RPE values 30 minutes after the race ( $4.9 \pm 1.7$ ) compared to DUA ( $2.6 \pm 1.1$ ). RPE increased during the race in TRI but not in DUA. Athletes adopted a negative pacing strategy in TRI and DUA cycling phase with a 19% and 5% velocity increase respectively. The cycling phase during TRI ( $32\text{km}\cdot\text{h}^{-1}$ ) was significantly faster than during DUA ( $31\text{km}\cdot\text{h}^{-1}$ ). No differences were observed in the POMS subscales except for tension that was significantly higher before the race in both events. sC increased significantly after DUA (157%) and TRI (145%) and remained elevated for 30 minutes. sAA increased significantly after DUA (278%) and TRI (392%) and decreased to baseline values 30 minutes post race in DUA but not in TRI. sC and sAA did not differ between events. Conclusion: The present findings indicate significant psycho-biological stress responses to DUA or TRI but no difference between competitions. sC and sAA have been used as objective markers of the hypothalamic pituitary adrenocortical axis and the sympathetic adrenomedullary system, respectively and sAA has been proven to be a sensitive marker of psychological and physical stress also during official competitions (1). As already seen in elite, youth athletes adopt a positive pacing strategy with a fast start to have an advantage during the subsequent biking phase. As previously seen during sprint triathlons (2), RPE is not reset after each transition and seems to remain a key pace regulator. TRI bike lag was faster than the DUA despite similar RPE values in the previous transition zone. Give the high performance levels obtained during the Youth Olympics, more research is necessary in this category of athletes. ## INDICATORS OF PHYSICAL LOAD AND STRAIN DURING SIMULATED TIME TRIALS IN TRAINED CYCLISTS – EFFECTS OF FATIGUE STATUS AND SUBJECT IDENTITY

Schwindling, S., Meyer, T., Skorski, S., Hecksteden, A.  
Saarland University

**Introduction** The strain induced by exercise training is a multifaceted phenomenon comprising e.g. cardiopulmonary, metabolic and perceptual components. Current concepts for the quantification of exercise intensity are usually based on 1 reference parameter (e.g. heart rate) and assume its close association with other aspects of strain. However, large variability in the relationship of intensity markers has been reported between subjects (2) but also within the same individual in response to changes in fatigue status (1). This study aims to analyse the variability in indicators of performance and strain as well as in their relationships by repeated simulated time trials (TT) during standardized phases of rest and fatigue. **Methods** 28 well-trained cyclists (age:  $29 \pm 7$  years;  $P_{max}$ :  $323 \pm 44$  W) completed 3 TT scheduled after a 3 day resting phase (day 1), following the subsequent 6-day simulated training camp (day 8) and after a 2-day recovery phase (day 11). TT performance in W (P) was used as parameter of physical load. Blood lactate concentration (BLa), heart rate (HR) and rate of perceived exertion (RPE) indicate physical and perceived strain. Relative values (% max) were used for P and HR. The effect of fatigue status and subject identity was assessed by linear mixed modelling. Results The main effect of fatigue was highly significant ( $p < 0,001$ ) for P, HR, BLa as well as for the ratios BLa/P and RPE/P but non-significant for RPE and the the HR/P ratio. The proportion of between subject variability attributable to subject ID was 78 % for BLa, 29 % for P, 44 % for HR, 55% for RPE, 21% for HR/P, 49% for BLa/P and 51% for RPE/P. For fatigue induced changes interindividual variability accounted for 65% of total variability for BLa, 57 % for P, 41 % for HR, 56 % for RPE, 22% for HR/P, 59% for BLa/P and 53% for RPE/P. **Discussion** Fatigue impacts considerably on the magnitude and characteristic of physical strain during simulated time trials. The contribution of interindividual differences to total variation varies widely but is above 50 % in the majority of cases. Taken together these results point to a relevant degree of variability in the characteristics of physical strain between as well as within subjects. Potential practical applications of this insight range from the assessment of fatigue to the prescription and control of accurately targeted training loads. **References** 1. Lamberts RP, et al. ## EFFECTS OF ISCHEMIC PRECONDITIONING ON PERFORMANCE MAY BE PARTLY A PLACEBO EFFECT?

Marocolo, M., Pelegrini, V., da Mota, G.R., Appel-Coriolano, H.J.  
Federal University of Triangulo Mineiro

The acute effect of ischemic preconditioning (IPC) on the maximal performance in 100-m free style swimming was studied in recreational swimmers. Fifteen swimmers ( $21.0 \pm 3.2$  yrs) participated in a random crossover model on three different days (control [CON], IPC or SHAM), separated by three to five days. IPC consisted of four cycles of 5 min occlusion (220 mmHg)/5 min reperfusion in each arm and SHAM protocol was similar to IPC, but with only 20 mmHg during the occlusion phase. After IPC, CON or SHAM the volunteers performed a maximal 100-m time-trial. IPC improved performance ( $P < 0.05$ ) in relation to the CON performance. Twelve out of 15 participants (80% of sample) improved their performance after IPC compared with CON. However, also 10 of 15 (67%) volunteers reduced 100 m time after the SHAM maneuver compared to CON, but for the whole group this improvement (0.7 sec) only showed a tendency ( $P=0.059$ ). We conclude that IPC improves maximal performance in recreational swimmers, but its increasing in performance could be partially from a placebo effect. Its effect should be test in future studies aiming to verify the real IPC effects on performance.

## THE RELATIONSHIP BETWEEN SEX ROLES AND NARCISSISM AND SELF-ESTEEM IN SPORT MANAGERS

Zargar, T.  
Department of sport management, faculty of physical education and sport sciences, south Tehran branch, Islamic Azad university, Tehran, iran

**Introduction:** Narcissistic behaviors are pervasive in contemporary world. Hence, dominant social conditions lead to manifestation of narcissistic attributes-which is present in different people to different degrees. Many other social critics consider that masculine attributes, egocentricity, exploitativeness, megalomania, and destructiveness are interrelated (Lasch, 1984). Numerous studies have reported that the biological sex is not the only and even the most important factor in sex adjustment. The most important reason to choose that the subjects of this study from Iranian female sport manager was to study of sex roles and how these roles are realized and actualized in females who are prone to collectivist traditional values from one side and individualist modern values on the other side because of living in a developing country . **Methodology:** 147 managers participated voluntarily in this research. Personal Attribute Questionnaire was utilized to classify the subjects into women, men, women-men, and indifferent groups. To measure narcissism we used Narcissistic Personality Inventory. Self-esteem scales of Rosenberg (1965) and empathy scales of Davis (1983) were used in order to measure the adjusted function. In order to study the relation of sex roles with adjustment and narcissism, a comparison of means was made through multiple variance analysis. **Findings:** masculinity was directly related to the score of narcissistic and self-esteem scale. It had a reverse relationship with empathic concerns and personal distress. Feminist was directly related to general score of narcissistic and subscales. There was a direct relationship between feminist and empathic concerns and distress. Tukey test showed that the mean difference in self-esteem was associated with the difference of feminine-masculine and feminine means ( $F=0.42$ ,  $p < 0.01$ ). **Discussion:** exploitativeness and entitlement were not related to self-esteem, however, their unadjusted functions which were tangible in other studies, did not show in this research. The control of the effect of authority, self-sufficiency, and superiority could not show the expected reverse relationship of exploitativeness and entitlement from one side and indicators of mental health, namely self-esteem and empathy on the other side. Feminine-masculine attributes are related to adjusted-authoritative subscale and irrelevant to exploitativeness and it is healthier than masculine and feminine roles. This role has exhibited the healthiest function among the sex roles because it showed a positive correlation both with self-esteem and perspective taking but its relationship with entitlement is the reason why we cannot consider it a quite

healthy role. References: Lasch, Christopher.(1979). *The Culture of Narcissism: American Life in an Age of Diminishing Expectations*. New York, NY, USA: W. W. Norton. Rosenberg, Morris. (1965). *Society and the Adolescent Self-Image*. Princeton, NJ, USA: Princeton University Press.

### **CAREER TRANSITIONS AND OCCUPATIONAL WELL-BEING IN LEADERSHIP: THE CASE OF WOMEN AS SPORTS COACHES**

Didymus, F.F., Norman, L., Widdop, P.

*Leeds Beckett University*

The United Kingdom (U.K.) is working to develop the world's leading sports coaching system by 2016. However, currently women only make up 28% of the profession and very few women reach senior levels. Little is known about why career pathways are gendered or how women coaches' occupational experiences affect their health and well-being. Therefore, the aim of this study was to further understanding of the occupational health and well-being of female sports coaches and to investigate the facilitators of and barriers to their careers and life transitions. Following ethical approval from a University research ethics co-ordinator, women coaches (n = 162) based in the U.K. were recruited on a voluntary basis. Each coach completed an online version of the Shortened Stress Evaluation Tool (ASSET; Cartwright & Cooper, 2002). This questionnaire has been shown to be a valid and reliable measure of job characteristics, health, psychological well-being, and organisational commitment. Descriptive statistics were computed using a Statistical Package for the Social Sciences to provide a broad overview of the data. These statistics demonstrated that 97% of the sample categorised themselves as 'White', 'White Irish', or 'White Other,' that the number of respondents over the age of 55 (n = 6) was dramatically lower than the number of responses from younger coaches (n = 156); and that 67% of the sample was educated to undergraduate degree level or higher. Over half of the sample (53%) was employed as a head coach at the time of completion and 56% of these head coaches were employed on a part-time basis. When compared to the normative data for ASSET, our sample reported above average psychological well-being (M = 27.75, SD = 4.87), sense of purpose (M = 18.72, SD = 4.01), and engagement (M = 19.18, SD = 3.78), and reported less strain on their psychological health (M = 21.06, SD = 6.91). However, the results also demonstrate that the coaches experience poorer work-life balance (M = 13.33, SD = 5.35), job security (M = 14.20, SD = 5.39), and work relationships (M = 18.02, SD = 7.88) than the normative sample. The findings suggest that, on average, our sample of women coaches are highly engaged with their role, feel a sense of purpose during their coaching practice, and are psychologically well. The results do, however, suggest that women coaches require better work-life balance, more job security, and more meaningful relationships with their colleagues. These findings provide insight to potential facilitators of and barriers to career progression for women coaches and offer interesting applied implications for national governing bodies (NGBs). In particular, NGBs should pay acute attention to interventions that support women coaches to connect with other coaches and effectively balance their personal and occupational commitments. Cartwright, S., & Cooper, C. L. (2002). *ASSET: Management guide*. RobertsonCooper Ltd, UK.

### **DO DRIVE FOR MUSCULARITY, BODY ESTEEM, SELF-EFFICACY AND PHYSICAL ACTIVITY LEVEL DIFFER BETWEEN SELECTED AND NON-SELECTED MALE AND FEMALE CANDIDATES TO OFFICER CANDIDATE SCHOOLS?**

Stornæs, A.V.1,2, Sookermany, A.M.2, Sundgot-Borgen, J.1

*Norwegian School of Sport Sciences*

Introduction: The traditional image and requirements of an ideal soldier and officer is associated with values such as physical fitness, hardiness, aggressiveness and courage. These values are considered masculine and traditionally not associated with women and femininity. Today young men and women experience extreme focus on bodily appearance and well-defined muscle tone and not necessarily physical fitness. Therefore, the aims of this paper were to examine drive for muscularity, body esteem ("physical condition"), self-efficacy and self-reported physical activity level among candidates to Officer Candidate Schools (OCS) in Norway and whether these variables differ between selected and non-selected male and female candidates. Method: Totally 1105 eligible candidates (who met at OCS-Joint Selection period in 2010) were invited to participate in this study during the three first days of the selection period. A total of 438 candidates did not participate due to early drop out, not reached, refused to participate or excluded due to duplicate/invalid ID number. Seventy percent (920 males and 131 females aged 18-30 years (median: 19 years) representing all 19 counties in Norway) were included in the study. Measurement includes both the standardized scales Drive for Muscularity Scale (DMS) and Body Esteem sub scale "Physical Condition" (BES-PC) and questions concerning self-efficacy (SE), age, height, body weight and physical activity. Results: Selected male and female candidates had significantly higher scores on the sub-scale BES-PC, the variable physical stamina, and on self-efficacy. Selected males but not females also reported significantly higher physical activity level. Selected and non-selected candidates did not differ in DMS sum scores. A significant difference was found in DMS scores between male and female candidates. Discussion and conclusion: The significant differences in "physical condition", physical stamina and self-efficacy between selected and non-selected male and female candidates are not surprising since these factors can be related to the selection criteria for both male and female candidates at OCS. However, it is of interest to further investigate whether these questionnaires alone can predict selected and not selected male and female candidates.

### **ASSOCIATIONS OF PHYSICAL ACTIVITY, CARDIORESPIRATORY FITNESS AND MOTOR SKILL TO EXECUTIVE FUNCTION: THE ACTIVE SMARTER KIDS STUDY**

Aadland, K., Moe, V.F., Aadland, E., Resaland, G.K., Anderssen, S.A., Ommundsen, Y.

*Sogn og Fjordane University College*

Aim: Executive functions play an important role in learning and may impact academic performance in children. Few studies have investigated the independent associations for motor skills, cardiorespiratory fitness and physical activity with executive functions in this age group [1]. The aim of this study was to examine the independent associations for motor skills, cardiorespiratory fitness and physical activity with executive functions in 10-year-old children. Methods: We included 876 children (mean (SD) age 10.2 (0.29) years, body mass index 18.1 (2.9), 49% girls) from 58 schools in Sogn and Fjordane county, Norway. Independent variables were physical activity (counts per minute measured by accelerometry), cardiorespiratory fitness (measured by the Andersen test) and a sum-score of motor skills (measured by Aiming & Catching 1 and 2 from the Movement ABC test battery (ageband 3) and the shuttle-run test and standing broad jump from the Eurofit test battery), as well as sex, age, puberty stage and body mass index. Dependent variables were several measures of executive functions (Stroop, Verbal fluency, WISC-IV (digit span) and Trail making). A linear mixed model was used to analyze the data.

Results: Motor skill was significantly associated with all measures of executive function ( $p \leq 0.008$ ). Cardiorespiratory fitness was significantly associated with Stroop, WISC-IV (digit span) and Trail making B ( $p = 0.001-0.043$ ), whereas other associations were non-significant ( $p \geq 0.852$ ). Physical activity was not associated with any measure of executive function ( $p \geq 0.060$ ). Conclusions: The present study showed that motor skill was associated with all measures of executive function in the 10-year-old children, whereas cardiorespiratory fitness were only partly-, and physical activity were not associated with executive functions. The findings supports previous studies [1] that have argued that training of motor skills are at least as important as general physical activity and increased cardiorespiratory fitness to improve cognitive function in children. Reference 1. Haapala, E.A., Cardiorespiratory Fitness and Motor Skills in Relation to Cognition and Academic Performance in Children - A Review. *Journal of Human Kinetics*, 2013. 36: p. 55-68.

### **EFFECT OF PHYSICALLY ACTIVE ACADEMIC LESSONS ON CHILDREN'S ACADEMIC ACHIEVEMENT: A RANDOMIZED CONTROLLED TRIAL**

Hartman, E., Mullender-Wijnsma, M.J., De Greeff, J.W., Visscher, C.

*Center for Human Movement Sciences*

**Introduction** Using physical activity in the teaching of academic lesson content is a promising way of learning. Moderate to vigorous physical activity has an immediate effect as a result of elevated levels of growth factors and monoamines which were related to retention of learned material (Winter et al., 2007). Physically active academic lessons contributed positively to academic engagement (Mullender-Wijnsma et al., submitted). In the long term, regular moderate-vigorous physical activity could lead to morphological changes in the brain underlying cognitive performance (Best, 2010). The aim was to investigate the effects of a physically active academic intervention on academic achievement of primary school children. The second aim was to examine whether or not the intervention affected socially disadvantaged children (SDC) and children without this disadvantage differently. **Methods** The study is part of the randomized-controlled trial 'Fit and Academically Skilled at School' (F&S). In F&S an in-class physical activity program is implemented (Mullender-Wijnsma et al., in press). Participants were 502 children (mean age 8.0, 112 SDC) from second and third grade classes of 12 primary schools. The intervention group participated in the program for 22 weeks, three times/week for 20-30 minutes. The control group attended regular classroom lessons. In a pilot, heart rate measurements and teacher reports demonstrated that F&S was successfully implemented. Pre- and post-tests included ability scores on spelling and mathematics that were retrieved from a child academic monitoring system (CAMS). In addition, a mathematics speed test and a one-minute reading test were conducted. **Results** Multilevel analysis showed that children in the intervention group had significantly greater changes in CAMS mathematics scores (Beta=5.53,  $p < .01$ ,  $d = .55$ ) and mathematics speed test scores (Beta=3.37,  $p < .01$ ,  $d = .31$ ). No significant main effects were found on spelling and reading. A significant interaction effect was found on reading, favoring SDC (Beta=5.65,  $p < .05$ ). **Discussion** Physically active academic lessons significantly improved the mathematics achievement of primary school children. In addition, socially disadvantaged children benefited more from the intervention with regard to reading. **References** Best JR. (2010). *Dev Rev*, 30(4), 331-351. ### **PERCEIVED TEACHING CONTROL AND PSYCHOLOGICAL NEED FRUSTRATION AS PREDICTORS OF STUDENT MOTIVATION AND MOTIVATION-RELATED OUTCOMES ACROSS A SCHOOL YEAR**

Ntoumanis, N., Bartholomew, K., Mouratidis, A., Katartzi, E., Thogersen-Ntoumani, C., Vlachopoulos, S.

*Curtin University*

**Introduction** Previous work drawing from self-determination theory (Deci & Ryan, 2000) has primarily focused on adaptive motivational teaching environments and how these support student motivation. Comparatively much less is known about the "dark motivation side" of controlling teaching environments and how these thwart student motivation. **Methods** We conducted two longitudinal studies, across a whole school year in Greek secondary education, to explore the interplay between PE students' (Mage = 14.55) perceptions of the controlling teaching environment, their experiences of psychological need frustration, and a number of motivation-related outcomes. All variables were assessed with well-validated questionnaires. **Results** Multilevel growth modeling indicated that changes in perceived teacher control related positively to changes in need frustration across the school year (studies 1 & 2) which, in turn, negatively predicted autonomous motivation and positively predicted controlled motivation and amotivation (Study 1; N = 419), and was positively related to fear of failure, contingent self-worth, and challenge avoidance in (Study 2; N = 447). Females tended to report lower levels of perceived psychological control and need frustration across both studies. In addition, students who participated in organized sport activities after school reported more autonomous motivation and contingent self-worth and less amotivation and challenge avoidance. **Discussion** These findings reinforce previous calls (e.g., Bartholomew, Ntoumanis, Ryan, Bosch, Thogersen-Ntoumani, 2011) for more research on the 'dark' motivational pathways linking maladaptive teaching environments with poor quality student motivation and related outcomes. **Practical implications** for teacher motivational environments in school physical education will be discussed. **References** Deci EL, Ryan RM (2000). *Psychological Inquiry*, 11, 227-268. ### **EFFECTS OF ACUTE YOGA PRACTICE ON CARDIAC AUTONOMIC CONTROL AND STRESS RESPONSE**

Lin, Y.J., Chu, I.H.

*KAOHSIUNG MEDICAL UNIVERSITY*

**Introduction** Psychological stress has been shown to be associated with cardiovascular disease development (Chida & Steptoe, 2010). Previous research indicated that individuals with exaggerated cardiovascular response to stress had increased risk for hypertension (Matthews et al., 2006). Most studies have investigated the effects of aerobic exercise on cardiovascular reactivity, the effects of other types of exercise, such as yoga, are undetermined. The aim of this study was to examine the effects of acute yoga practice on heart rate (HR) and cardiac autonomic control during mental stress. **Methods** 32 participants (mean age 24.75±4.10) were included in this study and completed three sessions (yoga, stationary biking SB, and video watching VW) in randomly assigned order. After each condition, participants underwent a Stroop task and mental arithmetic task, which serve as stressors. Electrocardiogram (ECG) was measured and heart rate variability (HRV) was analyzed to examine the effects of acute yoga practice on HR and HRV during mental stress. **Results** HR during SB condition was significantly higher than yoga ( $p < 0.001$ ) and VW ( $p < 0.001$ ). HR during yoga condition was also significantly higher than

VW ( $p < 0.01$ ). HR during mental stress was significantly higher after SB condition than after yoga ( $p = 0.001$ ) and VW ( $p < 0.001$ ) conditions. There was no significant difference in HR during mental stress after yoga and VW conditions. For HRV, high-frequency (HF) during SB was significantly lower than yoga ( $p < 0.001$ ) and VW ( $p < 0.001$ ). HF during mental stress was significantly lower after SB than after VW ( $p = 0.049$ ). Low-frequency (LF) during SB was significantly higher than VW ( $p = 0.027$ ). There was no significant difference in LF during mental stress after the three conditions. LF/HF during SB was significantly higher than yoga ( $p = 0.002$ ) and VW ( $p < 0.001$ ). There was no significant difference in LF/HF during mental stress after the three conditions. Discussion The results showed that HRV during mental stress was not significantly different between the three conditions, suggesting that acute yoga practice was not effective in reducing cardiovascular reactivity to mental stress. Since participants recruited for this study were healthy adults who did not have exaggerated HRV responses to stress, it may be difficult to see any significant change in HRV response after one bout of yoga in this population. Future studies may consider investigating individuals demonstrating exaggerated cardiovascular reactivity to further examine the effect of acute yoga practice on HR and HRV responses to mental stress. #### FOAM ROLLING OF THE ANKLE DORSIFLEXORS AND PLANTARFLEXORS DOES NOT AFFECT VERTICAL JUMP PERFORMANCE IN YOUNG HEALTHY ADULTS

Sempf, F., Brahms, C.M., Thienes, G., Fischer, T., Johannsmeyer, S.

*Georg-August-University Goettingen, University of Regina*

**Introduction** In recent years, self-myofascial release (SMR) techniques, such as foam rolling, have become a stable component of many warm-up routines [2]. Although several studies found that SMR techniques can improve range of motion [4,5], its effects on explosive force production and jumping performance are not well understood and existing research yields inconclusive results [1,3,4]. Furthermore, it is not known if different SMR protocols affect performance to the same degree. Therefore, the purpose of this study was to examine the effects of two distinctive foam rolling protocols on vertical jump performance. **Methods** 45 subjects (28 male/17 female) were randomly assigned to one of three groups. Participants in group 1 were asked to perform SMR using a foam roller of the gastroc-soleus complex (T1) while group 2 applied SMR to the tibialis anterior (T2). Group 3 served as control group (C). All groups performed a 5-minute warm-up on an elliptical trainer and were subsequently tested for their maximal CMJ height. Jump height was recorded using a GymAware Powertool that was connected via a waist belt to the participants. Retesting occurred after a 5-minute period, during which T1 and T2 applied SMR for 120 sec to the respective muscle group on each leg, while C rested. **Results** Jump height did not change significantly in any of the groups. Mean jump height of T1 increased by 0.39 cm ( $p = 0.512$ ), mean jump height of T2 decreased by 0.09 cm ( $p = 0.834$ ) and mean jump height for (C) increased by 0.51 cm ( $p = 0.104$ ). A one-way repeated measures ANOVA revealed no significant differences between groups,  $F = 0.506$  ( $p = 0.607$ ). **Discussion** The results show that foam rolling of the ankle dorsi-/ or plantarflexors has no effect on vertical jump performance in young, healthy adults. This observation is in agreement with other studies [3,4,5]. Although it has been suggested that foam rolling may have negative effects on performance [1] and should be avoided immediately before exercise, our findings do not confirm this. Our results suggest that foam rolling the lower leg muscles for up to 120 seconds does not impair explosive effort and can be used safely as part of a pre-exercise warm-up routine. **References** [1] Fama BJ, Buetti DR, (2011). #### STRENGTH AND BALANCE DEVELOPMENT IN FEMALE SOCCER PLAYERS

Roth, R., Donath, L., Zahner, L., Faude, O.

*University of Basel*

**Introduction** Isokinetic testing of leg and trunk strength serves as an important means to identify muscle imbalances between both sides. Muscle imbalances are considered relevant for injury prevention and sports performance. Data on this issue in female soccer players are scarce. This study aimed at analyzing how physical strength and balance performance develop from adolescence to adulthood in female soccer players. **Methods** Forty-five female soccer players of one high-level club (under-16:  $N = 19$ ; age = 15.0 (SD 0.7) years; body mass = 54.6 (5.8) kg; body fat = 20.3 (6.8)%; under-18:  $N = 15$ ; age = 16.8 (0.6) y; body mass = 59.9 (8.0) kg; body fat = 18.4 (8.8)%; adult team (A):  $N = 11$ ; age = 21.2 (2.4) y; body mass = 61.1 (6.1) kg; body fat = 16.0 (7.8)% agreed to take part in this cross sectional study. Strength of hamstrings (H) and quadriceps (Q) muscles were measured on an isokinetic device (IsoMed 2000) at a speed of 60°/sec, 240°/sec (concentric) and -30°/sec (eccentric). H:Q-ratio was calculated for both right and left side at 60°, 240° and -30°/240°. For trunk flexion, extension and rotation, strength was measured at 60°/sec and isometric. Strength ratios between flexion/extension and left/right rotation were calculated for each group, respectively. Dynamic balance performance, assessed with the y-balance composite score, was also analyzed with respect to preferred and non-preferred kicking leg. **Results** Physical development in female soccer players from the under-16 to the adult team is mainly displayed by an increase in weight (u16: 54.6 (5.8); u18: 59.9 (8.0); A: 61.1 (6.1)), while percent body fat decreased (u16: 20.3 (6.8); u18: 18.4 (8.8), A: 16.0 (7.8)). At all speeds leg strength in the preferred kicking leg is higher in all age-categories for extension (i.e. 60°, u16: +4%; u18: +7%; A: +13%) as well as flexion (60°, u16: +10%; u18: +9%; A: +18). Strength ratio for leg flexion/extension (Croisier et al., 2003) showed also a higher ratio in the preferred kicking leg. Trunk strength values also rose with age, and ratios between isometric trunk flexion and extension developed continuously (u16: 1.59; u18: 1.68; A: 1.86). Regarding balance performance, the composite score showed no differences between groups and legs ( $p = .75$ ). **Discussion** Our results show that an unequal development in physical strength over age categories can occur in high-level female soccer players. H:Q ratios as well as the composite score showed different development in preferred and non-preferred kicking leg. If this leads to potentially harmful imbalances is questionable, but to prevent injuries and detect aberration players should attend regularly assessments. **References** Croisier, J.-L., et al. (2003). *IES* 11(1): 61-62.

### COMPARISON OF VARYING INTENSITIES ON MUSCLE ACTIVATIONS DURING BENCH PRESS IN TRAINED AND UN-TRAINED MEN

Jeon, H.S., Seo, S.W., Song, S.H., Lee, H.S.

*Dankook university*

**Introduction** Strength development and muscle hypertrophy is dependent on the type and intensity of loading as well as volume of the strength training of each individual strength athlete at a given time (Juha et al., 2003). Trained subjects have been shown to perform the same or greater number of repetitions at a given exercise intensity than untrained subjects and that this relationship is likely affected by the habitual training habits of subjects (Hoeger et al., 1990). To our knowledge, there is no study that have examined activation and fatigue of muscle, and number of repetitions that trained and untrained men could perform at 60, 80, and 90% of 1RM during bench press. Therefore, this study tested the hypothesis that activation and fatigue of muscle, and number of repetitions would significant different in trained and untrained men. **Methods** Sixteen men, 8 trained (TG) and 8 untrained (UTG), volunteered to take part in the study. TG had been undertaking a continual, resistance weight training program at least twice a week for more than 6 months using bench press exercises. UGT previously had not been involved in a formal resistance weight training program during the last year. All subjects were tested for 1RM strength, and then subjects performed maximal number of repetitions at 3 different intensities (60, 80, and 90% of 1RM) during bench press. EMG signal were recorded from the pectoralis major, deltoid anterior, and triceps brachii for maximal voluntary contraction (%MVC) and median frequency (MDF). **Results** Significant increases in %MVC for pectoralis were observed at 80% and 90% for TG compared with UTG, but significant decreases in MDF were observed at 60% and 80% for UTG compared with TG. Significant increases in %MVC for deltoid anterior and triceps brachii were observed at 80% and 90% for UTG compared with TG, but significant decreases in MDF were observed at 60% and 80% for UTG compared with TG. The changes in maximal number of repetitions were not significantly different between groups. **Discussion** Our study showed that deltoid anterior and triceps brachii in untrained and pectoralis in trained men during bench press were mainly used. However, fatigues at the selected muscles were markedly higher in untrained. Therefore, it is thought that needed to scrupulously observe the movement of protagonist, when training untrained men. **References** Ahtainen JP, Pakarinen A, Alen M, Kraemer WJ, Häkkinen K. ### THE EFFECTS OF 8-WEEKS BALANCE TRAINING ON BALANCE, AGILITY AND JUMPING SKILLS OF COLLEGIATE ACTIVE FEMALE

Sahin, F.N., Soykan, A.N., Ertetik, G., Ersoz, G.

*Ankara University, Faculty of Sport Sciences*

**Aim:** Numerous studies established relationship between balance and athletic injury but balance and athletic performance relation is less clear (Hrysomallis,2011,Tamara 2009). The purpose of this study was to investigate the effects of 8 weeks Biodex balance system training program on some selected physical and performance parameters in active healthy females. **Methods:** 44 women who study at Ankara University (mean± SD : age 20,36±1,72 yrs; height 166,13±6,31 cm; weight 56,50±10,00 kg; bmi 20,41±3,03 %; PBF 23,49±4,74 %) volunteered to participate in this study. These groups consist of physically active female and don't have ankle or knee injury. These subjects were randomly assigned to either an experimental (Exp. n=22) or a control (C. n=22) group. At the beginning of the study homogeneity of the group were determined by Mann Whitney-U . Postural stability, limits of stability, athlete single leg balance, fall risk , agility and squat jump performance were determined at the beginning of the study. The experimental group trained on the biodex balance system training program three times a week, for 8 weeks and the control groups did not practice any balance exercise during this period. **Results:** At the end of 8 weeks training with Biodex Sd system make significant changes at all balance parameters and agility performance of experimental group ( p<0.05). There is no significant difference between squat and vertical jump pre -test and post test results. **Discussion:** Balance training improved performance of selected sport-related activities and postural control measures, although it is unclear whether the effect of training would transfer to general functional enhancement. **Conclusion:** Balance training improved performance of selected sport-related activities and postural control measures, although it is unclear whether the effect of training would transfer to general functional enhancement. ### ACCELERATION, AGILITY AND CHANGE OF DIRECTION SPEED OF SUB-ELITE U-15 SOCCER PLAYERS: VARIATION BY PLAYING POSITION

Trecroci, A., Frontini, M., Millefanti, A., Alberti, G.

*University of Milan*

**Introduction** Change of direction speed (CODS), acceleration and deceleration, combined to the technical skills are crucial qualities to elude (on offense) or to apply pressure (on defense) on opponents during a soccer match. The ability that encloses those qualities referred as agility, which is a specific key component of the soccer performance (Sheppard and Young, 2006). Since strategic factors also influence players activities (Lago-Peñas et al., 2014), it is reasonable think that agility performance may be present different characteristics within a team. In this context, the aim of this study was to assess speed, CODS and agility soccer-specific tests for positional playing and to investigate their relationship in youth sub-elite soccer players. **Methods** Thirty-three sub-elite soccer players participated in the study (mean ±SD; age: 14.5±0.5 years, weight: 52.1±9.7 kg, BMI: 19.2±1.9 kg/m<sup>2</sup>). All players had a minimum of 4 years of soccer training at baseline. Three playing positions were classified: defenders (DF, n=12), midfielders (MF, n=11) and forwards (FW, n=11). Participants were tested for 10-m sprint (acceleration), 'Modified Illinois change of direction test' (MICODT) and T-drill agility test with the addition of balls and goals (specific soccer skill). **Results** Data from the test batteries showed that FW were the fastest players in the 10-m acceleration and achieved the best performance in the MICODT and agility T-drill test compared to DF and MF. In spite of that, no statistical differences were found among playing positions (p>0.05). In addition, a moderate, but significant, correlation were found between 10-m sprint and MICODT (r = 0.63; p<0.0001), and between 10m-sprint and T-drill agility test (r = 0.52; p<0.01). **Discussion** The ability to accelerate, decel-

erate and to change directions is critical in soccer and it is considered as discriminant to predict inter-individual differences. In the MICODT test, FW tended to be faster than other roles suggesting a greater propensity in performing those patterns of movement during a soccer match (Hachana et al., 2014). However, in the present study, no differences were found in CODS ability as well as in the 10-m sprint among playing positions. T-drill agility test score also showed no significant difference in DF, MF and FW and the inconsistency of the results was probably due to the specific physical and cognitive abilities, which are widely linked among the roles. Lastly, correlations between agility and CODS with sprint performance suggest that different specific patterns of movement and physical tasks have common characters in terms of physiological and biomechanical determinants (Kutlu et al., 2012). ## MULTIVARIATE STATISTICAL ASSESSMENT OF PREDICTORS OF FIREFIGHTERS' MUSCULAR AND AEROBIC WORK CAPACITY

Lindberg, A.1, Oksa, J.2, Antti, H.3, Malm, C.4

1 and 4. *Winter and Sports Medicine Unit 2. Physical Work Capacity-team 3. Department of Chemistry*

**Introduction** Physical capacity has previously been deemed important for firefighters physical work capacity, and aerobic fitness, muscular strength, and muscular endurance are the most frequently investigated parameters of importance. Traditionally, bivariate and multivariate linear regression statistics have been used to study relationships between physical capacities and work capacities among firefighters. An alternative way to handle datasets consisting of numerous correlated variables is to use multivariate projection analyses, such as Orthogonal Projection to Latent Structures. The first aim of the present study was to evaluate the prediction and predictive power of field and laboratory tests, respectively, on firefighters' physical work capacity on selected work tasks. Also, to study if valid predictions could be achieved without anthropometric data. The second aim was to externally validate selected models. The third aim was to validate selected models on firefighters' and on civilians'. **Methods** A total of 38 (26 men and 12 women) + 90 (38 men and 52 women) subjects were included in the models and the external validation, respectively. One subject group (n = 38) performed a large battery of laboratory and field physical tests and five simulated firefighting work tasks. The other subject group (n = 90) performed simulated firefighting work tasks and a selected battery of field physical tests. Prediction and predictive power was analyzed with Orthogonal Projection to Latent Structure in SIMCA version 13.0 (MKS Umetrics AB, Umeå, Sweden) Results The best prediction (R<sup>2</sup>) and predictive power (Q<sup>2</sup>) of Carrying hose baskets up stairs, Hose pulling, Demolition, Carrying hose baskets over terrain and Victim rescue work capacities included field tests (R<sup>2</sup> = 0.73 to 0.84, Q<sup>2</sup> = 0.68 to 0.82). The best external validation was found for Carrying hose baskets up stairs work capacity (R<sup>2</sup> = 0.80) and worst for Demolition work capacity (R<sup>2</sup> = 0.40). **Discussion** The main finding in this study is that field tests can predict firefighters' physical work capacity equally well as laboratory tests and that models excluding anthropometric data are valid for prediction of physical work capacity for firefighting work tasks. Valid models were found for all simulated work tasks with all subjects included, with only firefighters included, and with only civilians included. The predictive power was satisfactory for all included work tasks except Demolition work capacity. Field physical tests valid for prediction of studied work tasks are Rowing 500 m (s), Maximal hand grip strength, (kg) Endurance bench press (n), Running 3000 m (s and s x kg<sup>-1</sup>), Barbell shoulder press endurance (n), Standing broad jump (m), Sub-maximal treadmill walking (% HR<sub>max</sub>) and Handgrip endurance. The paper has been accepted for publication in PLOS ONE

## PHYSIOLOGICAL PROFILES OF DIFFERENT COMPETITIVE LEVELS AND WEAPONS OF FENCERS

Lo, K.K., Dave, B., Chan, Y.Y., So, C.H.

*Hong Kong Sports Institute*

**Introduction** Extensive studies have been done using field-based physiological tests to assess the physical fitness level among fencers of various competitive levels (Nystrom et al., 1990). However, those conducted during the past decade took no account of fencer-specific movement patterns and thus test results could not accurately reflect fencers' physical abilities. With recent availability of fencing movement specific test, speed, agility and endurance of different levels of fencers were obtained, which can be served for future benchmarking and training guide. **Methodology** Subjects: A total of 78 Hong Kong Sports Institute Scholarship fencers participated in this study. The sample included the worldcup's champion at that time. Subjects were grouped into two competitive levels: elite and sub-elite and three weapons types: epee, foil and sabre. **Study design:** Anthropometric measurements including height, weight, arm span and leg length were collected. Fitness tests including fencing-specific endurance test, maximum lunge speed and distance, 5m shuttle run and 2-4-2m shuttle run were conducted. Results Elite fencers have better anthropometric advantages compared to sub-elite fencers. Test results were reviewed against data from other countries: (a) Hong Kong (HK) fencers have a lower mean lunge speed than Greek fencers (Tsolakis and Vagenas, 2010); (b) HK fencers have a lower mean movement velocity at the same lactate concentration level than German fencers (Weichenberger et al., 2012); (c) HK male fencers have a longer mean lunge distance than Iranian male fencers Gholipour et al., 2008); (d) HK fencers scored better than Greek fencers in 5m shuttle run test (Tsolakis and Vagenas, 2010); they also scored better than British fencers in 2-4-2 m shuttle run test (Turner A, 2010). **Discussion** The study has established the first fitness database for Hong Kong fencers, which provided a solid understanding of their fitness level. It extends the scope of study on the elite fencers by providing normative data and performance standard for elite, sub-elite players with different weapons. Also, it helps coaches to optimize their training programmes and identifies talents. The data comparison against overseas fencers allows better understanding of the physical fitness of HK fencers against others. References 1. ## EFFECTS OF DIFFERENT PACESETTERS DURING CYCLOERGOMETER EXERCISE

Lecce, D.1, Fattorini, L.2, Cortis, C.1, Giancotti, G.F.1, Rodio, A.1

1 *University of Cassino and Lazio Meridionale. 2 Sapienza University of Rome*

**Introduction:** Music has the capacity to generate emotions, increase work output, reduce inhibitions and encourage rhythmic movement, all of which have potential applications in sport and exercise(1). In fact, it can be applied to aerobic and anaerobic endurance performance among non-elite athletes and exercise participants with considerable ergogenic effect (2)(3). Besides acoustic, the visual stimuli also been reported to improve high intensity exercise tolerance(4). This study was aimed to assess the influence of acoustic and visual

pacesetters on the Energy Expenditure of a steady state no fatiguing exercise. Methods: Twelve healthy male subjects (age:29.3 ( $\pm$ 5.9) yrs; height:178.2 ( $\pm$ 8.1)cm; weight: 81.4 ( $\pm$ 9.1)kg) performed a 30 min long exercise at a constant speed and workload on a cycloergometer. Pedaling speed and exercise intensity were set at about 60 rpm and at a mechanical power requiring a metabolic expenditure corresponding to 70% of ventilator threshold respectively. Total Energy Expenditure (TEE) expressed as caloric equivalent for the total oxygen consumption during exercise was evaluated in 4 experimental condition: CONTROL (CON), no pacesetters; ACOUSTIC (AS), listening rhythmical acoustic stimuli at 120 beat per min; MIRROR (MS) seeing video representing an exercise performed by subject, and VISUAL (VS), seeing footage composed of two different images in a looped sequence at 120 frames per min. Results: TEE (Kcal) resulted: 549 ( $\pm$ 67) ml/kg, 536 ( $\pm$ 67); 516 ( $\pm$ 72) ml/kg; 511 ( $\pm$ 43) ml/kg in CON, AS, MS, VS respectively. In particular, it is significantly different in MS and VS compared to CON, resulting lower of an about 2%, 6 % and 7% in VS, MS and VS than CON. Discussion: Present findings show visual as well as acoustic stimuli acting as a pacesetter were able to increase performance in a 30-min steady-state aerobic exercise on cycle-ergometer. Results from this investigation could be used for the development of new training strategies, in which images projected at various frequencies can be showed to athletes to indicate the correct rhythm of the technical movement. #### CHANGES IN PHYSICAL PERFORMANCE AND BODY COMPOSITION OF SOLDIERS DURING A 6-MONTH CRISIS MANAGEMENT OPERATION

Pihlainen, K.1, Santtila, M.3, Kyröläinen, H.2,3

1: Defence Command, Finnish Defence Forces, Helsinki, Finland, 2: University of Jyväskylä, Jyväskylä, Finland, 3: National Defence University, Helsinki, Finland

**Introduction** Soldiers are required to maintain a high level of physical performance in order to fulfill their duties during deployment (Nindl et al 2013). However, most available studies focusing on soldier's physical performance during military operations indicate that aerobic capacity declines with a simultaneous increase in fat mass (Nindl et al 2013, Lester et al 2010). The purpose of the present study was to investigate the changes in body composition and physical performance in male soldiers during a 6-month deployment in Lebanon. **Methods** 25 soldiers (28.9 $\pm$ 6.6 yrs., 180.1 $\pm$ 7.1 cm, 78.9 $\pm$ 8.9 kg) volunteered for the study. All measures were obtained in Lebanon. Body mass (BM), skeletal muscle mass (SMM), fat mass (FATM) and fat percentage (FAT%) were determined after an overnight fast by using segmental multi-frequency bioimpedance analysis (InBody 720, Biospace Co Ltd, Seoul, South Korea). Maximal isometric strength of extensors of the lower and upper extremities was measured in a sitting position by using a bilateral electromechanical dynamometer (Häkkinen et al 1998). Aerobic capacity was evaluated by running a 3000 meter test. The test was performed on a standardized track covered with asphalt. The soldiers were instructed to complete the test within the shortest possible time. A stopwatch was used to record the time required to run 3000 meters. **Results** The pre-post relative changes (%) and absolute means $\pm$ SDs during the study period were 0.5% (78.4 $\pm$ 8.6 vs. 78.8 $\pm$ 9.0 kg,  $p=0.39$ ) in BM, 0.5% (24.1 $\pm$ 2.5 vs 24.2 $\pm$ 2.5 kg/m<sup>2</sup>,  $p=0.41$ ) in BMI, 0.9% (39.0 $\pm$ 4.5 vs. 39.3 $\pm$ 4.7 kg,  $p=0.08$ ) in SMM, 0.1% (10.3 $\pm$ 4.8 vs. 10.3 $\pm$ 4.8 kg,  $p=0.97$ ) in FATM and -0.5% (13.0 $\pm$ 5.4 vs. 13.0 $\pm$ 5.3%,  $p=0.86$ ) in FAT%, respectively. Changes in 3000 m running test and maximal isometric strength of extensor muscles of the lower and upper extremities were 0.9% (825.7 $\pm$ 70.7 vs. 832.8 $\pm$ 83.0 s,  $p=0.46$ ), 3.2% (431.4 $\pm$ 107.0 vs. 445.2 $\pm$ 101.4 kg,  $p=0.12$ ) and -0.5% (112.9 $\pm$ 24.0 vs. 112.3 $\pm$ 22.2 kg,  $p=0.80$ ), respectively. **Discussion** The present study demonstrated that soldiers maintained their body composition and physical performance throughout the 6-month deployment. Despite the statistically non-significant changes in the mean values, large inter-individual variation was observed in all measured parameters. In conclusion, high variations highlight the need for individual training programmes and follow-up to obtain more positive changes in soldier's physical performance during deployment. **References** Nindl B, Castellani J, Warr B, et al. *Eur J Appl Physiol*. #### A NEW ESTIMATION METHOD FOR MALE ATHLETE'S TOTAL SKELETAL MUSCLE MASS BY USING ULTRASONOGRAPHY: DIFFERENCE OF PREDICTION MODEL WITH SEDENTARY POPULATION

Toda, Y.1, Kimura, T.2, Taki, C.3, Kurihara, T.3, Homma, T.3, Kitamura, M.1, Hamaoka, T.3, Sanada, K.3

1: Mukogawa Women's University (Japan), 2: Kobe University (Japan), 3: Ritsumeikan University (Japan)

**Introduction** It is important for athletes to regularly evaluate the total body skeletal muscle mass (SMM) with a simple method. A previous study (Sanada et al. (2006)) developed a prediction model of SMM for sedentary population. This prediction model only requires the measures of muscle thicknesses determined by the ultrasound, which is practical considering its portability and short-time measurement. The first purpose of this study was therefore to assess whether the previous prediction model can be applied also for young male athletes (Study 1). Next, based on the results of Study 1, we developed a new model which estimates the SMM from the ultrasound measures, specifically for the young male athletes (Study 2). **Methods** Sixty one male athletes (20.4 (0.9) yr, mean (SD)) participated in both Study 1 and 2. The subjects were randomly assigned into two groups in the Study 2; 41 subjects were involved in the development of new prediction model (Development group), and the other 20 subjects were in the validation of the new model (Validation group). In the Study 1, all subjects underwent direct measurements of SMMs by using magnetic resonance imaging (MRI). Also, sum of the nine skeletal muscle thicknesses (MTH9) was measured by B-mode ultrasound, and the measure was assigned to the previous prediction model of SMM, thus comparing the estimated SMM with that measured by the MRI. In the Study 2, for developing a new prediction model for young male athletes, a linear regression equation between the MRI-measured SMM and the MTH9 multiplied by body height in the Development group was computed. The reliability of new prediction model was validated by using the measured data (MRI and ultrasound data) in the Validation group. **Results and Discussion** In the Study 1, we found the previous prediction model was not suitable for the young male athletes, as a paired t-test showed a significant difference between the averages of predicted SMM and MRI-measured

SMM ( $P < 0.001$ ). In the Study 2, in the Validation group, there was a high correlation between the SMM estimated by our newly developed prediction model and the MRI-measured SMM ( $r = 0.96$ ,  $P < 0.05$ ), and a paired t-test showed no difference between their averages ( $P = 0.983$ ). Also, the Bland-Altman analysis did not indicate a bias in the prediction of the SMM ( $r = -0.25$ ,  $P > 0.05$ ). These results indicate the prediction model developed in this study is a reliable estimation method for SMM and an alternative to MRI measurement, in young male athletes. ### **SENSIBILITY OF THE VO<sub>2</sub>PEAK AND ANAEROBIC CAPACITY TO MATURATION STAGES AND THEIR POSSIBLE RELATION WITH SWIMMING PERFORMANCE**

Campos, E.Z.1, Silva, M.S., Machado-Gobatto, F.2, Zagatto, A.1, Kalva-Filho, C.3, Loures, J.P.3, Papoti, M.3

1 Universidade Estadual Paulista; 2 Universidade de Campinas; 3 Universidade de São Paulo

Aerobic power and anaerobic capacity are two important parameters to swimming performance, and both seem to enhance with maturation. The aims of this study were to verify if aerobic power and anaerobic capacity are sensitive to maturation level, and their possible relation with performance. Thirty two swimmers (19 male and 15 female) performed one 100m, 200m, and 400m maximal effort. After the 400m, the peak oxygen uptake VO<sub>2</sub>Peak and the maximal accumulated oxygen deficit obtained in a single supramaximal exercise session (MAODRED) were determined. The VO<sub>2</sub>Peak was assessed by the backward extrapolation technique, while the MAODRED by the sum of lactic and alactic anaerobic contribution. The swimmers were divided into three groups according to pubic hair self-assessment (early-pubertal, middle-pubertal, and pubertal). The ANOVA one-way and the Pearson correlation were used to compare the values, and associate with performance, respectively. A 5% significance level was adopted. The absolute VO<sub>2</sub>Peak was higher in pubertal ( $3.85 \pm 1.12$  L•min<sup>-1</sup>) than other groups ( $2.73 \pm 0.65$  L•min<sup>-1</sup> and  $3.30 \pm 0.84$  L•min<sup>-1</sup>, for early and middle pubertal, respectively). The MAODRED was higher in pubertal ( $3.87 \pm 1.12$  L) than middle-pubertal ( $2.48 \pm 1.12$  L) and early-pubertal ( $2.10 \pm 0.90$  L), and higher in middle-pubertal than early-pubertal. Only middle-pubertal presented relation between VO<sub>2</sub>Peak and swimming performance ( $r = 0.67$  and  $0.65$  for 200m and 400m performance), while for middle-pubertal and pubertal MAODRED was significantly related with all swimming performance ( $r = 0.55$  to  $0.95$ ). In order to control gender influence on MAODRED and VO<sub>2</sub>Peak association with performance, the correlations were also performed separately (i.e. independently of biological age). No association was found for female group, while VO<sub>2</sub>Peak and MAODRED presented association with swimming performance. Moderate and strong correlations were observed when the entire groups were analyzed together (i.e. biological age and gender). Thus MAODRED is sensitive to maturation, however, VO<sub>2</sub>Peak is higher only in pubertal group. The relation of MAODRED with performance is also different between the groups and gender might influence the association of these parameters with performance. Finally the MAODRED seems to be an interesting tool to control the anaerobic capacity evolution during growth, since it increases and is associated with performance.

### **THE ACUTE EFFECTS OF DIFFERENT STRETCHING PROTOCOLS ON TAEKWONDO KICKING PERFORMANCE**

Wu, C.M.1, Wu, B.H.2, Chen, J.T.2, Tang, H.T.3, Tai, Y.C.4

1. Cheng Shiu University, 2. National Pingtung University of Science and Technology, 3. National Taiwan Sport University, 4. National Kaohsiung Marine University

Introduction Warm-up activity was an indispensable protocol before physical activities and sports training, especially in combat sports. Athletes will perform static stretch (SS), active stretch (AS), dynamic warm-up activities (DW), and even the pre-event working up. These activities were not appropriate for all kinds of sports events (Shrier, 2004), thus, pre-event warm-up protocols design should be event-oriented and athlete specific. Methods Nine trained taekwondo athletes were recruited in this study; all participants had to finish three pre-event warm-up protocols and kicking tests in different days with a balance design, including the dynamic warm-up activities (DW) without stretching, dynamic warm-up activities with static stretching (DWSS), and dynamic warm-up activities with active stretching (DWAS). Then following the kicking tests, the reaction time (seconds, from heel up to kick the target), normalized Rectus-femoris and Gastrocnemius muscles EMG (%MVC, maximum voluntary contraction) data were collected, repeat measures ANOVA to analyze the differences among these protocols. Results DWAS had better performance in reaction time than DWSS ( $p < 0.05$ ), but without differences compare with DW ( $0.107 \pm 0.011$ s,  $0.114 \pm 0.012$ s,  $0.110 \pm 0.009$ s, respectively). Normalized EMG of Gastrocnemius muscle in DWSS was higher than DW ( $p < 0.05$ , but without differences compare with DWAS ( $0.47 \pm 0.28$ ,  $0.31 \pm 0.26$ ,  $0.38 \pm 0.26$ , respectively). Discussion Active stretching had positive effects on acute kicking test performance; the characteristics of Taekwondo sports had higher percentage skills in lower extremity, in that, pre-event dynamic and active warm-up protocol could help athlete perform better in kicking performance. However, other research in power or sprint test did not have significant positive effects (Winchester et al., 2008), this may results from the event-oriented DWAS protocol. Active or static stretching protocol in our study did not shown significant difference in EMG, this result was similar to previous study in vertical jump performance (Unick et al., 2005). In conclusion, we suggest that dynamic and active warm-up activities had positive effects in short bout power sports. References Shrier, I. (2004). Does stretching improve performance? ### **SHOULDER STRENGTH RATIOS OF BOXER ATHLETES**

Tasiopoulos, I.G.1,2, Stergioulas, A.1, Tripolitioti, A.1, Nikolaidis, P.T.2

1: University of Peloponnese (Sparta, Greece), 2: Hellenic Army Academy (Athens, Greece)

Introduction The famous movement in boxing is the punch, with the shoulder joint and the rotators muscles playing important role (Tasiopoulos et al., 2014), which controls the twisting movements, and contributes to both mobility and stability of the joint, (Labriola et al., 2005). The aim of this study was to examine the bilateral and unilateral ratios. Methods Thirty five national men boxing athletes (age  $24.5 \pm 4.9$  yrs; height  $174 \pm 6$  cm; body weight  $76.5 \pm 11.1$  kg), participated in the present study. The evaluation of glenohumeral joint was performed using the Kin-Com<sup>TM</sup> isokinetic dynamometer, in the seated scapular plane, at  $60^\circ/s$ , and  $180^\circ/s$  angular speeds. Strength variables were peak torque (PT) of concentric (con) and eccentric (ecc) contractions, the ratios of dominant (D), non-dominant (ND), of external (ER) and internal rotators (IR). Results The PT of IRcon was from  $48.57 \pm 11.09$  to  $35.91 \pm 8.16$ Nm, the ecc from  $63.28 \pm 16.41$  to  $50 \pm 10.56$ Nm, with higher values of D ( $p = 0.003$ ,  $p = 0.001$ , respectively) than ND at  $60^\circ/s$  con and ecc, for ERcon was from  $29.11 \pm 6.5$  to  $24.88 \pm 5.1$ Nm, for ecc from  $38.37 \pm 8.94$  to  $33.82 \pm 6.91$ Nm, with  $p = 0.038$  between D and ND in ERecc at  $60^\circ/s$ . The bilateral ratios for IRcon

was  $3.41 \pm 19.97\%$ - $8.23 \pm 18.12\%$ , for ecc  $3.8 \pm 20.61\%$ - $8.63 \pm 21.06\%$ , for ERcon was  $0.39 \pm 10.51\%$ - $1.80 \pm 12.69\%$ , and ecc  $-0.54 \pm 10.93\%$ - $4.19 \pm 13.88\%$ . The unilateral ratios of con was  $61.40 \pm 13.93$ - $66.75 \pm 17.52\%$  at  $60^\circ/s$  and  $67.93 \pm 14.29$ - $71.04 \pm 14.25\%$  at  $180^\circ/s$ , with  $p=0.043$  between D and ND at  $60^\circ/s$ . Discussion The bilateral ratios for IR, ER con and ecc of D and ND, are considered normal and agree the symmetry of limbs in sports which use bilateral movements (Sakiko, 2006). The motor kinetics and the activity profile of the boxers' (Davis et al., 2013), confirm the results of the low bilateral ratios of both shoulders at  $180^\circ/s$ . The unilateral ratios at  $60^\circ/s$  have normal balance and values (Wathen, 1994), and at  $180^\circ/s$  was less higher than ordinary subjects,  $0.59$ - $0.62$ , (Shklar and Dvir, 1995) and lower than college pitchers,  $D=0.70$ ,  $ND=0.81$ , (Cook et al., 1987). ### THE RELATIVE AGE EFFECT IN EUROPEAN PROFESSIONAL SOCCER: DID TEN YEARS OF RESEARCH MAKE ANY DIFFERENCE?

Helsen, W., Baker, J., Schorer, J., Van Winckel, J., Williams, A.M.

*KU Leuven*

The relative age effect (RAE) refers to an asymmetry in the birth-date distribution favoring players born early in the selection year and discriminating participants born later in the year. While the RAE effect was initially reported in sport more than two decades ago, there have been few attempts to examine whether player selection strategies have changed over time in light of our improved understanding of the phenomenon. We compared the birth-date distributions of professional soccer players in ten European countries over a 10-year period involving the 2000-2001 and 2010-2011 competitive seasons, respectively. Chi-square goodness-of-fit tests were used to compare differences between the observed and expected birth-date distributions across selection years. Generally, results indicated no change in the RAE over the past 10 years in professional soccer emphasizing the robust nature of this phenomenon. We propose a change in the structure of youth involvement in soccer to reduce the impact of the RAE on talent identification and selection.

### EFFECTS OF CONTRAST BATHING ON AUTONOMIC ACTIVITY

Hironaga, I.1, Eda, N.2, Lee, E.3, Akama, T.2

*Waseda University*

1: Graduate School of Sport Sciences, Waseda University (Saitama, Japan), 2: Faculty of Sport Sciences, Waseda University (Saitama, Japan), 3: Waseda Institute for sport sciences, Waseda University (Saitama, Japan) Introduction Contrast bathing (CB) is a method of alternately repeating hot bathing and cold bathing for recovery in sport scenes (Hing et al., 2008). The aim of this study is to reveal the effect of CB on autonomic nervous activity by measure salivary  $\alpha$ -amylase (SAA), heart rate variability (HRV). Methods Seven healthy adult males ( $25.6 \pm 4.0$  yr) participated in this study. They performed 3 trials, which were sitting rest (REST) for 20 minutes, hot bathing (HB) at  $40^\circ\text{C}$  for 20 minutes, CB hot bathing at  $40^\circ\text{C}$  for 4 minutes and cold bathing at  $15^\circ\text{C}$  for 1 minutes 4 times repeats, and each trial was performed on different day. Saliva sampling and HRV measure were carried out before a trial (PRE), after a trial (POST), 30 minutes after a trial (POST 30), 60 minutes after a trial (POST 60). SAA concentrations were measured using enzyme linked immunosorbent assay (ELISA). We used natural logarithm of high frequency component (LnHF) of HRV as a marker of parasympathetic nervous activity and natural logarithm of low frequency / high frequency ratio (Ln(LF/HF)) of HRV as a marker of sympathetic nervous activity (Goto et al., 2010). Results In the REST ( $p < 0.05$ ) and the CB trials ( $p < 0.05$ ), SAA concentrations significantly increased at POST 60 (REST;  $43.1 \pm 31.6$  U/mL, CB;  $56.0 \pm 49.6$  U/mL) compared with PRE (rest;  $25.7 \pm 22.4$  U/mL, CB;  $41.0 \pm 38.3$  U/mL), and those were no significant change at post. In the HB trial, SAA concentration significantly increased at POST ( $54.9 \pm 43.8$  U/mL;  $p < 0.01$ ), POST 30 ( $49.2 \pm 45.7$  U/mL;  $p < 0.05$ ), POST 60 ( $51.4 \pm 43.5$  U/mL;  $p < 0.05$ ) compared with PRE ( $30.8 \pm 26.8$  U/mL). LnHF in the HB trial significantly decreased at POST ( $5.7 \pm 0.6$ ) compared with PRE ( $6.5 \pm 0.9$ ;  $p < 0.05$ ). However, LnHF in the rest and CB trials and Ln(LF/HF) in the each trials showed no significant change. Discussion In the HB trial, SAA concentration significantly increased, and LnHF significantly decreased. SAA concentration increases due to sympathetic nervous activity. Therefore, HB might activate sympathetic nerve and might depress parasympathetic nerve. On the other hand, CB might not change autonomic nervous activity. So, it is possible that CB is less stressful for athletes than HB. We conclude that CB might be better than HB for recovery after exercise. Reference Goto F, Mizutari K, Kunihiro T, Ogawa K (2010). Equilibrium Res, 69(4), 207-212. Hing WA, White SG, Bouaophone A, Lee P (2008). Phys Ther Sport, 9(3), 148-161. Contact [waseda-sp.sc@akane.waseda.jp](mailto:waseda-sp.sc@akane.waseda.jp)

### KIDNEY INJURY AND ATHLETES ANAEMIA AFTER THE SÃO PAULO INTERNATIONAL MARATHON

Sierra, A., Ghorayeb, N., Benetti, M., Jones, J.M., Boaventura, M.F.C., Smith, P., Lemos, L.C.V., Francisco, R.C., Sierra, C.A., Kiss, M.A.P.D.M.

*EEFE-University of Sao Paulo, UNINOVE - Medicine Department, IDPC, Cruzeiro do Sul University, Mackenzie*

The potential deleterious effects of prolonged strenuous exercise are severe dehydration, electrolyte abnormalities, rhabdomyolysis and acute myocardial infarction. However, the degree of kidney injury and the repercussions of this are not fully known. The aim of this study was to investigate kidney injury and the relationship with the athletes anaemia after the 2014 São Paulo International Marathon. Methods: 71 male marathoners, aged 24 to 54 years old were evaluated. Blood samples to analyse creatinine, haemoglobin, haematocrit, iron and bilirubin, and urine to analyse the presence of haemoglobin, protein, cylinders and leukocytes were collected 24h before, immediately after, 24h and 72h after the marathon. Results: The marathoners completed the marathon in  $282.31 \pm 52.9$  minutes. We observed an increase in iron, bilirubin and creatinine immediately and 24h after the marathon comparing with basal values. A decrease in haemoglobin and haematocrit occurred 24h and 72h after the marathon, which characterized athletes anaemia. We found protein in

14.7% and cylinders in 41.2% of the athletes. An increase in leukocytes and haemoglobin in the urine occurred, characterizing kidney injury. Nevertheless, the kidney injury markers were not correlated with the athletes anaemia markers. The increase in creatinine was correlated with the increase in leukocytes and cylinders in the urine. Conclusion: Marathon induces a reduction in haemoglobin, haematocrit and changes in kidney function. Although the marathon induces anaemia and impairment in kidney function, these two findings are not related.

### EFFECT OF SLEEP QUALITY ON COGNITIVE FUNCTION DURING EXERCISE IN ATHLETES.

Akazawa, N., Kumagai, H., Nakamura, Y., Myoenzono, K., Choi, Y., Maeda, S.

*University of Tsukuba*

**[Introduction]** In various ball sports games, athletes are needed to cognitive executive function such as learning, attention and information processing capability, and especially during exercise. Brain activity are strongly associated with sleep, sleep deprivation decreases cognitive function. Recently, it has been reported that sleep extension improves sports performances. However, it is known that sleep is important not only time but also quality such as sleep efficiency, sleep onset latency and snooze time. Furthermore, the effect of sleep quality on cognitive function during exercise is unclear. Therefore, the aim of the present study is to examine the hypothesis that cognitive function during exercise is greater in high sleep quality. **[Methods]** Twelve female volleyball athletes ( $20 \pm 0.3$  years) were participated in this study. Sleep time and quality were measured by using NemuriSCAN (Paramountbed Co.LTD., Japan) for one week before cognitive exercise test. The subjects were divided into high sleep quality ( $n=6$ ) and low sleep quality ( $n=6$ ) groups by their median value of sleep quality. The subjects performed cognitive function using a computer-adapted Stroop Task (Simple- and Difficult-task) at rest and during aerobic bicycle exercise at 30-40% (light intensity) and 60-70% (moderate intensity) of hear rate reserve. **[Results]** Sleep quality in high sleep quality group is higher than low sleep quality group, whereas sleep time was not different between the two groups. Average response times on the simple stroop task were faster during exercise than at rest in both groups ( $P < 0.05$ ). In high sleep quality group, the difficult-task response times improved during moderate intensity exercise ( $P < 0.05$ ). The difficult-task response time in low sleep quality group did not change during both exercise intensities. **[Discussion]** The present study demonstrated that cognitive function in athletes of high sleep quality is greater during moderate intensity than athletes of low sleep quality. These results suggest that sleep quality affects sport performance during relatively heavy exercise in athletes.

### INVESTIGATION OF THE ADEQUATE METHOD OF LIQUID INTAKE FOR DOPING CONTROL 2

Tanabe, Y.1, Dohi, M.1, Yamagishi, S.1, Miki, S.2, Sakashita, M.2, Mizutani, Y.1, Nakamura, M.1, Kamihigashi, E.1, Narumi, E.1, Iwahara, Y.1, Kawahara, T.1

*1: Japan Institute of Sports Sciences, 2: Medical Foods Research Institute, OS-1 division Otsuka Pharmaceutical Factory, Inc.*

**[Introduction & Purpose]** In competition, doping control might mentally and physically put stress on athletes, especially female athletes. This may cause poor condition and result in decreased performance, because they are forced to produce at least 90 ml of urine under the supervision of a witness after competition in spite of the presence of post-competition dehydration. However, little is known about the adequate method of fluid intake and the preferable type of fluid We found in our previous study that water intake at one time resulted in higher and faster urine production compared to multiple times, and that urine specific gravity can be significantly below the limit due to an increase in urine volume. The purpose of this study was to investigate the influence on urine specific gravity due to differences in the type of fluid. **[Subjects and Methods]** Sixteen female athletes 20 to 21 years (average  $20.1 \pm 0.2$ ) participated in this crossover study. After reaching 1% dehydration by exercising on a cycle ergometer, treadmill or rowing ergometer, subjects were asked to consume 800 mL of mineral water, OS-1, or POM orange. OS-1 (Otsuka Pharmaceutical Factory, Inc. Tokushima) is a hypotonic oral rehydration solution based on the guideline of American Academy of Pediatrics. OS-1 contains a moderately high amount of sodium (50 mEq/L) and 2.5% glucose to stimulate sodium and water absorption. POM orange (Ehime Drink, Ehime) is a 100% concentrated reduced juice made from mandarin orange. This juice contains 0% sodium and 10% saccharides and is hypertonic. Urine and blood samples were collected before, and at 0, 30, 60, 90, 120, 150 and 180 minutes after exercise to measure blood and urinary electrolytes. During the study, subjects were kept in an environment of controlled temperature and humidity. The data were analyzed using chi-squared test and Tukey's HSD test. **[Results]** The urine production after water consumption was statistically the highest at 90 minutes after exercise, followed by OS-1 and orange juice. The urinary specific gravity below the limit was observed the most after water consumption at 90 minutes after exercise. **[Discussion and Conclusion]** Compared with water, OS-1 consumption prevents an excessive decrease of specific gravity and maintains urine volume during the early stage. Consumption of orange juice did not result in a decreased specific gravity, however the urine volume was low during the early stage. Thus these results suggest that consumption of OS-1 might result in sufficient production of urine with adequate specific gravity.

### INVESTIGATION OF THE ADEQUATE METHOD OF LIQUID INTAKE FOR DOPING CONTROL

Etsuko, K.1, Michiko, D.1, Sachiko, Y.1, Shinya, M.1, Masaki, S.2, Yuri, M.2, Mariko, N.1, Yoko, T.1, Emi, N.1, Yasuko, I.1, Takashi, K.1

*1: Japna Institute of Sports Sciences, 2: Medical Foods Research Institute, OS-1 division Otsuka Pharmaceutical Factory, Inc.*

**[Introduction & Purpose]** In competition, doping control might mentally and physically put stress on athletes, especially female athletes. This may cause poor condition and result in decreased performance, because they are forced to produce at least 90 ml of urine under the supervision of a witness after competition in spite of the presence of post-competition dehydration. However, little is known about the adequate method of fluid intake and the preferable type of fluid, and is usually decided by the coaches and athletes based on experience. The purpose of this study is to investigate the influence of the urine volume due to differences in the method of fluid intake. **[Subjects and Methods]** Fifteen female athletes 20 to 21 years (average  $21.2 \pm 0.2$ ) participated in this crossover study. After reaching 1% dehydration by exercising on a cycle ergometer, treadmill or rowing ergometer, subjects were asked to consume 800 mL of mineral water based on one of the following three patterns: 1) all at once, 2) in two portions, and 3) in four portions. Urine and blood samples were collected before, and at 0, 30, 60, 90, 120, 150 and 180 minutes after exercise to measure blood and urinary electrolytes. During the study, subjects were kept in an environment of controlled temperature and humidity. The data were analyzed using chi-squared test and Tukey's HSD test. **[Results]** The highest and fastest urine production was statistically significant at 60 minutes after exercise under pattern 1. The urinary specific gravity at 60 minutes under pattern 1 was significantly lower than under pattern 2. **[Conclusion]** Our research showed that water intake at one time was efficient to obtain sufficient urine volume. However, there is a risk that specific gravity may be significantly below

the limit due to an increase in urine volume. Therefore, to obtain both adequate urine volume and specific gravity, not only the method to intake but also type of liquid should be considered.

### THE CHALLENGES AND NEEDS FACED BY NATIONAL SWIMMING FEDERATIONS IN PROMOTING HEALTH.

de la Cruz Marquez, J., Perez Diaz, C.

*University of Granada*

Introduction: International sport federations (IFs) and the International Olympic Committee (IOC) are increasingly concerned about developing sport worldwide. The aim of IOC Solidarity, a branch of the IOC, is to organise assistance for all National Olympic Committees (NOCs), particularly those with the greatest needs, through multi-faceted programmes. Some countries are still facing many barriers in terms of health promotion. The study "Prevalence of health promotion policies in sport clubs in Victoria, Australia" (S. J. Dobbins, J.A. Hayman, P. A. Livingstone, 2006) demonstrates that it is not just developing countries that face such barriers and finds that the main barrier in Australia is that clubs need more support from health agencies on policies. The FINA's Medical Commission's emphasis on health promotion, is reflected in the study conducted by two FINA Medical Commission members: "Sport Medicine in our national federations: The case of developing countries" (Diop M, Miller J., 2011) which suggests ways to overcome some existing barriers. Methods A multilingual survey was circulated by email and in person (at the FINA Swimming World Championships 2014 (25m) / FINA Aquatics Convention in Doha) to all 207 of the FINA NFs. The response rate was 65% (134 of the 207 NFs). The response rate among African countries was 62% (32 of the 51 African NFs replied). Results 69% of NFs reported a need for more support from the NOC, Continental or IF (training, advice, resources). In Africa that percentage increased to 78%. Also, 40% of n NFs reported a lack of health based policies and best practice guidelines. In Africa that percentage increased to 53%. Discussion NFs across the world face common barriers to health promotion. African NFs are at a disadvantage in part due to a lack of health based policies and best practice guidelines. They face many other significant barriers; therefore health promotion is not a top priority for them. Notably many NFs (62%) reported a lack of swimming facilities. In Africa this figure was 75% and it was 46% among European NFs. Conclusion Although many NFs face some common barriers to promoting health, those barriers are more significant for NFs in developing countries such as in Africa. Therefore, the means to overcome them will vary from region to region. References: Diop M, Miller J., 2011. "Sport Medicine in our national federations: The case of developing countries". ### INCIDENCE OF INJURIES AND ASSOCIATED FACTORS IN TRADITIONAL WRESTLING

Casals, M.1, Martínez, F.2, Blasco, M.J.2, Martín, A.2, Langohr, K.3, Fernández, T.2, Molina, A.J.2, Peña, J.4, Martín, V.2

1: CIBER de Epidemiología y Salud Pública (CIBERESP), Spain 2: University of Leon, León, Spain 3: Universitat Politècnica de Catalunya (UPC), Spain 4: University of Vic, Spain

Introduction Traditional wrestling is considered to be cultural heritage of humanity and it should be protected. The study of injuries and their associated factors can be useful to protect traditional wrestling (for this protection) through epidemiologic studies (Yard et al., 2008; Sánchez, V et al., 2013). The aim of this study was to analyze the incidence of injuries in traditional wrestling and its risk factors in order to carry out prevention and control programs in this sport. Methods A prospective cohort study which collected injuries during the summer seasons from 2005 through 2013. The incidence rates of injuries were calculated in cases for every 1000 combats (for the entire population) and as a function of age at the start of the season, age at initiation in wrestling, regularity in combats, winner type, and weight category, respectively. At the multivariate level, a generalized linear mixed model (GLMM) was used assuming the frequency of the injuries followed a Poisson distribution. Results A total of 277 wrestlers and 336 injuries were reported in 26950 combats. The incidence was 3 injuries for every 1000 combats. The incidence of injury was significantly higher in those who did not usually participate in the league (16.0 vs 10.9; RR = 1.47; 95% CI = 1.18 to 1.83) those receiving more falls than leading to falls " (15.2 vs 10.1; RR = 1.51; 95% CI = 1.22 to 1.87) and in those who started its practice at the age of 14 (14.4 vs 9.6; RR = 1.51; 95% CI = 1.18 to 1.54). The statistical interaction between winner type and weight category implies that non-winner type wrestlers are at much higher risk of injuries than winner type wrestlers in the semi heavy (IRR: 1.89; 95%CI: [1.09, 3.28]) and heavy weight categories (IRR: 1.80; 95%CI: [1.02, 3.16]). Discussion The incidence of injuries in this traditional wrestling is consistent with that incidence expected in contact sports (Yard et al., 2008; AFHSC 2014). The non-regularity and late start in their practice are risk factors for the incidence of injuries. The technical quality is particularly relevant at heavy weights category. References Yard, E. ### LIFESTYLE OF RUGBY PLAYERS IN COLOMBIA: A PILOT STUDY

Martínez-Rueda, R.1, Angarita, A.2, Puzovic, V.3

1. Universidad Manuela Beltrán, Bogotá, Colombia 2. Universidad Santo Tomás, Bucaramanga, Colombia 3. Faculty of Medical Sciences, University of Kragujevac, Kragujevac, Serbia

Introduction: Rugby players have already been the subject of research related to sports injuries, anthropometrics and physiological profile (Villarejo et al., 2010). However, there is a lack in studies about their lifestyle. The aim of the study was to describe Rugby player's lifestyles in Colombia and explore differences determined by sex and player's position. Methods: This is a cross-sectional study conducted on 116 rugby players from 7 cities in Colombia. Including criteria were subjects older than 18 years of age and that they practice rugby at least 12 months. All subjects fulfilled FANTASTIC questionnaire which inquired about their lifestyle (Ramírez-Vélez and Agredo, 2012). Results: From 116 rugby players, 67 (57.8%) were Backs and 49 (42.2%) were Forwards; sex distribution was 82 (70.7%) male and 34 (29.3%) female, while median age was 23 years. Median playing experience was 3 years (IQR 2-3). According FANTASTIC questionnaire, the average total score was 79.6 ± 8.9 points, while 56.6% reported a 'Good' lifestyle. There was no statistically significant difference in total score between male and female athletes (p=0, 46). However, tobacco domain score was significantly higher in women (p=0, 02).

When comparing players' position, Backs had significantly higher scores than Forwards at the average total score ( $81.2 \pm 8.9$  vs.  $77.3 \pm 8.5$   $p=0.017$ ), nutrition ( $8 \pm 2$  vs.  $6 \pm 2$   $p=0.019$ ) and personality type domains ( $6 \pm 2$  vs.  $4 \pm 2$   $p=0.001$ ). Discussion: The lower scores found in women tobacco domain are in contrast with previously published literature (Walsh et al 2012; Hessami et al. 2012.). In nutrition domain it is known that Forwards have greater weight and fat percentage than Backs (Monteiro, 2008). Regarding the type of personality, our study confirmed findings of Robazza and Bortoli, (2007), showing that Rugby players have a tendency to experience symptoms of anger. Although our study has the limitations of a pilot study, it suggests the domains where it should be intervene primarily so that studied population improve their lifestyle. References: Villarejo, D. ## SPORTS INJURIES DURING THE 2014 WORLD UNIVERSITY FLOORBALL CHAMPIONSHIP

Mukherjee, S., Leong, H.F.

*Nanyang Technological University, Singapore*

Introduction Floorball is a fast-paced sport with rising popularity across the world. Owing to high-intensity intermittent nature of the sport, it has been reported to present a variety of injuries. However, previous studies have been essentially season-based and injury surveillance data during international floorball tournaments is yet to be reported. This study reports prospective injury surveillance data during the 2014 World University Floorball Championship. Methods 178 male players representing 10 countries and 106 female players from six countries were observed during the championship. All the 29 men's games and 11 women's games were observed. The injury reporting system was based on that used in team sports during international tournaments. All injury documentation was done by direct on-location observation by a trained research team followed by confirmation from the team doctors or physiotherapists. Results 119 injuries during men's games and 32 injuries during women's games were documented during the tournament. Injury incidence for men and women was 4.1 and 2.9 per match and 341.7 and 241.7 per 1000 match hours respectively. Contusion was the commonest injury (~62%) followed by sprain and abrasion for both men and women athletes. Ankle was the most commonly affected part in men while it was the knee in women athletes. About 96% of injuries sustained were acute traumatic type in both men and women players. Player to player contact was the commonest cause of injury accounting for about 55% of the injuries in both men and women athletes. 75% of injuries in both men and women required medical or physiotherapeutic attention and two athletes each of men and women needed hospital transfer for specialist opinion and care. Following the injury 21 men (17.6%) and 8 women (25%) athlete could not continue in the match. Discussion International competitive floorball has a high injury incidence in both men and women categories and it was significantly higher than that reported in season-based studies. The severity of injuries in the championship was high with the majority of injured athletes requiring medical attention and a number of injured athletes being unable to continue in the game. Player contact was the commonest cause of injury during the tournament and may have an implication on game rules modification. This is apparently the first study to report the injury data during international floorball tournament. More studies are warranted to gain further insights into the cause and mechanisms of sports injuries during international floorball tournaments. References Pasanen K, Parkkari J, Kannus P et al. ### MO-PM36 Training and Testing: Strength and neuromuscular physiology

#### PERIODIZED MAXIMUM STRENGTH AND POWER TRAINING-INDUCED CHANGES IN MUSCLE ACTIVATION LEVEL AND CONCOMITANT CHANGES IN FORCE PRODUCTION

Peltonen, H., Walker, S., Väänänen, J., Koskinen, O., Häkkinen, K., Avela, J.

*University of Jyväskylä*

INTRODUCTION The interpolated twitch technique is a widely used method to determine changes in activation level (AL) of the neuromuscular system. Thus, it represents central and peripheral contributions to force production during maximal isometric contraction (MVC). However, the use of the interpolated twitch technique to distinguish training mode specific adaptations has recently been questioned (Taylor 2009). METHODS 23 healthy and physically active, but non-strength trained men performed 16 weeks of periodized strength training. The intervention included the first 4 weeks of muscle endurance (ME) training as a control period and after that the periods of maximum strength (MS)(8 wk) and power (P) training (4 wk). Training consisted of exercises for the whole body 2-3 sessions per week, but lower limbs were trained in every session. The measurements were performed at 0, 4, 12, and 16 weeks and consisted of; 1) maximum dynamic leg press strength (1RM), 2) explosive power at 60% 1RM load in leg press, 3) maximal rate of leg extension force development over the 10ms (RFD), and 4) maximum voluntary isometric knee extension using the interpolated twitch technique to the femoral nerve. RESULTS 1RM, power and RFD improved during the whole intervention ( $22 \pm 11\%$ ,  $P=0.001$ ;  $14 \pm 7\%$ ,  $P=0.001$  and  $17 \pm 39\%$ ,  $P=0.05$ ), respectively. MS training did not change AL ( $-0.8 \pm 2.5\%$ ), but during the following P training (week 12-16) AL decreased significantly ( $-2.1 \pm 3.0\%$ ,  $P=0.03$ ) with concomitant decreases in MVC ( $-7.5 \pm 13\%$ ,  $P=0.08$ ). Resting twitch-induced peak force increased during the MS training (week 4-12) compared to ME (week 0-4) ( $+13 \pm 15\%$  vs.  $-0.2 \pm 17\%$ ,  $P=0.03$ ) and P training periods ( $-5.1 \pm 13\%$ ,  $P=0.002$ ). DISCUSSION P training, after MS training mode, decreased AL, which reflects neural deficit during MVC. Electrical stimulation activates all motor units nonselectively, when P training aims to activate mainly fast ones. On the other hand, MS training improved force production capacities of peripheral components in a resting condition, which might contribute to increased muscle size. Traditionally, periodized MS and P training are associated to neural adaptations due to training (Fleck & Kraemer 1987) and in the present study they improved both dynamic and isometric fast force production. These results are in-line with previous observations, however ITT may not be the best method to characterize the extent of neural drive due to training with the intention of fast movements (Girard 2009). ## RELATIONSHIP BETWEEN MUSCLE POWER PRODUCED IN THE ACCELERATION AND THE DECELERATION PHASE OF TRUNK ROTATIONS WITH DIFFERENT WEIGHTS

Zemková, E., Pořr, O., Hamar, D.

*Faculty of Physical Education and Sports, Comenius University*

**Introduction** In sports like tennis, golf or box involving trunk rotations, high muscle force and power is produced in the acceleration phase of movement. The question remains whether the same effort is created in the deceleration phase, especially when performing with higher weights. This study investigates the associations between mean values of force, power, velocity, and torque in the acceleration and the deceleration phase of trunk rotations with different weights. **Methods** Sixty fit males (age  $21.9 \pm 3.8$  y, height  $177.5 \pm 7.7$  cm, weight  $84.7 \pm 12.3$  kg) completed two trials of trunk rotations to each direction (either from right to left or from left to right) in a standing position with a bar weight of 1, 5.5, 10.5, 15.5, and 20 kg placed on the shoulders. They were instructed to perform trunk rotations with maximal effort during both the acceleration and the deceleration phase. The FITRO Torso Dyne was used to monitor basic biomechanical parameters throughout the movement. The system consists of an inertia measurement unit in a small box with an integrated USB interface and software. While inserted on the barbell axis, the sensor unit registers instant angular of rotation movement. Calculations of force and power are based on the Newton's second law of mechanics. Force produced to accelerate and decelerate a rotation movement is obtained as a product of barbell mass and acceleration of its center of gravity (CoG). Angular acceleration is obtained by derivation of angular velocity. For the transformation of angular velocity and acceleration into their real values, a rotation radius (distance between rotation axis and barbell mass CoG) is used. Power is calculated as a product of force and velocity. **Results** Significant negative correlations ( $r$ ) were found between mean power in the acceleration and the deceleration phase of trunk rotations with weights of 1 kg ( $-0.77$ ,  $p < 0.01$ ), 5.5 kg ( $-0.78$ ,  $p < 0.01$ ), 10.5 kg ( $-0.82$ ,  $p < 0.01$ ), 15.5 kg ( $-0.90$ ,  $p < 0.01$ ), and 20 kg ( $-0.92$ ,  $p < 0.01$ ). Significant negative associations were also observed between mean force as well as mean torque in the acceleration and the deceleration phase of trunk rotations. In both cases  $r$  values ranged between  $-0.56$  ( $p < 0.05$ ) and  $-0.78$  ( $p < 0.01$ ). However, significant positive correlations ( $r$ ) were detected between mean velocity in the acceleration and the deceleration phase of trunk rotations ranging from  $+0.64$  to  $+0.84$  ( $p < 0.01$ ). **Discussion** These findings indicate that when attempting to perform a powerful rotational movement of the trunk and maximize its velocity over the entire range of motion, muscle power is not significantly different in the acceleration and the deceleration phase, regardless of weight applied. ## EVALUATION OF TRAINING LOAD DURING SUSPENSION TRAINING: IS SESSION-RPE A VALID METHOD?

Giancotti, G.F.1, Foster, C.2, Pezzotta, C.1, Lecce, D.1, Rodio, A.1, Capranica, L.3, Cortis, C.1

*1 University of Cassino and Lazio Meridionale; 2 University of Wisconsin-La Crosse; 3 University of Rome "Foro Italico"*

**Introduction** Suspension training (ST) has become a popular form of bodyweight resistance training, eliciting higher muscle activations with respect to traditional exercises secondary to muscle activity used to maintain body stability and balance (McGill et al, 2014; Snarr et al, 2014). To quantify training load, Rating of Perceived Exertion (RPE) and session-RPE (s-RPE) are widely used in sport activities. However, only a few studies have investigated the applicability of s-RPE in fitness activities (Cortis et al, 2013). Therefore, the aim of this study was to validate the use of s-RPE in ST using summated heart rate (HR) zone (Edwards-HR) as a criterion method. **Methods** Following informed consent, 8 women (age:  $30.5 \pm 11.5$  years; height:  $165.8 \pm 4.8$  cm; weight:  $59.2 \pm 3.4$  Kg; BMI:  $21.6 \pm 1.4$ ) regularly practicing ST (3 weekly sessions for previous 6 months) participated. During 6 different training sessions, s-RPE was recorded for each subject 30-min following the exercise session, and training LOAD calculated multiplying s-RPE (CR-10 scale) by training duration in minutes (Foster et al, 2001). Edwards-HR was determined using HR recorded during training and expressed as % age predicted maximal HR (HRmax). The product of accumulated training duration (minutes) in 5 HR zones by a coefficient ( $50\text{-}60\% \text{HRmax}=1$ ,  $60\text{-}70\% \text{HRmax}=2$ ,  $70\text{-}80\% \text{HRmax}=3$ ,  $80\text{-}90\% \text{HRmax}=4$ ,  $90\text{-}100\% \text{HRmax}=5$ ), was computed and summated. The relationship between s-RPE and summated HR zone was analyzed by Pearson correlation ( $p < 0.05$ ). **Results** Subjects perceived ST as hard (RPE= $5.7 \pm 1.8$ ), with high occurrence of  $\text{HR} > 70\% \text{HRmax}$  ( $72.3 \pm 9.8\% \text{HRmax}$ ). A significant ( $p=0.001$ ) very large ( $r=0.71$ ;  $R^2=0.51$ ;  $95\% \text{ CI}=0.32\text{-}0.90$ ) correlation was observed between training LOAD (s-RPE [ $222.7 \pm 73.5$  AU]) and Edwards-HR ( $109.9 \pm 32.1$  AU). **Discussion** Results suggest that ST could be classified as a moderate-to-vigorous intensity exercise according to ACSM guidelines (2014). Further, s-RPE can be used in ST to quantify training LOAD, helping the instructors evaluate training session more simply. **References** ACSM 2014, Guidelines for Exercise testing and prescription. 9th Ed. ## MUSCULAR ACTIVITIES DURING NORMAL, SPEED, AND JUMP BASED PUSH UP EXERCISE

Song, S.H., Kim, A.R., Lee, H.S.

*Dankook University*

Although the bench press usually requires expensive equipment, the push up can be performed anywhere (Calatayud et al., 2015). The push up is a popular exercise that is performed with the purpose of increasing and hypertrophy of upper extremity musculature (Uhl et al., 2003). Though extensive knowledge regarding push-ups performed in a dynamic regime, we know little about the same exercise when it is carried out different method. It is clear that plyometric push up provide an effective way of improving maximum force and muscular power (Vossen et al., 2000) but there has been no systematic study examining the concentric(CON) and eccentric(ECC) phase. We hypothesize that speed and jump push up exercise induces higher ECC muscleactivities than normal push up. Twenty four healthy males were randomly divided to speed push up group (spe-G  $n = 8$ ), Jump push up group (jum-G,  $n = 8$ ), or control group (nor-G,  $n=8$ ). Push up exercises performed maximum speed (spe-G), maximum jump (jum-G) and ECC (I-s) and CON (I-s) contraction (nor-G) during ECC and CON contraction. All subjects were performed one set of push up exercise to volitional repetition failure in each of the three conditions. The sEMG root mean square amplitude at first, middle, and last were recorded in the pectoralis major, triceps brachii and anterior deltoid during the push up exercise. The sEMG data were normalized to those obtained maximal voluntary contraction of each muscle (%MVC) in both ECC phase and CON phase. Compared with CON, first, middle, and last amplitude in the ECC were significantly higher muscle activities of the pectoralis major, triceps brachii, and anterior deltoid in the spe-G and jum-G. In contrast, first amplitude in the ECC were significantly lower than CON in the nor-G. It has been well-documented that eccentric contraction may elicit greater strength adaptation, muscular hypertrophy and force capabilities compared with concentric contraction (Kelly et al., 2015). In this study, we consider that speed and jump push up exercise may be effective muscle training to improving force and muscular strength, probably due to increased activity in eccentric contraction. ### THE ANALYSIS OF YOUNG TENNIS PLAYERS UPPER EXTREMITY MUSCLE STRENGTH CONTRA-LATERAL IMBALANCE DURING A ONE YEAR STUDY

Zusa, A., Lanka, J., Cupriks, L.

*Latvian Academy of Sport Education*

Introduction Tennis is an asymmetric sport and it could influence young player's locomotor system evaluation. To have a success in any sport, an athlete needs to have a specific muscle strength topography, but on the other hand it's important to work with muscles not specific to tennis, to avoid a critical level of muscle strength imbalance. This question is twice as important when we speak about young tennis players, because their locomotor system is in active developing stage. The aim of the study was to evaluate contra-lateral muscles strength imbalance level in upper extremities for 11-12 years old tennis players during a one year study. Methods Shoulder, elbow and wrist joint muscle maximal isometric strength torque were measured by isokinetic device REV-9000 (Italy). Participants of the study were three right handed young tennis players (weight  $47.0 \pm 6.6$  kg, height  $164.0 \pm 6.0$  cm). The dynamics of the results were analyzed individually as well as for the entire group. Results We found contra-lateral imbalance in shoulder joint internal rotators (27%), external rotators (26%) and wrist supinators (41%). During a one year period the biggest trends in the increase of the muscle strength were observed in shoulder joint adductors (45% for right and 65% for left hand) and abductors (27% and 29%), internal (18% and 32%) and external (38% and 47%) rotators. Discussion It is verified that during a period of 11-12 years children's physiological features don't evaluate much muscle strength increasing (Degache et al., 2010). This fact allows us to assume that increase of the muscle strength could be connected with performing a regular physical exercise and tennis practice influence (Zuša et al., 2012; Saccol et al, 2010; Chandler et al, 1992). References Chandler T.J., Kibler W.B., Stracener E.C., Zeigler A.K., Pace B. Shoulder strength, power and endurance in college tennis players. Am J Sport Med, 1992, Vol. 20, 455 – 458. ### POST-ACTIVATION POTENTIATION VS. FATIGUE USING TWO ISOMETRIC STRENGTH TRAINING PROTOCOLS: EFFECTS ON TWITCH TORQUE

Patikas, D., Xenofondos, A., Bassa, E., Hatzikotoulas, K., Vrabas, I.S., Kotzamanidis, C.

*Aristotle University of Thessaloniki, Greece*

Introduction Post-Activation Potentiation (PAP), defined as an enhancement in muscle twitch properties after a conditioning contraction, gains research interest during the past years. Our knowledge and understanding on the relationship between PAP and fatigue is limited, due to lack of systematic comparisons between different conditioning stimuli in similar settings, as used in isometric strength training sessions. Limited studies have examined twitch torque during a series of isometric maximal voluntary contractions (iMVC; Hamada et al., 2003; Hicks et al., 1991; Mettler and Griffin, 2012). However, these protocols cannot be characterized as typical strength training protocols. Methods Professional male handball players (n=14) were tested for PAP before and during isometric strength training protocols, consisted of 4x6 maximal plantar flexions of 3 or 6s duration (P3 or P6, respectively) with 15s interval between repetitions and 2min between sets. Sessions were assessed in separate days, after familiarization, in random order. After warm-up, twitch torque was collected every 30s, for 5 minutes before the protocols and between repetition/set intervals, starting 2s after each iMVC. PAP was expressed as % of change relative to the values recorded before the protocols. PAP after the 1st, 6th repetition of each set, as well as the best repetition in PAP within each set were analyzed for each protocol and set, using 2-way ANOVA, with  $\alpha$  set at 0.05. Results PAP on average for all sets, was higher in P6 vs. P3 when evaluating the 1st repetition ( $78.6 \pm 7.1$  vs.  $67.8 \pm 5.2\%$ ,  $p < 0.05$ ) and in P3 vs. P6 when evaluating the last one ( $86.9 \pm 6.7$  vs.  $73.9 \pm 5.8\%$ ,  $p < 0.05$ ). When evaluating the best trial in PAP, no differences in PAP in P3 vs. P6 were observed ( $92.3 \pm 6.1$  vs.  $91.3 \pm 7.2\%$ ,  $p > 0.05$ ). For the 1st repetition P6 had more PAP compared to P3 for the sets 1 and 2. In contrast, for the 6th repetition P3 was superior to P6 in PAP for sets 3 and 4. For the best in PAP repetition, P6 and P3 showed more PAP than P3 and P6 during the first and last set, respectively. Discussion P6 shows high PAP during the first repetitions of the first 2 sets, but P3 shows milder PAP effect for a longer period along the training session. However, both protocols have on average the same potential for PAP. The clear PAP vs. fatigue interaction that we demonstrate has many implications in setting training programs and experimental designs investigating PAP. ### ADAPTATIONS IN MOTONEURON AND MOTOR UNIT PROPERTIES TO THE CHRONIC COMPENSATORY MUSCLE OVERLOAD

Krutki, P., Krysiak, K., Drzymala-Celichowska, H., Mrowczyński, W., Haluszka, A., Celichowski, J.

*University School of Physical Education*

Introduction The most prominent response to overload is muscle hypertrophy, reflected in the increase of muscle mass, cross-section area, and the increased strength. The aim of the study was to determine whether chronic muscle overload has measurable effect on electrophysiological properties of motoneurons (MNs), and the force regulation of motor units (MUs). Methods The compensatory overload was induced in the rat medial gastrocnemius (MG) by bilateral tenotomy of its synergists (lateral gastrocnemius, soleus, and plantaris); as a result, only the MG was able to evoke the foot plantar flexion. To assure regular activation of the MG muscle, rats were placed in wheel-equipped cages and subjected to a low-level treadmill exercise. Electrophysiological experiments were performed after 12 weeks of the overload, and in a control group of intact rats. Results Some of the membrane and rhythmic firing properties were considerably modified in fast-type MNs, while remained unaltered in slow-type MNs. The significant changes included a shortening of the spike rise time, an increase of the AHP amplitude, an increase of the input resistance, a decrease of the rheobase, and a decrease of the minimum current necessary to evoke steady-state firing. The data suggest higher excitability of fast-type MNs innervating the overloaded muscle, and a shift towards electrophysiological properties of slow-type MNs. MUs after overload were able to produce higher absolute tetanic

forces than under normal conditions, but achieved the same relative force level at higher frequencies than control. Increase in motoneuronal stimulation frequency in fast MUs evoked considerably higher force increase in comparison to control, while the reverse effect could be observed in slow MUs. All three MU types responded to muscle overload unequally and likely transformational changes of muscle fibers took place. Discussion The observed adaptations in mechanisms of MU force development and whole muscle force regulation coincide with altered activity of motoneurons. Adaptations in motoneuron properties have implications for the force output of fast MUs and for the recruitment process. Therefore, initial MU composition of a muscle forms a base to predict desired effects of overload, which also depend on magnitude and duration of loading and activation pattern of the involved muscle. All these relations should be considered when planning strategies for maintaining or increasing muscle mass and strength. This is important both during training and in tailored rehabilitative interventions after debilitating muscles or nerve injuries. ## INVESTIGATION OF THE NEUROMUSCULAR CONTROL AND PLASTICITY OF INTRINSIC FOOT MUSCLE ACTIVATION IN HUMAN

Mileva, K.1, James, D.1, Solan, M.2

1: London South Bank University (London, UK); 2: Royal Surrey County Hospital (Guildford, UK)

Introduction Effective neuromuscular control of intrinsic foot muscles is essential to stabilise the tarsal and metatarsal bones during locomotion. Nevertheless, there is little knowledge concerning their neural connectivity. Thus, this study aimed to evaluate the strength of corticospinal pathways to an intrinsic foot muscle and the potential to induce neuromuscular plasticity via electrical muscle stimulation. Methods EMG and twitch responses to peripheral nerve (PNS) and transcranial magnetic (TMS) stimulation were recorded in m. abductor hallucis (AH) of 10 healthy male volunteers (mean±SD; 29±9y; 81.3±9kg; 179±5cm). Patterns of high (100Hz) and low (20Hz) frequency low-intensity wide-pulse (1ms, WPS) electrical stimuli were delivered for 30-min to the muscle (James et al., 2012). PNS (Digitimer) of the medial plantar nerve and TMS (Magstim) of the motor cortex area related to the right-side lower limb muscles (Bowtell et al., 2013) were performed prior to, immediately and 30-min after the intervention. Stimulation intensities were optimized by constructing the input-output recruitment curves. EMG responses to multiple single pulses of suprathreshold intensity (PNS: 130%; TMS: 150%) were averaged to quantify peripheral (maximal muscle compound action potential, Mmax) and corticospinal (motor evoked potentials, MEP) excitability. Time-amplitude parameters of the twitch responses were extracted for analysis of muscle contractility. Data were expressed as relative to baseline for statistical comparisons. Results Resting AH MEP threshold was achieved at 46±10.5% (max Magstim output) and Mmax was reached at 11.6±2.3mA PNS, (200µs pulse duration). Mmax amplitude (8.3±4.1mV) remained unchanged post- and 30-min after WPS whilst an increase in excess of 10% was seen in the MEP amplitude (1.3±0.6mV) and MEP/ Mmax ratio (18±8%). WPS session reduced the twitch amplitude (4.1±1.5N) and prolonged the twitch contraction (20±20%) and relaxation (20±14%) times (all p<0.05), suggesting decreased AH contractility. Discussion The observed MEP facilitation at the background of a decreased muscle contractility imply WPS-evoked augmentation in the neural input to AH, which was maintained for at least 30-min after intervention. Enhanced excitability of corticospinal circuits suggests potential for neuroplasticity, which is likely to facilitate improved motor function. Therefore, WPS may be a useful complementary technique for strengthening of the intrinsic foot musculature via neural plasticity. #### THE EFFECTS OF TENNIS ON QUADRATUS LUMBORUM MUSCLE IN CHILDREN: A VOLUMETRIC MRI STUDY

Sanchis-Moysi, J., Idoate, F., Dorado, C., Calbet, J.A.L.

Instituto Universitario de Investigaciones Biomédicas y Sanitarias (IUIBS), Las Palmas de Gran Canaria University (Spain); Radiology Department, Clínica San Miguel (Pamplona, Spain)

Introduction At a professional level, tennis induces the asymmetric hypertrophy of quadratus lumborum (QL) muscles [1]. The purpose of the present study was to assess if tennis is associated with the asymmetric hypertrophy of QL at prepubertal ages. Methods Magnetic resonance imaging (MRI) was used to determine the volume of QL in 7 male prepubescent tennis players (TP; 11.0 years) and 10 male non-active controls (11.0 years), all Tanner 1-2. The MRI images (L1-L2 intervertebral disc to pubic symphysis) were used to calculate the volume of QL. Differences between sides were assessed using Student's paired t-tests. Significant differences were assumed when P<0.05. Results In TP the volume of QL was greater in the non-dominant than in the dominant side (30.8±5.7 vs 26.2±7.0 cm<sup>3</sup>, respectively, P<0.05), whilst in control group non-dominant and dominant QL had similar volumes (26.1±5.6 vs 25.5±6.0 cm<sup>3</sup>, respectively, P=0.38). Discussion The asymmetry of QL in TP (15%) may be attributed to the forces generated to rotate and laterally flex the trunk over the non-dominant side during tennis strokes. Interestingly, in professional tennis players QL was symmetric side-to-side [1]. Trunk lateral flexion and rotation forces acting during the tennis serve are less consistent in pre-pubescent than in adolescent or adult tennis players [2]. The greater forces generated by the dominant QL during the tennis serve in adulthood might compensate the asymmetry observed in childhood [1]. In physically non-active children QL was symmetric side-to-side. In adult non-athletes non-dominant QL had 13% greater volume than dominant QL [1]. Daily living activities might increase the degree of asymmetry of QL as we age. The asymmetry of QL lead to unbalances in the forces acting on the lumbar spine which has been associated to low back pain in adulthood [3]. Conclusion Regular tennis practice at prepubertal ages induces the asymmetric hypertrophy of QL changing the pattern of hypertrophy observed in physically non-active children. ## RELATIONSHIP BETWEEN CONTRACTION INTENSITY AND MUSCLE HARDNESS ASSESSED BY REAL-TIME TISSUE ELASTOGRAPHY FOR THE ELBOW FLEXORS AT DIFFERENT JOINT ANGLES

Inami, T.1, Murayama, M.2, Shima, N.3, Nosaka, K.4

1: Waseda University (Japan), 2: Keio University (Japan), 3: Tokai-Gakuen University (Japan), 4: Edith Cowan University (Australia)

**Introduction** Elastography is used to assess muscle hardness, and the relationship between muscle contraction intensity and muscle hardness has been examined. For example, Yoshitake et al. [1] reported that biceps brachii muscle hardness assessed by shear wave elastography increased linearly from 15% ( $\approx 50$  kPa) to 60% ( $\approx 200$  kPa) of the maximal voluntary contraction (MVC) strength at 90° elbow flexion. Another type of elastography known as real-time tissue elastography (RTE) has also been used to assess muscle hardness, but no previous study has investigated the relationship between muscle contraction intensity and muscle hardness at different depths of muscle using RTE. The present study investigated the effects of contraction intensity and elbow joint angle on muscle hardness of biceps brachii at different layers of the muscle using RTE. **Methods** Sixteen men performed isometric contractions of the elbow flexors at 15, 30, 45, 60% of their MVC strength at 90°, 60° and 30° elbow flexion, in this order. Up to 45 elastograph images were recorded by RTE (Prosound F75, Hitachi Aloka Medical, Japan) while gently pressing a probe attached with a reference material (acoustic coupler, 22.6 Kpa), over biceps brachii mid-belly during the middle 3 s of 5-s sustained contraction. In an image, a circular ( $\phi=5$  mm) region of interest (ROI) was set in the coupler and the muscle at every 5-mm layer from surface to deep muscle, and a large ROI ( $\phi=30-50$  mm) was also set to include whole biceps brachii. Using a built-in software, strain ratio (SR: muscle/acoustic coupler) was calculated for each image. Changes in SR from 15-60% MVC were compared between the elbow joint angles and the different depths of ROI by two-way repeated measures ANOVA. Results SR in whole muscle decreased ( $P<0.05$ ) from 15% (90°:  $0.29 \pm 0.13$ , 60°:  $0.28 \pm 0.18$ , 30°:  $0.30 \pm 0.12$ ) to 60% MVC (90°:  $0.10 \pm 0.04$ , 60°:  $0.09 \pm 0.04$ , 30°:  $0.08 \pm 0.04$ ), but no significant intensity x angle interaction effect was evident. SR of deep layers ( $>25$  mm) was low even at low intensity contractions (e.g. 30-35 mm, 15% MVC,  $0.01 \pm 0.01$ ), and did not change with increasing in the contraction intensity. **Discussion** The effect of elbow joint angle was minor for the changes in muscle hardness, and SR did not change at deeper layers of the muscle with increasing the contraction intensity for biceps brachii muscle. This may be due to the limitation of RTE (e.g. deformation does not affect deep regions). Further study is necessary to investigate region specific muscle hardness using shear wave elastography. **References** 1) Yoshitake et al. (2014) *Muscle Nerve* 50:103-113. ## ACUTE EFFECT OF DIFFERENT WARM-UP PROTOCOLS ON MECHANICAL PROPERTIES OF THE BICEPS BRACHII MUSCLE IN HEALTHY SUBJECTS

Yu-Jen, C., Pei-Hsi, C.

KAOHSIUNG MEDICINE UNIVERSITY

**Introduction** Warm-up exercise before physical activity or sports competition is a well-accepted and recommended method to enhance sports performance and reduce the susceptibility of musculoskeletal injury (Bishop, 2002). Previous study indicated that different types of warm up exercise will affect the performance of exercise capacity (Holt et al., 2008). Most studies have investigated the effects of different types of warm up exercise on sports performance, but the change of mechanical properties of the skeletal muscle are not fully understood. The aim of this study is to examine the acute effect of different warm-up protocols on mechanical properties of the biceps brachii muscle. **Methods** Six participants (mean age  $20.7 \pm 1.0$ ) were included in this study. All participants completed three warm up sessions (general dynamic, static stretching, and whole body vibration) in randomly assigned order. Myoton Pro (Model #, Name of the company, State/Country of the company) was used to measure three mechanical properties including muscle tone (frequency), elasticity (decrement) and stiffness (stiffness) before and after each warm up session. Each subject performed three trials in a randomized, cross-over design, with trial separated by at least 1 day. **Results** After general dynamic (GD), there was no significant change on mechanical properties of the biceps muscle. After static stretching (SS), the values of frequency ( $p=0.025$ ) and stiffness ( $p=0.019$ ) were significantly decreased after intervention. On the contrary, whole body vibration (WBV) significantly increased the values of frequency ( $p=0.015$ ) and stiffness ( $p=0.009$ ). The decreasing values of frequency and stiffness in SS were significant higher than WBV ( $p=0.009$ ;  $p=0.007$ ) and GD ( $p=0.005$ ;  $p=0.024$ ). **Discussion** The results showed that static stretching (SS) was the most effective warm up method on decreasing muscle tone and stiffness. Previous studies had shown that static stretching (SS) improved muscle flexibility and preventing musculotendinous injuries, however, it also reduced the strength and power performances (Veevo et al., 2012). Further examination of muscle strength on different mechanical characteristics could be performed in future. **References** Bishop, D. (2002). *Sports Med*, 33(6), 439-454. Holt BW, Lambourne K. ## RESTING MUSCLE HARDNESS OF BICEPS BRACHII ASSESSED BY A PRESSURE METER IN COMPARISON TO REAL TIME ELASTOGRAPHY

Murayama, M.1, Nosaka, K.2, Inami, T.3, Shima, N.4, Yoneda, T.5

1: Keio Univ. (Japan), 2: Edith Cowan Univ. (Australia), 3: Waseda Univ. (Japan), 4: Tokai-gakuen Univ. (Japan), 5: Juntendo Univ. (Japan)

**Introduction** Muscle hardness is often assessed by a pressure meter (PM) that measures the force against the pressure applied to the tissue [1]. This method has revealed that muscle hardness is related to mechanical property of muscle fibers and/or muscle volume [1]. Recently, many studies use ultrasound elastography to evaluate muscle hardness [2]; however, the relationship between muscle hardness assessed by PM and elastography is not clear. The present study compared the muscle hardness measured by PM and that by real-time tissue elastography (RTE). **Methods** Resting biceps brachii muscle hardness was assessed by a pressure meter (TK-HS100, Tokushu-keisoku, Japan) and by RTE (Prosound F75 ; Hitachi Aloka Medical, Japan) for both arms of 21 young men. Each subject lay on his back on a bed relaxing his upper arm, and a PM probe was applied to the mid-belly of biceps brachii. To measure muscle hardness by PM, the displacement-force curve was divided into subcutaneous and muscle component from B-mode ultrasound images, then muscle hardness value (E) was calculated using the slope at a specific depth of the muscle component. In RTE measurement, a transducer was positioned on the mid-belly to obtain elastograph images, and several region of interest (ROI) were set in the biceps brachii, and strain ratio (SR) between the reference coupler placed on the top of the transducer and ROI was calculated ( $SR=1.0$ : the same hardness between muscle and the coupler  $<22.6$  kPa>). The relationship between E and SR was analysed by a Pearson's product moment, and several regression analyses. **Results & Discussion** Among several E values obtained, it appeared that the value at 40% of muscle thickness (E40%) was most reliable. E40% ranged from 16.3 to 65.8 kPa, and SR of the same region ranged from 0.34 to 2.35 (7.7 to 53.1 kPa). The correlation coefficient between SR and E40% was significant ( $r=-0.64$ ,  $R^2=0.40$ ,  $P<0.001$ ), but the correlation was not strong. The

relationship between SR and E40% was fitted better to an exponential curve ( $SR=26.8 \cdot E40\%^{-0.445}$ ), but the coefficient was 0.50. Other regression analyses using different E values from different depths of the muscle provided the coefficients less than -0.64. This suggests that the muscle hardness assessed by PM and RTE is different. One of the reasons for this may be the difference in the magnitude of muscle deformation during the measurement such that muscle tissue was deformed approximately 25 mm in depth for the PM measure, but was slightly deformed for the RTE measure. ## COMPARISON OF MUSCLE ELASTICITY BETWEEN PASSIVE AND ACTIVE CONDITION

Kato, E., Chino, K., Takahashi, H.

*Japan Institute of Sports Sciences*

**Introduction** Muscle elasticity can indicate muscle condition objectively (Yanagisawa et al. 2011) and it is determined from ultrasound shear imaging. Muscle elasticity is affected by muscle architecture, especially a degree of pennation angle. Also, in the case of active condition (exert torque by muscle contraction), muscle elasticity depends on the number of cross-bridge (the myosin heads attach to the actin filaments, Herzog 2007). In this way, there is a different causation which influences on muscle elasticity between passive and active condition. **PURPOSE** To compare the muscle elasticity of the plantar flexor muscle at an identical tendon force level of plantar flexion, between passive and active condition. **METHODS** The healthy men completed both passive and active condition tasks. In the passive condition, subject sat on the seat of dynamometer and seat their ankle joint was fixed to the foot-plate. Their ankle joint was rotated passively and passive torque was recorded at six different ankle joint angles (from 30° of plantar flexion to 20° of dorsiflexion, in each 10°). In the active condition task, subject exerted isometric plantar flexion torque under submaximal condition at 0° of ankle joint angle. Because ankle joint angle was different between passive and active condition to consistent tension of both conditions. We calculated tendon force using the value of moment arm (Maganaris et al. 2000). The target torque was adapted an identical of tendon force with maximal the passive torque in the passive condition task. Muscle fascicle length, pennation angle and elasticity of the medial gastrocnemius were measured by ultrasound shear imaging. **RESULTS** The values of tendon force and muscle elasticity were not significantly different on both conditions (tendon force:  $614 \pm 252$  N and  $638 \pm 270$  N, for passive and active condition, respectively,  $p=0.820$ , Muscle elasticity:  $158.4 \pm 33.8$  kPa and  $152.5 \pm 42.9$  kPa, for passive and active condition, respectively,  $p=0.739$ ). In addition, fascicle length in passive condition was longer than in active condition ( $63.0 \pm 6.4$  mm and  $49.4 \pm 7.1$  mm for passive and active condition, respectively,  $p<0.001$ ) and pennation angle was smaller ( $19.5 \pm 2.0^\circ$  and  $26.7 \pm 5.5^\circ$  for passive and active condition, respectively,  $p<0.01$ ). **CONCLUSION** Although there are different conditions in muscle architecture between passive and active condition, muscle elasticity did not different at an identical tendon force level. **References** Herzog W. ## EVALUATION OF FORCE-VELOCITY AND POWER-VELOCITY RELATIONSHIP OF ARM MUSCLES

Nedeljkovic, A.1, Sreckovic, S.1, Cuk, I.1, Djuric, S.1, Mirkov, D.M.1, Jaric, S.2,3

1: UB-FSVV (Belgrade, Serbia), 2: DKAP (Newark, Delaware, USA), 3: BMS-GPB (Newark, Delaware, USA).

**Introduction** A number of recent studies have revealed an approximately linear force-velocity (F-V) and, consequently, a parabolic power-velocity (P-V) relationship of multi-joint tasks (Yamauchi et al. 2009; Bobbert 2012; Samozino et al. 2012; Cuk et al. 2014). However, the measurement characteristics of their parameters have been neglected, particularly those regarding arm muscles, which could be a problem for using the linear F-V model in both research and routine testing. Therefore, the aims of the present study were to evaluate the strength, shape, reliability and concurrent validity of the F-V relationship of arm muscles. **Methods** Twelve healthy participants performed maximum bench press throws against the loads ranging from 20 to 70% of their maximum strength and linear regression model was applied on the obtained range of F and V data. The linear regressions directly revealed the maximum F (F-intercept;  $F_0$ ) and regressions slopes (a). They enabled the calculation of the maximum V (V-intercept;  $V_0=F_0/a$ ) and the maximum P outputs ( $P_0 = (F_0V_0)/4$ ). The P-V relationship was assessed by solely applying the parabolic model presuming that the F-V relationship is linear. One-repetition maximum bench press and medicine ball throw tests were also conducted. **Results** The observed individual F-V relationships were exceptionally strong ( $r = .96-.99$ ; all  $p<0.05$ ) and fairly linear, although it remains unresolved whether a polynomial fit could provide even stronger relationships. The reliability of parameters obtained from the linear F-V regressions proved to be mainly high ( $ICC>0.80$ ), while their concurrent validity regarding directly measured F, P, and V ranged from high (for maximum F) to medium-to-low (for maximum P and V). **Discussion** The findings add to the evidence that the linear F-V and, consequently, parabolic P-V models could be used to study the mechanical properties of muscular systems, as well as to design a relatively simple, reliable, and ecologically valid routine test of the muscle ability of force, power, and velocity production. Future studies could focus upon the shape of F-V relationship of other tasks and the measurement properties of the obtained parameters. Generalization of the observed findings to other multi-joint tasks is also needed. **References** Yamauchi J, Mishima C, Nakayama S, Ishii N (2009). *J Biomech* 42(13), 2151-2157. ## MUSCULOTENDINOUS MECHANICAL PROPERTIES AND LOWER LIMB MORPHOLOGY IN TRACK AND FIELD ATHLETES

Hisano, T.1, Kusumoto, K.2, Sano, K.1, Makino, A.1, Maitani, A.3, Kunimasa, Y.1, Akihara, Y.3, Oda, T.3, Ishikawa, M.1

1:OUHS(Osaka,Japan), 2:KUSA(Okayama,Japan), 3:HUTE(Hyogo,Japan)

**Introduction** Training methods and types of the movements of track and field athletes are different depending on athletic events. It is expected that mechanical properties of muscles and tendons would be affected by different track and field events. Therefore, the purpose of this study was to examine mechanical properties of both muscle and tendon tissues of triceps surae for different competitive track and field athletes. **Methods** Eleven sprinter (SP: 19 ± 1 years, 1.74 ± 0.05 m, 61.7 ± 5.6 kg), 12 long-distance runners (LD: 20 ± 1 years, 1.70 ± 0.07 m, 55.8 ± 6.6 kg), 12 jumper (JU: 20 ± 1 years, 1.75 ± 0.05 m, 64.7 ± 3.8 kg) and 8 thrower (TH: 20 ± 1 years, 1.73 ± 0.06 m, 84.6 ± 3.6 kg) participated in this study. Passive ankle joint torque were measured during passive dorsiflexion of each 10° from the 20° plantar-flexion position to 10° dorsiflexion position. During passive movements, the fascicle elongation of medial gastrocnemius (MG) was measured by B-mode ultrasonography and then passive muscle stiffness was calculated. By using the same method as Kubo et al. (2001), MG tendinous tissues stiffness was measured during the ramp maximal voluntary isometric planter flexion. The MG fascicle

length, pennation angle and cross-sectional area (CSAAT) of Achilles tendon and patella tendon length, CSAPT were evaluated by B-mode ultrasonography. Results During passive movements (20°→10°), passive stiffness of MG was significantly higher in TH than in all other groups. There were significant differences of the mechanical properties of MG fascicle and tendinous tissues between competitive track and field athletes. The CSAAT was smaller in LD than in all other groups. The CSAPT was significantly higher in SP than in all other groups. Discussion These differences between groups could be related to specific training program to lower legs for each group, such as high impact stress with the short contact time in SP and JU, and low impact stress but high volume in LD, and high impact stress with long contact in TH. ### THE EFFECT OF KINESIO TAPING ON QUADRICEPS PAIN PREVENTION

Hao-Wei, Y.

KAOHSIUNG MEDICAL UNIVERSITY

The Effect of Kinesio Taping on Quadriceps Pain Prevention Yang, H.W. 1, Chou,P.H. 1,2 1 Department of Sports Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan 2 Division of Sports Medicine, Department of Orthopedic Surgery, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan Introduction: Kinesio taping is widely used by rehabilitation professionals in recent years. In the past literatures, the application of Kinesio taping had shown inconsistent results on enhancing functional performance. The purpose of this study is to investigate the effect of Kinesio taping on quadriceps pain prevention. Methods: Twelve subjects (mean age  $\pm$  20.33 ) were randomly divided into two groups: Kinesio taping group (KT), and control group (CT). Kinesio-Taping was applied on vastus medialis, rectus femoris and Vastus lateralis muscle. They were asked to perform concentric contraction to induce muscle fatigue. In both groups, the maximal muscle strength, the Visual Analogue Scale of Pain (VAS-P) were recorded before the concentric contraction, immediately after the concentric contraction and 24 hours after the concentric contraction. Results: The maximal muscle strength of the KT group showed fewer declines than the CT group after concentric contraction. The KT group declines  $3.45 \pm 1.06$  N-m and the CT group declines  $4.28 \pm 2.05$  N-m. The VAS-P showed no significant differences the between two groups. Discussion: The Kinesio taping provided significant proprioceptive enhancement at the knee joint after uphill walking with poor proprioceptive ability. This may support its use in sports medicine for preventing knee injuries. But Chang HY[1], et al indicated Kinesio taping did not change maximal grip strength in either group. The effects of Kinesio taping on muscle maybe consider soft tissue proportion. Conclusion: The Kinesio taping is good for muscle fatigue decline after oncentric contraction that few to decrease maximal muscle strength. But the pain feeling is no improve. References 1. Chang, H.Y., et al., The Effectiveness of Kinesio Taping for Athletes with Medial Elbow Epicondylar Tendinopathy. International Journal of Sports Medicine, 2013. 34(11): p. 1003-1006.

### LONG TERM EFFECTS OF LANDING SURFACE STABILITY ON JUMP PERFORMANCE

Pollitt, L., Bissas, A.

Leeds Beckett University

Introduction Although the direct effect of unstable surfaces on explosive performance may be a reduction in power output due to impaired agonist functioning, the long term effects of unstable training (UST) on stable ground performance have not been investigated. With training, the sensorimotor system may modulate the detrimental compensatory responses on performance by reducing the sensitivity required on a stable surface, thereby allowing greater agonist force production due to reduced shear forces. This study examined the long-term effects of dynamic UST on subsequent stable ground drop jump (DJ) performance. Methods 44 males undertook a 6-week progressive DJ intervention training, randomly assigned to one of 5 groups based on landing surface stability: mini-trampoline (MT), BOSU, MIX (BOSU & stable), stable, or control. In total, participants completed 1080 DJs. Each session involved 4\*5 DJ from 3 drop heights which progressed from 0.2-0.4m (weeks 1&2) to 0.8-1m (weeks 5&6). Testing consisted of 3 maximal DJ at 0.2, 0.6 and 1m onto a Kistler force platform (1000Hz) before and after the training intervention. Instruction was to minimise ground contact time (GCT) while maximising subsequent jump height (JH). Results DJ1.0m: Statistical analysis showed that all groups improved their GCT ( $p < 0.01$ ). For RSI, all training groups significantly improved their performance (MT: 37%, BOSU: 28%, Stable: 25%, MIX: 18%,  $p < 0.01$ ) except for control (-7%). For JH, the performance for all training groups remained unaltered while the control experienced a significant drop in their pre-training values (-18%,  $p < 0.05$ ). DJ0.6m: Significant improvements over time ( $p < 0.01$ ) were found for all groups for GCT and RSI whereas for JH, the post-pre changes for stable (17%) and control (-9.4%) differed significantly ( $p < 0.01$ ) while the other groups remained unchanged. DJ0.2m: Significant improvements over time in GCT were recorded ( $p < 0.01 - 0.05$ ) with BOSU (-75ms) and controls (-80ms) exhibiting the greatest changes while the same trend was noted for RSI. In terms of JH, the post-pre changes for stable (+2.8cm) and control (-4.1cm) differed significantly ( $p < 0.01$ ) with the other groups unchanged. Discussion On the debate about UST, no significant differences in performance measures were observed between stable and unstable (BOSU, MT or MIX) groups. These findings of similar improvements suggest that exposure to UST may be as effective as stable training, which may be of particular interest to athletes in-season when reduced impact loads are necessary. Furthermore, although all groups recorded improvements in GCT across jump heights, JH was impaired in the controls at each height. Therefore, improvements in GCT alone may not represent the whole spectrum of performance adaptations when analysing DJ performance. Contact: l.pollitt@leedsbeckett.ac.uk

### MO-SH14 Sports statistics & Analysis III

#### ACTIVITY PROFILE OF 'LA LIGA' SOCCER PLAYERS DURING A SEASON

Buscà, B.1, López-Llata, J.1, Peña, J.2, Moreno, D.3, Morales, J.1, Solana-Tramunt, M.1

1: FPCEE Blanquerna. Ramon Llull University (Barcelona, Catalunya, Spain), 2: FCE University of Vic (Vic, Catalunya, Spain), 3: Club Joventut de Badalona (Badalona, Catalunya, Spain)

Introduction Distances covered and number of sprints is value information about the activity profile of professional soccer players during a match in a whole season (Di Salvo et al., 2009). The profile is clearly influenced by the playing position and the half period of matches

(Di Salvo, 2007). Fatigue seems to be a great influence on distances covered and number of sprints when comparing the first half and the second (Mohr et al. 2003). The aim of the study was to describe the distances covered and the number of sprints executed by the 'La Liga' players in a whole season. Methods A group of 197 male soccer players (age =  $28.2 \pm 1.8$ , height:  $177.3 \pm 4.8$  cm, weight:  $68.5 \pm 6.9$  kg), members of the different teams of the professional Spanish league, participated in this study. We analyzed the matches of the season 2011-2012. Kinematic parameters of activity were assessed using the Mediacoach System®, the official 3D tracking system of 'La Liga' based on time-motion analysis using 16 cameras that detects the position of players on the field. A descriptive analysis and a profile comparison by playing positions were performed. Results Central midfielders are the position that covers greater distances but not significantly greater than the other field players ( $p > .05$ ). Similar patterns were observed when comparing first half and second half. In respect the distance covered per minute, attackers covered  $10.54 \text{ m}\cdot\text{min}^{-1}$  more than central defenders and  $8.41 \text{ m}\cdot\text{min}^{-1}$  less than central midfielders ( $p < .01$ ). Moreover, lateral defenders covered  $9.92 \text{ m}\cdot\text{min}^{-1}$  more than central defenders and  $9.04 \text{ m}\cdot\text{min}^{-1}$  than central midfielders ( $p < .01$ ). We also found significant differences between positions in number of sprints. Significant differences in distance covered and number of sprints between first and second half were also found. Discussion The findings confirm the differences in distance covered and number of sprints in different playing positions in top-class soccer players (Mohr et al. 2003; Di Salvo et al., 2007). Differences between the profiles were also observed when comparing the first and the second half. In conclusion, different profiles could justify the use of different strategies for conditioning strategies in soccer. ### RELATIONSHIPS BETWEEN EXPERIENCE OF PLAYING GAMES AND THE EXPERT KNOWLEDGE IN FEMALE BASKETBALL PLAYERS

Sakuragi, K., Kiyonaga, A., Hirano, M., Aoyagi, O., Komure, I., Tagata, S.  
*Fukuoka University*

Introduction For proceeding advantageously with a basketball game, it is necessary to understand the tactics of one's own team and opponent team, personal data, and so on. Players need not only to acquire physical and fundamental skills, but also to understand the terminology of basketball and team tactics. Therefore the purpose of this study was to reveal relationships between experience of playing games and the expert knowledge in basketball. Methods 27 females who play basketball at Division I basketball team in Kyushu Collegiate Basketball Federation voluntarily participated in this study. They were divided into 3 groups; 1st group (players in the starting lineup and players with the average playing time for longer than 20 minutes per game:  $n = 10$ ), 2nd group (players with the average playing time for less than 20 minutes per game:  $n = 7$ ), 3rd group (players who had no chance to play during the season:  $n = 10$ ). The expert knowledge for basketball was measured by the test that was created based on the report of Sakaguchi et al.(2009) the test was composed of 39 questions asking the terminologies, rules, and set-play for team's tactics. The total score and the score of each category were calculated for analyzing 3 groups. The one-way analysis of variance was used to test differences in the average score for each question within 3 groups. The multiple comparisons of Bonferroni were used for post hoc test. The significance level was set at less than 5% ( $p < 0.05$ ). Results In the total score and score of the set-play, 1st group showed significantly higher values than 3rd group. ( $p < 0.05$ ). On the other hand, the total score and score of each category were not significantly different between 1st group and 2nd group, and between 2nd group and 3rd group. Discussion 1st group showed high score in all categories. However, there were no significant differences among 3 groups in the terminology and rule for basketball. This result may be due to that terminology and rule are basic knowledge for the basketball players. The reason why the significant difference was observed in the set-play was that 3rd group had less experience for playing the set-play than 1st group. It became clear that the experience of playing games is related to the expert knowledge for basketball. Contact sakuragikimiko@cis.fukuoka-u.ac.jp

### QUANTIFICATION OF NUMBER AND APPEARANCE RATIO OF A BALL CONTROL PLAY FACING OPPONENT'S GOAL IN SOCCER.

Kai, T., Takai, Y., Horio, K., Aoki, T., Kanehisa, H., Yamamoto, M.  
*National Institute of Fitness and Sport in Kanoya*

Introduction In soccer, a play which a field player receives the ball facing the opponent's goal is important for getting a score. However, there was no earlier finding on quantifying the ball control play with relation to wins and losses of matches. The purpose of this study aimed to quantify the ball control play facing opponent's goal with relation to wins and losses of the matches. In this study, a play which a field player receives the ball facing the opponent's goal was defined as oriented control play. Methods Participants were collegiate soccer players. Their 19 official and practice matches were recorded with a video camera (win,  $n = 9$ ; draw,  $n = 5$ ; loss,  $n = 5$ ). From the obtained films, the number of oriented control plays, and shoots within the opponent's goal, which is an index of offensive effectiveness (Harris & Reilly, 1987), were counted for each player. The number of oriented control plays and shoots was divided into playing time of each player, and converted to total number in 90 minutes. Appearance ratio (%) of the oriented control play was expressed as percentage of the number of oriented control plays to total number of the ball receiving plays. Result The results revealed that the number of oriented control plays was higher in win matches ( $14 \pm 10$  times) than in draw ( $11 \pm 12$  times) or loss ( $9 \pm 6$  times) ones. The appearance ratio of the oriented control plays was also higher in win ( $80 \pm 20\%$ ) and draw ( $83 \pm 27\%$ ) matches than in loss ( $74 \pm 24\%$ ) ones. The number of the shoots within the opponent's goal in 90 minutes were 8 for win matches, 5 for draw matches, and 6 for loss matches without the significant differences. The number of shoots within the opponent's goal in win matches was related to the number ( $r = 0.94$ ) and appearance ratio ( $r = 0.58$ ) of oriented control plays with median effect size. Conclusion The number and appearance ratio of oriented control plays is higher in win matches compared to loss matches, and is associated with the number of shoot within the opponent's goal. These findings indicate that the oriented control play is important for getting a score. Reference Harris, S., & Reilly, T. ## EXPLORING GOAL SCORING CERTAINTY IN SOCCER: THE INFLUENCES OF PLAYING LEVEL, PASSING AND SHOOTING SKILLS, AND FATIGUE

Tenga, A., Sigmundstad, E.

*1. Norwegian School of Sport Sciences 2. Sogn og Fjordane University College*

**Introduction** The notion of opposition interaction (Gréhaigne et al., 1997; O'Donoghue, 2009) states that the analysis of performance for invasion games must consider the interaction between the two opposing teams to be more valid. Therefore, goal scoring in soccer can be considered as a process of creating penetration against the opposition defence. In so doing, we managed to distinguish between goals scored under tight defensive pressure (lower scoring certainty) and a more favourable loose defensive pressure (higher scoring certainty) conditions created by the opposing team. Thus, the aim of this study was to investigate the influences of playing level, passing and shooting skills, and fatigue as determining factors of scoring certainty in soccer. **Methods** The sample included 2600 team possessions ended with a goal from seasons 2011, 2012 and 2013 of the Norwegian top professional league (1951 goals) as well as seasons 2011-12 and 2012-13 of the UEFA Champions league (649 goals), after excluding 192 (6.9%) goals from the penalty kicks. The sample was further distinguished into goals scored under tight (984 goals) and loose (1592 goals) defensive pressure conditions prior to goal scoring. Kappa correlation coefficient were used to test inter-observer reliability for all observational variables, while Chi-square analysis and multiple logistic regression were used to determine odds ratio in which the dependent variable was whether or not a goal was scored under loose defensive pressure condition. We used a significance level of  $P < 0.05$  in all tests. Results Kappa correlation values ranged from 0.43 to 0.95 showed acceptable levels of inter-observer reliability for all observational variables used (Altman, 1991). Multiple logistic regression analyses revealed that only passing and shooting skills had influence on whether a goal was scored under a more favourable condition (loose defensive pressure); with scoring from outside the 16 m area showing the greatest influence compared to scoring within the 5 m area (OR=4.91, 95% confidence interval: 3.48 to 6.93,  $P=0.001$ ). The factors of playing level and fatigue showed no significant effect. **Discussion** The results suggest that, regardless of the playing level, the chance to increase goal scoring certainty may increase from 56% to as far as five folds when employing a combination of passing and shooting skills including five or more passing sequences compared to four or less, four or more finishing touches compared to one touch, and making shooting attempt from 16 m compared to 5 m area of the pitch. **References** Altman DG. ## COMPARISON OF PHYSICAL PERFORMANCE AMONG BRAZILIAN YOUNG HANDBALL PLAYERS OF DIFFERENT AGE-CATEGORIES BEFORE AND AFTER CONTROLLING FOR MATURATION

Ramos, M., Souza, C., Luz, T., Medeiros, D., do Carmo, B., Cunha Júnior, A., Luz, L.

*Alagoas Federal Institute (IFAL) - Campus Palmeira dos Índios, Physical Education and Sports Institute - Rio de Janeiro University (UERJ), Alagoas Federal University (UFAL) - Campus Arapiraca*

**INTRODUCTION** The aim of this study was to examine the physical performance among brazilian young handball players of different age-categories before and after controlling for maturation. **METHODS** The sample consisted of 18 and 24 male players of two age-categories, that is, respectively, under 14 (U14) and under 16 (U16) years. Body mass (BM), stature (S), sitting height (SH) and skinfolds of triceps and subscapular were measured. The body mass index (BMI) and body fat percentage (BF%) were calculated. Biological maturation was evaluated by the somatic maturity offset method. The physical performance assessment was performed by six tests: 2-kg ball throw, vertical jump, 30-m dash, 40-s dash, 30-s sit-ups and 20-m shuttle run. Descriptive statistics and Kolmogorov-Smirnov normality test were performed. Student t test was used to compare age groups ( $p < 0.05$ ). Subsequently, analysis of covariance was used to examine groups' differences after controlling for somatic maturation given by maturity offset. **RESULTS** Comparison between age-categories were significant for age (U14: 13,6±0,1 years; U16: 15,7±0,1 years) and maturation (U14: -0,4±0,7 years; U16: 0,8±0,8 years). Among morphological variables, age-categories differences were noted for BM and BMI (U14

## RUGBY UNION MOVEMENT PATTERNS: THE IMPACT OF FATIGUE AND SUBSTITUTE PLAYERS

Tee, J., Lambert, M.I., Coopoo, Y.

*University of Johannesburg*

There is currently limited information on the effect of fatigue and the impact of substitutes on movement patterns in rugby union match play. This study investigated the effect of half on movement patterns of whole game players in different positions (backs and forwards), and how these contrast with substitute players. Global positioning system (GPS) data was collected from 105 professional match participations. Relative distance (m.min<sup>-1</sup>) increased in the second half for whole game players ( $7 \pm 9\%$ ), due to an increase in walking distance (1st  $29.1 \pm 3.9$  vs. 2nd  $34.2 \pm 3.7$  m.min<sup>-1</sup>). High-intensity running distance decreased in the second half for forwards (1st  $10.0 \pm 5.0$  vs. 2nd  $8.6 \pm 3.8$  m.min<sup>-1</sup>), but increased for backs (1st  $10.6 \pm 3.2$  vs. 2nd  $11.4 \pm 2.5$  m.min<sup>-1</sup>). Substitutes demonstrated increased relative jogging (Start  $19.5 \pm 5.0$  vs. Sub  $23.8 \pm 6.3$  m.min<sup>-1</sup>) and striding (Start  $7.9 \pm 2.4$  vs. Sub  $10.6 \pm 5.5$  m.min<sup>-1</sup>) distance versus whole game players. These findings indicate that fatigue may result in reduced high-intensity running distance and that this effect may be managed through the use of substitutes.

## VIDEO BASED NOTATIONAL ANALYSIS OF BALL POSSESSION IN US NATIONAL COLLEGIATE ATHLETIC ASSOCIATION DIVISION I MEN'S LACROSSE

Hauer, R.1, Tschan, H.1, Bauer, P.1, Lames, M.2

*1: University of Vienna, Austria, 2: Technical University Munich, Germany*

**Introduction:** Objective performance measures are important for success in sports. For the game of lacrosse most scientific papers focus on lacrosse specific injuries and its relevance (Carter et al., 2010; Lincoln et al., 2013), whereas in other areas there is a paucity of lacrosse specific research. Therefore, this study aims to describe and define the game structure and performance indicators of NCAA Division I Men's Lacrosse. **Methods:** With the help of a verified observation system (Hughes & Franks, 2008; Lames, 1994; O'Donoghue, 2010), seven playoff games of the 2013 NCAA Division I Men's Lacrosse Championship have been analyzed to assess duration, location and match activities of ball possession and its start and end events, respectively. Further differences between the winning- and losing team for relevant indicators have been collected to gain a better understanding of the game. **Results:** Results showed that there are an average of 107.3 ball possessions per game with a mean duration of 32.7 seconds. Of the 660.1 passes 70% were between 10 and 20 yards,

17% longer than 20 yards and 13% shorter than 10 yards. Most of the 530.3 runs per game were longer than 15 yards (61%), shorter runs (39%) occurred less often. The most frequent event that started a ball possession was a ground ball (39%) in contrast to a wide shot (21%) that ended a possession most of the time. Most ball possessions (n=14.0) was gained in the defending goal crease area, and lost in front of the opponent's goal (n=43.4), respectively. The match winner had a significantly higher overall ball possession time and more pass and run occurrences than the loser ( $p<0.05$ ). Discussion: In conclusion, college men's lacrosse is a game of possession with the total time of possession as a relevant indicator for success. Moreover, it can be concluded that longer single possession time and higher numbers of shots, passes and runs are closely related to success. Further, this study has shown that notational analysis seems to be a valuable source to get a better knowledge of lacrosse. References: Carter, E. A. et al., (2010). Int. ## EFFECTS OF AUGMENTED QUANTITATIVE FEEDBACK ON HIGH SCHOOL BASKETBALL PLAYERS' PERFORMANCE

Tay, C.

*Raffles Institution*

High school sports coaches tend to offer qualitative feedback of players' performance after a game because of limitations. As touchpads become more ubiquitous, it is easier to record and track quantitative aspects of players' performance. Several researchers have indicated that quantitative feedback is more useful to athletes than qualitative feedback (e.g., Magill and Wood, 1986; Reeve and Magill, 1981; Smoll, 1972.). Thus, this study was carried out to investigate the effects of receiving augmented quantitative feedback on high school basketball players' fitness levels and game performance statistics (GPS) in Singapore. Tests were carried out to assess the physical attributes of the players – speed, agility, lower and upper body strength and power, and aerobic endurance. This battery of tests was compiled after a review on sports fitness testing (e.g., Gore, 2000). GPS was captured during the competition season using an iPad application (iScore; Faster Than Monkeys, Inc, iScore Sports, USA). Using iScore, players' GPS were tracked for each game. Data was captured over a period of 2 years. Quantitative feedback offered the players a first time in-depth analysis of their game performance and fitness levels. The female team improved their jump heights by 8.9%, agility and speed scores by about 14%. The male players improved their agility and speed scores by 13.5% and their V02 max scores from 48.4 to 57.2. The female 2-points and 3-points field goal percentages improved by 4.2% and 2.1% whilst the male team had 2.5 more rebounds per game and increased their free throw percentage by 8%. Receiving quantitative as well as qualitative feedback appears to have raised both fitness levels and game performance in the basketball teams that were studied. A limitation of the study is the lack of control groups or historical data to show that improvements were not due to practice or game experience. However, the athletes have found the additional quantitative feedback beneficial, for instance, areas of weaknesses could be identified and improved upon. References: Ian M. Franks (1997). ## BIASED PENALTY CALLS IN THE NATIONAL HOCKEY LEAGUE

Swartz, T.

*Simon Fraser University*

This talk investigates penalty calls in the National Hockey League (NHL). Our study shows that teams that are leading in a match are more likely to have the next penalty called against them. Also, we observe that teams that have taken more penalties in a match are less likely to have the next penalty called against them. The biases that we have identified are not uniform amongst referees. We investigate specific referee effects across the NHL.

## TACTICAL ANALYSES OF BRAZILIAN FEMALE NATIONAL HANDBALL TEAM IN 2012 LONDON OLYMPICS

Vallner, T.T.1, Mercadante, L.A.1, Monezi, L.A.1, Almeida, A.G.2

*1: School of Applied Science, University of Campinas (Brazil), 2: Pontifícia Universidade Católica de Campinas (Brazil)*

Introduction Technical-tactical analyses in sports are an important tool to understand the game. Technical information is widely used by teams and is documented by the organizers of international championships. However, tactical information are less present in literature and further absent in female literature. From this point of view, this study aims to describe the tactical elements to analyze the offensive behavior of Handball Team. Methods Data was obtained by six videos of the Brazilian Female National Handball Team in 2012 London Olympics. The data from the videos considered: number of occurrences of each attack system: positioned (P) and fast-break (FB); offensive tactical elements: piston movement and sidestepping (PS), feint (F), crossing (CR), pass and go (PG), curtain (C) e block (B), as well as the number of shots, goals and efficiency of each one. To quantify these variables, the videos were played in Windows Media Player software 2014. Descriptive statistics were performed using mean and standard deviation of the data to verify the offensive tactical elements invested and the most efficient by the Brazilian Team in this competition. Results For the attack systems, P composed 91% of attacks, with an average ( $\bar{x}$ ) of  $58 \pm 6$  attacks and turnovers (to) per match and efficiency ( $\bar{y}$ ) of 50%. FB composed 9% with  $\bar{x} = 6 \pm 3$ ,  $\text{to} = 2 \pm 1$  and  $\bar{y} = 66\%$ . The most used tactical element (u) was the PS, with 63% of all attacks, with  $\bar{x} = 32 \pm 7$ ,  $\text{to} = 8 \pm 3$ , and  $\bar{y} = 50\%$ , followed by F ( $\bar{u} = 17\%$ ,  $\bar{x} = 9 \pm 2$ ,  $\text{to} = 3 \pm 1$  and  $\bar{y} = 93\%$ ), B ( $\bar{u} = 9\%$ ,  $\bar{x} = 8 \pm 2$ ,  $\text{to} = 0,6 \pm 0,8$  and  $\bar{y} = 58\%$ ), CR ( $\bar{u} = 8\%$ ,  $\bar{x} = 4 \pm 1$ ,  $\text{to} = 1 \pm 1$  and  $\bar{y} = 68\%$ ), PG ( $\bar{u} = 3\%$ ,  $\bar{x} = 1 \pm 0,5$ ,  $\text{to} = 0,5 \pm 1$  and  $\bar{y} = 66\%$ ). Curtain hadn't significant values. Discussion In comparison with this study, Ramari (2008) also used the tactical element quantity in male and female team. This author described the tactical element fixation as the most used. However this tactical element was not efficient expected. For the type of attack, Ferrari (2008) emphasizes the importance of FB in winning teams. Our aim was to implement a tactical analysis model which would allow quantification of the most used and efficient tactical elements to improve the training and understand the game using the example of the Brazilian Team in this competition. This type of analysis could determine the individual performances as well as group and team, assessing the interaction within team and the team with opponent. ### IS-PM08 TEAM SPORT & HEALTH \*

#### PLAYING FOOTBALL TO PREVENT CHRONIC DISEASES

Krustrup, P.

*University of Copenhagen*

It is now well-known that physical training is a cornerstone in the prevention and treatment of lifestyle diseases and it has recently been concluded that sport participation reduces all-cause mortality by 20-40% (Khan et al. 2012). Over the last 6 years, we have published 70 scientific articles describing the activity profile, physiological demands, fitness effects and health benefits of recreational football for untrained individuals across the life span, documenting that small-sided football (3v3 to 7v7) has broad spectrum fitness and health effects for 6-80-year-old participants, as it combines elements of high-intensity interval training (HIIT), endurance training and strength training (Krustrup et al. 2010, 2013). Small-sided football played 3v3, 5v5 or 7v7 elicits high heart rates and involves multiple intense actions such as sprints, turns, jumps, tackles, dribbles and shots, independently of age, gender, fitness status, socio-economic status and prior experience (Randers et al. 2010), providing effective cardiovascular training with multiple effects on VO<sub>2</sub>max, heart structure and function, endothelial function, capillarisation, lipid profile and oxidative enzyme activity, as well as multiple favorable effects on muscle mass, muscle function, postural balance and bone mineralisation (Krustrup et al. 2010). Recently, we investigated the health effects of football for patient groups with hypertension, type 2 diabetes and prostate cancer. Just 3 months of football training, 2x1 hour/week, lowered systolic and diastolic blood pressure by 12/8, 8/8 and 11/9 mmHg, respectively, in three RCT's, which is a more pronounced effect than usually seen after 3-6 months training interventions (Krustrup et al. 2013). Twice-weekly 45-60-min football sessions over 3 months was also shown to increase lean body mass, muscle strength and bone mass for elderly men with prostate cancer undergoing androgen deprivation therapy (Uth et al. 2014). These results and other recent results will be presented at ECSS in Malmø, altogether providing evidence that recreational football is an effective type of HIIT training that can improve fitness and serve as effective prevention, treatment and rehabilitation of noncommunicable diseases for individuals across the life span. #### FOOTBALL FANS IN TRAINING : A WEIGHT LOSS AND HEALTHY LIVING PROGRAMME DELIVERED TO MEN AGED 35-65 BY SCOTTISH PREMIER LEAGUE FOOTBALL CLUBS

Hunt, K.

*University of Glasgow*

Research on gender and health has recognized how constructions of masculinities may inhibit men's interest and participation in healthier lifestyles and health promoting interventions. Recently there has been increasing interest in how sports-based organizations may be utilized to engage otherwise 'hard-to-reach' men. The challenge now is to translate theoretical understandings of gender into effective interventions to improve health, and address public health priorities. One public health problem is the rapidly increasing levels of obesity in many parts of the world. In Scotland, around 4 in 5 men are 'overweight' or 'obese', and on current trends nearly 50% of UK men will be obese by 2030. A 5-10% weight loss can produce significant health benefits. However, attempts and motivations to manage weight are gendered in many ways. Existing weight management programmes are failing to attract men; they are often viewed as being geared towards women and fail to take account of how cultural constructions of masculinity influence men's feelings about their bodies and their attitudes towards health promoting activities. We report the development and evaluation of Football Fans in Training (FFIT), an innovative evidence-based, gender-sensitised weight management and healthy living intervention which is delivered to overweight/obese men in professional football clubs by club community coaches. We evaluated the effectiveness of Football Fans in Training (FFIT) in a two-arm, pragmatic RCT in 13 SPL football clubs. Men (n=747), aged 35-65, with BMI $\geq$ 28kg/m<sup>2</sup>, were randomly assigned to either the intervention (undertook FFIT within 3 weeks of measurement) or comparison (undertook FFIT 12 months later) group, and followed to 12 months. The results of the trial demonstrate the effectiveness and cost-effectiveness of FFIT. Men in the intervention group lost a significantly higher percentage of their weight at 12 weeks and 12 months (primary outcome) than those in the comparison group, and more achieved a clinically-significant ( $\geq$ 5%) weight loss at both time points. Improvements in other directly-measured and self-reported secondary outcomes were also significantly greater in the intervention group. Drawing on qualitative data, we will also present findings on men's experiences of taking part in FFIT, demonstrating: the power of the football club as a 'draw' for these men; and their positive experiences of making lifestyle changes in this context. The study demonstrates the importance of working with rather than against prevailing cultures of masculinity, and challenges views that men are uninterested or unwilling to make positive lifestyle changes. It demonstrates the great potential of sport settings for health improvement.

## PROSTATE CANCER PATIENTS' EXPERIENCES WITH PARTICIPATION IN FOOTBALL – A QUALITATIVE INVESTIGATION OF THE 'FC PROSTATE' RANDOMIZED CONTROLLED TRIAL

Midtgaard, J., Krusturup, P., Uth, J., Brasso, K., Hornstrup, T., Bruun, D.M.

*Rigshospitalet (Copenhagen University Hospital)*

**INTRODUCTION** Evidence is accumulating that exercise-based rehabilitation improves physical capacity and quality of life in cancer survivors. However, recruitment and persistence of male cancer patients in rehabilitation and physical activity are low and novel health promotion strategies are warranted. Therefore, the aim of this investigation was to gain an understanding of the meaning of recreational football as a team and interaction oriented health promoting activity in men with prostate cancer (n=26) including perceived acceptability of severe injuries. **METHODS** A qualitative sub-study of the 'FC Prostate' randomized controlled trial was conducted based on 6 focus group interviews (n=6x4-6) and 20 hours of participant observations. Moreover, in-depth individual interviews were performed with four men who had been injured during football training. Data were analysed using framework analysis and descriptive phenomenology, respectively. **RESULTS** The framework analysis produced 11 sub-themes that were structured into three overarching themes: 1) motivational drivers; 2) united in sport and 3) confirmation of own capacity. The findings indicated that participants regarded football as a welcome opportunity to regain control and acquire a sense of responsibility for own health without assuming the patient role, and football training legitimized and promoted mutual caring behaviour in a male-oriented context. In addition, the phenomenological analysis indicated that injuries acquired through football training, was experienced as 'perfectly normal', i.e. a psychologically harmless and meaningful consequence of participating in sport supporting the participants' feeling of masculinity. **DISCUSSION** The study suggests that football due to its cultural representation of masculine ideals may be a potent and unique strategy for increasing recruitment and adherence to physical activity in prostate cancer patients. Moreover, the risk of severe injuries related to football training may be outweighed not only by already documented positive physiological effects but equally by the men's acceptability and perceived psychological benefit of participation in high-risk sporting activities.

#### THE EFFECT OF RAST ANAEROBIC TEST ON CIRCULATING HEMATOPOIETIC AND ENDOTHELIAL PROGENITOR CELLS IN ATHLETES

Shady, K.1, Loffy, A.2, Shaalan, A.1, Sobh, M.2, Bazeed, F.2

*1faculty of physical education, Mansoura University, Egypt. 2faculty of medicine, Mansoura University, Egypt.*

**Abstract Introduction** Some studies documented the changes of hematopoietic stem cells and endothelial progenitor cells following aerobic exercise for example, (Mobius-Winkler et al., 2009; Thijssen et al., 2006). However, far less information is available on hematopoietic stem cells and endothelial progenitor cells in response to anaerobic exercise. Thus, the aim of this study was to know the responses of hematopoietic stem cells and endothelial progenitor cells in the 24 hours after RAST anaerobic test. **Methods** Ten healthy male's athlete's age (20.90± 0.27 y) performed running - based anaerobic sprint test (RAST). RAST consisted of six 35m sprint runs at maximum speed with 10 sec rest between them. Blood samples taken pre, and immediately, 30 min, 2h, 6h and 24h post exercise were analyzed for hematopoietic stem cells (HSCs), endothelial progenitor cells (EPCs), Vascular Endothelial Growth Factor Types – A (VEGF-A), Nitric Oxide (NO), Lactic Acid (LA) and White Blood Cells (WBCs) . **Results** After RAST anaerobic test, there was significant increase in HSCs, EPCs, VEGF-A, NO, LA and WBCs (p < 0.05). This increase will be at different rates according to the timing of taking blood sample. HSCs and EPCs were in the maximum rate of increase 6h after RAST anaerobic test. In addition to VEGF-A was in the maximum rate of increase 30min after RAST anaerobic test and NO 24h after RAST anaerobic test. While LA and WBC were in the maximum rate of increase immediately after RAST anaerobic test. The researcher noted that there was a significant decrease in HSCs immediately after the RAST anaerobic test (p<0.05). **Discussion** Increase in HSCs and EPCs was a result of many mechanisms represented by an increase in NO and VEGF-A after RAST anaerobic test. While the researcher sees that the increase in WBCs and LA after RAST anaerobic test immediately, led to muscle fatigue and inflammation in tissues which result in rapid migration of HSCs to the tissues that need it. And this explains the immediate decrease of HSCs in peripheral blood after RAST anaerobic test. **References** Mobius-Winkler S, Hilberg T, Menzel K, Golla E, Burman A, Schuler G, Adams V. (2009 ). #### ISCHEMIC PRECONDITIONING REDUCES THE CARDIOVASCULAR RESPONSE DURING THE MUSCLE METABOREFLEX ACTIVATION

Crisafulli, A., Sainas, G., Marongiu, E., Palazzolo, G., Boi, A., Orrù, A., Corona, F., Milia, N., Mulliri, G., Milia, R.

*university of Cagliari*

**Introduction** The typical hemodynamic response to the activation of the muscle metaboreflex (MR) is an increase in mean blood pressure (MBP). This response is the consequence of the activity of type III and IV free nerve endings in the muscle which respond to metabolite accumulation. In normal subjects, the activity of these nerve endings leads to increase in sympathetic tone, thereby causing systemic vascular resistance (SVR) and cardiac output (CO) elevation (Crisafulli et al. 2003). It has been recently demonstrated that ischemic preconditioning (IP) can reduce the discharge of these nerve endings (Amann et al. 2013). The aim of the present study was to test the hypothesis that IP was able to reduce the hemodynamic response during the MR. **Methods** Ten healthy male subjects (32.5±3.5 yrs) were enrolled and randomly assigned to the following study protocol: 1) control tests (CT) to assess the cardiovascular response to MR, which consisted in a post-exercise (dynamic handgrip, DH) muscle ischemia (PEMI) to study the MR and a control DH-recovery (CER) session. 2) the PEMI test was after IP, obtained with 3 cycles of 5 minutes ischemia-reperfusion in the forearm. Central hemodynamics were evaluated by means of impedance cardiography and echocardiography. The hemodynamic response due to MR activation was assessed by calculating the PEMI – CER test difference in each cardiovascular variable. **Results** The main findings were that, after IP the MBP response to PEMI was blunted as compared to the standard MR activation test (7.2 ± 6.5 vs. 3.6 ± 7.5 mmHg). Moreover, after IP SVR response to MR was reduced, whereas CO was unchanged. **Conclusion** Our results indicate that IP can effectively reduce the cardiovascular activation

during the MR recruitment. Probably this was the consequence of a reduction in type III and IV nerve ending sensibility to metabolites accumulation. This fact could have practical implications in sensation of fatigue-related and in the IP-mediated increase in physical performance (Crisafulli et al. 2011). Crisafulli A et al. ### THE RELATIONSHIP BETWEEN BLOOD FLOW AND POST-EXERCISE RECOVERY: A RANDOMIZED SINGLE-BLIND PLACEBO-CONTROLLED STUDY.

Borne, R., Hausswirth, C., Bieuzen, F.

*INSEP*

**Introduction** Competitive sport requires athletes to complete multiple bouts of high-intensity exercise with limited rest periods, which are not sufficient for full recovery. It appears therefore necessary to assist, with adequate recovery strategy, in restoration of physiological systems to a preexercise state in preparation for subsequent exercise. This study investigated how different leg blood flow levels undertaken for the duration of a short-term ( $\leq 30$ -min) recovery period after high-intensity sprint cycling affected subsequent exercise performance, blood lactate clearance and heart rate recovery. **Methods** 33 trained athletes completed 2 multiple 30-s Wingate test (WAnT) sessions, 3 x 30-s WAnT (WAnT 1-3) and 1 x 30-s WAnT (WAnT 4), on a cycling ergometer. Tests were separated by a randomly assigned 24-min recovery intervention consisting in either: neuromuscular electrical stimulation-induced blood flow (NMESBF+; Veinoplus Sport, Paris, France), placebo stimulation (NMESPlacebo), passive rest (PAS) or blood flow restriction (BFR). Measures of blood flow by strain gauge plethysmography, blood lactate and heart rate were regularly recorded throughout the recovery period. Performance values were obtained from peak power and mean power during WAnT 1 and WAnT 4. The effects of the different recovery setups were examined using traditional probability statistics and magnitude of correlation. **Results** A large ( $r = 0.68$  (90% CL 0.42; 0.83)), and a very large ( $r = 0.72$  (90% CL 0.49; 0.86)) positive correlation was observed between the change in blood flow and the change in mean power and peak power, respectively, following the recovery interventions. Examination of blood lactate and heart rate revealed no recovery effect. **Discussion** These data support the assumption of an effective, positive correlation between the blood flow increase and the performance recovery from high-intensity exercise. An increase of the oxygen supply to the exercised muscles (Zarrouk et al. 2011) and glucose uptake by the muscle cells (Heyman et al. 2009) as well as an acceleration of muscle metabolic by-products removal (Malone et al. 2012) could potentially explain the performance recovery improvement observed with the blood flow stimulation protocol used here (i.e. NMESBF+). Furthermore, these findings highlight a potentially greater physiological role of neuromuscular electrical stimulation in recovery than the hypothesized psychological role. **References** Heyman E, DE Geus B, Mertens I, Meeusen R. ### EXERCISE TRAINING INCREASES THE INHIBITORY EFFECTS OF PROSTACYCLIN ON PLATELETS IN POST-MENOPAUSAL WOMEN

Slingsby, M.H., Møller Jensen, L., Nyberg, M., Egelund, J., Bangsbo, J., Hellsten, Y.

*University of Copenhagen*

**Background** Following blood vessel injury and exposure of sub-endothelial collagen, circulating platelets aggregate to form a thrombus plug that prevents blood loss. In a healthy cardiovascular system, the endothelium continuously produces prostacyclin to inhibit unwarranted platelet aggregation. However, cardiovascular disease can reduce the platelet sensitivity to the inhibitory effects of prostacyclin [1] and rupture of an atherosclerotic plaque can lead to uncontrolled platelet aggregation and life-threatening thrombosis. Menopause is associated with endothelial dysfunction and an increased cardiovascular risk profile [2]. It is not yet known how exercise influences platelet function in post-menopausal women. **Aim** To investigate if a period of exercise training in sedentary post-menopausal women affects their platelet responsiveness to the inhibitory effect of prostacyclin. **Method** These are preliminary results from the ongoing Copenhagen Women Study (approved by the Copenhagen Ethics Committee). Four sedentary healthy post-menopausal women (aged 50-55 years) were tested at baseline and after 12 weeks of supervised spinning training (1h interval training above 80% of maximal heart rate, 3 times/week). Catheters were inserted into their femoral artery and vein and prostacyclin (epoprostenol sodium) was infused through the femoral artery at three different doses (2.5ng, 5ng and 10ng/dl leg volume/min). Blood was collected from the femoral vein into 3.2% citrate vacutainers and centrifuged (10 min, 180g) to obtain platelet rich plasma. A 96-well plate assay [3] was used to measure 1µg/ml collagen-stimulated platelet aggregation. Data are presented as mean  $\pm$  SEM % platelet aggregation from n=4 post-menopausal women, analysed using one-way ANOVA with Bonferroni post-hoc test. **Results** Before the training intervention, the arterial prostacyclin infusion resulted in a dose-dependent inhibition of the collagen-induced platelet aggregation (baseline: 85 $\pm$ 4 %, 2.5ng: 55 $\pm$ 11 %, 5ng: 24 $\pm$ 5 %, 10ng: 0 $\pm$ 0 %,  $p < 0.05$ ). After the 12-week training intervention, the % platelet aggregation at baseline remained the same but the inhibitory effect of the prostacyclin was significantly enhanced (baseline: 90 $\pm$ 3 %, 2.5ng: 24 $\pm$ 8 %, 5ng: 8 $\pm$ 4%, 10ng: 2 $\pm$ 2 %,  $p < 0.05$ ). **Discussion** Introducing post-menopausal women to regular exercise makes their platelets more than twice as sensitive to the inhibitory effects of prostacyclin. Since effective prostacyclin inhibition of platelet aggregation is essential for preventing thrombosis, these preliminary results indicate that regular physical activity have protective anti-thrombotic effects on platelet function in post-menopausal women. **References** [1] Kahn, N et al. *Circ Res*. 1990. 66:932-940. ### PHYSIOLOGICAL RESPONSES OF FIREFIGHTERS TO A FLASHOVER TRAINING

Inwinkl, S.1, Seiberl, W.1, Schwirtz, A.1, Hahn, D.2

*Technische Universität München\*; Ruhr-Universität Bochum\*\**

**Physiological responses of firefighters to a flashover training** **Introduction** Firefighting imposes high physiological and psychological strains. This is due to the variety of physically demanding tasks firefighters perform at an emergency scene as well as high ambient temperatures and wearing protection gears. However, most studies investigated simulated task-testing in absence of environmental stressors such as high ambient temperatures in order to determine the physical loads of firefighting. Moreover, firefighter's responses to suddenly occurring dangerous situations such as a flashover have not been established yet. A flashover describes the phenomenon

where a fire reaches its ignition temperature and spreads quickly due to inflammable gases emitting from materials and exposed surfaces in an enclosed area. This dangerous situation is explicitly trained by firefighters in a burning container that simulates flashovers. The aim of this research was to examine the contribution of aerobic and anaerobic energy systems to the physical performance of German firefighters in a flashover training. Methods Sixteen professional firefighters (age  $38.9 \pm 8.9$  yr, height  $177.3 \pm 6.9$  cm, weight  $81.5 \pm 9.3$  kg) performed firefighting tasks with a simulation of the flashover phenomenon in a container. In advance, a treadmill test in order to establish peak oxygen uptake ( $VO_{2peak}$ ), ventilatory threshold (VT1) and respiratory compensation point (RCP) was done under laboratory conditions. Three intensity zones were identified according to the HR values corresponding to VT1 and RCP. Simulated task-testing included ladder climb, hose advance and extinguishing different kinds of fires across the enclosed area of the training container. Subjects wore full protective clothing (24.5kg) and a self-contained breathing apparatus for air supply. Heart rate (HR) and depletion of air supply were measured during the drill. Results Mean time to complete the training was  $16.1 \pm 1.7$  min with a mean heart rate of  $147.8 \pm 12.4$  bpm across 16 subjects. The depletion of air supply averaged  $140.7 \pm 20.3$  bar. According to preliminary data of 6 firefighters, subjects spent  $18.9 \pm 11.0$  % of training-time below VT1,  $66.6 \pm 8.0$  % of time between VT1 and RCP and  $13.9 \pm 12.6$  % of time above RCP. These subjects performed the training with a mean percentage of 81.7% of maximal HR. Discussion According to our results, the highest energy contribution during a flashover training comes from the aerobic-anaerobic system (time spent between VT1 and RCP). Moreover, we found evidence for a high contribution of the anaerobic system in the second half of the flashover drill. Subjects with a higher  $VO_{2peak}$  in relation to age were able to supply a greater percentage of the total energy demand aerobically resulting in less physiological strain. Our results demonstrate the importance of an appropriate training level for professional firefighters.

### **A POWER-LAW MODEL REDUCES VARIABILITY IN TIME-TO-EXHAUSTION**

Cookley, S.L., Jobson, S.A., Nicolò, A., Giorgi, A., Passfield, L.  
*University of Kent*

**INTRODUCTION** A large inter-individual variability in time-to-exhaustion (TTE) occurs when working at the same relative intensity. This may be because exercise intensity prescribed as a percentage of  $VO_{2max}$  ignores differences in metabolic and neuromuscular stress. This study compared the inter-individual variability in cycling TTE when exercise intensity was prescribed using two different methods; as %  $VO_{2max}$ , or a power-law model. We also examined if TTE was related to muscle oxygen saturation, or one leg  $VO_{2max}$  expressed as a ratio of two leg  $VO_{2max}$ . **METHODS** Seventeen trained male cyclists (mean  $\pm$  SD;  $34 \pm 11$ y;  $178 \pm 6$ cm;  $75 \pm 10$ kg;  $VO_{2max}$   $4.39 \pm 0.51$ L.min<sup>-1</sup>) completed two incremental exercise tests to exhaustion (one leg and two leg) on a cycle ergometer to determine  $VO_{2max}$ . The exercise intensity for TTE at %  $VO_{2max}$  trials was set at 88% and 109%  $VO_{2max}$ . A power-law was derived from 3 TTE trials at 85%, 95% and 105% maximum minute power. This was then used to predict the intensity for TTE lasting exactly 20 min and 3 min. Participants then returned to the lab on two separate occasions, completing 2 x TTE trials on each occasion, with 30 min rest between trials. The tests of TTE for %  $VO_{2max}$  and power-law were administered in a randomised order. Thigh maximal leg oxygenation ( $sO_{2leg}$ ) was measured throughout the incremental tests and lower intensity TTE trials using near infrared spectroscopy (NIRS).  $VO_2$ , breathing frequency and heart rate were recorded throughout and blood lactate post-exhaustion. Participants self-rated their RPE throughout the TTE trials, by indicating when they felt it increased. Between participant coefficients of variation was calculated for each TTE trial. Comparisons between %  $VO_{2max}$  and power-law were made using an F-distribution. Pearson's correlation was used to investigate any relationships between variables. Data are presented as the means  $\pm$  SD. The level of significance was set at  $P < 0.05$ . **RESULTS** The coefficients of variation for the TTE trials were 58% and 29% for %  $VO_{2max}$  and power-law trials respectively ( $P < 0.05$ ). The ratio between one leg and two leg  $VO_{2max}$  did not relate to TTE performances for the %  $VO_{2max}$  ( $r^2 = -0.01$ ) and the power-law ( $r^2 = 0.46$ ) trials. Deoxygenated hemoglobin and TTE were negatively correlated ( $r^2 = -0.67$ ) for the %  $VO_{2max}$  trial; however, a positive correlation ( $r^2 = 0.60$ ) was found for the power-law trial. **CONCLUSION** Deriving a power-law model reduces variability in TTE and suggests that it may be a better method for standardising exercise intensity as it reduces inter-individual variability by 50%. The reason for the inter-individual variability in TTE warrants further investigation, but appears to be partly related to the methods used to standardise exercise intensity.

### **Invited symposia**

#### **IS-PM16 JSPFSM-RISK FACTORS AND BIOMARKERS OF REDUCED SKELETAL MUSCLE FUNCTION IN OLDER AGE –JAPANESE & EUROPEAN EXPERIENCE**

##### **ASSOCIATION OF HIGHER SERUM ADIPONECTIN LEVEL AND TRADITIONAL JAPANESE DIETARY PATTERN WITH REDUCED SKELETAL MUSCLE STRENGTH AND QUALITY OF LIFE OF OLDER JAPANESE**

Nagatomi, R.

*Tohoku University*

Reduced skeletal muscle mass accompanied by reduced force production in older age, namely sarcopenia, leads not only to increased risk of fall-associated fractures but also to loss of ability to live independently. Consequently, reduced muscle strength practically determines the quality of life of older people. In Japan, like in many other countries, older persons who demonstrate reduced ability to live independently are supported by long-term nursing care at home or at specialized institutions. In a prospective population study of Japanese people of 70 years and older, we investigated factors influencing two major outcomes, fall associated fracture and disability free living without official accreditation of long term care. Interestingly traditional Japanese diet characterized by low animal products and higher amounts of vegetables and whole grains, having similarities with Cretan or Mediterranean diet considered as healthy diet, was associated with higher incidence of fall associated fracture as compared to dietary pattern rich in poultry and meat (1). In a separate middle-aged population study in the same city in Japan, we focused on grip strength and leg extension power as outcome measures, and found that serum adiponectin level was inversely associated with grip strength and lower leg extension power (2). Back to the older population study, we found higher serum adiponectin level was inversely associated with disability-free survival requiring no long-term care requirement (3). Further analysis of the older population revealed that higher serum adiponectin is a risk factor for decreased muscle function (4). Serum adiponectin, otherwise considered as one of the potent protective adipokines for cardiovascular diseases, appears to have negative impact on skeletal muscle function. In the same middle-aged cohort study we identified traditional Japanese dietary pattern was associated with higher serum adiponectin (5) and was associated with reduction in systolic or diastolic blood pressure (6).

Higher serum adiponectin level was also associated with decreased incidence of acquiring cardiovascular risk factors in the same population (7). Taken together, a balanced life style is required for active health in the older age, Biomarkers such as adiponectin may be useful to identify an balanced life style for independent living. 1. ### COUNTERMEASURE AGAINST BLUNTED SKELETAL MUSCLE STEROIDOGENESIS

Fujita, S.

*Ritsumeikan University*

Sarcopenia is the age-associated loss of skeletal muscle mass and strength that develops slowly over decades and becomes a significant factor to disability among the elderly population. Progressive resistance training (RT) has been shown to be an effective countermeasure for sarcopenia. Previous studies have demonstrated that RT can increase skeletal muscle mass significantly in both young and older individuals, although anabolic response to a bout of resistance exercise may be blunted with aging. Sex steroid hormones regulate various physiological processes in target tissues. Dehydroepiandrosterone (DHEA) and its sulphate derivate (DHEA-S) both play critical roles in maintaining steroidogenesis in peripheral tissues. However, aging is also associated with decreased serum levels of DHEA, which has been linked to accelerated progression of sarcopenia. We have recently investigated the plasma and intramuscular levels of steroid hormones and steroidogenic enzyme expressions in healthy young and older men. Although intramuscular hormone levels and steroidogenesis-related enzyme expressions declined significantly with ageing, a 12-wk resistance training program restored both plasma and intramuscular sex steroid hormone levels in older men. Furthermore, improvements in intramuscular sex steroid hormone levels correlated with the training-induced changes in muscle size and strength. The presentation will include recent findings on possible biomarkers that may relate to the outcome of RT-induced muscle hypertrophy. Reference: Sato et al. FASEB J. 28(4):1891-7, 2014

### COUNTERACTING SKELETAL MUSCLE LOSS WITH AGEING: INFLUENCE OF NUTRITION AND EXERCISE

Holm, L.

*Bispebjerg Hospital*

The demographic prognosis in all European countries reveals a marked increase in the number of citizens above the age of 65 years in the coming decades. Along with improved treatments of various diseases also recommendations on actions and strategies appealing to self-responsibility among the elderly and pre-elderly citizens as to maintain muscle mass and physical independency must be made visible through public campaigns to limit the societal expenses on elderly care. Despite the endemic nature of loss of muscle mass and function with increasing age, sarcopenia is a treatable process. Although, multiple causes are responsible for the sarcopenic process, two factors however, are crucial for any actions in its prevention or delay, namely muscular exercise training and sufficient nutritional intake, with emphasis on adequate amounts of protein. Scientific evidence suggests that the need for daily protein intake for the elderly population is higher than the current recommendations from the World Health Organisation. Therefore, it could be claimed that in the future modern society, healthy elderly people should not suffer from functional disability. This presentation will present some scientific evidence for the beneficial effect on maintenance of muscle mass through enhancing protein intake for the elderly and elucidate the gaps of evidence on longitudinal investigations. Further, the potential of muscular training on muscle mass and strength will be faced with the paradoxical sedentary tendency and the incomppliance with heavy loading exercises among elderly people. The question being, what impact more tolerable exercise training with lower contraction intensity has on the development of muscle mass in elderly people. A strategy to study the impact different types of exercise training and protein intake in the elderly population will be presented with the off-set in the inter-disciplinary CALM-project, conducted at University of Copenhagen, Denmark.

### OP-PM43 Training & Testing: Teamsport I

#### QUANTIFICATION OF SESSION RATINGS OF PERCEIVED EXERTION IN ELITE SOCCER REFEREES

Weston, M.

*Teesside University*

Quantification of session ratings of perceived exertion in elite soccer referees Weston, M Teesside University (Middlesbrough, UK). Background Session ratings of perceived exertion (sRPE) are commonly used to measure training session intensity. Despite this, comparisons of sRPE from different training activities with match sRPE and analyses of repeated-activity sRPE elude the literature. Presented here, therefore, is an in-depth quantification of elite soccer referees' training and match sRPE. Methods Eight professional soccer referees were monitored over four consecutive soccer seasons. Data were collected as part of the sport science support provided to the referees and during each season detailed training diaries were compiled for each referee, including training activity, duration and intensity. The training activities included in this study were high-intensity aerobic intervals (sports scientist prescribed sRPE range 6-9; work:rest ratio ~1:1), repeated-sprints (5-7; ~1:3), medium-intensity aerobic (3-5; continuous), speed (including agility exercises, 2-5; ~1:10) and strength (including functional/injury prevention exercises, 2-4; ~1:10). Referees recorded their sRPE (CR10 scale) 30-min after each session to obtain a global session intensity rating (Foster et al., 2001). Only data from the competitive season were included in the analysis. Data were analysed via linear mixed modelling, with magnitude-based inferences subsequently applied. Results A total of 4659 sessions were included in the present study (high-intensity 688, repeated-sprints 387, medium-intensity 509, speed 963, strength 809 and match 1303). Mean  $\pm$  standard deviation sRPE was 6.6  $\pm$  1.7 AU (high-intensity), 5.8  $\pm$  1.6 AU (repeated-sprints), 4.6  $\pm$  1.6 (medium-intensity), 3.6  $\pm$  1.3 (speed), 3.1  $\pm$  1.1 (strength) and 6.4  $\pm$  1.6 (match). Contrasts of training sRPE with match sRPE were trivial for high-intensity (1.9%;  $\pm$ 90% confidence limits 8.6%), possibly small for repeated-sprints (-11.1%;  $\pm$ 7.6), likely moderate for medium-intensity (-28.7%;  $\pm$ 6.1%), likely large for speed (-43.7%;  $\pm$ 4.7%) and most likely large for strength (-51.7;  $\pm$ 4.1%). Within- and between-referee variability in training and match sRPE ranged from 0.9  $\pm$  0.1 to 1.1  $\pm$  0.1 AU and 0.7  $\pm$  0.3 to 1.4  $\pm$  0.7 AU, respectively. Conclusions The magnitude of the difference between training and

match sRPE is smallest when the intensity of the prescribed training is highest and the work:rest ratio lowest, providing further support for the relevance of high-intensity intervals and repeated-sprints as match-specific training for elite soccer referees. Despite large differences between match sRPE with speed and strength sRPE, speed and strength sessions should remain integral to the training process as they help to prepare referees for the entire spectrum of match-related physical demands. Finally, for all activities sRPE were relatively consistent within and between referees. References Foster et al. (2001). *J Strength Cond Res* 15(1), 109-115 Contact m.weston@tees.ac.uk

### ARE PHYSIOLOGICAL ABILITIES OF PROFESSIONAL SOCCER PLAYERS POSITION SPECIFIC?

Reer, R.

*University of Hamburg*

**Introduction** Soccer position-specific indices of physiological abilities of professional soccer players are seldom reported in the literature. These are especially evident when identifying new soccer player talent, training regimen, and player tactics (1,2,3). **Methods** We developed a standardized test protocol as results of observations of professional soccer team of the second German soccer division over 5 consecutive soccer seasons [Goalie G (n=9), Defense D (n=26), Mid-field MF (n=29) and Forward F (n=13)]. We measured sprint times (5m and 30m), counter movement jump (CMJ), the endurance (individual anaerobic threshold, IAT) in the field as well as strength and power measurements relative to their body weight in selected tests. The tests were administered before the start of the soccer season in July. **Results** The results indicated condition-specific indices of the second German soccer division players (mean±SD) and identified differences in position-specific indices [CMJ (cm): G 39.1±3.6Δ; D 42.3±3.8; MF 42.0±5.0; F 43.3±3.1Δ / Sprint (s): G 4.3±0.1#Δ; D 4.1±0.2#; MF 4.0±0.2; F 4.0±0.1Δ / Squat (kg/kgKG): G 1.3±0.1#Δ; D 1.6±0.2\*#; MF 1.4±0.2\*; F 1.5±0.3Δ / Body fat: G 13.3±2.1#X; D 10.1±1.6\*#+; MF 11.6±2.7\*X; F 12.5±2.6+]. \*significant between D & MF; +significant between D & FP; #significant between D & G; #significant between MF & FP, X significant between MF & G; Δ significant between FP & G. **Discussion** The results of our study revealed significant differences in physiological abilities depending on assigned soccer game position. The designed test protocol suggests that position-specific and physiological tests may serve in identifying indices that could be useful in constructed soccer specific training, game specific positions, and competition. **References** 1. ### CHANGES IN MUSCULAR AND NEUROMUSCULAR FUNCTIONS FOLLOWING SOCCER-SPECIFIC FATIGUE IN YOUTH MALE FOOTBALLERS

Lehnert, M., Švarc, R., Laštovička, O., Vařeková, R.

*Palacky University, Faculty of Physical Culture*

**Introduction** In soccer, ACL injury is frequent injury predominantly non-contact in nature (Walden et al., 2011). It was suggested that fatigue increases the risk of ACL injury and that the risk is higher in youth compared to adults. Limited epidemiological studies indicate that this relative risk of ACL injury may peak in pubertal and post pubertal years. It was also suggested that the functioning of the muscular and neuromuscular mechanisms that contribute to knee stability in a fatigued state was influenced by growth and maturation (Lloyd et al., 2011). The aim of the study is to assess the impact of soccer-specific fatigue on leg stiffness and reactive strength in young soccer players. **Methods** A group of young soccer players (n=19; age 15.1±0.6 years; body height 170.5±10.9 cm; body weight 60.4±9.9 kg) participated in this study. The reactive strength index (RSI), and lower limb stiffness were assessed before and after soccer-specific fatigue protocol SAFT90. The RSI was determined by means of a drop jump test. Absolute leg stiffness was determined based on the data of a two-legged sub-maximal hopping test. Absolute leg stiffness was normalized to relative leg stiffness (relative to leg length and body mass). **Results** A statistically significant decrease (t=2.41, p=0.027, d=0.55) in the RSI and absolute leg stiffness (t=3.96, p=0.001, d=0.91) and relative leg stiffness (t=3.94, p=0.001, d=0.90) after soccer-specific fatigue protocol was observed. **Discussion** The findings of our study of young soccer players indicate that soccer-specific fatigue induces a significant decrease in the functioning of the muscular and neuromuscular mechanisms that contribute to knee stability in a fatigued state. The results of the study support the opinion that boys have a lower ability to resist to neuromuscular fatigue than adult men and consequently are subject to an increased risk of ACL injury in a fatigued state (Oliver and Smith, 2010). The results point to the importance of prevention strategies included into training programs and the importance of the dosage of training load and game load in youth athletes. **References** Lloyd RS, Oliver JL, Hughes MG, Williams CA (2011). *J Electromyogr Kinesiol*, 22(1), 37-43. ### CHANGE-OF-DIRECTION SPEED TRAINING IN MINIMALIST FOOTWEAR MAY PROVIDE ADDITIONAL PERFORMANCE GAINS IN JUNIOR AUSTRALIAN RULES FOOTBALLERS

Graham, S.1, Taylor, S.1, McLaughlin, P.2, Zois, J.1

*Victoria University, Institute of Sport Exercise Science and Active Living (ISEAL)*

**Introduction** Training in minimalist shoes can increase straight-line running speed and jumping performance. This study assessed the performance adaptations following a five-week change-of-direction speed training program using a minimalist shoe intervention. **Methods** Junior Australian Rules Footballers were recruited (n=20) and stratified into a minimalist shoe (n=9) and shod group (n=11). The training program consisted of five-weeks of change-of-direction speed cutting exercises and plyometric activities. Pre and post change-of-direction speed measures (AFL agility test, Agility T-test and Pro agility shuttle) and foot muscle strength (plantar flexion, greater toe flexion and lesser toe flexion) were recorded pre and post the training program. Data was analysed using effect size statistics with 90% confidence intervals and percentage change to determine magnitude of effects. **Results** Minimalist shoes provided moderate gains compared to shod in two of the change-of-direction speed tests (AFL agility test -2.3 ± 2.3% ES:0.38, Agility T-test -2.0 ± 2.9% ES:0.41) and trivial in the other (Pro agility shuttle -0.1 ± 2.5% ES:0.01). Intrinsic foot strength measures showed moderate improvement in the minimalist shoe condition (greater toe flexion 8 ± 24% ES:0.2 right and 19 ± 32% ES:0.4 left) (lesser toe flexion 11 ± 30% ES:0.2 right and 11 ± 36% ES:0.2 left) compared to shod. Minimalist shoes moderately decreased extrinsic foot strength compared to shod (plantar flexion -10 ± 19% ES:0.4 right and -9 ± 13% ES:0.3 left). **Discussion** Junior Australian Rules Footballers experience some additional improvements compared to shod following five-weeks of change-of-direction speed training in minimalist shoes. A training program closer to eight weeks may be more beneficial. Additional gains may be attributed to the improved intrinsic foot strength capacity. These findings would be of particular interest to practitioners aiming to optimise agility training programs for young athletes.

## ANGIOTENSIN-CONVERTING ENZYME GENE EXPRESSION ASSOCIATED WITH SOCCER PLAYERS' PHYSICAL CAPACITIES

Coelho, D., Pimenta, E., Rosse, I., Carvalho, M., Silami-Garcia, E.

*Universidade Federal de Ouro Preto*

**INTRODUCTION** Among the many genes that have an effect on sports performance, one of the most studied is the insertion/deletion polymorphism of the gene encoding the angiotensin-converting enzyme (ACE-I/D), as it affects the performance of both aerobic and anaerobic activities. **METHODS** Were evaluated 138 male athletes (categories Under-17, Under-20 and adults) of a Brazilian first division Soccer team. Genotyping of DNA from leucocytes was performed using polymerase chain reaction and restriction fragment length polymorphism methods. The athletes were genotyped in DD, ID or II. The following three parameters were investigated: first, speed, using a 30-m sprint test with speed measured at 10 m (V10), 20 m (V20), and 30 m (V30); second, muscular strength, using counter-movement-jump and squat jump tests; and third, aerobic endurance using the Yo-Yo endurance test. The athletes were ranked in ascending order according to their performance in each test. After which they were divided into quartiles, first quartile (0–25%, Weak), second quartile (25–50%, Normal), third quartile (50–75%, Good), and fourth quartile (75–100%, Excellent), and clustered according to genotype frequency. The X<sup>2</sup> was used to compare the genotype frequencies (DD, ID and II) within and between the different quartiles of performance rating. **RESULTS** We identified significant difference in test values V20 and aerobic capacity. In the case of the V20 observed higher frequencies of the ACE-DD genotype in Excellent performance group compared to the others. In the aerobic capacity test, there was greater higher frequency of ACE-II individuals in performance groups Excellent and Good compared to the others. **DISCUSSION** As in the present study, we have observed an increased frequency of the ACE-DD polymorphism in higher levels of competitive sports with anaerobic predominance (Costa et al., 2009) and when these modalities are compared to athletes modalities of aerobic predominance (Scanavini et al., 2002). The reverse also observed by these authors. It is concluded the players that have higher performance in aerobic and anaerobic tests are ACE-II and DD genotypes respectively. **REFERENCES** Costa A, Silva A, Oliveira A, Oliveira R, Granadeiro L. ### OP-PM59 Health & Fitness: Age I

#### ASSOCIATION BETWEEN CARDIOVASCULAR FITNESS AND QUALITY OF SLEEP IN YOUNG ADULTS

Keng, C.F., Lin, C.Y., Chen, J.J., Lin, I.C., Ye, Y.J.

*National Yang Ming University*

**Background and purpose:** Young adults with sleeping disorders are increasing due to the changing of life style and stress, especially in college students. Poor quality of sleep are highly related to cardiovascular diseases and sudden death from overwork. However, the study of quality of sleep and cardiovascular fitness are lack of cardiac output data during exercise tests. Thus, we used a non-invasive monitor of cardiac output during exercise to investigate the association between cardiovascular fitness and quality of sleep in college students. **Methods:** A total of 42 college students (male: 21, female: 21, mean age: 20.57±0.737years; mean height:166.056±8.423 cm; mean weight:59.20±11.836) was recruited in this study. For sleep quality evaluation, a valid Chinese version of the Pittsburgh Sleep Quality Index (PSQI) was used. The definition of poor sleep was PSQI score >5. We used 6-minutes walking test as cardiovascular fitness tests. Cardiac output during exercise was measured by a non-invasive monitor (PhysioFlow®, Manatec type PF05L1, Paris, France ) with modified Bruce Protocol for 12 minutes treadmill walking. Independent t-tests were used in data analysis. **Results:** The basic data of body weight, body height, BMI, gender and age of poor sleep and control group were all non-significant. Subjects with poor sleep quality (PSQI score >5) were more likely to have lower levels of cardiovascular fitness. The fatigue and dyspnea level before exercise and fatigue level after exercise were significantly higher in the poor sleeping group (p<0.001, p=0.001, p=0.042). The diastolic blood pressure (DBP) was also higher in poor sleeping group before exercise (p=0.038). **Conclusion:** Poor sleeping quality would increase the fatigue and dyspnea level before and after exercise, and the DBP would also been interfered by the quality of sleep. People with higher level of fatigue and dyspnea might have higher risk of sudden death from overwork. Higher DBP in resting also imply the deficiency of cardiac muscle contractility. Further studies of cardiovascular disease should take the quality of sleep into consideration.

#### DEVELOPING OF MODEL HEALTH HOLISTIC CARE OF THE ELDERLY BY THE COMMUNITY PARTICIPATION IN TAM-BONBUGRASUNG AMPHOE NONGKEE BURIRAM PROVINCE IN THAILAND

Chuntiima, W.

*suranree university of technology*

**Introduction** This research has 3 objective to evaluate the quality of life and quantitative and focus group discussion of 11 stakeholders in the community. of the elderly , to analyze the relations between independent factors and dependent (the quality of life of the elderly ) and to find out viable strategies to improve the health holistic care for the elderly through individual, family care and community support. **Methods** The study comprises two steps of research design. The first step adopted a qualitative approach based on the interview of 243 elderly along multi – stage method. The quantitative result were used in the final step , and quantitative based on focus group discussion at the individual and family levels, and in-depth interviews at the community level of total 25 samples were studied. **Results** The Result showed that elderly average age of 70.6 years. The factor analysis for quality of life evaluation in elderly of the quality of life . A multiple regression analysis showed that the total of 13 independent variables could explain adjusted R square of 99.4 percent . Ten independent variables significantly relate to the quality of life **Discussion** To improve the quality of life for elderly , the strategies for each individual empowerment is to be well prepared for the following : knowledge and self- practice for a healthy life elderly . , on money – savings, self-reliant elderly and active elderly involving in family and community activities. At the community level , a proactive approach of strengthened community is need for community members supporters , and participation in community activities based on wisdom, culture and

### THE EFFECT OF HEALTH PROMOTION INTERVENTION ON CARDIOVASCULAR RISK FACTORS IN ACTIVE COMMUNITY DWELLING ELDERLY

Wang, Y.P., Tseng K.W., Chen, T.C., Tsai, M.W.

*National Yang Ming University*

**Introduction** People volunteered to participate the health promotion programs may have better healthy awareness and/or more active lifestyle (From et al.,2013; Haskell et al.,2007).However, it is uncertain the intervention remains effectively to modify cardiovascular (CV) risk factors even in active community dwelling elderly. The aim of this study was to compare the effect of 12-week health promotion programs involving different mode on CV risk factors in active community-dwelling elderly. **Methods** This was a retrospective cohort study. 66 participants (69.0±5.4 years) were included for study analysis. Based on usual physical activity (PA) and program attended, we categorized participants into 3 groups: moderate PA with exercise (Gr1, n=23), high PA with exercise (Gr2, n=20), and high PA with intensive stair climbing exercise (Gr3, n=23). Outcome variables including resting heart rate (RHR), systolic blood pressure (SBP), diastolic blood pressure (DBP), total cholesterol (TC) and fasting blood glucose (FBG) were extracted at baseline and program completion. Within group difference was assessed by paired t-test. One-way ANOVA was used to compare baseline data among groups, and one-way ANCOVA was used to compare the change of RHR and risk factors among groups. The significant level was set at  $p < 0.05$ . **Results** The baseline values were significantly different among groups except FPG. All subjects showed significantly change in SBP (-8.9±26.2 mmHg,  $p=0.029$ ), FBG (-7.1±27.6 mg/dL,  $p=0.005$ ) and TC (-22.6±41.2mg/dL,  $p<0.001$ ). Gr 1 got decrease in SBP(-8.7±17.8 mmHg,  $p=0.029$ ), FBG(-11.9±21.8 mg/dL,  $p=0.016$ ),and TC(-20.6±35.6 mg/dL,  $p=0.011$ ), Gr2 got decrease in TC(-50.3±50.8 mg/dL,  $p<0.001$ ), and Gr3 got decrease in RHR (-14.7±27.3 bpm,  $p=0.002$ ).By adjusting the baseline value, Gr 2 showed greater improvement in TC than the others( $p=0.010$ ) and more reduction in RHR in Gr3 than Gr1 and Gr2 ( $p=0.030$ ). **Discussion** A 12-week community-based health promotion program could modify and modestly improve some cardiovascular risk factors in active older adults. The effect showed more obvious in elderly with regular high PA behavior than moderate PA. Our results also highlighted the intervention mode and PA level dependent effect on CV risk factor modification in active community dwelling elderly. **References** From, S., Liira, H., Leppavuori, J., Remes-Lyly, T., Tikkanen, H., & Pitkälä, K. (2013). BMC Public Health, 13, 125. Haskell, W. L., Lee, I. M., Pate, R. R., Powell, K. E., Blair, S. N., Franklin, B. A., Bauman, A. (2007). Med Sci Sports Exerc, 39(8), 1423-1434.

### THE EFFECT OF HIGH INTENSITY INTERVAL TRAINING ON THE BODY COMPOSITION AND FUNCTIONAL CAPACITY OF OLDER OBESE ADULTS

Nieuwoudt, S., Terblanche, E.

*Stellenbosch University*

**Introduction** The implementation of High Intensity Interval training (HIIT) in older adults for health and fitness is relatively uncommon. However, the literature indicates that HIIT is well tolerated by older adults and clinical populations, while significant improvements in health and fitness are reported (Tjønnå et al.,(2008). Minimal studies have been done on older, obese adults. The aims of this study were to determine if HIIT was safe and more effective than a Moderate Continuous Aerobic Training protocol (MCAT) in changing the body composition and functional capacity (FC) of older obese adults. **Methods** 24 sedentary older adults (age 63±6 years; 37±8 % body fat) volunteered for this 16 week intervention study. They were randomly allocated into 2 groups that performed HIIT or MCAT. HIIT consisted of 4 x 4 minutes on a treadmill at 90-95% of age predicted maximum heart rate (APMHR) with 3 minutes of active recovery. MCAT consisted of treadmill walking for 47 minutes at 70-75% of APMHR. The two interventions were isocaloric (Tjønnå, et al., 2008). Body mass (BM), waist (WC) and hip circumference (HC) were measured according to the International Standards for Anthropometric Assessment and measured with a spring loaded, non-extensible anthropometric tape measure. Abdominal diameter (AD) was measured supine using a Holtain-Kahn abdominal calliper. FC was measured using the Timed up and Go test (TUG). The magnitude of the differences between the two programmes was calculated using Cohen's effect sizes. Ethics approval was obtained from Stellenbosch University. **Results** There was a large practically significant reduction in BM in the MCAT group (2.26 ± 1.2kg), with no significant change in the HIIT group (0.96 ± 1.69kg). Both exercise interventions resulted in statistically significant reductions in AD, WC and HC ( $p<0.0001$ ), but only small practically significant differences were observed between the groups (ES=0.07, 0.09 and 0.01 respectively).The change in FC was practically significant in both groups with a greater magnitude of difference in the HIIT group (HIIT 0.3 ± 0.39s; MCAT 0.2 ± 0.27s; ES=0.3). **Discussion** When work volumes are the same, a 16 week HIIT protocol results in positive changes in body composition and functional capacity similar to an MCAT protocol in older, obese adults. No adverse effects were reported. The findings suggest that HIIT can be a safe and effective method of training for older, obese adults, adding variety and possibly better compliance to regular exercise. **References** Tjønnå, A.E., Lee, S.J., Rognmo, Ø. et al. (2008). Aerobic Interval Training Versus Continuous Moderate Exercise as a Treatment for the Metabolic Syndrome A Pilot Study. American Heart Association, 118:346-354. Contact 15617572@sun.ac.za

### PREVALENCE OF PHYSICALLY DEPENDENT ELDERLY IS INFLUENCED BY OBESITY STATUS: THE EXERNET MULTICENTER STUDY

Alcazar, J., Mata, E., Gomez-Cabello, A., Pedrero-Chamizo, R., Gusi, N., Villa, J.G., Espino, L., Casajus, J.A., Gonzalez-Gross, M., Ara, I.

*University of Castilla-La Mancha*

**Introduction** Promoting older people to remain healthy and independent seems critical to reduce the negative consequences of aging. Therefore, it has been recommended that elderly should manage their body weight (1) and should be screened for disability in functional activities on an annual basis (2). To our knowledge, no studies reporting the prevalence of older people with problems of functional limitations using objective functional fitness (FF) tests and obesity assessment can be found. **Methods** A cross-sectional study was conducted on a representative sample of non-institutionalized Spanish older adults (n=3,136) aged from 65 to 92 years. Lower- and upper-body strength, agility and endurance were assessed using the Senior Fitness Test (3). Criterion-referenced standards for FF scores (3) were used as cut-off points to classify older people in 3 groups: physically dependent, pre-dependent and physically independent. Body composition was analysed using bioelectrical impedance, waist circumference and body mass index (BMI). Chi square and Cochran-Mantel-Haenszel tests were applied. **Results** The prevalence of low functioning-physically dependent elderly in Spain was 6.9%. No

difference between genders was found. Those subjects with problems of physical dependence showed higher levels of obesity both assessed by BMI (OR, 2.29) or body fat percentage (OR, 2.41), and also with central obesity (OR, 2.87) compared to the non-physically dependent group (all  $P < 0.01$ ). These associations remained significant when gender and age were considered (all  $P < 0.01$ ). Discussion Almost 7% of the non-institutionalized elderly population in Spain is physically dependent. Additionally, in physical dependent subjects the odds of being obese or having central obesity were more than two-fold higher compared to non-physically dependent subjects. These results are in agreement with data reported by Koster et al. (4). Interventions to prevent and treat the FF decline including obesity assessment should be a public health priority. ### **GENDER DIFFERENCES IN SELF REPORTED WALKING AND SITTING TIME IN PRE-DIABETIC PARTICIPANTS ENROLLED INTO A LIFESTYLE INTERVENTION: PRELIMINARY BASELINE RESULTS FROM THE PREVIEW PROJECT.**

Swindell, N.1, Drummen, M.2, Fogelholm, M.3, Handjieva-Darlenska, T.4, Lam, T.5, Larsen, T.6, Macdonald, I.7, Mackintosh, K.1, Martinez, A.8, McNarry, M.1, Pipard, L.5, Poppitt, S.9

*Raben A.6, Schlicht W.10, Simpson K.11, Stratton, G.1*

1: SU (UK) 2: UM (Netherlands) 3: HEL (Finland) 4: MU (Bulgaria) 5: NetUnion 6: UCPH (Denmark) 7: UNOTT (UK) 8: UNAV (Spain) 9: UOA (NZ) 10: USTUTT (Germany) 11: UNSYD (Australia) Low physical activity, high sedentary behaviour and insulin resistance are precursors of type-2 diabetes (Wilmot et al. 2012). The current study quantified walking and leisure time sitting (LTS) in a sub-study of pre-diabetic participants recruited into an on-going lifestyle intervention study (PREVIEW - PREvention of diabetes through lifestyle Intervention and population studies in Europe and around the World). Methods Pre-diabetic (WHO/IDF 2006), overweight BMI  $\geq 25.0$  kg/m<sup>2</sup> participants aged 25-70 years were recruited from 6 EU countries, Australia and New Zealand into a 3year diet and exercise program. At baseline prior to the start of the intervention, 652 participants (462 female) self-reported 7 consecutive days of walking time (all intensity) and LTS. Results There was no gender difference in mean ( $\pm$ SD) walking time 279 $\pm$ 204 min/wk (male) 295 $\pm$ 209 min/wk (female)  $p = 0.44$ ; 72% of men and 70% of women were sufficiently active according to international guidelines (WHO, 2010). Mean ( $\pm$ SD) sitting time did not differ by gender 1827 $\pm$ 988 (male) 1680 $\pm$ 926 min/wk (female);  $p = .09$ ; 50% of men and 40% of women exceeded 4h/d of LTS. There was a significant inverse relationship between walking and LTS in women ( $r = -.108$ ;  $p = .03$ ), but not men ( $r = -.039$ ;  $p = .63$ ). Conclusion After being screened for diabetes risk the majority of pre-diabetic participants self reported that they were sufficiently active (WHO 2010). In contrast LTS exceeded previously reported thresholds for increased risk (Sisson et al. 2009). These findings provide data on self-report activity of adults choosing to enter an intervention to help them reduce their risk of diabetes. These findings are based on subjective methods; future research will include objective measures. Funding FP7/2007-2013 Grant agreement no. 312057. NHMRC - EU Collaborative Grant, AUS. #### **POLYMORPHISMS IN RAS CODING GENES ARE ASSOCIATED WITH EXERCISE TRAINING-INDUCED CHANGES IN CARDIORESPIRATORY FITNESS**

He, Z., Tian, T., Hong, P., Huang, C., Zhao, J., Wang, M., Li, R.

*China Institute of Sport Science*

Purpose: Individuals differ in the response to regular exercise. Our objective was to examine the hypothesis that tag SNPs polymorphism in the coding genes of the rennin-angiotensin system influences aerobic exercise training-induced changes in cardiorespiratory fitness through genotype-specific increases in Maximal oxygen uptake (VO<sub>2</sub>max). Methods: 596 normal body mass index (BMI), no regularly exercising subjects completed 16 week aerobic training. Ages are 20-59 year old. Among them, 344 are women. The exercise training load is 20-30min under 75%-85% AT in the first week, 85%AT and 30min from second to fourth week, 85%AT and 40min from fifth to eighth week, 95%AT and 40min from ninth to twelve, 100%AT and 40min from thirteen to sixth week. 89 tag SNPs were selected by haplotype and genotyped by a matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) platform. VO<sub>2</sub>max was measured breath-by-breath by a continuous incremental intensity protocol. Results: After 16 week aerobic training, VO<sub>2</sub>max (ml/min/kg) increased significantly. For male, it improved from 32.96 $\pm$ 7.88 to 34.21 $\pm$ 7.48ml/min/kg ( $P < 0.001$ ). For female, VO<sub>2</sub>max enhanced from 26.23 $\pm$ 5.14 to 27.70 $\pm$ 5.32ml/min/kg ( $P < 0.001$ ). For individual response, 44 males (17%) and 54 females (16%) decreased more than 10%, 82 males (33%) and 132 (38%) females increased more than 10%. For males, AGTR1 rs2675511 and REN rs4951313 were associated with VO<sub>2</sub>max training response, which can explain 3.5% individual difference. For females, FNDC5 rs3480, AGTR1 rs2675511, and AGTR1 rs385338 might explain 5% individual training response difference. Conclusion: Those results suggest that polymorphism significantly affect training-induced cardiorespiratory fitness changes, which can guide make individual exercise training plan for health improvement.

#### **EFFECTS OF 4 WEEKS OF MAXIMUM LIPID OXIDATION RATE INTENSITY TRAINING AND RESISTANCE TRAINING ON ADIPOSE TISSUE DISTRIBUTION AND MORPHOLOGY OF OBESE YOUTH**

Zhang, L.

*China Institute of Sport Science*

Objective: Although many studies have found the usefulness of aerobic and resistance training in reducing body fat. But few studies was about maximum lipid oxidation rate (MLOR) intensity exercise, or has been compared its effect with resistance training. This study aimed to find out the difference of the effect between the 2 training approaches on reducing body fat when combined with same diet restrict

methods. Methods: 37 obese youth were divided into 2 groups: aerobic training group (AT, n=20, 10 male and 10 female, age 20.8±2.2 years, BMI 30.3±2.2 kg/m<sup>2</sup>, body fat percentage 38.7±5.6 %) and resistance training group (RT, n=17, 8 male and 9 female, age 20.7±1.5 years, BMI 30.1±2.4 kg/m<sup>2</sup>, body fat percentage 38.5±5.5 %). The experiment lasted for 8 weeks. Subjects were submitted to different physical training plus the same diet restriction during 1st-4th week and no intervention during 5th-8th week. The exercise forms in AT group included brisk walking, jogging and aerobic dancing. Personal MLOR point was detected by ergospirometry device. The exercise forms in RT group were resistance strength training. The exercise time for both groups was 1.5 hours per day and 6 days per week. The diet was based on every subject's own resting metabolic rate (RMR) which was measured by ergospirometry device. Besides RMR, parameters including height, weight, body composition by DEXA, and body girth by 3D scan device were measured in pre-training and at the end of the 4th and the 8th week. Results: (1) When compared with pre-training level, all parameters detected at the end of the 4th and 8th week decreased significantly (p<0.05/0.01). The scale of decrease in AT and RT groups were: BMI -8.22±1.95% and -7.72±1.70%, total fat mass (TFM) -19.89±7.69% and -18.36±6.18%, total lean body mass (LBM) -2.28±2.16% and -1.77±3.77%, arm fat mass (AFM) -22.04±9.36% and -16.30±8.45%, leg fat mass (LFM) -8.78±27.22% and -15.80±4.63%, trunk fat mass (TrFM) -21.97±9.68% and -20.04±9.03%, waist circumference (WC) -5.11±2.81% and -4.46±2.80%. However, between AT and RT groups, only the scale of decrease in AFM showed the trend of different (0.05).

## WALKING ENERGY EXPENDITURE AND RECOMMENDATION IN CHINESE ADULTS

Wang, H., Jiang, C.M., Xu, L.L.

*China Institute of Sport Science*

Introduction: Among all the activities, walking is regarded by public as the most common exercise. The purpose of the study was to measure walking-related energy expenditure during field testing, to identify step-rate cut-point associated with moderate and vigorous intensity, and to translate physical activity (PA) guidelines into walking goals for Chinese young adults, and to explore the application of walking recommendation in community. Methods: Design: Cross-sectional analytic study Participants: A sample of 226 Chinese adults (117 men, 109 women) with age from 30~60 yrs. volunteered to participate in the study. All Participants were recreationally active without orthopedic limitations, free of chronic diseases, not taking any medications that affect metabolism and non-smokers. All the participants completed four 6 min incremental over ground walking at different speeds of 3.8, 4.8, 5.6 and 6.4 km/h, respectively. Indirect calorimeter was used to measure energy expenditure at each speed. Receiver operating characteristic curves were used to determine the step-rate cut-points associated with moderate and vigorous intensity activity. Results: At the same walking speed, step counts per minute were higher in women than in men. No significant differences were found in VO<sub>2</sub> per weight (ml/kg/min) between women and men. Step-rate cut point associated with walking at 3 metabolic equivalents (METs) and 6METs were 110 and 130 step/min when analyzing men and women together. There were slight differences on the cut-points between women and men if data were analyzed separately. Discussion and Conclusion: In order to associate our step-rate cut-point with PA guideline, the minimum walking steps of 3300 steps daily for MPA were considered based on our study result. It should be emphasized that 3300 steps need to be taken above the basic number of daily steps. Recent study has reported the daily walking steps goal for American people is 8000 steps, derived from accelerometer data, but an earlier study reported 10 000 steps. Since people have different PA patterns, it is difficult to establish consistent total number of walking steps for everyone. Moreover, there is not a comprehensive walking recommendation if only walking steps is involved but not the intensity. Therefore, it is practical and useful to provide a general suggestion that how many extra steps individual needs to take above the daily activities and how fast to walk for health promotion. Specially, Chinese adult should walk at least 30 min with a minimal 110 steps/min, or 3300 steps or 2 km with the same step rate daily to meet PA guidelines. They will perform vigorous-intensity activity if 130 step/min is reached and this will provide more health benefit.

## PHYSICAL ACTIVITY AND SITTING - HEALTH PROMOTION INTERVENTIONS AT THE WORKPLACE.

Proper, K.

*1) National Institute for Public Health and the Environment, and 2) VU University Medical Center*

Despite known benefits of physical activity, still an important proportion of the adult population is not sufficiently active. Physical activity and health promotion can be done in several settings, including the workplace. The promotion of physical activity in the working population is of particular importance considering the increased automation and technology, leading to a change in the nature of our work. In the last years, our work has changed from physically demanding to more mentally demanding requiring sedentary behaviours (sitting) rather than physical activity. Interventions through the workplace to promote physical activity and reduce prolonged sitting hours are thus necessary. There are several ways to promote physical activity and reduce sedentary behaviour in workers. In this presentation, different types of such health promotion interventions and their effects will be given. Examples of such interventions include individual counselling on physical activity, environmental interventions, or group-based exercise programmes. Next to effectiveness, the question is whether the employers return their money invested in these programmes. Based on our economic evaluations and systematic reviews, results on costs and benefits (return-on-investment) of workplace physical activity and health promotion interventions will be presented. In the implementation of workplace health promotion, ethical issues may arise because of different views of the stakeholders involved, such as employers, employees, or occupational physicians. Through focus group interviews, we explored the views of all stakeholders involved in worksite health promotion. This presentation will provide the results of the ethical considerations that resulted from the differences between the views of the stakeholders. References 1. ### IS-SH03 INTERNET OF SPORTS: AUGMENTING SPORTS TECHNOLOGY FOR PERFORMANCE AND PLEASURE

#### INTERNET OF SPORTS APPLICATIONS

Nylander, S., Tholander, J.

*Swedish Institute of Computer Science*

Mobile Life is doing research in "Internet of Sports", exploring how to design the next generation of services for sports and physical activity. A wide range of sensors for body metrics are available, and many consumer products for exercise and sports have been released in the past few years. At Mobile Life we have been looking at how we can use this technology to enhance the experience of doing sports and avoid reducing humans to data through studying people's practices around sports, and through a number of design projects and service prototypes. A closer look at how elite and recreational athletes use heart-rate monitors reveals many purposes beyond improving performance. Heart-rate monitors are also used as tools to get to know the body, learn how to calibrate exertion as well as improving the experience of exercise. In our design work on running and golf, we have aimed to support the experiential aspects in combination with improving performance.

#### GOLF DATA ANALYTICS

Johansson, U., König, R., Dahlbom, A., Riveiro, M., Brattberg, P.

*University of Borås*

This lecture will present work-in-progress from the Golf Data Analytics (GOATS) – project at the universities of Borås and Skövde, Sweden. The overall purpose of GOATS is to use machine learning and data mining techniques for analysis of swing and ball flight data in combination with high-resolution video. One high-level task is to discover patterns by modeling and analyzing golf swings from large and heterogeneous data bases. Specifically, a prioritized goal is to identify general, but non-trivial, differences in the swing between good and poor players. Another ambition is to establish a modern framework for combining quantitative data about swing and ball flight with video analysis in golf training and instruction. One example is to design a systematic approach to identifying (individually for each golfer) the most important areas for improvement. Naturally, combining video and quantitative data allows a more advanced analysis, compared to using just video, but this requires new paradigms and innovative supporting tools for the golf instructor. In the talk, we will present data-driven models, found from a completed study with more than 300 golfers of different levels, describing the most important differences between highly-skilled and recreational golfers. We will also show some initial results from utilizing the Kinect sensor as an affordable alternative to more costly 3D-modeling tools. Finally, we will briefly describe future work in the project.

#### INTERACTION IN MOTION

Marshall, J.

*University of Nottingham*

Over the last 10 years, there has been a big increase in use of commodity technology to track and support sports activity. For example the wide range of sensors embedded in a modern smartphone means that these devices can support a wide variety of sports activities, and have the potential to go far beyond the current focus on quantity and distance of running and cycling. In particular the ability to sense form and identify the quality of movements means that cheap, widely available technology could be used for skill learning and improvement. This has potential to massively increase access to high quality skill learning for amateur athletes who are largely un-coached. However, this is fundamentally hampered by a major design assumption inherent in current technology, which is that it is not designed to be actively used while moving. Instead, it is designed around a 'stop to interact' paradigm, where any time users want to actively control the system, they must stop and look at a screen. In general this causes serious problems when users attempt to interact with technology whilst they are actually moving (see [1] for a more general analysis of these problems), but it is particularly problematic for sports interaction, where users are often more constrained than in normal usage situations. Touchscreen interfaces used on most mobile technology are inherently visual and lacking in spatial cues. Whilst various solutions to this have been presented, such as tactile displays and interfaces designed for purely audio and touch usage (e.g. [2]), they are both limited and specialised, so currently, the primary interaction method with mobile systems both requires looking at them, and touching them. When moving, particularly when doing sports, people are constrained in terms both of visual and mental attention and in their ability to physically touch user interfaces. If we are designing applications to be used during sports activities, we need to consider how we design for 'interaction in motion'. I propose 4 potential ways of designing taking movement into account: 1) Design with minimum interaction during the sporting activity, as is done by most current software. 2) Using interaction and user feedback at appropriate points in the activity (and sensing when they are). 3) Designing modified sporting activities which consider the technology being used to track them, such as targeted training sessions which are aware of when the user will be too busy to consider. 4) Interacting through sensing the activity itself. **IS-SH11 SPORT FOR DEVELOPMENT AND PEACE: critical perspectives****APPROACHING 'SPORT FOR DEVELOPMENT AND PEACE' AS AN INTER-DISCIPLINARY PROJECT**

Darnell, S.

*University of Toronto*

One of the features of recent research in the field of Sport for Development and Peace (SDP) has been inter-disciplinarity, with scholars from management, sociology, education and policy studies all asking important questions and producing significant findings and criticisms. While this trend illustrates the growing depth of the field, it also has the potential to create silos within the research community, particularly between a monitoring & evaluation (M&E) approach on the one hand, and critical analyses on the other. In this presentation, I attempt to reconcile these perspectives in productive ways. I suggest that M&E-focused research can inform a critical understanding of SDP by analysing the development effects of sport, both positive and negative. Vice versa, a critical sociology of sport-for-development – using, for example, macro theories of political economy and post-colonialism – can inform and improve SDP policy and practice by highlighting inequalities and challenging historical amnesia. Overall, I put forth that SDP, in both practice and research, is inextricably inter-disciplinary, and therefore scholars are charged with embracing multiple perspectives, rather than defending particular paradigms.

**MAKING TRANSNATIONAL, CROSS-CULTURAL CONNECTIONS IN SPORT FOR DEVELOPMENT AND PEACE: EXPLORING MULTI-SITED SOCIAL AND POWER RELATIONS**

Hayhurst, L.

*University of British Columbia*

Over the past decade, studies of Sport for Development and Peace (SDP) have examined programs through case studies of non-governmental organizations (NGOs), corporations, government agencies and international entities such as the UN. However, research into the SDP sector that engages with multiple stakeholders and global/local dynamics to examine how social relations among SDP actors influence and shape norms, policies and practices 'on the ground' remains mostly absent from existing studies. In this paper, I draw on multi-sited, transnational and cross-cultural empirical studies of SDP conducted over the past five years in order to highlight the importance of exploring complex social and power relations translated through diverse actors and contexts. Throughout this discussion, I consider the ways that global and cultural flows – and multiple connections – expand across transnational SDP and 'hold it together' against the diverse forces of disparate social locations, interests, identities and access to resources (see Thayer, 2010). In conclusion, I suggest that combining a multi-sited approach (e.g., Marcus, 1995) inspired by global ethnographies (e.g., Burawoy, 2001) that combine multiple geo-political perspectives (i.e. top-down and bottom up) provides new insights and meanings into the transnational nature of SDP studies. While studies of SDP-focused organizations in isolation of transnational forces are useful for providing in-depth accounts of policies, programming and impacts, I contend such studies potentially ignore crucial transnational, cross-cultural and postcolonial dynamics that influence these same issues. Overall, this perspective might also serve as a starting point for untangling the complexity of cross-cultural dynamics by focusing on SDP aid relations, its (un)intended effects, and the political rationalities and discursive relations that underpin it.

**LOCAL VOICES, SENSE-MAKING AND AGENCY IN THE 'UPTAKE' OF SDP PROJECTS IN AFRICA**

Burnett, C.

*University of Johannesburg*

Introduction Scholars are increasingly raising issues of complexity and contextual understandings of the multi-layered 'uptake' of Sport for Development and Peace projects in local settings. Positivist log frames often underpin donor dominated delivery models and translate in reductionist foci of indicator-driven impact assessments. Developing a body of knowledge from such research seldom transcends the mapping of the field. Critical reflexivity of unequal power relations, stakeholder dynamics and the 'uptake' processes of social learning should be considered in relation to delivery models and programme mechanisms. Utilizing a grounded theoretical approach in synthesis with critical conceptual frameworks seems crucial for theory building and social policy development. Methods The paper is based on secondary analyses of data from three different case studies, namely: i) the GIZ/YDF (German Development Corporation and European Union funded) programme in multiple African countries; ii) the Commonwealth Games Federation's internship programme in selected African countries. Results The 'uptake' differs according to the framework of proposed development (measured by indicators) in the GIZ/YDF programme where the main implementation was channelled through non-government partners (NGOs). On-site interviews of 11 international volunteer placements from Commonwealth Games Canada and representatives from the National Olympic Committees from different African countries, gave a rich view on the 'uptake' of such a programme. Discussion If SDP programmes provided insights into the partnership and stakeholder dynamics which are interpreted against a human justice framework and showing real-life experiences and exploitative practices. Understanding multiple perspectives and socially-engineered agency call scrutiny of critically pragmatic research practices that would reach beyond technocratic reporting to meaningfully contribute to academic discourses. Addressing the discourse of 'new colonialism' and 'pan-African paternalism' found special meaning in a partnership exchange with exploitative dimensions observed in 'non-indentured' programme outcomes. ### OP-PM39 Training & Testing: Endurance III

#### ECCENTRIC CYCLING WARM-UP AS AN ALTERNATIVE METHOD PRIOR TO A TIME TRIAL

Bosio, A.1, Ferioli, D.1, Induni, M.1, Morelli, A.1, Martin, D.T.2, Menaspà, P.2,3, Fell, J.4, Rampinini, E.1

1:Mapei Sport (Olgiate Olona, Italy), 2:AIS (Canberra, Australia), 3:ECU (Perth, Australia), 4:UTAS (Tasmania, Australia)

**INTRODUCTION** The warm-up characteristics can influence cycling time trial (TT) performance (Christensen and Bangsbo, 2014; Bishop, 2003). When compared to concentric (CON), eccentric (ECC) exercises are associated with a lower cardiovascular response for a given muscular strain. Therefore, the aim of this study was to test the effect of an ECC cycling warm-up compared to a conventional warm-up on cycling TT. **METHODS** After 6 weeks of familiarization to ECC cycling, 8 amateur cyclists performed a 5 Km TT on 2 separate days preceded by ECC or CON warm-up. ECC consisted of four 2-min bouts alternating low to high intensity ECC cycling (40% and 120% of aerobic PPO) on a custom-built ergometer preceded and followed by 6-min conventional cycling at 100W. CON consisted in 5-min light cycling followed by an 8-min ramped protocol progressively building intensity up to above the anaerobic threshold. Neuromuscular function (MVC and VA), lactate (La), creatine kinase (CK), pH, bicarbonate, heart rate (HR), RPE and muscle pain (MP) were quantified during the warm-ups. Power Output (PO), Cadence (CAD), HR and RPE were monitored during the TTs. **RESULTS** CK and pH were similar in the 2 conditions, bicarbonate was lower and La was higher after CON compared to ECC. HR and RPE were lower after the ECC warm-up ( $115 \pm 12$  bpm and  $2.8 \pm 0.3$  au) compared to CON ( $141 \pm 11$  bpm and  $3.9 \pm 1.2$  au). MP was similar in the 2 conditions (with a likely peak at the end of TT). TT performance ( $471 \pm 27$  and  $466 \pm 23$  s for ECC and CON respectively) was not statistically different ( $p=0.112$ ). RPE and HR increased similarly in the 2 conditions during the TT ( $p<0.001$ ). Pacing, as reflected by PO distribution, was negative (start hard, end easy); in spite of a significant interaction ( $p=0.037$ ) differences between conditions at the 500 and 2000 m mark were subtle. CAD was similar in the 2 conditions. MVC did not change during the entire duration of the experiment, while VA was on average lower during CON ( $p<0.05$ ). **DISCUSSION** It is likely that ECC cycling, as a form of warm-up, has the potential to be a viable alternative to conventional warm-up. In fact, ECC elicited lower cardio-circulatory, metabolic and perceptual strains than CON without compromising subsequent TT performance. Furthermore, some evidence suggests that ECC might prevent the onset of central fatigue despite the very high level of forces sustained during ECC compared to conventional cycling. Further research is required to understand the influence of ECC on pacing strategies. **REFERENCES** Christensen PM, Bangsbo J. (2014). Int J Sports Physiol Perform, [Epub ahead of print] Bishop D. #### MONITORING HRV DURING REPEATED ELITE SWIMMING TRAINING-CAMPS

Ganzevles, S.P.M., de Haan, A., Beek, P.J., Daanen, H.A.M., Truijens, M.J.

VU University Amsterdam

**Introduction:** Heart Rate Variability (HRV) is a widely used measure to assess autonomic nervous system activity of athletes with the aim to optimize the individual training process. However, the underlying assumption that HRV provides an appropriate index of training load has not been tested to date, leaving the daily training practice without evidence basis (Koenig et al. 2014). In this study we monitored HRV in elite swimmers of the Dutch National team during their yearly training camp (TC) in January over the past three years. Although goals were similar over the years, i.e. enhancing aerobic condition, the specific implementation of training loads varied over the years. Therefore, we compared changes in training load with short-term (daily) and long-term (the complete training camp) changes in HRV. We hypothesized that changes in HRV parameters would reflect the variation in daily and weekly training load. **Methods:** Measurements took place one week before, during and one week after a three week TC in the same period of the swimming season over the course of three years. The same six swimmers participated in all three TC's. Measurements took place twice a week. The protocol consisted of lying in a supine position for 7 minutes in which beat-by-beat heart rate (HR) data were collected. Breathing frequency was controlled by a visual metronome at 0.2 Hz. From the HR data, HRV parameters were calculated for minute 2 to 6 (5 minutes in total). After normalization of the data, Pearson's correlation was determined between daily training load and HRV parameters. In addition, Pearson's correlation was determined for weekly training load and average HRV during one week. **Results:** We found no significant relation between daily training load and HRV parameters and between weekly training load and average week HRV. The highest correlation was found for weekly training load and RMSSD:  $r = 0.27$ ,  $p = 0.34$ ,  $CI = -0.65 - 0.96$ . **Discussion:** In contrast to commonly made assumptions, changes in HRV parameters did not reflect the variations in daily and weekly training load. This finding is in contrast with current literature on HRV. We conclude that it is unclear why HRV measurements should be incorporated in the daily training program of elite swimmers. **Reference:** Koenig, J., Jarczok, M. N., Wasner, M., Hillecke, T. K., & Thayer, J. F. (2014). Heart Rate Variability and Swimming. Sports Medicine 44(10):1377-91. doi:10.1007/s40279-014-0211-9.

#### VALIDATION OF A PROTOCOL THAT DETERMINES THE CAPACITY TO OXIDIZE FAT DURING EXERCISE IN OBESE ADULTS

Præst, C.1,2, Dandanell, S.1,2, Skovborg, C.1, Dela, F.1, Helge, J.W.1

(1.) University of Copenhagen (2.) Metropolitan University College

**Introduction** Achten et al. introduced a cycle ergometer test that determines the maximal whole body capacity to oxidize fat (MFO) and validated this in lean and well trained men by indirect calorimetry [1]. Interestingly a test modified and thus suitable for obese untrained individuals has not yet been validated. Therefore, the aim of this study was to validate a protocol that determines MFO and the relative intensity at which it occurs (Fatmax) in obese individuals. **Methods** Six overnight fasted subjects (3 W & 3 M; BMI:  $36 \pm 4$ ) performed two tests; a graded cycle exercise test (GE-test), starting at 30 watt for 6 min and increasing 20/25 watt/3 min in W/M, respectively. The test was stopped when the respiratory exchange ratio (RER) reached 1.0. On a separate day three 10-min bouts (CE-test) at 35, 50 and 65 % of  $VO_{2max}$ , interspersed with 30 and 40 min breaks, were performed. A Fatmax-curve was constructed from the GE-test and fat oxidation rates (g/min) were compared at the CE-test intensities using an Interclass Correlation Coefficient (ICC) 2.1 and a Bland-Altman plot with 95 % Limits of Agreement (LoA). **Results** A 2nd degree polynomial fit was used to estimate MFO and Fatmax in the GE-test ( $R^2 = 0.89$ ). Fatmax was reached at  $44 \pm 2$  % of  $VO_{2max}$  (range: 38-50). Despite a relatively good fit of the Fatmax-curve, as described above, the agreement between protocols was limited. The relative agreement was low (ICC: 0,331) and the absolute agreement, illustrated with a Bland-Altman

plot with 95 % LoA, indicated a large variation (LoA: +0.21 to -0.19 g/min). Discussion Based on the 6 subjects (out of 12) included in this ongoing study, the protocol using 3-min stages to determine MFO and Fatmax in obese individuals, showed limited validity. The lack of agreement between the two tests may be explained by 3 min being too short to reach steady state in obese untrained individuals [2] or it may be due to the small sample size. A more definitive conclusion of the validity of the 3-min stages protocol requires more subjects. References 1. Achten, J., M. Gleeson, and A.E. ### **INCREASES IN CIRCULATING CELL-FREE DNA DURING AEROBIC RUNNING EXERCISE DEPEND ON INTENSITY AND DURATION**

Haller, N., Tug, S., Jörgensen, A., Simon, P.

*Johannes-Gutenberg-University Mainz*

**Introduction:** Circulating cell-free DNA (cfDNA) is an upcoming molecular marker with a potential wide-range of applicability as a so called liquid biopsy in clinical diagnostics. Increases in cfDNA concentrations have recently been demonstrated to occur in a variety of exhausting and vigorous exercise settings. Here we assessed for the first time the effects of a moderate aerobic endurance exercise on cfDNA levels. **Methods:** 13 subjects (mean age: 24.38 years  $\pm$  2.90 years; mean height: 176 cm  $\pm$  10.06 cm; mean weight: 69.54 kg  $\pm$  12.22 kg) took part in our study, beginning with a step wise incremental test until exhaustion to determine their individual anaerobic threshold (IAT) (range: 10.8 km/h-13.4 km/h). Speed of the two endurance runs was set to 9.6 km/h for 40 minutes and therefore well below the IAT of all participants. Participants were dichotomized in two groups with above and below median (12.8 km/h) IAT. Capillary cfDNA, and rate of perceived exertion (RPE) by the Borg-Scale were assessed before, every 10 min during, and after the runs. **Results:** Lactate only increased significantly in the first minutes of the aerobic run in participants with a below median IAT remaining constant thereafter. In contrast steady increases for cfDNA during the endurance run and decreases after the run were observed for both groups. Significantly higher absolute concentrations and higher mean fold changes were observed for the group with below median IAT. Retest correlations for cfDNA were high ( $r=0.71$ ,  $p<0.0001$ ) for the whole collective, but even higher analyzing only male participants ( $r=0.84$ ,  $p<0.0001$ ). The correlation of cfDNA with RPEs were  $r=0.58$  ( $p < 0.0001$ ) and lactate values correlated moderately  $r=0.32$  ( $p < 0.05$ ) with RPE. **Discussion:** Both, duration and subjective level of intensity are associated with accumulation of cfDNA during a moderate aerobic running exercise. Along with a high test-retest correlation and a highly significant correlation with RPE indicated that cfDNA measurements might be applicable in the near future as a marker to estimate the individual level of exhaustion during aerobic exercise. This finding is surprising given that half of the participants were only exercising in a regenerative mode not showing increases in lactate above resting levels. The quite low intensity level applied in this study might have hampered higher correlations between RPE and cfDNA. Future randomized controlled longitudinal training studies will have to reveal the full potential of cfDNA as a marker in aerobic exercise settings.

### **MAXIMAL OXYGEN UPTAKE AND CARDIORESPIRATORY KINETICS BEFORE AND AFTER 6 WEEKS OF ENDURANCE TRAINING**

Drescher, U.1, Koschate, J.1, Scheffer, T.2, Brixius, K.2, Hoffmann, U.1

*German Sport University Cologne*

**Introduction** Endurance training improves the capacity and the regulatory responses of the cardiopulmonary and respiratory systems. To increase physical fitness, different training procedures (e. g. continuous, interval) can be applied. In this regard, diverse physiological adaptations of the training procedures have to be taken into account. Therefore, we were interested, whether six weeks of endurance training increases maximal oxygen uptake ( $\dot{V}O_{2max}$ ) and regulatory variables (cardiopulmonary kinetics) similarly. **Methods** Eight men (age: 43  $\pm$  9 years; height: 179  $\pm$  5 cm) performed pseudo random binary work rate (WR) changes on a leg cycle ergometer (30 W, 80 W) before (PRE; weight: 89.1  $\pm$  10.6 kg) and after (POST; weight: 89.2  $\pm$  8.8 kg) six weeks of endurance training. Four subjects were trained with a continuous (at 60% oxygen uptake reserve ( $\dot{V}O_{2Reserve}$ )) and the remaining four subjects with an interval (at 90%  $\dot{V}O_{2Reserve}$ ) intervention method, each three times a week. Heart rate was measured beat-to-beat via ECG, pulmonary oxygen uptake was determined breath-by-breath, and muscular oxygen uptake was estimated by the method of Hoffmann et al. (2013). Given a linear, time-invariant, first order system the peak of the cross correlation function (CCF) of work rate and a second parameter (heart rate, pulmonary and muscular oxygen uptake) indicates the kinetic responses of this parameter (Hpeak, Ppeak, Mpeak). Higher peaks denote faster system responses. Differences in the physiological variables between PRE and POST were statistically analyzed considering all subjects applying Wilcoxon's ranked samples test. The alpha level was set to 0.05 for statistical significance. **Results** Significant differences were found between PRE and POST in absolute  $\dot{V}O_{2max}$  (3.3  $\pm$  0.2 vs. 3.7  $\pm$  0.2 L $\cdot$ min $^{-1}$ ;  $p<0.05$ ;  $n=8$ ) and relative  $\dot{V}O_{2max}$  (37.5  $\pm$  4.8 vs. 41.2  $\pm$  4.1 ml $\cdot$ min $^{-1}$  $\cdot$ kg $^{-1}$ ;  $p<0.05$ ). No significant differences ( $p>0.05$ ) were observed in Hpeak, Mpeak or Ppeak. **Discussion** Six weeks of endurance training increases maximal oxygen uptake, but has no effect on the cardiorespiratory kinetics. However, analyzing the data of the two groups separately, continuous and interval training show contrary effects on cardiopulmonary and respiratory kinetics. The study was funded by the DLR (Deutsches Zentrum für Luft- und Raumfahrt), Germany (FKZ 50WB1426). #### IMMUNE RESPONSE TO A SWIMMING SESSION DURING A 24-H RECOVERY PERIOD

Morgado, J.P.1,2, Monteiro, C.P.1,2, Alves, F.1,2, Matias, C.1,2, Seixas, M.T.3, Alvim, M.3, Bourbon, M.3, Teles, J.1,2, Laires, M.J.2

1-FMH, University of Lisbon, Portugal. 2-CIPER, FMH, University of Lisbon, Portugal 3-Unidade Laboratorial Integrada, Departamento de Promoção da Saúde e Doenças Crônicas, INSA, Lisbon, Portugal

Exercise immunology studies have shown convergent findings about total leukocytes, neutrophils, total lymphocytes, and monocytes response to exercise but lymphocyte subsets behavior has shown inconsistent results. Also, seldom real team training sessions have been studied. This study aimed to evaluate the acute systemic immune cell response to a real swimming session during a 24h recovery period, taking into account, sex, menstrual cycle phases for females, maturity and swimming age groups. Swimmers (30 females; 15+/-1.3yrs., and 35 males; 16.5+/-2.1 yrs.) performed a high intensity swimming training session (main set at 91.4+/-4.7 % of personal best time) at the end of the first macrocycle of the season. Blood samples were collected before (Pre), immediately after (Post), 2h after (Post2) and 24h after (Post24) exercise, by standard procedures for assessment of leukogram by automated counting (Beckman Coulter LH 750) and lymphocytes subsets by flow cytometry (FACS Calibur Becton, Dickinson and Company). Subjects were grouped according to the Portuguese Swimming Federation age groups, and monitored for pubertal Tanner stage, and girls for menstrual cycle phases. Statistical significance was set at  $p < 0.05$ . Only swimming age group influenced the response of neutrophils, total lymphocytes, and lymphocytes subsets CD3+, CD4+, and CD19+ to exercise. Monocytes and CD16+/56+ values were higher for males than for females at rest and along the 24h period. At Post, we observed neutrophilia, lymphopenia, reflecting the decrease of lymphocytes subsets CD3+, CD4+, CD8+, CD19+, and CD16+/56+, and low monocyte and eosinophil counts. At Post2, a delayed leucocytosis occurred and neutrophilia, lymphopenia, and low eosinophils count persisted, while monocytes and CD19+ had recovered to pre exercise values. At Post24, total lymphocytes and subset CD3+ maintained below pre-exercise levels in the junior group and all other parameters had fully recovered to baseline values, independently of the swimming group. These findings support the idea that a demanding swimming session, like other exercises, induces leukocytosis and neutrophilia and an acute depression of the acquired immune system lasting for at least 2h. This does not necessarily imply an enhanced immune response immediately after exercise followed by increased risk of infection or suppressed immunity. However, when considering the junior group, a 24h period may be insufficient to attain total recovery of the acquired immunity.

#### THE COL5A1 3'-UTR AND MUSCULOSKELETAL SOFT TISSUE INJURIES: A FUNCTIONAL STUDY

Collins, M., Laguetta, M.J., Prince, S.

University of Cape Town

COL5A1 encodes the  $\alpha 1$  chain of type V collagen, a minor fibrillar collagen that is an important regulator of collagen fibril assembly. Several polymorphisms, including rs12722 (C/T) within the 3'-UTR of COL5A1 is associated with chronic Achilles tendinopathy and other musculoskeletal soft tissue injuries as well as exercise-related phenotypes. It is hypothesised that polymorphisms within the 3'-UTR regulate synthesis of the  $\alpha 1(V)$  chain and type V collagen production thereby influencing the mechanical properties of musculoskeletal soft tissues. In our laboratories, two major functional forms, namely the T- and C-allelic forms, were identified and associated predominately with severe chronic Achilles tendinopathy and healthy asymptomatic control individuals. To further investigate the functional differences between the two major 3'-UTR functional forms as well as to start mapping the regions which are responsible for the tendinopathic phenotype, skin biopsies from donors having a known genotype at rs12722 and primary fibroblast cell lines were established in order to quantify COL5A1 and COL1A1 expression levels in a pilot study. Lastly, in preliminary RNA EMSAs, biotinylated C- and T-allelic RNA probes for a specific 57bp functional region within the 3'-UTR were incubated with either fibroblast nuclear or cytoplasmic protein extracts to investigate putative distinguishing RNA:RBP complex formation. An overall higher relative mRNA expression of both COL5A1 ( $p < 0.001$ ) and COL1A1 ( $p = 0.0015$ ) were observed in primary skin fibroblasts from donors having a rs12722 TT genotype compared to donors with a CC genotype. A unique RNA:RBP complex was also identified with the C-allelic probe. These novel results have important implications for our understanding of the proposed role of type V collagen in the aetiology of musculoskeletal soft tissue injuries and other exercise-related phenotypes. not insert authors here

#### PHYSIOLOGICAL PERFORMANCE AND BIOCHEMICAL PROFILE OF INDIAN ELITE FEMALE FOOTBALLERS DURING PRE-COMPETITION PHASE

Purohit, S., Medabala, T., Adhikari, S., Biswas, S.

Sports Authority of India, Netaji Subhash National Institute of Sports

**Abstract Introduction** Female football is one of the fastest growing sports in the world. There are, however, limited scientific data on how elite female players respond to the physical stress imposed by a football game. The game comprises activities like sprint and jumps in the attack as well as defense. Though, both aerobic and anaerobic capacities are very important to exhibit better performance, it is dominated by the aerobic capacity as the game lasts for one and half hour or even more (Malcovic et al., 1994). The evaluation of heart rate during games is very important to monitor the training load. Biochemical markers such as Lactate Dehydrogenase (LDH), Creatine kinase (CK), urea and uric acid (UA) are used for the evaluation of the physiological stress imposed by exercise. Increases in serum creatine kinase levels in response to strenuous exercise may be a consequence of both metabolic and mechanical stress (Brancaccio et al. 2007). **Methods** Twenty one elite Indian female football players were selected during the pre-competition phase. Peak and recovery heart rates were recorded during and after the game situations. Following overnight fasting blood markers of physical stress; creatine kinase and lactate dehydrogenase, urea and UA were measured. Results The results are expressed as mean  $\pm$  standard deviation. The mean peak heart rate recorded during training was  $186 \pm 13$  beats/min and during recovery it became  $157 \pm 16$  beats/min. The mean concentrations of the various biochemical parameter viz. LDH, CK, urea and uric acid were  $348.40 \pm 15.38$  U/L,  $143.71 \pm 52.63$  U/L,  $30.25 \pm 3.31$  mg% and  $3.61 \pm 0.68$  mg% respectively. **Discussion** This study was undertaken to examine the physiological performances and biochemical profiles of Indian elite female football players during the pre-competition phase. The mean peak heart rate was reported earlier as  $198 \pm 6$

beats/min in Sweden and Norway players having age of 27±1yrs (Andersson et al, 2008). Even though the mean peak heart rate for Indian players was relatively low as 186±13 beats/min, but the age group was studied varied 24±3 yrs. CK, LDH, UA and urea are the indicators of the physiological stress imposed by exercise. All the values after 12 hour of game situations came back with in the normal range, signifies better bodily response to the exercise. This preliminary result clearly indicates their ability for the adaptations were better during and after the game. References Andersson H, Ekblom B, Krstrup P. #### VARIABILITY OF THE METABOLOMIC RESPONSE TO ENDURANCE EXERCISE IN MODULATED BY THE TRAINING STATE

Vaughan, D., Brogioli, M., Laczko, E., Flück, M.

*University of Zurich*

**Introduction** Exercise is a major stimulus for energy metabolism. Classical exercise biochemistry provided an initial description of the induced biomechanical pathways. A holistic picture of the metabolic processes being induced in exercised muscle, and the influence of inter-individual factors such as gene x environment interactions has not been carried out. We hypothesised that I) exhaustive exercise alters the abundance of a sizeable portion of molecular species in skeletal muscle and II) that this depends on the training state and angiotensin-modulated capillary supply lines. **Methods** Twenty-two 20-40 years-old, healthy volunteers were assessed for exercise capacity using ergospirometry (MetaLyzer 3B, Cortex) and for the ACE I/D polymorphism from muscosal DNA. After two days of rest and an overnight fast, subjects reported to the laboratory and carried out a bout of exercise with one leg (50% of maximal aerobic performance for 25 minutes, followed by a ramp composed of 10 Watt increments each minute) until exhaustion. Biopsies were collected from knee extensor muscle pre and 30 minutes post exercise and assessed for capillarity, glycogen content, and polar and non-polar metabolites using ultrahigh performance liquid chromatography – tandem mass spectrometry based on established protocols. Molecular species with pre-post changes were identified using statistical analysis of microarrays at a false discovery rate of 1%, mapped based on the exact neutral mass and the affected ontology (Progenesis Q1 - Nonlinear Dynamics) and explored statistically with principal component and cluster analysis (Statistica, Statsoft). Results 12 of 924 detected polar metabolites and 79 of 2059 non-polar metabolites were modified post exercise. Apart from a 2-fold reduction in the gold standard, glycogen, a number of novel metabolites from previously not identified ontologies associated with the metabolism of amino acids, prenol-, sterol- and sphingo-lipids, and food, were affected post exercise. Alterations of the muscle metabolome were explained by the training state, rather than capillarity and the ACE I/D gene polymorphism. **Discussion** The data point out that a relative short endurance stimulus induces a response of metabolite species that are not typically thought to be important for these types of stimuli. The identified influence of training state on muscle's metabolic response to exercise implicates that repeated muscle work alters the pool sizes of metabolic substrates. #### AB-CRYSTALLIN MODULATION AFTER ACUTE EXERCISE IN SKELETAL MUSCLE: THE ROLE OF OXIDATIVE STRESS AND FIBER COMPOSITION

Grazioli, E.1, Dimauro, I.1, Mercatelli, N.1, Fittipaldi, S.1, Barone, R.2, Macaluso, F.2, De Felice, V.2, Caporossi, D.1

*1University of Rome (Italy), 2University of Palermo (Italy)*

**INTRODUCTION** αB-crystallin (CRYAB) is a member of the small heat shock proteins implicated in various biological processes, particularly in skeletal muscle where it is involved in adaptive remodelling processes and activation of gene transcription (Ito et al. 2001; Singh et al. 2007). We analysed αB-crystallin' response in mouse gastrocnemius after recovery from exercise, correlating its modulation with oxidative stress level and fiber composition. **METHODS** In vivo model: BALB/c mice of 3 weeks age were divided in two groups: Sedentary (S) and Exercised (EG, 15). The EG performed 1hr of aerobic exercise at 5.5m/min on a rotor and red gastrocnemius (RG), white gastrocnemius (WG) and soleus (SOL) were collected after 0', 15' and 30'. In vitro model: C2C12 myotubes were treated with hydrogen peroxide (H2O2) for 1 hr at 200μM and 300μM. After 0hr, 3hr, 6hr and 9hr of recovery time, stress proteins response (CRYAB, HSP70, HSP27), oxidative damage (carbonylated protein and 4-HNE), antioxidant proteins (TrxR1 and MnSOD), as well as survival and apoptotic pathways (p38MAPK, Caspase3, Akt, c-Jun, NFκB-p65 and NRF2) were evaluated in all samples. **RESULTS** While no increase in CRYAB protein level was observed, we clearly demonstrated that the acute exercise lead to a rapid, specific increase of phospho-CRYAB in the RG, but not in the WG. Moreover, this induction resulted correlated with increased levels of 4-hydroxynonenal (HNE), suggesting a putative role for exercise-induced oxidative stress in driving CRYAB, but not hsp70 or hsp27, activity. These data were also confirmed in the C2C12 in vitro model, where we detected a significant enhancement of pCRYAB in H2O2-treated C2C12 myotubes. Moreover, the specific inhibition of p38 activity was able to counteract the H2O2-mediated phosphorylation of CRYAB, confirming the involvement of this MAPK in the molecular pathway driving pCRYAB. **DISCUSSION** We demonstrated for the first time a fiber-dependent, p38MAPK-related role of CRYAB in the response of skeletal muscle to acute aerobic exercise. Further experiments are in progress to clarify both the molecular pathway driving CRYAB phosphorylation and its fiber-specific induction. In particular, we aim to identify the protein interactions to pCRYAB leading to the preservation of oxidative fibers' integrity and/or survival (Sakurai et al., 2005; Bullard et al., 2004). **REFERENCES** H. #### OP-PM33 Sports Medicine & Orthopedics: Injury prevention I

##### MONITORING OF SPORT INJURIES IN YOUNG ELITE SOCCER PLAYERS

Richardson, A., van Beijsterveldt, A.M.C., Blikendaal, S., Stubbe, J.

*Amsterdam University of Applied Science*

**Introduction** Little information exists on the magnitude of injuries in elite development programs for young talented soccer players. The purpose of this study is to investigate the magnitude of the injury problem and to explore different monitoring methods. **Methods** During

a 5 month period (aug.– dec. 2014), 24 talented female soccer (mean age  $17.2 \pm 1.2$ ) players filled in the OSTRC Overuse Injury Questionnaire (Clarsen et. al. 2014) on a 2-weekly basis to monitor injuries. In this questionnaire, 4 questions are used to monitor the severity (range 0 – 100) of any physical problem. Subsequently, all players were asked to retrospectively report all time-loss injuries after the 5 month period. Results The response rate over the 5 month period for the online OSTRC questionnaire was 97%. A total of 256 questionnaires were filled in by all 24 players. Based on the OSTRC questionnaire, 63 injuries were reported. The most common localisations were ankle (18%), knee (14%) and the front side of the upper leg (14%). Most injuries were acute (76%) and 24% of the injuries was a re-injury. The duration of injuries ranged from 0 to 71 days, with a median of 2 days. In total, 17 time-loss injuries were reported. The most common localisations of the time-loss injuries were the ankle (29%), the knee (17%) and the back side of the upper leg (12%). Time-loss ranged from 9 to 65 days, with a median of 31 days. The total burden of each injury, calculated by summing the severity score for each 2-week period, was higher in time-loss injuries (mean = 185 vs 38). The sum of the severity score correlated significantly with the duration of the injury problems ( $r=0.91$ ,  $p<0.001$ ). The sum of the score of only the first question of the OSTRC questionnaire (the existence of health problems) also correlated significantly with the duration of the injury problems ( $r=0.91$ ,  $p<0.001$ ). Discussion The presented data show that many reported injuries do not necessarily lead to time-loss. This indicates that participation in training and matches with physical discomfort is common. Future studies may investigate the risk of physical discomfort on future time-loss injuries. Finally, simplifying the OSTRC questionnaire will benefit monitoring in a practical setting, especially with younger athletes. Our findings suggest that the first question of the OSTRC questionnaire is representative for the total injury severity. This result can form a starting point for further research on practical and valid injury monitoring tools. Contact a.richardson@hva.nl

### CAN MOTION CONTROL SYSTEMS PREVENT RUNNING-RELATED INJURY?

Malisoux, L.1, Chambon, N.2, Delattre, N.2, Guéguen, N.2, Urhausen, A.1,3, Theisen, D.1

1: Sports Medicine Research Laboratory, Luxembourg Institute of Health, Luxembourg; 2: Decathlon, Movement Sciences Department, France; 3: Sports Clinic, Centre Hospitalier de Luxembourg

**Introduction** A recent prospective study suggested that pronation is not a risk factor for running-related injuries (RRI).[1] Nevertheless, runners with pronated feet are usually recommended to wear shoes with motion control systems (MCS). Therefore, the aim of this study was to determine whether or not runners using shoes with MCS will sustain fewer RRI than runners using standard neutral shoes. **Methods** This double-blinded randomized control trial included 372 recreational runners. Foot morphology was analysed using the Foot Posture Index.[2] The participants were randomly allocated to either the experimental group (MCS) or the control group (STD). The only difference between the shoe models was the presence of MCS in the shoes distributed to the experimental group. Training and injury data were collected during 6 months on an internet based platform: www.TIPPS.lu. A RRI was defined as a physical pain or complaint, located at the lower limbs or lower back region, sustained during or as a result of running practice and impeding planned running activity for at least 1 day. Cox regression analyses were used to compare the occurrence of RRI rates between the two groups based on hazard rate ratios (HR) and their 95% confident intervals (CI). Stratified analyses were conducted to evaluate the effect of MCS in runners with supinated, neutral and pronated feet. **Results** 93 participants (25%) experienced at least one RRI during the observation period. The adjusted Cox regression analysis revealed that the runners from the MCS group had a lower hazard rate for RRI (HR=0.55; 95%CI=0.36-0.85). Previous injury was identified as a risk factor (HR=2.72; 95%CI=1.79-4.41), while running experience over the last 12 months (HR=0.91; 95%CI=0.84-1.00) and session distance (HR=0.91; 95%CI=0.84-0.99) were protective factors. When stratified according to foot morphology, results showed that only runners with pronated feet benefited from MCS shoes (HR=0.28; 95%CI=0.11-0.72). **Discussion** The MCS tested in this study was found to reduce the risk of RRI amongst runners with pronated feet. Further research should analyse if these results are generalizable and investigate what the underlying mechanisms are. **References** 1 Nielsen RO, Buist I, Parner ET, et al. ### PARALYMPIC ATHLETES' PERCEPTIONS OF THEIR EXPERIENCES OF SPORTS-RELATED INJURIES: A QUALITATIVE STUDY

Fagher, K.1, Forsberg, A.1, Jacobsson, J.2, Timpka, T.2, Dahlström, Ö.2, Lexell, J.1

1. Lund University; 2. Linköping University

**INTRODUCTION** Our knowledge of sports-related injuries in Paralympic athletes is limited (1), and there are no data on how the athletes themselves perceive an injury and how the disability itself influences their perceptions. The aim of this study was to explore Paralympic athletes' perceptions of their experiences of sports-related injuries. **METHODS** Eighteen elite athletes were recruited by a purposive sampling from the Swedish Paralympic program. Athletes with vision impairment, spinal cord injury, cerebral palsy, intellectual disability, myelomeningocele, dysplasia and neuromuscular disorders participated. They represented goalball, wheelchair rugby, athletics, cycling, skiing, boccia, ice sledge hockey, table tennis and swimming. Data were collected through individual interviews. For the detection and interpretation of the athletes' perceptions of their experiences a qualitative phenomenographic design was used. **RESULTS** The analysis revealed eight different categories of the perception of the experiences of the cause of a sports-related injury. The athletes perceived that the disability itself influences the cause and impact of an injury. Another perception was that the impact of elite training was seen as a cause of injury, and this may be explained by the inability to train correctly. Also, a majority of the athletes perceived that injuries could be self-inflicted. The domain to this category was described as one's own performance and the essence as guilt. Other categories identified were: the normalized pain, the impact of injury, individual possibilities to prevent injuries, the dangerous elite sports and the unequal prerequisites. **CONCLUSION** The results from this study indicate that Paralympic athletes' perceptions of their experiences of sport-related injuries are complex and multifactorial. This needs to be considered in the design of future injury surveillance systems and prevention programs. Also, these perceptions need to be taken in account in the sports safety work within the National Paralympic Committees to be able to secure a safe future sports career for Paralympic athletes. **REFERENCES** 1. Fagher K & Lexell J, Sports-related injuries in athletes with disabilities, *Scand J Med Sci Sports*. 2014 Oct;24(5):e320-31 **CONTACT** kristina.fagher@med.lu.se

## A MULTIFACTORIAL INJURY PREVENTION PROGRAM IN PHYSICAL EDUCATION TEACHER EDUCATION STUDENTS: PROCESS EVALUATION USING RE-AIM

Goossens, L.1, Cardon, G.1, Witvrouw, E.2, Verhagen, E.A.L.M., De Clercq, D.1

*\*Ghent University; \*\*Aspetar Orthopaedic and Sports Medicine Hospital; °VU Amsterdam*

**Introduction** Efficacy of a multifactorial injury prevention program delivered through physical education teacher education (PETE) sports lecturers in PETE students has been proven in terms of injury incidence (Goossens et al., 2015). To describe further implementation possibilities, a process evaluation is requisite. Therefore, this study aimed to evaluate the feasibility of this multifactorial injury prevention intervention in PETE programs. The study aimed to determine both the proximal effects of this researcher delivered intervention on self-reported behavior, autonomous motivation and knowledge of PETE sports lecturers acting as intermediary delivery agents, and the more distal effects on self-reported behavior, autonomous motivation and knowledge of their PETE students. **Methods** A randomized trial was conducted in curriculum managers, sports lecturers and students from PETE programs in Flanders. A multifactorial injury prevention intervention ran during one school year. The curriculum managers and sports lecturers delivered the multifactorial injury prevention intervention: an injury awareness program and the implementation of prevention strategies in the sports lessons. A process evaluation was conducted using RE-AIM. Changes in self-reported behavior, autonomous motivation and knowledge were measured through questionnaires. **Results** The study had a good reach at setting (57%), staff (58%) and student level (59%). In sports lecturers, there was a trend to significantly greater increase in the intervention than the control group for the delivery of dynamic stabilization and functional strengthening and the weekly registrations revealed significantly more implementation of static stretching, dynamic stabilization and core stability in sports lecturers of the intervention group. In students, there was a significantly greater increase for knowledge in the intervention group. Adoption was very high. Implementation of the prevention strategies was high, but implementation of the posters and hand-outs was low. Maintenance in terms of intentions was reasonable on all levels. **Conclusion** A multifactorial injury prevention intervention for PETE students is feasible to a large extent. With only a very limited researcher delivered intervention, some effectiveness was found in sports lecturers and students. Future researcher delivered interventions should put emphasis on the importance of high implementation of an awareness program in order to achieve behavioral change in the targeted health beneficiaries. **References** Goossens L et al. A multifactorial injury prevention intervention reduces injury incidence in Physical Education Teacher Education students. *EJSS*—Accepted February 1st, 2015 Contact lennerf.goossens@ugent.be

### OP-PM48 Training & Testing: Agility

#### EFFECTS OF VISUAL TRAINING ON DECISION-MAKING AND REACTIVE AGILITY IN ADOLESCENT FOOTBALL PLAYERS

Nimmerichter, A., Weber, N., Haller, A.

*University of Applied Sciences Wiener Neustadt*

**Introduction** Perceptual cognitive skills in team sports have been described as key-components for successful players. These skills include fast and accurate decision-making. This study investigated the trainability of these skills via video-based visual training as well as the transfer to a reactive-agility sprint test in young athletes. **Methods** 34 members of a national football academy (age:  $14.4 \pm 0.1$  y) were randomly assigned to a training- (VIS;  $n = 18$ ) or a control group (CON;  $n = 16$ ). In addition to the football training, the VIS completed a video-based visual training twice a week over a period of 6 weeks. The visual training consists of 32 video sequences (approximately 10 sec) of one-on-one situations. Before the study, 12 amateur players were asked to record a total number of 800 videos with a helmet camera (GoPro HD Hero 2) worn by the forwards. The defenders were instructed to attack in one of four ways: Block Tackling, Sliding Tackling, Front- and Back-foot Side Tackling. Using the temporal occlusion technique, 8 videos of each defending category were randomly presented during visual training. During a 2-sec occlusion, the subjects must decide the direction the forward could successfully pass the defender. To assess anticipation and decision-making, the number of successful decisions and the response timing was measured with a video-based test (40 videos). Reactive agility was assessed using the sprint-test described by Sheppard et al. (2006). Statistical analyses were performed with a two-factorial ANOVA with group (VIS vs. CON) and time (pre vs. post) as model factors. **Results** VIS significantly improved the number of successful decisions ( $22.2 \pm 3.6$  vs.  $29.8 \pm 4.5$ ;  $p < 0.001$ ) and response timing ( $0.41 \pm 0.10$  sec vs.  $0.31 \pm 0.10$  sec;  $p = 0.04$ ). No significant differences were found for CON ( $21.6 \pm 4.2$  vs.  $23.3 \pm 3.8$  and  $0.43 \pm 0.09$  sec vs.  $0.45 \pm 0.08$  sec; both at  $p > 0.05$ ). There were significant main effects of the group for the video-based test ( $p = 0.003$ ). Reactive agility was significantly improved in the VIS ( $2.22 \pm 0.33$  sec vs.  $1.94 \pm 0.11$  sec;  $p = 0.002$ ) but not in the CON ( $2.16 \pm 0.24$  sec vs.  $2.09 \pm 0.14$  sec;  $p = 0.67$ ). No significant group effect was observed ( $p > 0.05$ ). **Discussion** Our results have shown that a video-based visual training improves the time to make decisions accompanied by an increase in successful decisions. The transfer to a field-based reactive agility test suggests, that such training can improve game performance. **Reference** Sheppard, J.M. et al. (2006). An evaluation of a new test of reactive agility and its relationship to sprint speed and change of direction speed. *J Sci Med Sport* 9 (4):342-349. Contact: alfred.nimmerichter@fhwn.ac.at

#### COMPLEX AGILITY PERFORMANCE ANALYSIS OF ELITE YOUTH ACADEMY SOCCER PLAYERS. AGE AND POSITION SPECIFIC ASSESSMENT.

Zalai, D., Safar, S., Holanek, Z., Halmaj, T., Kesedi, G., Csaki, I.

*Hungarian Football Federation*

**Introduction** In the 21st century soccer requires players to think and act with extreme speed both in the physical and mental performance. The players change direction several times and perform shorter and longer sprints in the game situations (Meckel, 2009). These abilities related measures are considered the most relevant objective soccer specific tests (Young, 1996). Agility is an effectively developing skill during competition season and coaches can actively integrate agility developmental exercises into their training (Jovanovic, 2010). The aim of this study was to identify how agility measures can be examined among elite youth soccer players. **Methods** Elite academy youth players ( $N=179$ ) were examined from three academies in Hungary (U16 to U21). We are used the international validated well-established Arrowhead Agility (AA), Illinois Agility (IA) and ZigZag (ZZ) tests. The players performed and completed all tests with and without a ball. **Results** ANOVA analysis showed significant difference between age-groups in the Arrowhead test, with and without a ball (AA right:

$F(3,154)=5,72, p<0,01$ ; AA left:  $F(3,153)=5,76, p<0,01$ ; AA right with ball:  $F(3,153)=2,78, p<0,05$ ; AA left with ball:  $F(3,153)=3,9, p<0,05$ ). There was also a significant difference between playing positions in the IA both with and without a ball (IA:  $F(5,152)=3,96, p<0,01$ ; IA with ball:  $F(5,152)=4,51, p<0,01$ ). There was a strong correlation between results in the ZZ test with and without the ball ( $r=0,949, p<0,01$ ) and between the AA with and without the ball to the left ( $r=0,729, p<0,01$ ) and right ( $r=0,632, p<0,01$ ). This was also a weak connection between the results of the IA with and without the ball ( $r=0,334, p<0,01$ ). Discussion We established through our research, that there is a correlation between every test result; however, this study has confirmed that the agility structure is much more complex when examined with and without ball performance. These results demonstrate that decision-making must be incorporated in agility training programs, include game specific quick reaction elements and anticipation, furthermore indicate that players technical skills and the agility performance are different. In soccer, most of total running distance is performed without the ball. The outcome of competitive game situations is dictated by player's specific skills in relation to fast change of direction and acceleration without the ball as well. ## ANALYSIS OF A KOMPLEX STRESS STRAIN DYNAMIC IN A TECHNIC COMPOSITORIAL SPORT

Bubeck, D., Schlechtweg, S., Alt, W.

*University of Stuttgart*

Introduction Success in optimization of training processes in elite sports is only then achievable when it is possible to develop sport specific effective preparation models in the field of scientific accompanying training management (Hohmann 1986). Especially in technic sports high training loads and volumes are necessary to develop an optimal level of performance. But there is a thin line between success and overload or overtraining in these sports. Therefore the aim of this study was to analyse the stress strain dynamic during a competition orientated training phase. Methods In a single case study the training input and stress reaction of an athlete of the rhythmic gymnastic national team was analysed over 6 weeks including a world cup competition. Training load as a stressor was analysed by using an expert based categorical training documentation tool. Heart rate variability (HRV), resting pulse were measured by Pulse7©, subjective feeling by a borg scale (TQR), PH of urine, body weight, subjective burden of the training load as the resultant strain operationalized by a borg scale were measured daily, the recovery progress protocol (EVP) form Kellmann (2010) has been used weekly. Results Training consisted of 9577 min in the 6 weeks. 60% of this training was technical training. Athletic training was only 10% of the whole input. Comparing the total training load with the SDNN values of the HRV measurements it can be seen that a high volume training day is followed two days later by a deep point in the SDNN curve. Training load and EVP show opposite effects during the 6 weeks. Using a time series analysis shows a statistic relevant relation with the lag of one day between the training load and the SDNN value of the HRV and the TQR. Discussion According to Arvay and Hofmann (2001) it can be seen that the resetting process of the SDNN value as an indicator of recovery takes about one day. So this measurement can be used as a valid parameter for measuring the stress - strain values of an athlete. This can be confirmed by the measurements of TQR and EVP values. Conclusion Using the SDNN, TQR and EVP as strain parameters can be useful to scientifically analyse the sport specific training process in elite sports. References: Hohmann, A. (1986), *Leistungssport* 5, 5-10. Kellmann, M. (2010), *Scand. J. Med Sci Sports* 20, 95-102. Arvay S. & Hofmann, P. (2001), *Spektrum Sportwissenschaften* 13, 5-13.

## PHYSIOLOGICAL RESPONSES TO REPEATED SPRINT ABILITY TEST < 10X15 M> IN YOUNG BASKETBALL PLAYERS: THE EFFECT OF CHANGE OF DIRECTION

Meletakos, P.1, Tasiopoulos, I.2,3, Kostoulas, I.3,4, Ganavias, P.3, Padulo, J.5, Nikolaidis, P.T.3

1: *University of Athens (Greece)*, 2: *University of Peloponnese (Sparta, Greece)*, 3: *Hellenic Army Academy (Athens, Greece)*, 4: *University of Thrace (Komotini, Greece)*, 5: *University e-Campus (Novedrate)*

Introduction Repeated sprint ability (RSA) has been studied with protocols using longer distance than 20 m for each sprint, whereas basketball players cover on average less than 20 m distance per sprint during match. Therefore, the aim of the present study was to examine the physiological impact of RSA 10x15 m straight-line (RSASL) or with change of direction (RSACOD, i.e. 10x(7.5+7.5 m)) in young national level basketball players. Methods Young basketball players (n=11, age 17.1 (1.0) yrs, body mass 76 (6) kg, height 184 (4) cm, body mass index 22.6 (1.8) kg.m<sup>-2</sup>, sport experience 6.9 (2.7) yrs, mean (standard deviation)) and a control group consisting of high-school athletes (n=7, 16.1 (0.7) yrs, 67 (6) kg, 177 (6) cm, 21.5 (1.0) kg.m<sup>-2</sup>, 7.7 (1.6) yrs, respectively) performed RSASL and RSACOD on a counter-balanced order. Sprints (timed by Brower photocells, USA) started every 30 s (active recovery) and there was 30 min break between RSA protocols; time variables were total time (TT), best time (BT) and fatigue index (FI). Countermovement jump (CMJ, Optojump, Italy) was tested before and after each RSA protocol. Heart rate (HR) was continuously monitored (Polar team2, Finland) during testing procedures. Results Compared with RSASL, TT and BT were worst in RSACOD (38.13 vs. 27.52 s and 3.67 vs. 2.66 s, p<0.001, respectively), whereas FI did not differ (3.8 vs. 3.5%, p=0.388). A 2x2 repeated measures ANOVA showed main effect of RSA on CMJ (pre-test vs. post-test, +1.8 cm, p=0.020,  $\eta^2=0.28$ ); there was neither main effect of RSA protocols (RSASL vs. RSACOD +0.7 cm, p=0.251,  $\eta^2=0.08$ ) nor an interaction between pre-post measurements and RSA protocols (p=0.578,  $\eta^2=0.02$ ). Compared with RSASL, RSACOD induced higher mean and peak HR responses (175 vs 172 bpm, p<0.001, and 185 vs 182 bpm, p=0.002, respectively). No statistical difference was observed between basketball players and control group neither for TT (27.98 vs. 26.80 s, +4.4%, p=0.149) and BT (2.71 vs. 2.59 s, +4.5%, p=0.157) in RSASL nor for TT (38.55 vs. 37.47 s, +2.9%, p=0.169) and BT (3.70 vs. 3.63 s, 1.8%, p=0.414) in RSACOD. Conclusions In conclusion, RSASL and RSACOD differed for time variables (TT and BT) and HR responses. Despite being non-significant, the trend that adding COD reduced the percentage differences in TT and BT between the two groups highlighted the role of sport specialization.

## EFFECTS OF PRACTICE AGAINST ELASTIC RESISTANCE ON JAB PUNCH PERFORMANCE

Suzovic, D., Markovic, P., Djuric, S., Kasum, G., Jaric, S.

*Faculty of Sport and Physical Education*

Introduction High performance of rapid open kinetic chain movements (e.g., kicking, throwing, hitting, or punching) are important prerequisite for success in various sports. The use of ERT methods for improving the kicking performance has been already recommended (Davies, 2003). The effects of elastic resistance training (ERT) on rapid movements conducted on Taekwondo competitors revealed the improvement in the leg kick velocity (Jakubiak and Saunders, 2008). The aims of the present study were to investigate the effect of ERT on the performance of jab punch, to explore the associated changes in movement kinematic and kinetic patterns. Methods The national level junior competitors in kick boxing, savate, and boxing (N=40; age 17.2±1.0 years; means ± SD) practiced jab punch against elastic

resistance for 15 minutes per day, 3 times a week for 6 weeks. Results The results revealed a marked increase in maximum jab punch velocity in all groups (6-11%; all  $p < 0.01$ ). This finding was associated with an increase in both the maximum velocity and displacement of the ipsilateral elbow, shoulder and, particularly, hip joint, while no change in the movement time was observed. ERT associated increase was also revealed in the agonist (7-11%, all  $p < 0.01$ ), but not antagonist muscle strength. Discussion We conclude that addition of a relatively small amount of ERT, because it requires only increased agonist activity, could be recommended for the purpose of improving the performance of punching and, possibly, other rapid limb movement even in high level athletes. Since the applied resistance acts as an antagonist per se (Hofman and Strick, 1993) the observed performance improvement could be partly based on increased strength of agonist muscles, as well as on increased motion amplitudes particularly regarding the pelvis movement. Acknowledgments This work was supported by a National Institutes of Health grant R21AR06065, and Grant from the Serbian Research Council (#175037). References Davies, J.G. ### OP-SH07 Psychology (Mental health and stress)

#### **"FROM WORLD CLASS TO UNABLE TO SHOOT IN THREE ARROWS"- AN UNDERSTANDING OF THE PERSONAL EXPERIENCE OF 'TARGET PANIC' IN ELITE ARCHERS**

Clarke, P., Akehurst, S., Sheffield, D.

*University of Derby*

The yips are a psycho-neuromuscular movement disorder, which affects sports where fine motor precision skills are required for success. This results in a yips-affected athlete experiencing a range of physical (jerks, tremor, freezing) and psychological symptoms (self-consciousness, anxiety, embarrassment). In archery, these symptoms have been labelled target panic and have yet to be investigated in yips literature. The current study aimed to qualitatively explore the psychological experiences of target panic in elite archers. This approach allowed an unrestricted exploration into the concepts of target panic and the long term nature of the yips. Seven elite level archers (males  $n=3$ , females  $n=4$ ; Mage= 32, SD +/- 11.03) who have experienced target panic (including Olympic, World, European and Commonwealth medallists) took part in semi-structured interviews. In line with previous yips studies in cricket and golf (Bawden & Maynard, 2001; Phillipen & Lobinger, 2011), the archers' thoughts, feelings and emotions before, during and after their experience of target panic were explored. A thematic analysis revealed five main themes, consisting of 15 sub-themes. These included: perceived control (control over movement, commitment, conscious control), coping (rationalise, mental, technical), emotions (anxiety, fear and depression), negative mind-set (confidence, expectations, self-consciousness) and focus (intrusive thoughts, conscious effort, analytical). These findings support target panic as a sport-specific form of the yips. They also support previous findings in yips literature with regard to the role of focus, both internally (technique) and externally (self-consciousness). One novel finding of this study was the extent to which archers felt a lack of control over commitment to their decision-making, during their target panic experiences. This is particularly important as archers have a limited time period to release their arrows, so decision making is a key component for performance. This study also provides some insight into the important role psychological factors play in the onset, development and consequential outcomes of target panic symptoms. Moreover, findings reinforce that yips in sport share a number of similar characteristics to severe choking. References: Bawden, M., & Maynard, I. (2001). #### **MENTAL TOUGHNESS IN ELITE MUAY THAI**

Powell, A., Myers, T.D.

*Newman University Birmingham*

Introduction There have been suggestions that exploring Mental Toughness (MT) in sport using mainstream psychological theories is needed (Anderson, 2011). Following attempts to conceptualise MT in team sports using Personal Construct Psychology (e.g. Coulter et al., 2010; Jones, et al., 2014), this study explored MT in Muay Thai, an individual sport. Anecdotally, MT is perceived to be an important prerequisite for success at an elite level in Muay Thai. Therefore, the aim of this study was to explore constructs associated with MT and its development in Muay Thai from elite fighters and coaches. Methods The perceptions and experiences of MT in Muay Thai were gathered from a purposeful sample of elite Muay Thai fighters ( $n=6$ ) and coaches ( $n=3$ ) using semi-structured interviews in accordance with Personal Construct Psychology (Fransella et al., 2004). The data were transcribed verbatim and initially analysed using grounded theory analytical techniques in order to elicit constructs. Results The initial analysis resulted in a series of bipolar constructs. MT in Muay Thai was conceptualised as: physical toughness vs physical fragility; focus while experiencing pain vs distracted by pain; functional vs dysfunctional under pressure; self-belief vs self-doubt; high self-confidence vs low self-confidence in their preparation; and perceived high technical competence vs perceived low technical competence. The development of MT in Muay Thai was conceptualised as: engagement in challenging and adverse situations vs avoidance of challenging and adverse situations; exposure to a culture valuing and rewarding mental toughness vs exposure to a culture that does not value or reward MT; and supportive task oriented environment vs non-supportive ego oriented climate. Discussion The findings support some attributes identified in previous studies of MT, including the importance of physical toughness, self-belief, handling pressure, maintaining focus and resilience (Gucciardi & Gordon, 2008). In addition, Muay Thai athletes also considered confidence in preparation, remaining focused and being able to operate functionally when in pain, and perceived technical competence to be particularly important for MT in Muay Thai. Participants highlighted particular types of experiences and the formation environment as being crucial in developing MT in Muay Thai. References Andersen, M.B. ### OP-SH19 Philosophy & Ethics I

#### WALKING ON THE EDGE? THE DEVELOPMENT OF TALENTED CHILDREN IN ELITE SPORTS

Pilz-Burstein, R.

*Sport Excellence Academies*

**WALKING ON THE EDGE? THE DEVELOPMENT OF TALENTED CHILDREN IN ELITE SPORT** Introduction Sport academies have been recognized as an effective model for developing talented children towards top achievements in the international sport arena. Yet the process of talent identification (Burgess & Naughton 2010), the age of integration, training procedures and competing schedules are not being controlled by any objective body. Discussion The costs-benefits of developing a young athlete in elite sport academies are of ethical significance and deserve special attention of a professional team. Athletes entering the academy at 12-13 years take this major decision early in life dreaming of 'gold'. They develop self-discipline and make a full commitment to this challenging journey. Each athlete chooses the platform that will provide him with the best conditions to meet his goal: a top professional team in sport, a high standard educational-social system, excellent medical support and the best training facilities. Yet, beside all of these advantages the cost of this unique process should be seriously reviewed: the unnatural decision of leaving home at this early age; focusing on one specific target with repetitive, monotonous training; and belonging to one specific group (Rutenfranz 1986) while eliminating other social activities which often lead to debilitating emotional problems. In addition, facing failure and success along this journey can be a positive experience that strengthens the child, but occasionally may lead him to give up and quit, resulting in a strong sense of frustration. All of these issues are ignored by the young athlete and should not distract him from his goals. But can we control the cost and benefits? Can we avoid physical and mental damage when, for example, participation in a critical competition contradicts health considerations? And finally, is our responsibility as professionals to assist the national sport bodies with their mission pushing the boundaries of our youngsters to the top in the international arena, or should we be committed to balance between the extreme demands and the long-term well-being of our children? Recommendations Optimizing the process of fostering young athletes in the academy model requires careful screening procedures focusing on the mental and physical readiness of the child. It needs routine, on-going holistic support: social-psychological-medical with special attention to critical episodes of failure and success. Ensuring careful consideration of all of these issues by coaches, families and the professional team, the development of young athletes in sport academies can be recommended as an effective way to achieve top performance, yet avoiding any harm to our highly motivated children. #### HORSE - THE INVOLUNTARY CONTESTANT?

Andersson, P.

*University of Gothenburg*

Introduction In equestrian sports, horses are used as essential parts of the sports – in daily training and at competitions as well. Traditionally, horses used as parts of sports, have not been questioned, though some contest rules have been changed from time to time for the sake of horse welfare and security. Nowadays, however, animal ethicists and various animal rights organizations formulate strong criticism of sports that benefits from horses, claiming that equestrian sports are nothing more than expression of human superiority and arrogance. Methods Literature study, and studies of internet-based debates between animal right activists and horse people, followed by ethical, philosophical analysis of the argumentations. Results Animal right activists introduce several interesting and provoking arguments and conceptual distinctions in the debate. Special emphasis is given to a distinction between animal right-thinking and animal welfare-thinking, and to a distinction between actual and symbolic damage as well. Discussion While philosophy – animal ethics – is almost silent about equestrian sports, animal rights movement is the more talkative. The arguments used by animal right movements are often inspired by philosophers such as Tom Regan (2001) and Peter Singer (1990), and the activists develop and clarify them at several interesting points (Jönsson, 2012). The study examines the animal rights movement's arguments in detail. What is clarified by the introduced distinctions, and what aspects do they fail to clarify? Furthermore, the study analyses how the relation between rider and horse is understood. In the animal right movement rhetoric, the relation seems to be nothing more than an unjustified power asymmetry, expressing human superiority over the subordinated horse. Using horses in sports is hence claimed to be a disrespectful exploitation of horses, and cannot be considered to be in the horses' interest, as the horses do not participate voluntarily. References Regan, T. (2001). *Defending Animal Rights*. University of Illinois Press. Singer, P. (1990) [1975]. *Animal Liberation*. New York Review Books. Jönsson, K. #### SUBJECTIVITY AND THE BODY

Hogenova, A.

*Charles University*

This text discusses the transformation of the body from the validity of a thing to the validity of an object and the consequences of this transformation for human life and for sport. The subject-object figure of thought is the result of a Cartesian relationship with the world, which is the basis of current scientism. The body as an object transforms into a resource, it alienates itself. The Modern Age is the inauguration of a new role of subjectivity. The subject becomes the only source of truth to be asked for and accepted. It is certainty - certitudo. Everything must be perceived by the senses, everything must be felt, seen, verified inter-subjectively. Falsification is a necessity in this day and age. Even with the body we seek only for what is verifiable by the senses. As is the case with all things around us, so it is with our body. We have lost the distance from things, which allows the "thinging" of a thing and we have turned things into objects that lie to against us, and so everything began with a subject-object figure, which is the basic structure of our relationship to the world. We live in a subject-object structure which determines everything, without us even particularly noticing it; this shows the blindness of modern man

with all his technical achievements. Even the body has become an object, an exclusive object; it has been reduced to a tool for amazing sporting achievements which the world demands from individuals. A jug is a thing only when we are able to see into the jug and understand the "poured gift". The water in the jug comes from heaven but it flows from a spring in the earth; however, it fell to the earth from heaven. Water connects heaven and earth, and we drink it as proof of this matrimony – a sacred game between heaven and earth - our foremothers. It is hieros gamos - the sacred game between heaven and earth, the sacred matrimony and invisible harmony, in which our lives take place. Such a harmony takes place between the body and the mind, the body is the earth and the soul is our own heaven. Exactly the same thing takes place during the Olympic Games, the clash of the athletes is captured by the formation of this perfect harmony between heaven and earth. Earth is represented by our bodies and heaven by the purity of agon, which is the same as the purity of the Olympic flame. The Olympic Games were never just about races where money was won, this is true for today as it is for the recurring final stages of the Olympic Games in the history of Europe. ## NOVEL SPORTS MEDICINE TREATMENTS AND THE PLACEBO EFFECT: ETHICAL, EPISTEMOLOGICAL AND SOCIAL ISSUES

McNamee, M., Coveney, C.M., Gabe, J., Faulkner, A.

*Swansea University*

Introduction In elite sports, there is a potentially conflicting duplex of medicine and science in the treatment of injured athletes. Not only is there a conflict between long and short-term player welfare, but the evident commercial and competitive pressures that drive novel treatments whose evidence base is often less than robust. The aim of this study was to explore the ethical, epistemological and social issues that attend novel treatments in football medicine. Methods Our data are qualitative in nature, drawn from semi-structured interviews held with physiotherapists and doctors with experience of working in the English Premier league, high profile sports physicians and surgeons (n= 18). These explored the structure and composition of sports medicine departments, the most prevalent forms of novel treatments used, and the justification thereof in terms of ethics and evidence. Data were analysed using a thematic approach to identify topics and issues of significance. Analysis was facilitated using the qualitative analysis software program NVivo 10. Results The size of medical departments ranged between 6-15 persons, whether full or part time. Some were physio-led teams, others physician-led. The three most popular novel treatments were actovegin, platelet-rich-plasma therapy (PRP), and prolotherapy, while PRP the most frequently used among them. Discussion The rationale for using each of the treatments was heterogeneous. Evidentiary bases for them are not supported strongly by randomised control trials. Only PRP among them has been subjected to RCTs, yielding indifferent results (Engerbretsen, 2010) and with limited professional support (de Vos, 2010;). The justification for their use was based variously on clinical judgment, subjective experience, and validation or provenance from respected actors in their medico-"sportsnet"(works) (Nixon, 1993). These notions were compounded by player desires under conditions of partial consent, pressures from agents and coaches, and the complex use of placebo, whose application is ethically ambiguous. ### OP-PM66 Nutrition: Clinical

#### DECREASED ENERGY AVAILABILITY DURING INTENSIFIED TRAINING INCREASES SIGNS OF OVERREACHING AND IMPAIRS MENSTRUAL FUNCTION IN COMPETITIVE FEMALE RUNNERS

Schaal, K., Hausswirth, C., Van Loan, M., Le Meur, Y., Casazza, G.

*University of California, Davis*

INTRODUCTION: Athletes training for endurance sports expend a very large amount of energy on a daily basis, and maintaining energy balance (energy intake – energy expenditure) can prove challenging, particularly during periods of high training volume. The suppression of ovarian function as a result of energy deficiency has been well studied, and is frequent among runners. Furthermore, it is likely that energy deficiency would also decrease the athlete's resilience to periods of training overload, predisposing them to excessive, training-induced fatigue (overreaching, OR). The study aimed to quantify the changes in energy balance of well-trained female runners during a period of training overload, and to test the hypothesis that failing to maintain a positive energy balance would increase the likelihood of developing both OR and menstrual disturbances. METHODS: 14 runners were recruited. After 1 full menstrual cycle of baseline training (P1), the training load was increased by 30% for 28 days (P2, starting on day 1 of the next menstrual cycle), followed by a taper period, reducing the training load to 50% of Baseline (P3). For 7 days during each phase, exercise energy expenditure (ExEE) was measured (Actiheart), and energy intake (EI) recorded. Running performance (distance covered on treadmill during a graded running test) was assessed at the end of each phase, together with perceived fatigue (Profile of Mood States), to diagnose each athlete as OR (high perceived fatigue and decreased performance) or not fatigued (NF) at the end of P2. Using urinary luteinizing hormone kits and menstrual cycle logs, a cycle was characterized as normal if: ovulation occurred, the luteal phase was > 10 days, and the cycle was < 35 days. Core temperature was assessed at the end of each phase. RESULTS: Upon completing P2, 6 were OR, and 8 runners were NF (Δ performance P2-P1: -10±5% vs +7±4 %). At the end of P3, performance was still suppressed in OR (-8±% from Phase 1), indicating a non-functional OR type. Energy balance decreased significantly in OR from P1 to P2, but not in NF (-5.6 ± 3.9 vs +1.6± 2.7 kcal/kg LBM/d), due to a failure to increase EI (+0.4±5.0, vs 4.0±2.5 kcal/kg LBM/d for NF) despite the increase in ExEE. Overall energy balance was negative in OR only (-7.9±4.4 kcal/kg LBM/d). A subset of 10 runners displayed normal menstrual function at P1. Of these, all 6 AF athletes maintained normal

menstrual function through P2, while 3 of 4 OR athletes displayed abnormal cycles (2 anovulatory, 1 short luteal phase). Core temperature decreased significantly for OR, but not AF ( $-0.5 \pm 0.2$  vs  $-0.2 \pm 0.2^\circ\text{C}$ ), possibly suggesting reduced progesterone production. **CONCLUSION:** This is the first prospective study, to our knowledge, to show that failure to increase energy intake and maintain energy balance during a period of heavy training significantly increases the risk of developing non-functional OR and menstrual disturbances.

### **A ONE YEAR STUDY OF DAILY DISTRIBUTION OF CALORIES AND BODY COMPOSITION CHANGES IN A GROUP OF MODERATELY ACTIVE PEOPLE**

Ghiani, G., Marongiu, E., Melis, F., Sanna, I., Pinna, V., Palazzolo, G., Crisafulli, A., Tocco, F.

*University of Cagliari*

**Introduction** It is well known that an active lifestyle and good eating habits are major components of a healthy lifestyle. It is also known that, to achieve a good nutritional status, along with a proper quantity of calories the nutritional value of meals is crucial. Garaulet and Gómez-Abellán (2014) show that a rich breakfast can influence overall daily food intake and weight loss in humans. Despite this fact, the typical Italian breakfast is inadequate, providing less than the 20% of the total daily energy intake. The aim of this study was to check whether a proper diet with a rich breakfast, providing the 30% of daily needs, could have a positive impact on the body composition of a group of moderately active people during one year follow up. **Methods** 32 moderately active, normal weight subjects (average Physical Activity Level  $1.7 \pm 0.2$  average Body Mass Index  $23.9 \pm 2.8$ ) participated in the present study. They followed a personalized diet for one year and were asked not to change anything in their lifestyle with the exception of the diet. To assess their energy expenditure, each of them wore a SenseWear Armband (SWA) for 48 hours (Casiraghi et al. 2013). They also attended an interview about their usual diet. Then, a proper diet was provided, both in terms of calories and nutrients. The given diet provided 30% of total daily intake at breakfast, that was different from their usual one, which provided less than 20% of total daily intake. For each subject fat mass (FM) was detected by means of plicometry method (Durnin and Womersley, 1974) at the beginning of the study (T0) and at the 6th (T6) and 12th (T12) month after T0. **Results** Data collected from SWA emphasized that their daily energy requirements was on average  $2652 \pm 470$  Kcal/day. After starting the diet, participants reported a better feeling of wellness, and their FM was significantly reduced from T0 ( $12.7 \pm 4.7$  kg) to T6 and T12 ( $10.5 \pm 4.01$  and  $10.9 \pm 4.0$  kg respectively,  $p < 0.05$ ). At the same time, they significantly gained free fat mass (FFM) from T0 ( $54.5 \pm 10.5$  kg) to T12 ( $56.6 \pm 11.2$  kg,  $p < 0.05$ ). **Discussion** The present data suggest that a high-intake breakfast diet can easily induce positive adjustments of body composition in moderately active healthy people. Skipping breakfast is to be considered an unhealthy habit and should be avoided. Further investigations are needed to better clarify this concept. **References** Garaulet M, Gómez-Abellán P. ### **EFFECT OF CAFFEINE SUPPLEMENTATION ON METABOLISM AND PHYSICAL AND COGNITIVE FUNCTION IN FEMALE INTERMITTENT GAMES PLAYERS**

Ali, A.

*Massey University*

The aim of this study was to investigate the effects of caffeine ingestion on metabolism and physical and cognitive performance in female team-sport players taking monophasic oral contraceptives of the same hormonal composition. In a randomised, double-blind, placebo-controlled crossover design, 10 healthy participants (age  $23.6 \pm 4.1$ y; height  $1.62 \pm 0.06$ m; body mass  $59.7 \pm 3.5$ kg;  $\text{VO}_2 \text{ max}$   $50.0 \pm 5.3 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ) completed a 90 min intermittent treadmill-running protocol twice, during days 5-8 and 18-22 of their pill cycle. During the familiarisation session participants completed a maximal oxygen uptake test, practiced the cognitive, perceptual, mood, strength and jump tests and underwent 30 min of the running protocol. Upon arrival at the laboratory for the main trials, hydration status was measured via urine specific gravity (USG) using a handheld refractometer and a heart rate (HR) monitor fitted. A capsule containing 6 mg·kg<sup>-1</sup> body mass (BM) of anhydrous caffeine or placebo (Maltodextrin, 1.62 kJ·g<sup>-1</sup>) was administered 60 min before commencing exercise with a 500 ml bolus of water. Further 3 ml·kg<sup>-1</sup> BM boluses of water were provided every 15 min during exercise. Before, during and after the exercise protocol, venous blood samples were taken and cognitive (Choice Reaction Time, CRT; Digit Vigilance, DV; Stroop test), perceptual (Ratings of Perceived Exertion, RPE; Feeling Scale, FS; Felt Arousal Scale, FAS; Profile of Mood States, POMS), and physical tests (countermovement jump, CMJ; strength testing on the isokinetic dynamometer) were administered. These tests were repeated  $12 \pm 2$  h post-exercise, and an assessment of sleep quality was conducted using the Leeds Sleep Evaluation Questionnaire (LSEQ). Plasma caffeine concentration was significantly higher in the caffeine trial and peaked 100 min after ingestion. Paraxanthine and theophylline levels were significantly elevated at  $12 \pm 2$  h post-exercise with no differences in theobromine. There were no significant effects of caffeine supplementation on HR, USG, CMJ, isometric strength, RPE, cognitive performance or glucose and insulin concentrations. Caffeine supplementation improved levels of pleasure (FS), activation (FAS) and vigour (POMS) compared to placebo ( $P < 0.05$ ) with a tendency for reduced levels of fatigue (POMS). Caffeine supplementation also improved average torque in eccentric contractions of the knee extensors and flexors, and peak torque in the eccentric contractions of the knee flexors ( $P < 0.05$ ). Getting to sleep and subsequent quality of sleep was impaired following caffeine supplementation ( $P < 0.05$ ). Free fatty acid (FFA) concentration increased over the duration of exercise ( $P < 0.05$ ), and increased at a greater rate on the caffeine trial ( $P < 0.05$ ). In conclusion, caffeine ingestion showed improvements in some strength indices but no improvement in cognitive performance in this cohort. Perceptual and mood responses were also improved as a result of caffeine supplementation.

### **THE EFFECTS OF 14-DAYS OF CREATINE SUPPLEMENTATION ON CREATINE PHOSPHATE LEVELS IN MUSCLE AND BRAIN IN YOUNG AND OLDER SUBJECTS**

Berk, E., Glover, E., Miller, S., Newbould, R., Parkin, J.

*GlaxoSmithKline and Imanova Centre for Imaging Sciences*

Creatine supplementation has been demonstrated to improve muscle energetics but the mechanism and on-set of the benefit is not well known. We performed a randomized, double-blind study of the effects of 14-day creatine supplementation on creatine phosphate (CrP) levels in muscle and brain using phosphorus-31 magnetic resonance spectroscopy (<sup>31</sup>P-MRS) in 15 healthy young male recreational athletes (Group 1, mean age  $26.7 \pm 4.8$  years) and 15 healthy older subjects (Group 2, mean age  $59.3 \pm 5.2$  years). In each cohort, 10 subjects took a creatine supplemented protein drink twice daily (total/day 10 g creatine, 60 g whey protein), and 5 took a control product (total/day 10g placebo, 60 g whey protein). Subjects took the product for 14 days and complied with a structured exercise intervention

program (3x/week). Serial static measurements were taken for muscle CrP (Days 0, 3, 7 and 14) and brain CrP (Days 0 and 14). Additionally, dynamic measures of muscle activity were assessed using a standard pedal test while subjects were in the MRI scanner. Within both groups, static levels of CrP were similar at baseline. By Day 7 the CrP supplemented individuals had significantly greater muscle CrP levels compared to the protein alone group (Group 1,  $43.87 \pm 4.34$  vs.  $38.31 \pm 4.52$  (mM);  $P=0.029$  and Group 2,  $41.93 \pm 3.98$  vs.  $38.14 \pm 1.96$  (mM);  $P=0.003$ ) and continued to increase and remain significantly higher at Day 14 (Group 1,  $44.04 \pm 4.74$  vs.  $37.80 \pm 5.62$  (mM);  $P=0.024$  and Group 2,  $45.03 \pm 4.77$  vs.  $38.36 \pm 3.01$  (mM);  $P<0.001$ ). Likewise the % change in brain CrP was significantly greater to the protein alone group at Day 14 (Group 1,  $6.30 \pm 7.36$  vs.  $-0.78 \pm 2.92$  (%);  $P=0.01$  and Group 2,  $8.45 \pm 6.92$  vs.  $0.83 \pm 1.16$  (%);  $P=0.0035$ ). For the pedal test, the subjects were instructed to perform a standardized routine to exhaustion; however we observed an inconsistent adherence of non-exhaustive to exhaustive exercise for all subjects across the multiple visits. As a result, there is limited interpretation of the data towards exercise related changes in CrP, ADP,  $T_{1/2}$  of CrP and  $T_{1/2}$  of ADP, and pH, yet some significant trends are observed within the two week timeframe. This study demonstrated that within 7 days (muscle) and 14 days (brain) both healthy, young recreational male athletes and healthy older subjects significantly increased their CrP levels with a 10 grams/day of creatine supplementation regimen. As a result, this study increases our understanding of the onset of the effects of creatine supplementation. Clinical Trial Registry #NCT02058654 Contact: evan.s.berk@gsk.com

### THE EFFECTS OF OMEGA-3 POLYUNSATURATED FATTY ACID SUPPLEMENTATION DOSE LEVEL ON HYPERPNOEA INDUCED BRONCHOCONSTRICTION SEVERITY AND AIRWAY INFLAMMATION IN PHYSICALLY ACTIVE ASTHMATICS

Williams, N.C., Johnson, M.A., Sharpe, G.R., Hunter, K.

*Nottingham Trent University*

High dose omega3-PUFA supplementation reduces airway obstruction and inflammation in asthmatics with HIB [1] but such doses are costly and may cause gastrointestinal side effects. The optimal dose level of omega3-PUFA for alleviating HIB is yet to be determined, therefore, the aim of the current study was to investigate the effectiveness of a lower omega3-PUFA dose on HIB and markers of airway inflammation. Eight asthmatics with HIB ( $\geq 10\%$  fall in forced expiratory volume in 1 s [FEV1] after eucapnic voluntary hyperpnoea [EVH]) and 8 non-asthmatic non-HIB controls were studied. Participants received, in a counter-balanced order under double-blind conditions, one of the following interventions for 21 days (each separated by a 2 wk washout): a) 6.2 g.d-1 of omega3-PUFA (8 omega-3 capsules containing a total of 3.7 g EPA and 2.5 g DHA) b) 3.1 g.d-1 of omega3-PUFA (4 omega-3 capsules containing a total of 1.8 g EPA and 1.3 g DHA + 4 placebo capsules) c) Placebo (8 placebo capsules of medium chain triglyceride per day) At day 0 and day 21 of each intervention, participants underwent EVH for the assessment of HIB, and neutrophil phospholipid fatty acid content was assessed from a venous blood sample. Asthma participants provided a pre-EVH fraction of exhaled nitric oxide (FENO) sample. Asthma and control participants provided urine samples before and 12, 60, and 90 min post-EVH for the assessment of eicosanoid 9a,11b-PGF2. No changes were observed after placebo. Conversely, the post-EVH  $\% \Delta FEV1$  had improved by  $\sim 35\%$  from  $-28 \pm 18\%$  and  $-28 \pm 17\%$  at day 0 to  $-19 \pm 15\%$  and  $-18 \pm 14\%$  following the 6.2g.d-1 and 3.1g.d-1 omega3-PUFA interventions, respectively ( $p<0.05$ ); these changes were not different between doses. Both omega3-PUFA interventions equally reduced resting FENO ( $\sim 30\%$ ) and day 21 post-EVH urinary 9a,11b-PGF2 concentration ( $p<0.05$ ). Both omega3-PUFA interventions reduced ( $\sim 9\%$ ) the pre-EVH arachidonic acid content, and increased EPA ( $\sim 75\%$ ) and DHA ( $\sim 15\%$ ) content of the isolated neutrophils ( $p<0.05$ ). All changes after both omega3-PUFA interventions were different compared with placebo ( $p<0.05$ ). This study shows for the first time that 3.1g.d-1 of omega3-PUFA is as effective as a much higher dose in attenuating HIB and markers of airway inflammation in physically active asthmatics. This lower dose represents a potentially beneficial management strategy for physically active asthmatics suffering with HIB whilst reducing the financial cost, compliance issues and potential for gastrointestinal distress associated with higher omega3-PUFA doses. 1. #### CARDIOVASCULAR DIFFERENCES DURING ACTIVE VERSUS PASSIVE RECOVERY IN ICE-HOCKEY MEASURED USING IMPEDANCE CARDIOGRAPHY

Burr, J.1, Slysz, J.1, Boulter, M.1, Fowles, J.2

1: *University of PEI (Charlottetown, Canada)*, 2: *Acadia University (Wolfville, Canada)*

Introduction Competitive and recreational ice hockey is a popular sport in North America, Europe and many parts other parts of the world. Although the specific demands of ice-hockey differ somewhat according to the level of play, ice hockey is characterized by high-intensity exercise interspersed by periods of seated inactivity (Cox et al., 1995). Light activity during recovery has been demonstrated to improve the power output observed during repeated sprint activities (Connolly et al., 2003) and compared to passive rest, offers the potential to augment venous return and consequent cardiovascular function (Takahashi et al., 2005). Such alterations have implications for high level athletes and aged recreational participants alike. Therefore, the purpose of our study was to examine the efficacy of light intensity lower body exercises (standing and pacing) on the player's bench for altering hemodynamic function following a simulated on-ice hockey shift. Methods Young, healthy hockey players ( $n=15$ ,  $23 \pm 1$ yr,  $54 \pm 3$  mL.kg<sup>-1</sup>.min<sup>-1</sup>) were recruited to perform two simulated hockey shifts in a randomized cross-over design. During each on-ice trial, participants skated up to 85% of age predicted heart rate maximum, followed by either passive or active recovery while haemodynamic measures were tracked from cessation of work through 180s of rest. Results Even while wearing full hockey gear within the confines of an ice-hockey bench, light active recovery in the form of standing and pacing was effective for augmenting cardiac output at 45, 50, and 120s (an average of  $2.5 \pm 0.2$  L/min,  $p=0.03$ ). These alterations were consequent to a trending increase in stroke volume (11.6 mL,  $p=0.06$ ) coupled with a sustained elevation in heart rate (12 bpm,  $p=0.05$ ). Discussion Standing and pacing between shifts offers a realistic in-game solution to help slow the precipitous drop in cardiac output (heart rate and stroke volume) that typically occurs with seated passive rest. Prolonging the duration of elevated cardiac output further into recovery may be beneficial for promoting recovery of the working skeletal muscles and also avoiding venous pooling and reduced myocardial perfusion (Connolly et al., 2003; Franklin. 2005). This could have important implications for high-end sport performance or amongst participant with underlying vascular disease that have an increased risk of an ischemic event during high intensity

exercise. References Connolly DA, Brennan KM, Lauzon CD. (2003). *J Sports Sci Med* 2:47-51. Cox MH, et al. (1995). *Sports Med* 19:184-201. Franklin BA. (2005). *J Cardiopulm Rehabil* 25:189-95. Takahashi T et al. (2005). *Eur J Appl Physiol* 94:576-583. Contact jburrr@upei.ca

### FOREARM MUSCLE BLOOD FLOW AND DEOXYGENATION DURING DYNAMIC HANDGRIP EXERCISE IN LIMB SPECIFIC TRAINED ATHLETES

Bourgois, J.G., Dumortier, J., Boone, J., De Backer, T., Celie, B.

*Ghent University*

**Introduction** Rock climbers and oarsmen are frequently exposed to quasi-isometric or dynamic contractions of forearm muscles. Only limited information is available about vascular and muscular responses in the forearm during exercise in limb specific trained athletes. The purpose of this study was to investigate forearm blood flow (FBF) and deoxyhemoglobin and -myoglobin (deoxy[Hb+Mb]) in these limb specific versus non limb specific trained populations during a reliable incremental cyclic contraction protocol (ICCP)[1]. It could be hypothesized that, due to limb specific training adaptations, FBF and deoxy[Hb+Mb] will be higher in rock climbers and oarsmen compared to endurance runners and healthy control subjects. **Methods** 13 Belgian elite rock climbers, 13 oarsmen from the Belgian national squad, 13 high level endurance runners and 13 healthy control subjects, matched for gender, participated in this study. Before ICCP, maximal voluntary contraction (MVC) was determined for each individual, whereas FBF (in ml/min) and deoxy[Hb+Mb] (expressed in % towards the arterial occlusion maximum value[1]) were measured during ICCP using Doppler ultrasound (Doppler US) and Near Infrared Spectroscopy (NIRS). To determine efficiency, FBF and the highest deoxy[Hb+Mb] values (in %) were divided by force (N) for every step during ICCP. A repeated measures ANOVA was used to compare these parameters between the four groups. Results Absolute FBF was significantly higher for rock climbers and oarsmen during ICCP compared to endurance runners and healthy control subjects ( $p < 0.001$ ). When individual FBF values were divided by force (ml/min.N) for every step in the ICCP, oarsmen showed significant higher values compared to endurance runners and healthy controls ( $p = 0.001$ ). No significant differences were found between the different populations for relative deoxy[Hb+Mb] ( $p = 0.613$ ) and relative deoxy[Hb+Mb] normalized for individual force (%/N) ( $p = 0.191$ ) during ICCP. **Discussion** The higher FBF values in rock climbers and oarsmen compared to endurance runners and healthy controls can be explained by specific vascular and muscular training adaptations. The different response of rock climbers and oarsmen for the normalized FBF compared to endurance runners and controls, can be explained by a different cardiovascular strain as well as a different nature of forearm muscle contractions during specific rock climbing (quasi-isometric) and rowing (dynamic) training. The lack of significant differences in deoxy[Hb+Mb] between the 4 groups can be explained by the test protocol where relative deoxy[Hb+Mb] values were used.[1] 1. Celie B, et al. *Eur. J. Appl. Physiol.* 2012;112(6):2369-74.

### HEMOGLOBIN MASS IS DETERMINED BY LEAN BODY MASS IN YOUNG BOYS

Hallén, J.I, Landgraff, H.I, Riiser, A.2

*1: Norwegian School of Sport Sciences (Oslo, Norway), 2: Sogn and Fjordane University College, Faculty of Teacher Education and Sports (Sogndal, Norway)*

**INTRODUCTION:** In a homogenous group of endurance trained male athletes, hemoglobin mass (Hb-mass) was more related to lean body mass (LBM) than total body mass (Schumacher, Ahlgrim & Pottgiesser, 2008). Whether this is the case in children is unknown. The aim of the present study was to investigate if Hb-mass is higher in a group of boys with high VO<sub>2</sub>max (recruited from cross-country ski clubs) compared to a control group with lower VO<sub>2</sub>max. **METHODS:** Forty boys (age 13.4 ± SD 0.2) were recruited from cross-country ski clubs (XCS-boys) and 20 boys (age 13.5 ± 0.2) were recruited from a school. Hb-mass was determined using the optimized CO rebreathing method. VO<sub>2</sub>max was measured directly while running to exhaustion on a motor-driven treadmill. LBM was determined by InBody 720 bioelectrical impedance analysis. Differences between the schoolboys and the XCS-boys were assessed by Student's t-test for independent samples. Correlations between variables were assessed by Pearson's product-moment correlation. **RESULTS:** Schoolboys were 19 % heavier than the XCS-boys (53.2 ± 11.9 vs 44.9 ± 6.2 kg;  $p < 0.001$ ), while LBM was 9 % higher (44.6 ± 6.9 vs 40.9 ± 5.6 kg;  $p = 0.03$ ). There was no difference in body height (164 ± 9 vs 160 ± 9 cm). VO<sub>2</sub>max in absolute terms was similar between the two groups (2906 ± 410 vs 2920 ± 520 ml/min) while, relative to body mass, the VO<sub>2</sub>max in the schoolboys was 85% of that of the XCS-boys (55.2 ± 8.1 vs 64.8 ± 5.0 ml/kg min;  $p < 0.0001$ ). VO<sub>2</sub>max relative to LBM in the schoolboys was 92 % of the XCS-boys (65.4 ± 4.8 vs 71.2 ± 4.4 ml/kgLBM min;  $p < 0.0001$ ). Hb-mass relative to body weight was 6 % lower in schoolboys (10.3 ± 1.3 vs 11.0 ± 0.9 g/kg;  $p = 0.016$ ). However, when Hb-mass was normalised for LBM, there was no difference between the groups (12.1 ± 0.7 vs 12.0 ± 0.8 g/kgLBM;  $p = 0.81$ ). With the two groups pooled, the correlation between VO<sub>2</sub>max and Hb-mass relative to body weight was very high ( $r = 0.73$ ;  $p < 0.0001$ ) while the correlation was moderate ( $r = 0.31$ ;  $p = 0.02$ ) when VO<sub>2</sub>max and Hb-mass were related to LBM. **DISCUSSION:** The present data indicate that Hb-mass is determined by LBM in 12-13 year old boys. The higher VO<sub>2</sub>max relative to LBM in XCS-boys is not related to a higher Hb-mass since Hb-mass relative to LBM was similar between the groups. Also VO<sub>2</sub>max seems to be more related to LBM than total body mass, since the variation in VO<sub>2</sub>max relative to LBM was less than 50 % (SD 7 %) compared to the variation in VO<sub>2</sub>max relative to body weight (15 %). **REFERENCES:** Schumacher YO, Ahlgrim C, Pottgiesser T. *J Sports Med Phys Fitness.* 2008 Dec;48(4):509-14. ### POST-AEROBIC EXERCISE METABOREFLEX STIMULATION DELAYS HEART RATE RECOVERY

Forjaz, C., Peçanha, T., Brito, L., Fecchio, R., Sousa, P., Silva-Junior, N., Abreu, A., Silva, G., Mion-Junior, D.

*University of Sao Paulo*

**Introduction:** The role of metaboreflex on heart rate recovery after exercise (HRR) is controversial. Classic studies suggest no influence after handgrip exercise. However, it is speculated that this mechanism may be active after exercises with larger muscle masses. Thus, the aim of this study was to evaluate the influence of metaboreflex on HRR after aerobic exercise. **Methods:** 15 healthy middle-aged men (114 ± 6/77 ± 3 mmHg, BMI = 29 ± 3 kg/m<sup>2</sup>, VO<sub>2</sub>peak = 26 ± 4 ml.kg<sup>-1</sup>.min<sup>-1</sup>) randomly underwent 2 exercise sessions (cycle ergometer, 70% VO<sub>2</sub>peak, 30 min) followed by 5 min of inactive recovery. Recovery was performed with (occlusion session) and without (control session) leg circulatory occlusion (cuffs at the hips inflated to supra-systolic pressure). ECG was registered and HRR was assessed by: heart rate reduction after 60 (HRR60s) and 300s (HRR300s) of recovery; short-term time constant of HRR (T30); time constant of the HRR after exponential fitting (HRRt); and mean values of HR in segments of 30s (HR30s). Heart rate variability (HRV) was assessed by the root mean square residual (RMS) and by square root of the mean squared differences of successive R-R intervals (rMSSD), on subsequent 30-s segments. Paired T-test, Wilcoxon test and two-way ANOVA (session vs. time) were employed (Newman-Keuls post-hoc;  $p < 0.05$ ). **Results:**

HRR60s, T30 and HRR<sub>t</sub> were similar between the control and the occlusion sessions (26±9 vs. 24±9 bpm, p=0.30, 340±191 vs. 224±74 s, p=0.20; 79±33 vs. 40±30 s, p=0.18, respectively). HRR300s was significantly lower in the occlusion session (28±10 vs. 38±13, p=0.00). HR30s, rMSSD and RMS present significant time vs. session interactions, showing slower recovery of HR30s from 120s (106±10 vs. 99±13 bpm, p = 0.00), of rMSSD from 270s (1.2 ± 0.5 vs. 1.7 ± 0.7 ms, P=0.01) and of RMS from 180s (1.6±0.7 vs. 2.1±0.7 ms, P=0.01) in the occlusion session in comparison to the control session. Conclusion: In conclusion, metaboreflex stimulation during the recovery period of aerobic exercise delays HRR, particularly the slow phase of HRR. Funding: FAPESP 2013/044997-0 and 2013/05519-4

### EXERCISING OPPORTUNITIES TO PREVENT CHRONIC DISEASES: THE CAPO KIDS TRIAL [ESSA]

Candiota Nogueira, R.

*Griffith University*

**Introduction:** The increasing incidence of both chronic bone and obesity-related disease places a heavy burden on health economies. Both conditions may arise in childhood. While exercise in youth is beneficial for both bone and metabolism, the nature of exercise recommendations for each traditionally differs. **Aim:** Our goal was to determine the effect of a brief, novel, enjoyable, school-based exercise regimen targeting both bone and fat in primary school children. **Methods:** A controlled exercise intervention trial was conducted over a full school year (9 months). The intervention comprised 10 minutes of thrice-weekly capoeira and jumping activities. Anthropometrics, waist circumference (WC), calcaneal broadband ultrasound attenuation (BUA) and stiffness index (SI) (Lunar Achilles, GE), maximum vertical jump (VJ), cardiovascular endurance (predicted VO<sub>2</sub> max), resting heart rate (HR), blood pressure (BP) and maturity (YAPHV) were recorded at baseline and 9 months. A subset of whole body (WB), lumbar spine (LS) and femoral neck (FN) BMD, lean and fat mass (DXA, XR800, Norland), and indices of tibial and radial morphology and density (pQCT, XT3000, Stratec) was also collected. Changes in outcome variables were compared between groups using two-way ANOVA, controlling for YAPHV and initial values. Stepwise linear regression were performed to determine the relationships between bone parameters. **Results:** 296 children, including 130 control (CON) (10.7 ± 0.6yo; YAPHV -1.9 ± 0.9y) and 166 treatment (EX) (10.5 ± 0.5yo, YAPHV -2.1 ± 0.9y) participated. EX improved WC (EX: 1.95 ± 2.82 cm; CON: 4.09 ± 4.05 cm; p = 0.001), HR (EX: -4.11 ± 3.35 BPM; CON: 0.22 ± 3.8 BPM; p = 0.001), VJ (EX: 3.47 ± 4.01; CON: -0.59 ± 5.16; p = 0.001), predicted VO<sub>2</sub> max (EX: 2.68 ± 3.96; CON: -0.20 ± 3.38 ml/kg/min; p = 0.001), SI (EX: 6.25 ± 10.04%; CON: 4.09 ± 6.99%; p = 0.05) and BUA (EX: 3.99 ± 9.06 dB/MHz; CON: 1.33 ± 8.3 dB/MHz; p = 0.01) compared to control. Sex-specific effects largely mirrored those findings. Baseline BUA and maturity predicted 32.2% of the variance in BUA change (p = 0.001) for boys; while BMI and baseline BUA accounted for 16.4% of the variance in BUA change (p = 0.006) for girls. **Conclusion:** School-based capoeira with jumping improved markers of metabolic and musculoskeletal health in primary school children. The exercise program was safe, enjoyable and easily incorporated into the school schedule.

#### RADIOLOGICAL STUDY OF CHANGES IN MUSCLE VOLUME USING MR IMAGING IN PATIENTS UNDERGOING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION OF THE KNEE WITH SEMITENDINOUS AND GRACILIS AUTOGRAFT

Setuain, I.1,4, Izquierdo, M.1, Idoate, F.2, Bikandi, E.3,4, García Tabar, I.1,3, Alfaro-Adrián, J.2,4

*1Public University of Navarra. Spain; 2 San Miguel Clinic. Navarra. Spain; 3- Research and Sports Medicine Studies Centre. Navarra. Spain; 4. TDN Traumatology and advanced Rehabilitation Centre. Spain*

**INTRODUCTION** There is still controversy with respect to muscle performance in association with muscle cross sectional area (CSA) in thigh musculature one year after original ACL reconstruction. **OBJECTIVE :** To analyze the cross sectional area (CSA) of quadriceps and hamstring muscles in a sample of 29 recreational athletes following two different rehabilitation programs: conventional (15, CG) and accelerated (14, AG), before and one year after having undergone ACL surgical reconstruction with autologous hamstring graft. **MATERIAL AND METHODS:** 29 athletes were exposed to MRI studies (1.5 TMagnetom Avanto; Siemens-Erlangen©, Germany). before and 12 months after ACL reconstruction. CSA was calculated (mm<sup>2</sup>), on Quadriceps (Q), Biceps femoris (BF), Semitendinous, (ST) Semimembranosus (SM) and Gracilis (GR) muscles, at 30, 50 and 70% of the femur's length level. The same surgeon (J.A.A) performed all the surgical interventions with standardized procedures. Isokinetic knee joint flexo- extension torque evaluations (N.m) (Cybex – Human Norm© CA. USA) were also performed in the same time points at an angular velocity of 180°/sec. T-tests of paired comparison (injured limb before and after 1 year from the reconstruction; injured limb vs. contralateral limb after 1 year from the reconstruction) and independent sample T test for inter-group comparison (healthy and operated limbs of both groups before and after surgical procedure) were made, setting the significance level at p < 0.05 (SPSS v. 17.0). **RESULTS:** Significant (p < 0.05) muscle CSA reductions (ST at 50% and GR at 70% levels in the reconstructed limb before and one year after ACL reconstruction) were observed in both treatment groups: [mean ± SD: ST: 861.9 ± 278.97 vs. 625.81 ± 208.35; 95% CI: 51.94 – 420.25 GR: 131.50 ± 87.76 vs 50.72 ± 79.90; 95% CI: 18.0 – 143.54 mm<sup>2</sup> ] and [ST: 807.62 ± 178.06 vs 630.56 ± 158.22; 95% CI: 46.20 – 307.91 GR: 165.24 ± 130.94 vs 53.13 ± 60.40; 95% CI: 29.56 – 194.64 mm<sup>2</sup> ] in CG and AG respectively. With respect to muscle isokinetic performance, subjects allocated in AG group, demonstrated significantly (p < 0.05) greater knee flexion torque in their reconstructed limbs in comparison to CG subjects [mean ± SD: 186.29 ± 37.96 vs 141.23 ± 34.79 N.m respectively] that were not present before ACL reconstruction [ mean ± SD: 142.38 ± 38.54 vs 141.95 ± 52.04 N.m for both groups respectively] **CONCLUSION** Objective atrophy of the implicated musculature (ST and GR) related to the surgical reconstruction present in both groups persisted in the reconstructed limb 1 year after ACL reconstruction. Surprisingly, subjects following an accelerated rehabilitation protocol exhibited greater muscle force despite persisting muscle size reduction. The results suggest possible neural drive optimization derived strength gains predominating in relation to function restoration in the harvested musculature. **REFERENCES.** Janssen.R et al. ### MUSCLE FUNCTION AFTER ACL INJURY CAN PREDICT FUTURE SELF-REPORTED OUTCOMES

Flosadottir, V.1, Roos, E.M.2, Ageberg, E.1

*Health Sciences*

1 Dept. of Health Sciences, Lund University, Lund, Sweden, 2 Dept. of Sports and Clinical Biomechanics, University of Southern Denmark, Odense, Denmark. Introduction The long-term consequences of an anterior cruciate ligament (ACL) injury often include worse self-reported outcomes and a decrease in activity level. Muscle function, such as muscle strength, hop performance and postural orientation (the ability to stabilize body segments in relation to each other and the environment), is a modifiable factor which can be improved by targeted exercise. The association between lower extremity muscle function and later consequences of an ACL injury is poorly investigated. Aim To investigate the association between lower extremity muscle function and future self-reported outcomes after ACL injury. Methods Fifty-four patients, a subgroup from the Knee Anterior Cruciate Ligament, Nonsurgical versus Surgical Treatment (KANON) study, were assessed at mean 3 years (SD 0.85) after ACL injury or reconstruction with three hop tests (vertical jump, one-leg hop for distance and side hop), three muscle power tests (knee flexion, knee extension and leg press) and visual rating of Postural Orientation Errors (POEs) during performance of five functional tasks. POEs were determined as Knee Medial to Foot Position (KMFP) across the five tasks and an overall score for all tasks based on the orientation of several segments. Self-reported outcomes were assessed with the Knee Injury and Osteoarthritis Outcome Score (KOOS) subscales Function in sport and recreation (KOOS Sport/rec) and Knee-related Quality of life (KOOS QoL), the Knee Self-Efficacy scale (K-SES) subscore Present (K-SES Present) and Tegner Activity Scale (TAS) at follow-up 5 years after injury. Univariate linear regression analyses were used to test relations between muscle function and self-reported outcomes. Correlations with  $p$ -value  $<0.2$  were included in a multivariate regression model, adjusted for baseline scores, sex, age, body mass index and treatment. Results A worse overall score of POEs, and KMFP, was associated with worse K-SES Present at follow-up (unadjusted  $\beta$  -0.83 and -2.93, respectively and adjusted  $\beta$  -0.81 and -4.63, respectively,  $p \leq 0.002$ ). There were no associations between muscle function test scores and KOOS Sport/rec, KOOS QoL or TAS scores at follow-up ( $p > 0.081$ ). Conclusions Worse overall score of Postural Orientation Errors and Knee Medial to Foot Position at mean 3 years predict worse present self-efficacy of knee function at 5 years after ACL injury. This suggests that treatment should target exercises aimed at maintaining the ability to stabilize body segments in relation to each other and the environment, i.e., good postural orientation, to improve future self-efficacy of knee function in people with ACL injury.

### EFFECTIVENESS OF EXERCISE THERAPY COMPARED WITH STEROID INJECTION FOR LATERAL EPICONDYLITIS: A RANDOMIZED CONTROLLED TRIAL

Gara, E., Murtezani, A., Haxhiu, B., Ibrahimaj, A., Durguti, Zh.

*University Clinical Center of Kosovo*

Effectiveness of exercise therapy compared with steroid injection for lateral epicondylitis: A randomized controlled trial Eqrem Gara, Ardiana Murtezani, Bekim Haxhiu, Arbnore Ibrahimaj, Zheraldin Durguti. University Clinical Center of Kosovo, Prishtina, Kosovo. Introduction Lateral elbow tendinopathy (LET) or 'tennis elbow' is a common disorder with a prevalence of at least 1.7%. Typical symptoms are pain at the lateral epicondyle of the humerus and pain on resisted dorsiflexion of the wrist. A wide variety of treatment strategies has been described. As of yet, no optimal strategy has been identified. Exercise therapy have been used either alone or in conjunction with physical interventions. Corticosteroid injection for LET may be beneficial but not well maintained. The aim of the study was to compare the effects of exercise therapy with local corticosteroid injections in the treatment of tennis elbow. Methods The study was a prospective RCT performed in the Physical and Rehabilitation Medicine outpatient department. At a first appointment the diagnosis was checked by pain on palpation, and Maudsley's middle finger test. Thirty-nine patients with lateral epicondylitis were randomly distributed into two groups as follows: exercise therapy group ( $n=20$ ) and injection group ( $n=19$ ). Exercise treatment consisted of progressive, slow, repetitive wrist and forearm stretching, muscle conditioning, and occupational exercise. Injection therapy consisted of a single injection of 10 mg of triamcinolone acetonide and of 2% lignocaine hydrochloride. The effect of eight weeks treatment was measured by a pain questionnaire (visual analogue scale), isokinetic muscle performance testing of wrist and forearm, and painfree grip strength measurements. All patients were evaluated before treatment and at the 8 week. Results Our results showed that after eight weeks of treatment there was a significant improvement in the entire group of patients but the corticosteroid injections were better than the exercise group. VAS values during activity and pain levels during resisted wrist dorsiflexion were significantly lower in Group II than Group I at the eight week ( $p < 0.001$ ). Discussion We conclude that at eight week, treatment with corticosteroid injections was more effective than exercise therapy. Current evidence suggests that corticosteroid injections offer the best prospects for short term relief of symptoms, and physiotherapy (perhaps the exercise component of physiotherapy) offers the best prospect for good long-term outcomes (Bisset et al., 2005) References Bisset L, Paungmali A, Vicenzino B, Beller E. A systematic review and meta-analysis of clinical trials on physical interventions for lateral epicondylalgia. (2005). Br J Sports Med, 39:411-22 Barr S, Cerisola FL, Blanchard V. ### EFFECTIVENESS OF A MULTICOMPONENT APPROACH PROMOTING PHYSICAL ACTIVITY IN CHRONIC LOW BACK PAIN PATIENTS: SIX MONTHS FOLLOW-UP RESULTS OF A RANDOMIZED CONTROLLED TRIAL

Schaller, A., Froboese, I.

*German Sport University Cologne*

Introduction The promotion of health-enhancing physical activity (PA) is widely recommended to increase the sustainability of rehabilitation (Pfeifer et al., 2010). Hence, adherence to self-directed exercise and implementing health-enhancing PA into a daily routine following rehabilitation is a common problem for patients (Haaf, 2005). The aim of the present study was to estimate the effectiveness of a multi-component intervention (Movement Coaching) compared with a low intensity intervention (control group) in terms of promoting leisure time PA in chronic low back pain (LBP) patients. Methods The study was conducted as a two-arm randomized controlled trial including 412 patients. Measuring points were at the beginning of inpatient rehabilitation (T1) and at six months follow-up (T2). Three different outcomes were assessed: "MET-min/week during leisure time", number of patients "achieving WHO recommendations" and number of patients showing "any physical activity". Between-group differences at T2 were tested. Results The patients' mean age was 50.4 ( $\pm 8.1$ ) years, 286 patients were men (69%), and 86% reported duration of pain of more than twelve months. There were no significant differences between Movement Coaching and the control group in regard to effectiveness at T2. Although it was not significant ( $p = 0.21$ ), the Movement Coaching group showed tendentially a higher median (270 MET-min/week vs. 180 MET-min/week) and more patients

“achieving WHO recommendations” ( $p = 0.27$ ). In contrast, number of patients reporting “any physical activity” was higher in the control group ( $p = 0.86$ ). Overall, 84 % in the Movement Coaching group and 91 % in the control group did not achieve the WHO recommendations on PA during leisure time and therefore were classified “not sufficiently active” at T2. Discussion The evaluation underlined the assumption that chronic LBP patients in inpatient rehabilitation were an appropriate target group for PA promotion. Overall, the results of the present study broadly agreed with the current research that no superior intervention strategy or method could be identified. A noticeable aspect of the present study was that Movement Coaching and the control group tended to show different effects according to the PA outcome criteria assessed. In this context a cost-effectiveness study is planned to gain information for resource allocation. References Haaf, H.-G. ### INJURY INCIDENCE AND INJURY PATTERNS OF ELITE-LEVEL MALE SOCCER PLAYERS IN KOSOVO

Shalaj, I.1,2, Tishukaj, F.1,2, Gashi, F.2, Gjaka, M.4, Bachl, N.1, Wessner, B.1, Csapo, R.3, Tschan, H.1

1:(University of Vienna, Institute of Sport Science, Austria), 2:(University of Pristina, Kosovo), 3:(University of Innsbruck, Department of Sport Science, Austria), 4:(University of Rome, Foro Italic

Introduction Soccer players have a substantial risk of injury and teams that can avoid or minimise injuries have a greater chance of success. To establish prevention programs it is important to identify risk factors, to study injury patterns and to learn about injury incidence during match and training, respectively. The current study therefore aims to describe the incidence and nature of sport-related injuries in elite soccer players over a complete season. Methods Over the autumn and spring season 2013/2014 a total of 143 male players (age:  $23.2 \pm 4.1$  yrs.; body mass  $74.2 \pm 6.7$  kg; height  $180.0 \pm 5.0$  cm) were tracked. Players who volunteered for these studies were members of the highest league in Kosovo. Following a baseline data sampling during preseason team injury, training and match play data were submitted by the medical staff on a weekly basis using Injury Report Form (F-Marc) suggested by FIFA (Fuller et al., 2006). Results A total of 272 injuries occurred during 36,833 hrs of exposure giving an injury incidence of 7.4 injuries per 1,000 hrs. Injury incidence during matches was distinctly higher (35.3) than in training (3.1). The single most common injury subtypes were muscle strains (24%) and ligament injuries (21%), respectively. 63% of all injuries occurred during the match versus 37%, which occurred during training. Traumatic injuries comprised 71% of all injuries 29% were overuse injuries. Moderate injuries (causing absence of 8-28 days) accounted for 40% of all injuries. Discussion Injury incidence and injury patterns of the current study are largely in agreement with data from the UEFA injury study on professional players (Ekstrand et al., 2011). #### AN EXPLORATORY STUDY ABOUT THE REACTION TIME IN HANDBALL GOALKEEPERS

Estriga, L.1, Carvalho, J.2, Carvalho, E.3, Velhote, M.3

*Sports Faculty*

1:FADEUP (Porto, Portugal), 2:UM (Minho, Portugal), 3:FEUP (Porto, Portugal) Introduction It is commonly accepted that a successful performance in goalkeeping depend not only of efficient and accurate execution of movements to intercept the ball trajectory but also of the ability to read the thrower intention/actions and to react on time. The aim of this study was to investigate the whether the goalkeeper in a 7-meter throw can decide based only on the free ball trajectory or if it must include a heuristic reasoning based on the thrower traits and actions. Methods The sample consisted of 13 field players (6 best Portuguese senior females and 7 best Portuguese junior males) and 9 goalkeepers (5 male and 4 female). A set of three goalkeepers were evaluated per session. In each session there were two setups: a regular 7m throw – in an official court, with an official ball, standard illumination, etc. – and a blind setup were, at the 7m line there was an apparatus that did not disturb the thrower but did not allowed the goalkeeper to see the thrower/ball. Every 7m throw was preceded by a whistle signal, so the throw was taken within 3 seconds (like in a regular match). The sequence of trials – goalkeeper/thrower/setup – was completely randomized, with each player having between 1min and 5min intervals between shots. The scene was fully recorded with 3\*3 high speed video cameras (working at 200 fps in the visible range). Each goalkeeper was carrying a set of 6 wireless EMG sensors (biceps brachii, latissimus dorsi, gastrocnemius medialis) and 4 wireless three-axial accelerometers (wrists and ankles) sampled at 296 samples per second. All devices (cameras, EMG and accelerometers) were electronically synchronized i.e., shared a common time base. Main results and conclusions The results showed, as expected, that women shot at goal at lower velocities than men – a difference of about 25% in the ball’s velocity was found. In the other hand, the reaction times of male and female were found quite similar (almost within the experimental uncertainty). However, when the reaction time is exhausted, the ball has moved 2.5m (females) to 3m (males). It will reach the goal in about 0.4s (females) to 0.3s (males), and the body parts still need to move to the interception place. What is apparent from this experiment is that females have time to react to the real ball trajectory while men don’t, at least in the case of difficult shots. So men must speculate, from the movements of the thrower, what the balls trajectory will be, while women can probably guess less and react more. To have similar decision time than women, men must speculate and make a decision 60ms before the ball is launched. This is a huge time and in a fast throw coincides with the final launch of the arm. This is where the thrower’s deception strategies can be most efficient.

#### THE INFLUENCE OF DIFFERENT WORK AND REST DISTRIBUTIONS ON PERFORMANCE AND FATIGUE DURING SIMULATED TEAM HANDBALL MATCH PLAY

Moss, S., Twist, C.

*University of Chester*

INTRODUCTION: Team handball players evidence fatigue-induced decrements in high intensity activity from the first to second half of matches. Effective management of player work and rest periods during matches could help to minimise physiological loading and better

maintain performance. This study aimed to establish the effect of two different interchange strategies on performance and pacing strategy during a simulated team-sports protocol. METHODS: Eight outfield youth male team handball players (age:  $16.1 \pm 1.0$  y, stature:  $1.82 \pm 0.11$  m, body mass:  $69.3 \pm 6.6$  kg) completed two conditions of a team sport simulation. LONG comprised 3 x 13:00 min periods of work, separated by 8:00 min rest between activity periods. SHORT comprised 5 x 7:48 min periods of activity, separated by 3:45 min rest between work periods. Absolute work time (39:00 min) and rest (16:00 min) periods were the same for both conditions. Participants were tested for 20 m sprint, counter-movement jump and throwing performance during each condition, with heart rate being monitored continuously. Post-condition measures included Repeated Shuttle Sprint and Jump Ability, session rating of perceived exertion, blood lactate and blood glucose. RESULTS: Sprint time deteriorated progressively throughout the simulation ( $P = 0.005$ ), but overall faster sprint performance was apparent in SHORT ( $3.87 \pm 0.27$  s) rather than LONG ( $3.97 \pm 0.24$  s,  $P = 0.03$ ) by a 'likely small' difference. Throwing velocity revealed a 'likely small' difference that was indicative of better performance in SHORT ( $70.02 \pm 7.40$  km·h<sup>-1</sup>) compared to LONG ( $69.04 \pm 5.57$  km·h<sup>-1</sup>,  $P > 0.05$ ). There were no differences in throwing accuracy or counter-movement jump performance ( $P > 0.05$ ). Practically meaningful higher average heart rate ( $166 \pm 8$  b·min<sup>-1</sup> cf.  $169 \pm 9$  b·min<sup>-1</sup>) and summated heart rate ( $150 \pm 15$  cf.  $157 \pm 21$ ) were apparent in SHORT compared to LONG by a 'likely small' difference ( $P > 0.05$ ). Post-condition measures showed that SHORT resulted in 'most likely moderate' lower sRPE ( $224 \pm 45$  AU cf.  $282 \pm 35$  AU,  $P = 0.001$ ), in addition to 'most likely moderate' higher blood glucose ( $6.06 \pm 0.69$  mmol·l<sup>-1</sup> cf.  $4.98 \pm 1.10$  mmol·l<sup>-1</sup>,  $P = 0.03$ ) compared to LONG. However, there were no differences in blood lactate ( $P > 0.05$ ) between conditions. Repeated shuttle sprint running performance was also better preserved after SHORT work and rest periods, with 'moderate' decreases in 10 m and 25 m sprint times ( $P < 0.05$ ). CONCLUSIONS: Collectively, these findings suggest that interchange strategies using SHORT as oppose to LONG periods of work and rest result in overall lower physiological load that leads to improved fatigue resistance and a better preservation of high-intensity movements throughout a match. This information could prove valuable to maximise player performance both during a match and a tournament where multiple matches are played consecutively.

### PERFORMANCE DIAGNOSTICS, TRAINING LOAD AND RECOVERY ASPECTS IN MALE ELITE TEAM HANDBALL PLAYERS

Knöller, R.1, Nicolaus, M.2, Nordmeyer, C.3, Kahlfeldt, A.4, Tegtbur, U.5

1 Olympic Service Centre Niedersachsen; 2 University of Hildesheim, Institute of Sport Science; 3 TSV Burgdorf Handball GmbH; 4 Berufsgenossenschaftliches Unfallkrankenhaus Hamburg; 5 Medical High Sch

Introduction Team handball was undergoing severe rule changes in the last years and since then matches with 55 or more goals are often to be seen. We investigated a first division team over two years in motor performance and injuries and various data concerning their recovery status. Our goal was to achieve deeper insight in the interaction between performance, trainload and recovery. Methods N = 16 male elite team handball players (incl. 10 players of various national teams) participated in this study. Several parameters related to regeneration were analysed: body composition (via bio impedance), aerobic capacity (standard field test), sprint ability (2x5x30m sprint protocol) and force-resistance (series of jumps). Assessments were conducted in July before the pre-seasonal preparation period, in September after the preparation period, and in the half-seasons break (January). Results The players (N=16, average age 27,1 years and 192,1cm height) showed the following anthropometric data in the season: 95,6 kg weight, 10,4% body fat. Training load in the preparation period was 11 sessions/week (20h/w) and was reduced during the season to a weekly average of 7 sessions/week (12h/w) due to the energetic cost of the 52-60 matches the team players had to perform in the season 2013/14. Results revealed that handball players improved their aerobic capacity (+0,2 m/s to v14 4.2 m/s) and decreased average weight (-2,3kg) and body fat (-2,2%) during the preparation period and maintained those values until the winter break. Peak aerobic performance (v14 4.2 m/s, 3,9-4,4 m/s) was slightly better than compared to previous own findings from second division teams. Maximum sprint performance was 2.91 sec/30m (2,78-3,23 m/s) and like their sprint ability and force-resistance did not change significantly over the year. Discussion Despite the players' high level of motor performance and training quality, 33 injuries occurred, leading to six cases of severe injuries resulting in long term match absence. In elite team sports the level of fatigue, and the probability of injury are linked together. Despite a quantifiable improvement in the players' motor performance one may therefore assume that the quality of the human regeneration processes may dictate performance limits, and also the ability to maintain a healthy status. Resources may therefore mainly be found in optimizing the interplay between the total load and the recovery in each individual player. Further studies and tools are needed in this field. ### DIFFERENCES IN GENERAL AND GAME BASED PERFORMANCE IN ELITE, HIGH EXPERIENCED AND EXPERIENCED MALE TEAM-HANDBALL PLAYERS

Wagner, H., von Duvillard, S.P., Müller, E.

University of Salzburg

Introduction Team-handball is an Olympic sport characterized by fast paced defensive and offensive action during a game. These actions include team-handball specific movements, fast accelerations and decelerations, changes of directions and frequent changes with low intensity movements. However, team-handball performance is mostly measured using standardized endurance, strength and agility tests (Gorostiaga et al., 2005), therefore knowledge about differences in general and team-handball specific performance in players of different performance level is lacking. Consequently, the aim of the study was to compare general and game based performance in elite, high and experienced team-handball players. Methods 36 (12 elite, 12 high experienced and 12 experienced) team-handball players performed a game based performance test (Wagner et al., 2014), an incremental treadmill-running test, a 30m sprinting test, lower and upper body strength test, and a counter movement jump (CMJ) test. We measured peak oxygen uptake (VO<sub>2</sub>peak), utilizing portable metabolic system (Cosmed K4B2), blood lactate concentration (BLCPeak) (EKF, Biosen C), heart rate (Polar, Kempele, Finland), sprinting time, and offensive and defensive time actions (Inmotion LPM-system, Abatec, Austria), ball velocity and jump height during a jump throw (PeakMotus, Vicon Peak, UK), isometric leg force and shoulder and trunk rotation torque (ISOMED, D&R Ferstl, Germany), as well as jump height in the CMJ (AMTI, Watertown, USA). One-way ANOVA was utilized to analyze differences in performance between elite, high and experienced team-handball players. Results We found significant differences ( $P < .05$ ) between elite, high and experienced players in VO<sub>2</sub>peak, defensive time and fast break time in the game based performance test, VO<sub>2</sub>max in the incremental treadmill running test, isometric leg force, shoulder and trunk rotation torque as well as body mass. Elite players performed best in isometric leg force (2400N), shoulder (90Nm), trunk rotation (250Nm) torque and body mass (93kg). Surprisingly, we found no significant differences in ball velocity, jump height and general sprinting time. Discussion In conclusion, we found that general and specific endurance, strength and power as well as specific agility and sprinting performance is essential to increase the level of performance in team-handball. However, elite team-handball players need a very high level of upper and lower body strength and power to tolerate hard physical contact (tackles in offence).

and defense) in team-handball competition. References Wagner H, Orwat, M, Pfusterschmied J, Hinz M, Bacharach D, von Duvillard SP, Müller E. (2014). *J Strength Cond Res*, (in press) Gorostiaga EM, Granados C, Ibanez J, Izquierdo M. (2005). *Int J Sports Med*, 3, 225-232.

### CHANGES IN PERCEIVED STRESS AND RECOVERY RELATE TO CHANGES IN SUBMAXIMAL PERFORMANCE IN TEAM SPORT PLAYERS.

van der Does, H.

*Hanze University of Applied Sciences*

**Introduction** In team sport, it is known that players perceive more stress and less recovery during the competition phase compared to pre-season (di Fronso et al., 2013). It is assumed that these changes in perception of stress and recovery have an effect on athletic performance. Unfortunately, studies relating perceived stress and recovery to performance in team sport players are limited. Therefore the aim of this study is to investigate whether changes in perceived stress and recovery are related to field-test performance. **Methods** During one full season 47 male and female players (age:21.7±3.5yr, length:186.9±11.5cm, weight:82.5±14.9kg) reported perceived stress and recovery every 3 weeks by filling out the Recovery Stress Questionnaire for Athletes (RESTQ-Sport) (Nederhof et al., 2008). Furthermore, the Heart Rate Interval Monitoring System (HIMS) test was used to determine (submaximal) performance (Lamberts et al., 2004). The heart rate at the end of the test as a percentage of the maximal HR (%HRsubmax) was used as performance indicator with lower values indicating better performance. Between each consecutive RESTQ-Sport and HIMS test differences scores were calculated for perceived stress and recovery and %HRsubmax, respectively. Pearson correlations were used to determine the relation between changes in perceived stress and recovery and changes in HIMS performance. **Results** An increase in perceived General and Sport Stress correlated with an increase in %HRsubmax, ( $r=0.27$  and  $0.21$  respectively,  $p < 0.05$ ). An increase in perceived General and Sport Recovery correlated with a decrease in %HRsubmax ( $r=-0.24$  and  $-0.16$  respectively,  $p < 0.05$ ). **Discussion** Results show that increased perceived stress resulted in a performance decrease while an increase in perceived recovery results in a performance increase. To the best of our knowledge this is the first study relating perceived stress and recovery to submaximal HR in team sport players. However in triathletes similar results were shown (Coutts et al., 2007). More research is needed to explore the relation between perceived stress and recovery and performance in team sport players to optimize training regimens. **References** Di Fronso S, Nakamura F, Bortoli L, Robazza C, Bertollo M (2013). *Int J Sports Phys Perf*, 8:618-622. ### EFFECT OF A COMPETITIVE SEASON ON ANTHROPOMETRIC, AEROBIC AND BIOCHEMICAL PARAMETERS IN BRAZILIAN FUTSAL PLAYERS

Barbieri, R.A.1, Milioni, F.1, dos Santos, J.W.2, Palucci, L.H.V.3, Gobbi, R.B.1, Papoti, M.3

1: São Paulo state University - UNESP - Rio Claro - Brazil, 2: UNESP (Bauru, Brazil), 3: EFEERP – USP (Ribeirão Preto, Brazil)

**Introduction** Competitive season is a stress time because the busy calendar with a lot games can reduce the training days and may affect the performance of the athlete. Therefore, the aim of study was to describe the effects of a competitive season period on anthropometric, aerobic capacity and biochemical parameter in Brazilian futsal players. **Methods** Eleven Brazilian professional futsal players were monitored during 6 weeks of the competitive season composed of 13 games being the three last eliminatory. Anthropometric parameters were determined by Dual-energy X-ray absorptiometry, aerobic capacity (AT) and maximum aerobic velocity (MAV) by lactate minimum test in the specific circuit to futsal and arterial blood was collected after 24h of rest. The assessments were performed in the beginning and final of the season. The weekly training load was assessed using rating of perceived exertion from (RPE) and calculation of the training impulse (Trimp). The t-student test and one-way ANOVA were performed to compare the results between the weeks. **Results** The mean volume and intensity (RPE) were 378.1±142.7min and 5.7±0.13a.u. respectively. Trimp average was reduced through the season with a big reduction in the last week compared of the others weeks (365.4±101.5a.u.; 280.3±61.1a.u.; 419.7±51.0a.u.; 258.5±37.5a.u.; 275.4±46.5a.u.; 79.5±16.6a.u.; respectively,  $P < 0.05$ ). For the anthropometric parameters only bone mineral content had an increased (0.9±1.0%,  $P < 0.05$ ). However, the AT (pre=7.41±0.3km.h<sup>-1</sup>; post=8.08±0.7km.h<sup>-1</sup>) and MAV (pre=8.6±0.9km.h<sup>-1</sup>; post=9.7±0.7km.h<sup>-1</sup>) had a significant increase (9.0% and 13.5% respectively). Lactate dehydrogenase (pre=409.7±349.8U.L<sup>-1</sup>; post=349.7±77.8U.L<sup>-1</sup>) and creatinine (pre=1.1±0.1U.L<sup>-1</sup>; post=1.0±0.2U.L<sup>-1</sup>) were significantly reduced. However, the creatine kinase (pre=394.7±106.5U.L<sup>-1</sup>; post=326.3±177.2U.L<sup>-1</sup>) kept high in relation of the basal levels. **Discussion** The competitive season could not change the anthropometric parameters (Soares-Caldeira et al., 2014). However, the AT and MAV were significantly increased. In addition, the manipulation of workload can change the biochemical parameters (Milanez et al., 2014), although the training load were reduced through the season, this was not efficient to reduce all metabolic stress markers, in special the creatine kinase. Thus, only the strategy of reduce the workload seems not be a good strategy to reduce the metabolic stress during the competitive season. **References** Soares-Caldeira et al., (2014). *J Strength Cond Res*. 2014 Oct;28(10):2815-26. ### OP-PM60 Health & Fitness: Age II

#### PHYSICAL FITNESS IS PREDICTIVE FOR A DECLINE IN DAILY FUNCTIONING IN OLDER ADULTS WITH INTELLECTUAL DISABILITIES

Oppewal, A., Hilgenkamp, T.I.M., van Wijck, R., Schoufour, J.D., Evenhuis, H.M.

*Erasmus MC, University Medical Center Rotterdam*

**Introduction:** The life expectancy of people with intellectual disabilities (ID) is increasing. Daily functioning, the ability to perform basic and instrumental activities of daily living (IADL), determines one's level of independence and need for care, and is an important predictor of hospital admission and mortality in older adults of the general population. Physical fitness is an important aspect for daily functioning, and low physical fitness levels have been found in older adults with ID. The aim of this study was to assess the decline in daily functioning

in older adults with ID ( $\geq 50$  years) over a 3-year follow-up period, and assess the predictive value of physical fitness for a decline in daily functioning. Methods: At baseline, an extensive physical fitness assessment was performed. In addition, professional caregivers completed the Barthel index, the Lawton IADL scale, and a questionnaire regarding mobility, both at baseline and at follow-up 3 years later. Results: A significant decline in daily functioning was seen over the 3-year follow-up period: 54.8% declined in their ability to perform ADL, 44.3% in their ability to perform IADL, and 37.5% declined in their mobility. At follow-up, only 12.6% of the participants were completely independent in ADL, 1.3% in IADL, and 48.5% had no mobility limitations, versus 15.1%, 2.7%, and 62.0% being completely independent at baseline in ADL, IADL, and mobility, respectively. For a decline in ADL, significant predictors were manual dexterity, visual reaction time, balance, comfortable and fast gait speed, muscular endurance, and cardiorespiratory fitness. For a decline in IADL, manual dexterity, balance, comfortable and fast gait speed, muscular endurance, and cardiorespiratory fitness were significant predictors. For a decline in mobility, manual dexterity, balance, comfortable and fast walking speed, grip strength, muscular endurance, and cardiorespiratory fitness were all significant predictors. Discussion: These results show that physical fitness is predictive for a decline in daily functioning in older adults with ID. This study shows that even though older adults with ID already experience dependency on others due to cognitive limitations, physical fitness is an important predictor of daily functioning, which stresses the importance of using physical fitness tests and physical fitness enhancing programs in the care for older adults with ID. ### IS THERE A LINK BETWEEN ASYMMETRIES IN STRENGTH, GAIT AND BALANCE IN SENIORS?

Hammes, D., Donath, L., Roth, R., Zahner, L., Faude, O.

*University of Basel*

Introduction Balance, strength and gait asymmetries are independent risk factors for falls. It remains, however, unclear whether strength asymmetry affects balance and gait asymmetries in elderly people. Methods Leg strength and gait as well as balance were assessed in 48 healthy seniors ( $70 \pm 5$ y,  $1.68 \pm 0.09$ m,  $74 \pm 14$ kg). Unilateral leg press and plantar flexion were tested on an isokinetic dynamometer (IsoMed 2000, D&R Fersil, Hemau, Germany). Gait analysis was conducted on a one-dimensional ground reaction force measuring treadmill (FDM-T system, Zebris Medical GmbH, Isny, Germany). Single-limb stance with closed and open eyes (SLEC and SLEO) was tested on a force plate (Kistler, 9286BA, Winterthur, Switzerland). We calculated symmetry indices (SI) for strength, gait and balance variables and coefficients of variation (CV) for gait variables. Symmetric and asymmetric participants were defined by dichotomizing the whole group by median split for leg press and plantar flexion force and rate of force development (RFD), respectively. Then, between-group differences were calculated for gait and balance. The smallest worthwhile difference was considered as 0.2 of the between-subject standard deviation. Results Participants with asymmetric plantar flexion force and RFD showed likely (probability: 89% and 77%; standardized mean difference: 0.4 and 0.7) higher SLEC SI. Leg press force asymmetric participants showed likely (94%, -0.7) higher SLEO SI, however, the weaker balance was present at the stronger leg. There was also a likely (86%, 0.6) higher asymmetry in SLEO SI in participants with asymmetric leg press RFD. In terms of gait asymmetry, participants with asymmetric plantar flexion force had a likely (76%, -0.4) higher weight acceptance force SI going along with less weight on the strong leg and a likely (88%, 0.5) higher step length SI. Step length SI was very likely (95%, -0.6) higher in participants with asymmetric leg press force, with stronger side being shorter, and very likely (99%, 0.9) higher in participants with asymmetric leg press RFD. Step time SI was likely (79%, -0.5) higher in participants with asymmetric leg press RFD, with shorter steps with the stronger leg. Gait variability was likely or very likely (76 to 99%, 0.4 to 1.0) higher in stride width, cadence, stride length and double support time CVs in participants with asymmetric plantar flexion force and plantar flexion RFD. Discussion Especially plantar flexion force and RFD showed interesting associations with gait and balance asymmetries and variability. The development of more symmetric strength might be a strategy to influence gait and balance and possibly fall risk. However, this is yet to be determined in further intervention studies. ### PHYSICAL ACTIVITY IN OLDER ADULTS: ITS ASSOCIATION WITH LOWER EXTREMITY JOINT RANGE OF MOTION AND MUSCLE FORCE

Jung, H.G., Yamasaki, M.

*hiroshima university*

Introduction Aging is commonly linked to a reduction in lower extremity joint range of motion (ROM) and physical function (James and Parker, 1989). The decreased health and function in older adults were related to less physical activity (Mor et al., 1989). Therefore, the aim of this study was to identify lower extremity ROM and muscle force that significantly contribute to physical activity in older adults. Methods Ninety-one older adults (16 men and 75 women; age,  $71.5 \pm 5.2$  years; height,  $1.54 \pm 7.0$  m; weight,  $54.0 \pm 6.9$ kg) were recruited for this study. Pain, smoking, alcohol consumption, and comorbidity were obtained by self-report. Active ROM for 9 lower extremity motions and 2 lower extremity muscle forces were measured. The Japanese version of Physical Activity Scale for the Elderly (JPASE) was used to examine physical activity in older adults. JPASE was divided into two components; leisure activity component and housework and job activity component. To quantify the influence of participant demographics, physical characteristics, active ROM and muscle force on JPASE, hierarchical stepwise models were constructed using leisure activity and housework and job activity as the dependent variable. The first model (model 1) contained all lower extremity ROM, the second model (model 2) participant demographic and physical characteristic variables were added, and the third model (model 3) included all variables. Results In model 1, hip extension ROM was the independent variable to emerge as a predictor of leisure activity. In model 2, pain was a significant predictor of leisure activity, and a loss in the significant influence of hip extension ROM on leisure activity. In model 3, only hip flexion muscle force was a predictive factor of leisure activity. However, all variables were not found to be significant independent predictors in housework and job activity. Discussion The findings of this study indicate that mild or no pain, wide hip extension ROM and strong knee flexion muscle force were important factors for maintenance of vigorous physical activity in older adults. However, hip extension ROM and knee flexion muscle force may not be related to housework and job activity, because all lower extremity ROM and muscle force were not correlated to housework and job activity. **SMART: IS PAIN A RELEVANT BASELINE CHARACTERISTIC IN THE ELDERLY? RESULTS FROM A RCT**

Fleckenstein, J.1, Engeroff, T.1, Füzeki, E.1, Matura, S.2, Pilatus, U.3, Vogt, L.1, Pantel, J.2, Banzer, W.1

*Goethe-University Frankfurt/Main*

Background: Physical activity exerts a variety of long-term health benefits in older adults. In particular it is assumed to be a protective factor against cognitive decline and dementia. However, several side factors such as pain have been correlated to the topic of cognition, thus possibly influencing these trials. Methods/Design: Randomised controlled assessor blinded two-armed trial (n = 60) to explore the exercise induced neuroprotective and metabolic effects on the brain in cognitively healthy older adults. Participants (age > 65), recruited within the setting of assisted living facilities and newspaper advertisements were allocated to a 12 week individualised aerobic exercise program intervention or a 12 week waiting control group. The main outcome is the change in cerebral metabolism. Secondary outcomes include a broad range of psychometric (cognition) and movement-related parameters such as nutrition, history of physical activity, history of pain and functional diagnostics. The randomisation sequence is compiled by a computer program. For allocation exercise physiologists open opaque envelopes assigning groups of 5 participants to the respective group, with assessors and study personal other than exercise physiologists being blinded. The trial registration is NCT02343029 (clinicaltrials.gov). Results: At this conference we will present for the first time the baseline characteristics and the impact of pain on a group of 60 participants (mean age: 75.5 years / 33 female) enrolled in the above described SMART-study. Moreover, the exercise program as well as MRSI methods and psychometric tests used in this study will be introduced. Discussion: Strength of the present protocol is to control for a large subset of possibly influencing factors, in particular the influence of the history and incidence of pain. This comprehensive understanding allows to identify or control for confounders predicting improved or reduced benefit from physical exercise in the elderly.

**EFFECT OF MILK VS LEUCINE FORTIFIED MILK SUPPLEMENTATION ON BODY COMPOSITION AND STRENGTH IN OLDER ADULTS UNDERGOING 12 WEEKS OF RESISTANCE TRAINING.**

Soto Méndez, F.

*Catholic University of Murcia (UCAM)*

Introduction Protein supplementation (PS) and resistance training (RT) has been proposed as effective strategies to enhance muscle mass and strength. However, less evidence suggested that the consumption of milk or leucine fortified milk may enhance muscle protein synthesis and attenuate protein breakdown. The aim of our study was to compare the effect of milk and fortified milk supplementation combined with or without 12-week of RT on body composition and strength in elderly. Methods One hundred and forty two healthy untrained men and women aged 55-75 yr, were randomly assigned to 1 of 6 groups: milk group + exercise TS (MTS), fortified leucine-milk group +exercise (LMTS), milk group + exercise HRC (MHRC), fortified leucine-milk group +exercise HRC (LHRC), milk group (MG) and fortified milk group (LMG). Exercise groups performed 2 days-per-week of periodized resistance training program for 12 weeks. All groups consumed 500 ml/day. Timing of ingestion was protocolised (250ml/morning and 250ml/night). Fat free mass (FFM) and fat mass (FM) were assessed on a whole-body Dual-energy X-ray absorptiometry (DXA). Strength was assessed by isokinetic dynamometry in the upper and lower body. Results After 12 weeks, there were significant improvements in FFM and FM ( $p < 0.05$ ). Only MG have no significant changes in FFM and a significant increase in FM. There were statistical differences between groups in FFM and FM ( $p < 0.05$ ). There were significant increases in isokinetic strength in all groups ( $p < 0.05$ ). Discussion Our main finding is that daily supplementation with 500ml of fortified leucine milk only, further augment SPM in elderly population. The present data are consistent with another results that have showed that low-intensity activities of daily living, such as walking, improve MPS and insulin-sensitivity in the elderly (Fujita S, et al., 2007). Another findings of the current study showed that FFM and strength increased in the RT groups, however FM decreased in all groups less MG. Our findings support the speculations that RT and/or consumption of leucine-fortified-proteins could cause a decreased MSB and lower protein requirements for maximal stimulation of MPS (Moore DR, et al., 2015). **Oral presentations****OP-PM57 Health & Fitness: Children I****THE IMPACT OF CYCLING DESKS ON IN-CLASS ENERGY EXPENDITURE.**

Torbeyns, T., de Geus, B., Meeusen, R.

*Vrije Universiteit Brussel*

Introduction Sedentary behaviour has negative effects on several physical and cognitive health parameters. However, at school, pupils spend the majority of their days in sedentary behaviours. In this study, we aimed to investigate whether providing cycling desks in classrooms, can have an effect on pupils' in-class energy expenditure (EE) and to quantify this effect. Methods Participants were recruited in the 3th and 4th grade of a Belgian high school and were randomly assigned to control (CG) (12 girls, 13 boys) and intervention (IG) (13 girls, 9 boys) group. Anthropometric parameters, performance on the 20m shuttle run test and pubertal status were measured at baseline. The pupils of the IG were provided with a cycling desk for 4 class hours of 50 minutes per week. All participants wore a Sensewear armband on the right upper arm for 6 consecutive days (4 school days, 2 weekend days). An independent samples t-test was used to determine if EE was different between CG and IG, during normal class hours. Subsequently, a repeated measures anova mixed design was performed to check if a possible difference in EE depended on the group to which the pupils were assigned. In case of a significant interaction-effect, a repeated measures anova was performed within the IG and the CG. Results Average age ( $14.4 \pm 0.6$  y;  $14.2 \pm 0.6$  y), height ( $1.68 \pm 0.07$  m;  $1.68 \pm 0.07$  m), body weight ( $56.1 \pm 9.3$  kg;  $55.2 \pm 10.9$  kg), BMI ( $19.8 \pm 3.4$ ;  $19.6 \pm 3.5$ ), fat percentage ( $18.1 \pm 10.0\%$ ;  $18.7 \pm 8.9\%$ ), waist circumference ( $66.6 \pm 5.1$  cm;  $66.3 \pm 7.2$  cm), level 20m shuttle run test ( $6.2 \pm 2.4$ ;  $6.6 \pm 2.6$ ) and pubertal status ( $2.8 \pm 0.4$ ;  $2.7 \pm 0.4$ ) were not significantly different ( $p > 0.05$ ) between CG and IG. EE was not significantly different between CG and IG during normal class hours ( $p > 0.05$ ;  $95.6 \pm 12.5$  kcal/h vs.  $94.4 \pm 17.8$  kcal/h). However, the difference in EE in the different classroom settings, was depending on the assigned condition ( $p < 0.001$ ). Mean EE of the IG was significantly higher during the class hours in which they had access to the cycling desks than during the normal class hours ( $p < 0.001$ ;  $126.1 \pm 35.3$  kcal/h vs.  $94.4 \pm 17.8$  kcal/h), while this was not significantly different for the participants of the CG ( $p > 0.05$ ;  $95.3 \pm 14.9$  kcal/h vs.  $95.6 \pm 12.5$  kcal/h). Discussion and conclusion In this

study we found a 32% increase of EE during class when bike desks were available. This shows that providing bike desks in classrooms can be effective to increase in-class EE. However, the experience of the pupils using these desks as well as the effect of cycling during class on attention and academic performance needs further investigation. ### IMPACT OF LIVING AREA ON ANTHROPOMETRIC AND PHYSICAL FITNESS PARAMETERS AMONG 15-YEAR-OLD ADOLESCENTS IN KOSOVO

Tishukaj, F.1,2, Shalaj, I.1,2, Gjaka, M.3, Tschan, H.1, Bachl, N.1, Wessner, B.1

1: (University of Vienna, Austria), 2: (University of Pristina, Kosovo), 3: (University of Rome Foro Italico, Italy)

**Introduction** Overweight and obesity have been increasing systematically over the past decades and physical fitness values on the other hand have been decreasing (1). However, in low- and middle-income countries we observe the co-occurrence of over- and under-nutrition at the same time – a phenomenon that has been termed the ‘dual burden’ (2). In addition, it is discussed whether the urban-rural environment is a facilitating factor for developing obesity and low physical fitness levels (3,4). The aim of the current study was to test for the impact of the living area on body composition and physical fitness parameters among 15-year-old adolescents in Kosovo. **Methods** Three-hundred fifty-four subjects (55% boys, 46% girls; mean age: 14.6 ± 0.4) participated in the current cross-sectional study conducted in 2014. Out of the total sample, 39% of the participants were living in a rural environment and 61% in an urban area (Pristina) in Kosovo. Anthropometric parameters including skinfold measurement and physical fitness levels (handgrip strength, sit and reach, standing long jump, countermovement jump, medicine ball throw, 10-m, 20-m sprints and multistage fitness test) were tested. A two-factorial ANOVA (sex, area of living) was used to test for differences between groups. **Results** The prevalence for underweight was 13.8%, normal weight 61.9% and 24.3% for overweight adolescents respectively. Living area had no impact on anthropometric variables ( $p > 0.05$ ). Differences in physical fitness tests were observed only in medicine ball throw ( $p < 0.001$ ) with urban living adolescents performing better, whilst contrary 10-m ( $p = 0.012$ ), and 20-m ( $p = 0.035$ ) sprint test were executed faster by rural counterparts. **Discussion** Similar to another study in low-income countries (5) we observed a high incidence of both, under- and overweight in Kosovar adolescents while rural or urban environment had no influence on anthropometric variables and only a modest and controversial impact on physical fitness. The reasons for these findings remain speculative and may rely on socioeconomic conditions, access to sports facilities, and differences in general lifestyle behavior (6). **References** (1) Ng M et al., *Lancet*. 2014;384(9945):766-81 (2) Popkin BM & Slining MM. *Obes Rev*. 2013; 14 Suppl 2:11-20 (3) Albarwani S et al., *Metab Syndr Relat Disord*. 2009;7(4):369-74 (4) Lutfyyia MN et al., *Obesity* (Silver Spring). 2007; 15(9):2348-56 (5) Jaacks LM et al., *Pediatr Obes*. 2015 Jan 5. doi: 10.1111/ijpo.12000 (6) Davison KK & Lawson CT. *Int J Behav Nutr Phys Act*. 2006 Jul 27;3:19 Contact faton.tishukaj@uni-pr.edu

### LOCALIZATION OF PHYSICAL ACTIVITY IN PRIMARY SCHOOL CHILDREN USING ACCELEROMETER AND GLOBAL POSITIONING SYSTEM

Bürgi, R., Tomatis, L., Murer, K., de Bruin, E.D.

*ETH Zurich*

**Introduction** Ecological approaches highlight the importance of the built environment as factor which can influence physical activity (PA) (1). However, data on children’s activity patterns are still incomplete. Particularly, little is known about where PA takes place. Therefore, assessing in which context PA occurs would be a first fundamental step to design future location-based interventions to promote PA. Using the new combination of global positioning system (GPS) and accelerometer, the study aimed to identify locations where children spend time and engage in moderate-vigorous physical activity (MVPA). **Methods** In spring 2013, 119 Swiss children (age=12.5±0.4) participated in the study. During waking hours of a regular school week, participants wore an accelerometer and a GPS sensor for seven consecutive days. Accelerometer and GPS data were matched by time and mapped with a geographical information system. Seven location categories which relate to active living were defined. For each location, total time spent was assessed and the amount and percentage of MVPA was calculated. Multilevel analyses were conducted for three outcome measures accounting for the hierarchical structure of the data (2). Furthermore, contrasts were used to investigate any gender differences. **Results** Children spent 37.5% of the time at home, 26.7% at own school, 0.7% at other schools and 14.2% on streets. Only about 20 minutes (0.7%) were recorded in recreational facilities such as parks or sports fields. The only gender difference was found at other schools where boys spent significantly more time than girls. In general, children recorded 8.4% of the time as MVPA. Boys were more active than girls, spending an average of 348.5 minutes vs. 284.6 minutes per week in MVPA. Girls achieved most of their MVPA on streets (38.0%), whereas boys were most active at own school (28.7%). Both, at own and other schools, boys achieved significantly more minutes in MVPA than girls. Taking into account the total time spent in a location, the percentage children engaged in MVPA was highest in recreational facilities (19.4%), other schools (19.2%) and streets (18.6%). The percentage spent as MVPA at own school was only 8.6%. However, the proportion at home was even smaller (3.0%). **Discussion** The results indicate that streets and school grounds are important locations where children can achieve their recommended PA level. However, it seems that the school environment is more likely to encourage boys than girls to be physically active. The high use of streets may be an indicator for active transportation which can be an important contributor to an active lifestyle. **References** (1) Bauman AE et al. (2012). *Lancet*, 380, 258-271. ### LONGITUDINAL CHANGE IN PHYSICAL ACTIVITY OF CHILDREN IN HUNAN, CHINA

Pengyu, D., Liangfu, Z., Naito, H.

*Juntendo University*

**Introduction** An important strategy in order to achieve healthier body composition is to encourage a lifetime physical activity participation in overweight/obese children (WHO, 2004). Therefore, assessing physical activity (PA) is especially important because increasing PA in childhood might be essential to develop a physically active lifestyle. However, most previous investigations have been cross-sectional studies on Chinese children. No longitudinal studies that address this issue among children have been reported and whether these same causes are related to PA in Chinese children is uncertain. In this study we examined the association between longitudinal change and weight status in schoolchildren’s PA. **Methods** Baseline measures were collected in 2011, when the children were aged 7~8 years, and follow-up data were collected in 2014, when the children were aged 10~11 years. The children (n=77) consisted of normal-weight children (NW), overweight/obese children (OW/OB) who determined by BMI according to Working Group for Obesity in China cut offs over two time point between 2011 and 2014. We describe change in daily step counts and moderate to vigorous physical activity ( $\geq 3$  METs, MVPA) was studied using one axis accelerometer in children. **Results** Between 2011 and 2014, the daily time spent in MVPA were de-

clined from  $67.4 \pm 21.7$  min to  $64.1 \pm 30.8$  min for boys and  $54.5 \pm 14.2$  min to  $45.5 \pm 19.6$  min for girls. The girls were significantly higher rate of change (RC) of MVPA than boys (-13.5% versus -0.1%,  $p < 0.05$ ). In the boys group, the daily time spent in MVPA of NW were increased from  $71.2 \pm 23.5$  min to  $73.9 \pm 29.4$  min, while OW/OB were declined from  $62.1 \pm 18.0$  min to  $50.5 \pm 27.6$  min. In the girls groups, MVPA were declined from  $54.5 \pm 14.2$  min to  $49.4 \pm 17.8$  min for NW and  $54.5 \pm 14.4$  min to  $39.1 \pm 21.0$  min for OW/OB. Hence, in both boys and girls group, OW/OB children were also significant higher RC of MVPA than NW children (-15.8% versus +10.1% for boys; -28.2% versus -4.4% for girls,  $p < 0.05$ ). Discussion The present study was the first study to report on the longitudinal investigation between PA and overweight/obesity in the Chinese children. There were decreases in MVPA by weight statue in both boys and girls, supporting previous studies that reported age-related declines in PA1) and the notion that declines in daily physical activity starts at a young age2), especially OW/OB children. Hence, OW/OB children had lower MVPA through our study and the extent of RC did differ from NW children, suggesting that OW/OB children should also be a priority for PA promotion. Reference 1. ### SMARTPHONE APPS TO IMPROVE CARDIORESPIRATORY FITNESS AND INCREASE PHYSICAL ACTIVITY LEVELS AMONG YOUNG PEOPLE: THE AIMFIT RANDOMISED CONTROLLED TRIAL

Direito, A., Jiang, Y., Whittaker, R., Maddison, R.

*University of Auckland*

Introduction: Worldwide, 80.3% of adolescents aged 13-15 years do not reach current physical activity (PA) recommendations and are at risk of preventable non-communicable diseases (Hallal et al., 2012). There is an age-related decline in PA in young people, which tracks into adulthood (Nader, Bradley, Houts, McRitchie, & O'Brien, 2008). Common technologies, such as smartphones and apps, may enhance the appeal of interventions to increase levels of PA among this population. The AIMFIT trial investigated the effects of a mHealth delivered PA intervention to improve fitness compared with usual behaviour in young people not meeting the PA recommendations. Methods: A three-arm, parallel, randomised controlled trial was conducted in 2013-14 in Auckland, New Zealand. Fifty-one eligible participants aged 14-17 years were randomised to one of three conditions: 1) use of an immersive smartphone app ( $n=17$ ), 2) non-immersive app ( $n=16$ ), or 3) usual behaviour (control  $n=18$ ). The apps consisted of an eight-week training program designed to improve fitness and ability to run 5 km. Data were collected at baseline and 8 weeks. The primary outcome was cardiorespiratory fitness, assessed as time to complete the one mile run/walk test at 8 weeks. Secondary outcomes were PA levels (PAQ-A and accelerometry), self-efficacy (PASES), enjoyment (PACES), psychological need satisfaction (PNSES) and acceptability and usability of the apps. Results: Participants were on average 15.7 years old (14-17 years), mostly NZ Europeans (61%) or Pacific Islanders (22%) and females (57%). Preliminary findings indicate group assignment did not have a significant effect on fitness. Compared to the control, mean ( $\pm$ SE) baseline fitness test-, sex-, and multiple comparisons-adjusted fitness test changes were  $-28.4 \pm 15.4$  and  $-24.7 \pm 15.7$  seconds for the immersive and non-immersive app groups, respectively. Most participants used the app 2 times/week (32%), 25% only used it 1 time/week and 9% none. 81% were interested in trying different apps in the future. Discussion: While our pragmatic approach using commercially available apps as a stand-alone instrument to improve fitness did not show significant effects, interest in future use of PA apps is promising and suggests a potential role of such instruments in a multifaceted approach to promote PA. 1: JYU (Jyväskylä, Finland), 2: UTU (Turku Finland), 3: UEF (Kuopio, Finland), 4: JAMK University of Applied Sciences (Jyväskylä, Finland), 5: University of Helsinki (Helsinki, Finland) Introduction Considering the recognized health consequences of intra-abdominal fat and growing trends of abdominal obesity, understanding the role of physical activity in preventing intra-abdominal fat accumulation already among younger adults is of great importance. We aimed to investigate the differences in abdominal fat compartments between young adult monozygotic (MZ) twin pairs discordant for leisure-time physical activity. MZ twins are matched on genetic makeup and multiple childhood experiences, allowing for better control of known and unknown confounders. Methods Ten young adult male MZ twin pairs (age range 32-36 y) discordant for leisure-time physical activity during the past 3 years (mean difference 3.3 MET-h/d) were systematically selected from a population-based Finnish twin cohort. Physical activity discordance of MZ twin-pair was determined by physical activity questionnaires and interviews. MRI of abdomen was conducted to define intra-abdominal (both intraperitoneal and retroperitoneal fat) and subcutaneous fat masses. Prediction of fat masses was based on single MRI slice at the level of lumbar (L2-L3 intervertebral disc (Abate et al 1997). Dietary intake was assessed with a 4 d food diary. Differences in abdominal fat compartments and dietary intake between co-twins were analyzed with pairwise tests. Results Inactive twins had 31% more intra-abdominal fat than their active co-twins (mean difference 0.52 kg, 95% CI 0.12 to 0.91,  $P=0.016$ ), whereas the difference in subcutaneous abdominal fat was only 13% ( $P=0.21$ ). Intraperitoneal fat mass was 41% higher among inactive compared to active co-twins (mean difference 0.41 kg, 95% CI 0.11 to 0.70,  $P=0.012$ ). In retroperitoneal fat the intrapair difference was 16% ( $P=0.10$ ). Dietary intake did not differ between co-twins. In individual based correlations intra-abdominal fat was strongly associated with the markers of glucose homeostasis, i.e. fasting glucose ( $r=0.675$ ,  $P=0.001$ ), fasting insulin ( $r=0.516$ ,  $P=0.02$ ) and HOMAindex ( $r=0.579$ ,  $P=0.008$ ). Conclusions A lower level of physical activity is related to larger amount of intra-abdominal fat already among healthy adult males in their mid-30s. The findings highlight the importance of leisure-time physical activity, independent of diet and genes, in the prevention of intra-abdominal fat accumulation already from early adulthood onward, and hence in avoiding possible development of related metabolic complications. ### OP-SH08 Psychology (Challenges within Sport Psychology I)

#### LINKS BETWEEN ADOLESCENTS' INVOLVEMENT IN SPORT, ATTACHMENT TO PARENTS AND PROSOCIAL BEHAVIOUR

Lisinskiene, A., Sukys, S.

*Lithuanian Sports University*

**Introduction** Adolescents' attachment to key caregivers is of the highest importance and likely to reflect the nature of internal working models in youth sports that may well function as a psychological template during the construction of youth prosocial behavior (Carr 2009). The aim of this study was to examine links between adolescents' involvement in sport, attachment to parents and prosocial behaviour. **Methods** The sample included 1348 adolescents, aged 12–16 (716 girls and 632 boys, M age=14.20 years, SD=1.52). 39.2% of the research participants (n=529) were involved in sports for at least two years. Prosocial Tendencies Measure – Revised (Carlo, Hausmann, Christiansen et al., 2003) was used in this study to measure adolescents' prosocial behaviour. Adolescents attachment to their parents was measured by modified Inventory of Parent and Peer Attachment – Revised (Gullone & Robinson, 2005). Hierarchical regression analyses were applied to examine the effects of participation in sport and attachment to parents on prosocial behaviour. **Results** Regression analyses revealed that involvement in sport was significantly positively associated with total attachment to parent ( $\beta=.08$ ,  $p<.01$ ) and prosocial behaviour ( $\beta=.06$ ,  $p<.05$ ). Total attachment to parents was significantly associated with adolescents prosocial behaviour ( $\beta=.14$ ,  $p<.001$ ). The overall model entering involvement in sport and attachment to parent explained 15% of the variance in prosocial behaviour, and was statistically significant ( $F(2,1347)=16.56$ ,  $p<.001$ ). **Discussion** Adolescents' participation in sport plays a considerable role in relation to parent-child attachment and prosocial behavior in adolescents. Our research has found that children securely attached to their parents and actively involved in sport will be protected from delinquent behaviour and will behave in a more prosocial manner. Our research supports Holt, Knight (2014) statements that children's involvement in sport changes parents' behaviour and interest in sport activities, encourages positive emotions and improves relationships between children and parents. Early parent-child relations are a critical factor for interpersonal relationships in youth sports and have an influence on further relations and formation of behaviour (Carr, 2014). **References** Carlo, G., Hausmann, A., Christiansen, S., Randall, A. #### NEUROPSYCHIATRIC DISORDERS FOLLOWING PEDIATRIC SPORTS-RELATED CONCUSSION

Ellis, M.J., Ritchie, L., Cordingley, D., Chu, S., Selci, E., Leiter, J., Russell, K.

*University of Manitoba*

**Introduction:** Psychiatric outcomes following sport-related concussion (SRC) in youth are not well understood but their clinical management can be difficult and require a multi-disciplinary approach including behavioral and pharmacological treatment options. The objective was to describe the psychiatric diagnoses, treatments, and outcomes of youth who presented with a SRC. **Methods:** A retrospective chart review was completed on all youth aged 13-18 years of age who presented to the Pan Am Concussion Program in Winnipeg, Canada and who met the Zurich Consensus Statement definition of a SRC. Baseline characteristics included age, sex, sport, previous concussions, initial Post Concussion Symptom Scale score, family history of psychiatric disorders, and previous psychiatric disorders that met the Diagnostic and Statistics Manual of Mental Disorders IV criteria. Psychiatric outcomes of interest included the diagnosis of novel psychiatric disorders or the worsening of a pre-SRC psychiatric disorder. Novel psychiatric disorder was defined as a newly diagnosed psychiatric disorder that occurred in the youth with or without a different lifetime pre-injury psychiatric disorder following a concussion. Characteristics of those with and without psychiatric outcomes were compared using the Chi-square test. **Results:** The study included 174 youth, 61.5% were male, the mean age was 14.2 years (SD 2.3), 13.3% had a pre-SRC psychiatric disorder, and the most common sports were hockey (35.6%) and soccer (18.4%). Overall, 20 (11.5%) youth experienced a psychiatric outcome: 16 were diagnosed with a novel psychiatric disorder and four experienced a worsening of pre-SRC psychiatric disorder. Eleven youth were diagnosed with novel depression-related disorder and five with novel anxiety-related disorders. Youth who met the criteria for a post-SRC psychiatric diagnosis were significantly more likely to have a pre-morbid psychiatric disorder ( $p<.001$ ) or a family history of psychiatric disorders ( $p=0.002$ ). They were significantly more likely to report sadness ( $p=0.001$ ), nervousness ( $p=0.001$ ), and being more emotional ( $p=0.008$ ) at their first medical appointment than those with no psychiatric outcome. There was no difference in irritability ( $p=0.089$ ). Fifteen youth were referred to a psychiatrist. Seven youth reported suicidal ideation and three attempted suicide, one of which was successful. Three youth were prescribed medication alone, three received cognitive behavioral therapy, and nine received a combination of treatments. Nine youth remain in treatment. **Discussion:** Increased frequency of post-SRC psychological difficulties was associated with pre-morbid or family history of psychiatric disorder. Subjective report of emotional symptoms on intake was associated with a higher rate of psychiatric disorders following SRC. Successful management of the neuropsychiatric manifestations of SRC requires prompt recognition and a multi-disciplinary approach utilizing trained medical experts in pediatric concussion and psychiatry.

#### SPECIFICS AND CHALLENGES IN FEMALE ATHLETES' CAREER DEVELOPMENT

Tekavc, J., Wylleman, P., Cecic Erpic, S.

*Vrije Universiteit Brussel*

**Introduction** Developmental lifespan model (Wylleman, Reints, & De Knop) identifies several stages (i.e., initiation stage, development stage, mastery stage, discontinuation stage) through which the athletes progress in their athletic career development. Since the model provides a gender non-specific description of athletes' career development, the aim of this study was to investigate into female athletes' athletic career and identify possible specifics and challenges they face in comparison with male athletes. **Methods** Semi-structured interviews with 90 talented and elite Slovene athletes (n = 45 males, 45 females) were used for the purposes of this study. Participants came from various types of sport and equally represented three stages of athletic career development: development stage (n = 30), mastery stage (n = 30), and discontinuation stage (n = 30). The interview guide was based on the Holistic Athletic Career model (Wylleman et al., 2013). The interviews lasted between 45 and 75 minutes. They were transcribed verbatim and content analyzed using the qualitative analytic software program (QSR NVivo 10). **Results** Both, male and female athletes experienced several transitions and

challenges in different stages of their athletic career. In comparison to male athletes, female athletes reported some specific characteristics and difficulties connected to different levels in their athletic career: (1) at the athletic level, they more often reported missing additional professional support and ended their athletic career earlier than male athletes; (2) at the psychological level, they more often mentioned dealing with low levels of self-confidence and weight issues; (3) at the psychosocial level, female athletes more often complained about their coach not being supportive enough or reported about coach's negative behaviour; (4) at the academic/vocational level, female athletes showed a high determination to finish their education and more often than male athletes decided to continue their education on a higher education level. Discussion The findings of this study support the general framework of athletes' development as proposed by the Holistic athletic career model (Wylleman et al., 2013) and give some additional findings about female athletes' development in particular. They suggest that female athletes face some specific demands and challenges in their athletic career development, which calls for additional research in this field. References Wylleman, P., Reints, A., & De Knop, P. (2013). A developmental and holistic perspective on the athletic career. In L. Wei (Ed.), Abstracts of the ISSP 13th World Congress of Sport Psychology. (p. 2). Beijing: ISSP - Beijing Sport University.

## PARADOXICAL FUNCTIONS OF EXERCISE IN WOMEN WITH ANOREXIA NERVOSA

Kolnes, L.

*Norwegian school of sport sciences*

Introduction Despite the substantial role of compulsive exercising (CE) in the development, aetiology and maintenance of anorexia nervosa (AN) (Davis et al., 1997) and the emphasis on CE as a major emotion regulation strategy in AN (Boyd et al., 2007, Lawson et al., 2007), the nature of this relationship and the experiential meaning of exercising for individuals with AN has received little attention. The aim of this study is to build a portrayal of subjective experiences of CE in individuals with AN. Method A qualitative interview was conducted with six female participants who have AN and who were compulsive exercisers. Four participants were former athletes. IPA was used to explore and situate the means whereby participants make sense of their experiences (Smith et al., 2009). Results This paper reports on the first superordinate theme that conceptualizes the participants' experiences of CE, paradoxical functions of exercise. First, an account of the participants' feelings about their engagement with CE as an experience of emotion escape and regulation is presented. Second, the participants' experience of embodied emotional states and how exercise is used to ease the body are explored. Third, the meaning of exercise in relation to the participants' sense of self and identity is examined. Discussion The obligation to exercise seems to be essentially connected with avoidance of participating in emotional and relational talk and potential conflicts. Contrary to previous observations of impaired emotion recognition in the self, participants in this study vividly described sensing of feelings as bodily sensations suggesting that they recognize emotions in the self and grasp what goes on within and around themselves through their bodies. Embodied feelings seem to offer some sense of connecting with their emotions. The substantial role of self-expression and belonging through compulsive exercising was particularly obvious in the accounts of the four women who were former athletes. For them, being good at sports and exercising was fundamental in determining a sense of self. This study shows that the multi-layered and meaningful endeavour of exercising in individuals with AN, makes it extremely difficult to reduce or end the exercising. ## THE RELATIONSHIP BETWEEN STUNKARD IMAGES, PERCEPTION OF BMI AND PERCEPTION OF SELF-CONCEPT IN SPANISH ADOLESCENTS

Sánchez-Miguel, P.A., Pulido, J.J., Chamorro, J.L., Sánchez-Oliva, D., Aamado, D., González-Ponce, I., Leo, F.M., García-Calvo, T.

*University of Extremadura*

Introduction The aim of this study was to examine the relationships between a subjective assessment Body Mass Index (BMI), a perception of the body image with Stunkard figure Rating Scale, as well as perception of self-concept in youth scholars from Extremadura (Spain). Methods The sample was formed by 2061 youth scholars from Extremadura (Spain), both males (N = 1038) and female (N = 1023), ranging in age from 15 to 17 years old (M = 15.68; SD = 0.94), belonged to different High Schools from Extremadura (Spain). Participants were measured through perception of height and weight, and were asked to select the figure that best resembled their current body size on the Stunkard's figure rating scale. Finally, the adaptation into Spanish by Moreno & Cervelló (2005) of the Physical Self-Perception Profile (Fox & Corbin, 1989) was used to measure perception of self-concept. Results The outcomes revealed normal values in perception of BMI in participants (BMI = 20.65), and Stunkard figure rating Scale. Moreover, results showed a significant relationship between perception of BMI, Stunkard's current body size and perception of self-concept. In accordance to this aspect, self-concept emerged as a strong predictor of estimated physical dissatisfaction. Discussion The results showed the importance and incidence of body size and body status in order to have a good perception of self-concept. Moreover, the results emphasized the necessity to measure perception of body mass index in great samples in adolescents. On the other hand, these outcomes highlighted the importance to have an adequate body status in order to improve psychological factors, mainly in adolescents' ages. Finally, the study concluded that current body size is a potentially useful indicator to measure weight status of adolescents. Further investigations are needed to enhance the knowledge about these relationships between perception of BMI, body dissatisfaction and self-concept. References Fox KR, Corbin CB. ### OP-SH21 Sociology

#### **'YOU ARE JUST AN IDIOT FOR NOT BEING DOING ANY PHYSICAL ACTIVITY RIGHT NOW': PRE-SERVICE HEALTH AND PHYSICAL EDUCATION TEACHERS' CONSTRUCTIONS OF BODY FAT**

Varea, V.

*University of New England*

This paper explores how a cohort of pre-service Health and Physical Education (HPE) teachers from an Australian university describe and construct discourses about body fat. Risk and uncertainty are characteristics of our current society. In this context, it is expected for people to understand the diverse 'risks' and engage in self-monitoring strategies (Garrett & Wrench, 2012). The well known 'obesity epidemic' is a major discourse in today's society and the obesity epidemic is a clear indicative of a control society. Furthermore, panic is widely created through media campaigns using 'alarming' statistical information, mainly based in BMI levels. It has been suggested that HPE teachers usually have fat phobia tendencies (Sykes, 2009; Sykes & McPhail, 2008) and they can even transmit these beliefs and attitudes to their students (Yager & O'Dea, 2009). Taking a poststructuralist Foucauldian perspective, the aim of this paper is, therefore, to explore how these discourses about fatness have been constructed among pre-service HPE teachers and the effects that they may have on teaching practices. References Garrett, R., & Wrench, A. (2012). 'Society has taught us to judge': cultures of the body in teacher education. *Asia-Pacific Journal of Teacher Education*, 40(2), 111-126. Sykes, H. #### **THE ECOLOGICAL HABITUS, SPORT AND PHYSICAL CULTURE**

Brown, D.

*Cardiff Metropolitan University*

Recently, environmental sociology and in particular the sociology of climate change have presented strong arguments asserting the view that while climate change is a phenomenon taking place in the natural world it is social problem in so far as it is substantially caused and accelerated by unsustainable patterns of social organisation and consumption, which are forms of social behaviour. Therefore, if climate change is, in this sense a problem of social behaviour, then its mitigation and adaption are also rooted in the social with all forms of sport and physical culture centrally implicated in any attempts at change. However, one of the enduring problems rests with conceptualisations of social behaviour, which have tended towards either overly cognitive behaviourist or individualist explanations and applications, each of which presuppose intellectually determinist or voluntarist leanings respectively. This paper explores an alternative view of (un)sustainable social behaviour that stresses embodied beliefs and social practices emerge from prolonged engagement in sociocultural fields of activity such as particular sports and physical cultures. In so doing it identifies the 'ecological habitus' as articulated by Kasper (2009: 322) as a continuum of dispositions ranging from the 'ecologically supportive to antagonistic'. It is argued that this approach allows researchers to map the alignment between the core dispositions of a given sport or physical culture with dispositions of an ecologically supportive or antagonistic habitus. Better understanding this (mis)alignment will provide clearer picture of the specific dispositions and their related social practices that might need addressing or reinforcing if sustainable social behaviour in sport and physical culture is to become a more widespread reality.

#### **SPORT AS A RESPONDING SOLUTION TO SOCIAL PROBLEMS? CONTEXTUALIZING SPORT AND WELFARE**

Ekhholm, D.

*Department of Social and Welfare Studies*

Sport have in recent decades gained more and more attention in social policy as a means of responding to social problems. This role ascribed to sport have been studied in various disciplines foremost in a US and UK context. The issue has thus far received poor attention in Swedish research. This presentation targets some considerations on the design of three interrelated studies constituting the main body of a forthcoming doctoral thesis on sport as a responding solution to social problems. First, it is noted that Swedish research disregard a distinction between social objectives as a premise of sport (so called Plus Sport) or as an effect from sport. As a consequence, there is a lack of research on Plus Sport practices, something which my research intends to redress. Moreover, Swedish research is empirically driven but however vaguely related to the historical and political context within which sport have emerged in this seemingly new role. Second, such observations call for further theoretically informed research relating contemporary sport practices with social objectives to the transformations in welfare provision of recent decades. Third, as a result two studies focusing on a Plus Sport program (SP) responding to the observed gaps in research were designed. The SP is a local welfare intervention initiated by municipal public authorities in partnership with a social entrepreneur and local voluntary sport clubs in a larger Swedish city targeting crime and segregation. Statements on sport as a responding solution to social problems articulated by social entrepreneur representatives and by municipal policy makers is examined from a constructionist strand. In short, one study focuses on the pedagogical governing techniques promoted within the SP by the social entrepreneur representatives as well as what kind of desirable citizen subjects the SP aim to produce. The other study focuses on the organizational side of the SP concerning the policy makers conceiving of sport in relation to state-centered public welfare provision and civil society and market involvement. The presentation aims to discuss the design of the latter two studies with respect to potential blind spots and its' contribution to research on sport's role in society and welfare provision.

## HEALTH COMMUNICATORS' ALTERING THEIR PRACTICE BY IMPLEMENTING PHYSICAL ACTIVITY FOR NEWLY ARRIVED REFUGEES

Fabri, A.

*Education and society. Malmö university*

Introduction Swedish experience has shown that health problems contribute to a slower, and longer integration process among newly arrived refugees (Povrzanovi Frykman et.al.2011). Health is crucial for learning, integration and establishment in the labour market for these groups. Physical activity presents itself as a possible way to develop and maintain both physical and mental health among refugees, thus facilitating their integration process. Within Sweden, more broadly, 'communicators', who are previous refugees themselves, work with recent arrivals to educate and inform about the Swedish society. Within the province of Scania, a recent initiative has been introduced where the communicators also inform about health issues, including the promotion of physical activity and recreation for active living. The concept of working with and through physical activity is new in this context for the health communicators (HC). Understanding the working methods among HC in Scania is important, not only because of their central role in the re-settlement programme, but also because of the new methodologies surrounding physical activity that HC are having to engage with. Methodology Action Research (AR), with its focus on understanding and improving professional practice was adopted for the current project. Data was collected through, open ended interviews, observations, field notes and participation in the field. The data was read through the lens of 'practice theory' with a particular focus on practice architecture (Kemmis & Grootenboer, 2008). This framework allowed for a focus on the 'doings' 'sayings' and 'relatings'. Results and Discussion Practice architectures was used as a theoretical framework in order to understand what constitutes and affects a practice. The relationships between material-economic, social-political and the culture-discursive structures determine the HC opportunities for professional practice. The HC expressed the need for increased co-operation within and between national and local departments involved in the receiving of refugees. This is especially important if health promotion is to be central within the refugee establishment process. Conclusion There is great value for newly arrived refugees to meet in different health-promoting locations and to engage in physical activities on a practical level. For sustainable health promotion among refugees to become reality it is required that different authorities cooperate with the HC on a more concrete level than is the case today. ### OP-PM62 Health & Fitness: Mixed

#### SELF-ADMINISTERED PHYSICAL EXERCISE TRAINING AS TREATMENT OF NECK PAIN AMONG MILITARY HELICOPTER PILOTS AND CREW – A RANDOMIZED CONTROLLED TRIAL

Murray, M.1, Lange, B.2, Nørnberg, R.B.3, Bøtcher, L.P.1, Rasmussen, G.T.1, Sjøgaard, K.1, Sjøgaard, G.1

*(1) Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Denmark*

Introduction: Flight related neck pain is frequent among helicopter pilots and crew and affect individual health, operational capacity and flight safety. Exercise training has proven effective in reducing neck pain within other job professions. The aim of this study was to investigate if an exercise intervention might reduce neck pain among helicopter pilots and crew. Methods: A total of 31 helicopter pilots and 38 crew members were randomized to an exercise-training-group ETG (n=35) or a reference-group REF (n=34). ETG received 20 weeks of strength, endurance and coordination training targeting the deep and superficial neck muscles. Training was self-administered due to irregular work schedules. REF received no training. Primary outcome: Intensity of neck pain the previous 3 months (self-reported on a 0-10 numeric box scale) and pressure-pain threshold (PPT) in the trapezius m. (TRA) and upper neck extensors (UNE). Secondary outcome: Maximal voluntary contraction (MVC) for cervical extension/flexion and shoulder elevation. Training compliance was self-reported and categorized as regular if performed  $\geq 1$  times a week. Results: Neck pain at baseline was  $1.9 \pm 1.7$  (mean  $\pm$  SD) in ETG and  $2.5 \pm 1.9$  in REF, and PPT in TRA and UNE (right/left)  $424 \pm 187/434 \pm 188$  kPa,  $343 \pm 153/366 \pm 161$  kPa in ETG and  $416 \pm 177/405 \pm 163$  kPa,  $334 \pm 147/329 \pm 144$  kPa in REF. Intention-to-treat analysis revealed no significant effect on self-reported pain between groups. Within ETG PPT in left TRA was significantly reduced at follow-up:  $381 \pm 169$  kPa ( $p=0.009$ ). Also, within REF PPT was significantly reduced in TRA and UNE at follow-up (right/left)  $342 \pm 143$  kPa ( $p=0.003$ ) /  $331 \pm 154$  kPa ( $p=0.001$ ),  $294 \pm 116$  kPa ( $p=0.024$ ) /  $291 \pm 121$  kPa ( $p=0.035$ ). Per-protocol analysis for pain in ETG, only including subjects who trained regularly ( $n=10$ ), was  $2.2 \pm 0.6$  at baseline and  $1.3 \pm 1.3$  at follow-up, but not significantly different from REF. MVC for cervical extension/flexion was in ETG  $248 \pm 64/184 \pm 60$  N at baseline and  $261 \pm 56/194 \pm 63$  N at follow-up, and correspondingly for REF  $241 \pm 60/174 \pm 52$  N and  $226 \pm 58/175 \pm 43$  N. MVC for cervical extension was significantly improved in ETG compared to REF ( $p=0.016$ ). Discussion: Specific neck training significantly increased MVC in UNE in ETG. Also, PPT decreased significantly in left TRA in ETG and in REF in both TRA and UNE. No significant difference was observed between groups for self-reported neck pain. This may be due to low compliance since only  $\sim 1/3$  of subjects in ETG engaged in regular training. E-mail: [mmurray@health.sdu.dk](mailto:mmurray@health.sdu.dk)

#### CARDIAC AUTONOMIC CONTROL INDEPENDENT ASSOCIATIONS WITH CARDIORESPIRATORY FITNESS AND RESTING METABOLIC RATE IN NAFLD PATIENTS

Pimenta, N.M.1,2, Cortez-Pinto, H.3, Silva-Nunes, J.4, Sousa, P.5, Calé, R.5, Melo, X.1, Sardinha, L.B.1, Fernhall, B.6, Santa-Clara, H.1

*1:CIPER, FMH-UL (Lisbon, Portugal), 2:ESDRM-IPS (Rio Maior, Portugal), 3: Sta Maria Hosp., FM-UL (Lisbon, PT), 4:Curry Cabral Hosp. (Lisbon, PT), 5:Sta Cruz Hosp. (Lisbon, PT), 6: UIC (Chicago, IL, US)*

Introduction Parasympathetic control of heart rate is dominant at rest. Heart rate recovery (HRR) after exercise, a marker of parasympathetic reactivation, is associated with cardiorespiratory fitness (CRF). Body composition (BC), particularly body fat (BF) distribution is highly related with HRR in Non-Alcoholic Fatty Liver Disease (NAFLD) patients. The association of HRR with both CRF and resting metabolic rate (RMR) is not yet known in NAFLD patients. The aim of this study was to determine if HRR is independently associated with CRF and RMR, and if such associations were influenced by markers of BC, in NAFLD patients. Methods We assessed 28 NAFLD patients (19 males, 51 +

13 yrs, and 9 females, 47 + 13 yrs), who were diagnosed through liver biopsy or ultrasound. All subjects underwent both RMR and treadmill maximum graded exercise testing (GXT) assessment with indirect calorimetry and 12 lead ECG and. RMR was expressed as kcal/day and CRF was assessed as the maximal oxygen uptake (ml/kg/min) in the GXT. HRR was the difference between peak exercise heart rate (HR) and the HR at 1 (HRR1) and 2 minutes (HRR2) immediately after GXT. BC assessment consisted of anthropometry, specifically: weight, height, waist circumference (WC), body mass index (BMI) and waist-to-height ratio (WHtR). Partial correlations were used to test associations. Only  $r \geq 0.5$  were considered to attain statistical significance ( $\alpha=5\%$  and  $\beta=20\%$ ). Results HRR1 and HRR2 were associated with CRF ( $r=0.63$  and  $r=0.52$ ; respectively,  $p<0.01$ ), as were WHtR and WC ( $r=0.69$  and  $r=0.64$ ; respectively,  $p<0.01$ ), but not BMI ( $r= -0.25$ ,  $p=0.243$ ), controlled for age and sex. When controlling also for BMI, both HRR1 and HRR2 were still related with CRF ( $r=0.64$  and  $r=0.54$ ; respectively,  $p<0.01$ ). The relation with CRF, when controlled for age and sex plus WC or WHtR, was absent both for HRR1 ( $r=0.43$  and  $r=0.45$ ;  $p=0.050$  and  $p=0.041$ ) and HRR2 ( $r=0.34$  and  $r=0.38$ ;  $p=0.110$  and  $p=0.081$ ). HRR1, HRR2 and all studied BC markers were not related with RMR in these NAFLD patients, despite the control variables used. Discussion HRR was found related with CRF in NAFLD patients, though not independently of BC, specifically central BF accumulation markers. The relation between HRR and CRF may be mediated by BC in NAFLD patients. HRR was not related to RMR. Thus, exercise-related cardiac autonomic control does not appear to influence RMR.

## THE EFFECT OF PHYSICAL FITNESS AND PHYSICAL EXERCISE TRAINING ON WORK PRODUCTIVITY AMONG HEALTH CARE WORKERS

Kongstad, M., Sjøgaard, G., Sjøgaard, K., Christensen, J.R.

*University of Southern Denmark*

**Introduction** Workplace health promotion involving physical exercise training may negate lifestyle diseases and improve work productivity (WP) mediated by physiological variables such as BMI, cardiorespiratory fitness (CRF), and maximal voluntary contraction (MVC). The aim of this paper was to examine 1) the relationship between WP and the physiological variables BMI, CRF, and MVC in a cross-sectional sample of health care workers, as well as 2) the change in WP in relation to changes in the before mentioned physiological variables following workplace health promotion. **Methods** Secondary analyses were performed on a subsample of 139 female health care workers in Denmark participating in a cluster randomized controlled trial (Holtermann et al. BMC Public Health 2010, 10:120). WP was assessed as a summed score using selected, validated questions from three questionnaires (Health and Work Performance Questionnaire, Work Ability, and Quantity and Quality Method). Height and weight were measured to calculate BMI, CRF was measured using a bicycle ergometer maximal exercise test, and MVC was measured during arm abduction, shoulder elevation, back flexion and extension using a Bofors dynamometer. Partial correlation as well as one-way analysis of variance with Tukey HSD post-hoc testing was used for analyses. **Results** Cross-sectional analyses at baseline showed a significant relationship between WP and strength in back flexion ( $r = .28$ ,  $p = .03$ ) and back extension ( $r = .32$ ,  $p = .02$ ) as well as an inverse relationship between WP and BMI ( $r = -.22$ ,  $p = .02$ ). Also, the group of participants with BMI > 30 had significantly lower WP than the group with BMI < 25 ( $p = .04$ ). Over a period of three months a subgroup of the participants had participated in health promotion, and a significant positive relationship was found between change in WP and changes in strength in back flexion ( $r = .46$ ,  $p = .005$ ) and back extension ( $r = .41$ ,  $p = .01$ ). A significant inverse relationship between change in WP and change in BMI ( $r = -.33$ ,  $p = .004$ ) was found. No corresponding relationships were found between WP and CRF or strength in arm abduction and shoulder elevation. **Discussion** The present study is the first to examine the relationship between WP and MVC, as well as among the first to examine the relationship between WP and CRF. Results from the present study suggest that increased WP in health care workers may be attained by lowering BMI as well as increasing the strength in back flexion and extension. The prospect of increased WP may increase enthusiasm among employers towards introducing workplace health promotion, which could result in healthier employees and reduced costs for both the employers and national health services. ## EFFECTS OF ACUTE EXERCISE ON BRAIN MECHANISMS ASSOCIATED WITH SINGLE- AND DUAL-TASKS DURING LOCOMOTION

Duncan, S., Panchuk, D., Schneider, S., Polman, R.C.J.

*Victoria University, Australian Institute of Sport, German Sports University & Bournemouth University*

**Introduction:** Numerous studies have examined behavioural outcomes, such as task completion time and/or errors made, when we execute a single-task (e.g., locomotion) or dual-task (e.g., locomotion while counting backwards). Yet few studies have examined the neural mechanisms that underlie behavioural differences in the execution of single- and dual-tasks or whether acute exercise can alter these mechanisms. This study examined the effects of two different forms of acute exercise on neural activity while individuals performed a locomotor (single) task or locomotor task and cognitive, decision making (dual) task. **Method:** In a randomized, cross-over design, 15 participants (7 M, 8 F; mean age: 27.3 years) performed single and dual-tasks prior to and following an acute bout of exercise. In the single task condition participants walked around a grid-based track travelling in different directions at each junction. Direction of travel was determined by a stimulus that required the participant to turn left (green light), turn right (red light), or continue straight ahead (no light). In the dual-task condition participants performed the same locomotor task while concurrently performing a memory task (remembering a shopping list). Neural activity was recorded before and after exercise using wireless EEG during all tasks; analyses were conducted using sLORETA (standard low-resolution brain electromagnetic tomography; Pascual-Marqui, 2002) of the ERP N2 and P3. The acute bouts of exercise required either a 45 min bout of aerobic exercise (cycling at 60 – 70%  $VO_{2max}$ ) or 45 min of upper and lower body strength training (12 reps x 3 sets at 65 – 75% of the 1RM) separated by 1-week. **Results:** Preliminary results of sLORETA analyses showed a significant increase after the aerobic bout of exercise in N2 ( $p < 0.01$  post exercise measurements, single and dual task conditions compared to baseline) as well as an increase in the P3 in the single and dual task conditions compared to baseline ( $p < 0.01$  and  $p < 0.05$  respectively). **Discussion:** We suggest that the differences observed between conditions indicate an increased motor network coherence (functional connectivity) resulting in improved performance and/or that a more efficient allocation of attentional resources was necessary to perform a more complex and attention demanding task. **References** Pascual-Marqui, R. D. (2002). Standardized low-resolution brain electromagnetic tomography (sLORETA): Technical details. *Methods and Findings in Experimental and Clinical Pharmacology*, 24(SUPPL. D), 5-12

**BREAKING UP PROLONGED SITTING TIME DOES NOT AFFECT APPETITE OR GUT HORMONE CONCENTRATIONS IN SEDENTARY ADULTS**

Bailey, D.P., Broom, D.R., Christmas, B.C., Taylor, L., Flynn, E., Hough, J.P.

*University of Bedfordshire*

Introduction: Exercise influences the release and metabolism of appetite-regulating hormones, suppressing appetite during and following a single continuous bout of high-intensity exercise. Engaging in prolonged sitting has received overwhelming attention recently following evidence that this results in deleterious metabolic consequences. Breaking up sitting time with frequent, brief bouts of activity can negate these deleterious effects but the influence on appetite and gut hormone concentrations is unknown. Methods: 13 sedentary (7 female), inactive participants took part in three, 5 h trials in random order: 1) uninterrupted sitting (SIT), 2) seated with 2 min bouts of light-intensity walking every 20 min (SIT+LA), and 3) seated with 2 min bouts of moderate-intensity walking every 20 min (SIT+MA). A standardised test drink was provided after an initial 1 h period of uninterrupted sitting. Appetite ratings were taken at 30 min intervals and blood samples taken hourly to measure plasma concentrations of acylated ghrelin, peptide YY, glucagon-like peptide-1, insulin, and glucose. Total area under the curve (AUC) was calculated for each variable. An ad libitum pasta test meal was provided at the end of each trial. Results: AUC values for appetite ratings and gut hormone concentrations were unaffected by frequent brief bouts of activity compared with uninterrupted sitting (linear mixed modelling:  $p > 0.05$ ). Glucose and insulin concentrations also did not differ significantly over the 5 h trial period ( $p > 0.05$ ), nor was there any difference in absolute ad libitum energy intake during the post-trial test meal ( $p > 0.05$ ). However, relative energy intake (energy intake minus the net energy expenditure of exercise) was lower in the SIT+LA and SIT+MA trials than in the SIT trial (SIT,  $441 \pm 296$  kcal; SIT+LA,  $298 \pm 254$  kcal; SIT+MA,  $111 \pm 151$ ;  $p < 0.05$ ). Conclusion: Appetite and gut hormone responses to a meal are not altered over a 5 h period with frequent short bouts of light- or moderate-intensity walking. Increased energy expenditure from intermittent activity could promote an energy deficit that is not compensated for in a subsequent meal. Contact: daniel.bailey@beds.ac.uk

**SEQUENTIAL AND ALTERNATING PHYSICAL EDUCATION DIDACTIC UNITS WITH TEAM VS. INDIVIDUAL SPORTS – EFFECTS ON PHYSICAL FITNESS**

Póvoas, S.1,2, Silva, P.2,3, Lopes, M.2, Krstrup, P.4,5

1:CIDESD/CIDESD-ISMAI, 2:Univ. Institute of Maia-ISMAI(Maia,PT), 3:CIAFEL(Porto,PT), 4:Copenhagen Centre for Team Sport and Health, Univ. of Copenhagen (NES) (Copenhagen,DEN), 5:Univ. of Exeter(Exeter,UK)

Introduction In physical education (PE) classes, teachers can choose between sequential or alternating planning of the didactic units throughout each of the three school trimesters. In sequential planning a team sport is used during the first half of the trimester followed by an individual sport (TS/IS) during the second half (or vice-versa, i.e., IS/TS). In alternating planning, team and individual sports are alternating in the two PE sessions conducted each week (TS-IS), one lasting 60 min and other 90 min. The purpose of this study was to analyse the effects of sequential and alternating planning on pupils' physical fitness. Methods Two hundred and two pupils from 7th, 8th and 9th grade (12-16 years) participated in this study. Three classes from each grade were cluster-randomized into the three types of planning: TS/IS, IS/TS and TS-IS. Football was the chosen team sport and gymnastics the individual sport. Evaluations were performed at the beginning, middle and end of a school trimester. Aerobic fitness was assessed by the Yo-Yo intermittent endurance level 1 test (YYIE1) (1), leg muscle power by the countermovement jump and postural balance by a single-legged Flamingo balance test (2). Continuous heart rate monitoring and rating of perceived exertion were used to evaluate the exercise intensity during PE classes. Results Aerobic fitness and postural balance significantly increased during team sport classes and significantly decreased during individual sport, when evaluating the planning types TS/IS and IS/TS ( $p \leq 0.05$ ). Leg muscle power significantly increased during team sport classes ( $p \leq 0.05$ ). Alternating between team and individual sports in PE classes within each week had no significant effect on pupils' physical fitness levels. Discussion In accordance with previous studies (3), these study results show that team sports (football) can improve pupils' physical fitness during short-term interventions, probably due to a combination of high aerobic loading and multiple specific intense actions like sprints, turns, dribbles, tackles, jumps and shots. The present data also suggest that some of the individual sports currently chosen for PE are not sufficiently intense to improve the fitness profile of 12-16-year-old school children. **Oral presentations****OP-PM72 Molecular Biology and Biochemistry: Gene expression & signaling****EFFECT OF ACUTE INTERVAL EXERCISE ON OXIDATIVE STRESS IN CANOEISTS**

Chien, L., Lee, T., Lu, K., Li, T.

*National Taiwan Sport University*

Introduction Canoeists are usually trained via the pattern of intensely interval training. However, it is still unknown if the pattern-induced stress influences oxidative stress. The purpose of this study was to investigate the effect of acute interval exercise on oxidative stress in canoeists. Methods Nineteen healthy male canoeists (age  $16 \pm 2$  yr, height  $172.0 \pm 5.8$  cm, weight  $63.3 \pm 7.4$  kg, mean  $\pm$  SD) participated in this study. The subjects completed a single interval training session (six 90-sec bouts of high-intensity rowing separated by 4 min recovery period). Blood samples were taken at pre-exercise, post-exercise, and 3 hours post-exercise for analyzing plasma levels of thiobarbituric acid reactive substances (TBARS), superoxide dismutase activity (SOD), and catalase activity (CAT). Repeated one-way ANOVA was adopted and statistical significance was set at  $\alpha = 0.05$ . Results The results of this study showed that the TBARS levels at post-exercise ( $2.88 \pm 0.74 \mu\text{M}$ ) were significantly higher than pre-exercise ( $2.43 \pm 0.57 \mu\text{M}$ ) and returned to baseline at 3 hours post-exercise ( $2.43 \pm 0.56 \mu\text{M}$ ). A trend was found that SOD activity was increased with time, but only the levels at 3 hours post-exercise ( $4.72 \pm 3.14 \text{ U/ml}$ ) were significantly higher than pre-exercise ( $3.49 \pm 2.12 \text{ U/ml}$ ). The CAT activity at post-exercise ( $663.86 \pm 173.12 \text{ U/ml}$ ) was significantly higher than pre-exercise ( $475.19 \pm 146.79 \text{ U/ml}$ ) and decreased significantly at 3 hours post-exercise ( $329.12 \pm 110.42 \text{ U/ml}$ ). Discussion The main results of this study are similar to previous findings. Ji et al. (2010) indicated that exercise-induced reactive oxygen species could

improve antioxidant system to increase antioxidant enzymes and called it hormesis. Subsequently, studies reported that TBARS levels were significantly increased after an acute session of hypertrophy resistance interval exercise (Deminice et al., 2011). Furthermore, TBARS and CAT levels were significantly elevated after a short-term high-intensity interval exercise (four to six 30-sec bouts of high-intensity cycling separated by 4 min recovery period) (Boqdanis et al., 2013). The findings of this study suggested that acute interval exercise increased the oxidative stress and subsequently improved antioxidant capacity to blunted oxidative damage. ### **EFFECTS OF A SINGLE RESISTANCE EXERCISE BOUT ON NF- $\kappa$ B SIGNALLING IN SKELETAL MUSCLES OF MASTERS WEIGHTLIFTERS AND AGE-MATCHED CONTROLS**

Wessner, B., Hofmann, M., Ploder, M., Tschan, H., Bachl, N.

*University of Vienna*

**Introduction** Masters athletes who continue a regular, performance-oriented training throughout life provide a unique model for studying successful aging as changes observed in master athletes are considered the results of primary (physiological) rather than secondary (lifestyle) ageing [1]. With this in mind, the current study aimed to compare the effects of an acute resistance exercise on Nf- $\kappa$ B signalling (known to be a key regulator of inflammatory pathways) in the muscles between trained masters weightlifters and healthy untrained individuals. **Methods** Sixteen older men (8 masters weight lifters (WL), 8 age-matched controls (CO)) volunteered to participate in the study (61.2  $\pm$  8.2 years, height: 1.73  $\pm$  0.07 m, weight: 77.9  $\pm$  14.0 kg, BMI: 26.0  $\pm$  3.9 kg/m<sup>2</sup>). Two days after assessing 1-RM, an acute exercise protocol (3 sets, 70-75% of 1-RM until voluntary fatigue) was applied unilaterally on the dominant leg while the other leg served as control. Three hours after termination of the exercise, skeletal muscle tissue was obtained via percutaneous biopsy of m. vastus lateralis from both legs and subjected to gene expression analyses using the human Nf $\kappa$ B Signaling Pathway RT<sup>2</sup> Profiler™ PCR Array (SABiosciences). Promising results were confirmed by q-PCR. In order to test the main study hypothesis, interactions between training status (WL, CO) and resistance exercise (exercised leg, resting leg) were tested by two-way ANOVA with repeated measures. **Results** The results of the Nf- $\kappa$ B PCR array demonstrated only marginal differences in gene expression levels between WL and CO in both, the exercised and the non-exercised legs. Acute resistance exercise led to an up-regulation (> 1.5-fold) of 14 genes in CO and of 13 genes in WL. The transcription factors FOS and early growth response 1 (EGR1) comprised the most responsive genes to resistance exercise (EGR1:15.7-fold increase, p=0.003, FOS: 36.3-fold increase, p<0.001) but no group or interaction effects could be detected (p>0.05). **Discussion** With this study we confirm previous data showing that resistance exercise triggers a subclinical inflammatory response that is thought to play an important role in skeletal muscle regeneration [2]. We could not confirm our initial hypothesis that this response would be different in trained and untrained elderly. However, it has to be considered that the sample size was quite small. Furthermore, we focused on the immediate response in gene expression. It cannot be excluded that differences would be present at later time points [3]. **References** [1] Tanaka & Seals (2003) *J Appl Physiol*, 95(5):2152-62 [2] Vella L et al. ### **THE EFFECTS OF AEROBIC EXERCISE ON NF- $\kappa$ B, LIN 28B AND LET-7A MICRORNA EXPRESSIONS AND LEVELS OF TUMOR TISSUE IL-6 IN MICE WITH BREAST CANCER**

Anoosheh, L., Kordi, M.R., Gaeini, A.A., Mahdian, R., Mirakhori, Z., Amani Shalamzari, S.

*University of Tehran*

**Introduction** Inflammatory response has a pivotal role in tumorigenesis, progress and metastasis of most cancers particularly breast cancer (Taniguchi and Karin 2014). An epigenetic switch, from normal breast cell to cancer, is activated by an inflammatory signal, and epigenetic inheritance is mediated by a positive feedback loop involving Nf- $\kappa$ B, Lin28B, let-7a and IL-6 (Iliopoulos et al. 2009). The aim of the present research was to assess the effects of 6 weeks of aerobic exercise on Nf- $\kappa$ B, Lin28B, let-7a microRNA, and IL-6 of tumor tissue of mice with breast cancer. **Method** 20 female BALB/c mice (4 to 5 weeks old) were inoculated with MC4-L2 estrogen receptor positive breast cancer cells. They were, then, divided into two groups of Tumor-Exercise (TE)(n=10) and Tumor-Control (TC)(n=10). TE group performed aerobic exercise five days per week for six weeks. After emergence of tumor, the widths and the lengths of the tumors were weekly measured by digital caliper. Mice were sacrificed 48 hours after the last exercise session and tumor tissue was removed. Nf- $\kappa$ B, Lin28B and miRNA let-7a gene expression were quantified with Real time-PCR and tumor tissue IL-6 was measured by ELISA test. Repeated measures ANOVA and independent t tests were used to assess tumor size and IL-6, respectively. Statistical analysis of Nf- $\kappa$ B, Lin28B and let-7a were performed by REST software. **Results** Tumor volume, expression of Nf- $\kappa$ B and Lin28B genes and IL-6 levels diminished significantly in TE group compared with TC group, but let-7a microRNA showed a significant increase (P<0.05). **Discussion** In the present investigation, diminution of tumor volume in TE group compared to TC is observed following aerobic exercise training. Inflammatory status is one of the mechanisms involved in growth of tumor; it has been demonstrated that aerobic exercise can reduce this status. In present research it is shown that the levels of IL-6 diminished significantly following aerobic exercise training and seems to be effective in decreasing tumor volume. The results of the present investigation also demonstrate that regular aerobic exercise could have an effective role in diminution of Lin28B and Nf- $\kappa$ B and increase of microRNA let-7a. As it has been demonstrated that perturbation of any component of the regulatory circuit (inhibition of Nf- $\kappa$ B or Lin28B or IL-6 or over-expression of let-7a) could induce significant reduction of tumor growth and mortality in breast cancer (Iliopoulos et al. 2009), it could be claimed that regular aerobic training can at least have a therapeutic role in estrogen-receptor-dependent breast cancers. However more studies are needed to be conducted. **References** Iliopoulos D., Hirsch HA., Struhl K. (2009) An epigenetic switch involving Nf- $\kappa$ B, Lin28, Let-7 MicroRNA, and IL6 links inflammation to cell transformation. *Cell*. 139(4):693-706. **DEGRADOME EXPRESSION PROFILING IN STRAINED AND PATHOLOGICAL TENDON – ARE THERE COMMON PATTERNS IN EXERCISE AND TENDINOPATHY?**

Legerlotz, K., Jones, E.R., Riley, G.P.

*Department of Training and Movement Sciences, Humboldt University Berlin*

Introduction The exact mechanisms leading to tendinopathies and tendon ruptures remain poorly understood while their occurrence is clearly associated with exercise. Overloading is thought to be a major factor contributing to the development of tendon pathologies. However, as animal studies have shown, heavy loading alone won't cause tendinopathies. It has been speculated, that malfunctioning adaptation or healing processes might be involved, triggering tendon tissue degeneration. By analysing the expression of the entirety of degrading enzymes (degradome) in pathological and non-pathological, strained and non-strained tendon tissue, the aim of this study was to identify common or opposite patterns in gene regulation. This approach may generate new targets for future studies. Methods RNA was extracted from different tendon tissues: normal (n=7), tendinopathic (n=4) and ruptured (n=4) Achilles tendon; normal (n=4) and tendinopathic (n=4) posterior tibialis tendon; normal hamstrings tendon with or without subjection to static strain (n=4). The RNA was reverse transcribed, then pooled per group. The expression of 538 protease genes was analysed using Taqman low-density array quantitative RT-PCR. To be considered relevant changes had to be at least 4fold and measurable at a level below 36 Cts. Results In general, there was little common regulation when exercised was compared with pathological tissue. The expression of PAMR1 and TNFAIP3 was upregulated with both exercise and Achilles tendon pathology, while DDIT1, PSMB11 and PSH5 which were down-regulated with exercise were upregulated with Achilles pathology. However, 69% of genes regulated in Achilles tendinopathy were also regulated in the same way with Achilles tendon rupture, while only 12% were similarly regulated in posterior tibialis tendinopathy. Discussion The incongruent protease expression pattern in Achilles and posterior tibialis tendinopathy, as previously shown for members of the IL6 family (Legerlotz et al. 2012), indicates substantial differences in pathological processes. The newly found targets may deliver insights into the initiation and progression of tendon pathologies. Our data indicate, that the overexpressed PAMR1, a regeneration associated muscle protease which has been shown to be downregulated in Duchenne muscular dystrophy and upregulated in regenerating muscle fibers (Nakayama et al. 2004), is also involved in tendon regeneration. **Oral presentations****OP-PM34 Sports Medicine & Orthopedics: Injury prevention II****COMPARISON OF MECHANICAL INJURY RISK FACTORS BETWEEN MALE AND FEMALE WORLD CUP ALPINE SKIERS IN THE DISCIPLINE SUPER-G**

Gilgien, M., Haugen, P., Reid, R.

*Norwegian School for Sport Sciences / Norwegian Ski Federation*

Introduction Alpine ski racing is considered a sport with high injury risk. Most injuries per run occur in the speed disciplines downhill (DH) and super-G (SG). In World Cup SG skiing 14 male and 7 female athletes get injured per 1000 runs (Florenes et al., 2009). Recent studies have shown that injury risk in SG and DH is related to speed, race duration and jumps (Gilgien et al., 2014). However, such investigations were undertaken for male skiers only. The mechanics of female alpine skiers is largely unknown and therefore also their relation to injury risk. Therefore this study compares—for the first time—mechanical injury risk factors of a female World Cup alpine skier to a male World Cup alpine skier when skiing on the same SG course. Methods One male and one female skier with similar performance levels compared to the world best within their sex (male: 5.42 FIS points, ranked 26; female: 5.99 FIS points, ranked 30) skied 6 runs each on a SG race simulation. The skiers were equipped with a differential global navigation satellite system (dGNSS) tracking the skiers head trajectory at a frequency of 50Hz (Gilgien et al., 2015b). The snow surface of the course was captured by static dGNSS and a digital terrain model was reconstructed (Gilgien et al., 2015a). The digital terrain model in combination with a virtual pendulum model attached to the helmet trajectory was used to compute the center of mass position, speed, kinetic energy and the ground reaction force (GRF) (Gilgien et al., 2013). Finally, mean and standard deviation of the parameters for the runs within sex were computed. 1RM back squat strength as measured as a part of the athletes' normal test program. Results The male skier had a 5.0±0.6% higher mean speed compared to the female skier (28.9±0.1 vs 27.5±0.2 m/s), and as a consequence 9.7% higher kinetic energy on average. While mean GRF was similar (1.48±0.01 body weight (BW) and 1.42±0.01 BW for the male and female, respectively) while 1 RM back squat strength was substantially greater for the male skier (2.3 BW and 1.7 BW for the male and female athlete, respectively, a difference of 35%). Discussion When skiing in the same course male skiers might be able to compensate increased injury risk due to GRF and kinetic energy involved in crashes with superior physical strength. The decreased injury risk for female skiers might therefore be related to less dangerous characteristics of female courses. References Florenes, T. et al. (2009). *Br. **CONTACT INJURIES OF THE FEMALE FIELD HOCKEY PLAYERS**

Ozer, C.M.1, Gümüş, M.1, Kudak, H.H.1, Akalın, T.C.1, Ayoğlu, F.1, Açıkgöz, B.1, Yıldız, S.2, Çekin, R.3

*1: BEÜ (Zonguldak, Turkey), 2: GATA (Ankara, Turkey), 3: Amasya Üni (Amasya, Turkey)*

Introduction Field hockey is classified as a non-contact sport, however it is clear from literature review that most injuries occur by contact. Despite the old history of the sport, field hockey has only recently started to develop in Turkey. This is the first research about the field hockey injuries which take place especially due to contact. The aim of this study was to evaluate the types of contact injuries, number of occurrences, body parts injured, and contact mechanism of injury with positions of players. Methods 96 Turkish female field hockey players took part in this study and they filled an anonymous questionnaire including field hockey information (position, and playing experience) and contact injury history of players in the 2011-2012 season (numbers of contact injuries, type of injuries, contact mechanism of injuries and detailed body parts injured with positions of players). The statistical analysis was carried out using SPSS 11.0. software. Chi-square test was used to determine whether there were significant differences between selected variables. To determine the average risk of injury of the players according to their positions, average injury rate was calculated by the total number of injuries of players/according

to playing position number of players. Results The most common type of injury was contusion (50% of the total 382 contact injuries). Injuries caused by the contact of the ball are the main reasons of such injuries and they constitute 46% of the contact injuries. Besides, it was found out that the body part affected most commonly by contact injuries is the upper limb (48%). Defenders have the highest rate of contact injury as common as 41%. There were significant differences between types of injuries and mechanisms of the contact injuries ( $p=0,001$ ). Discussion As a result of, it was concluded that more protective clothes and equipment would make contact injuries less common and probably make field hockey more popular. The regular and systematic data collection about sport injuries will improve the prevention and control of these injuries.

### **PROTECTIVE EFFECT BY MAXIMAL ISOMETRIC CONTRACTIONS AGAINST MAXIMAL ECCENTRIC CONTRACTION-INDUCED MUSCLE DAMAGE OF THE KNEE EXTENSORS**

Tseng, K.W., Tseng, W.C., Lin, M.J., Chen, H.L., Nosaka, K., Chen, T.C.

*University of Taipei*

**Introduction** It has been reported that 30 maximal voluntary isometric contractions (MVIC) at a long muscle length (20° elbow flexion) that induced little changes in indirect muscle damage markers conferred potent protective effect against muscle damage after 30 maximal eccentric contractions (MaxEC) of the elbow flexors (EF) performed 3 weeks later [1]. However, no previous studies have examined whether the protective effect of MVIC is evident for other muscles such as the knee extensors (KE). Since KE are major muscles used in our daily activities, exercise and sports, it is important to determine whether the findings based on the EF are applicable for the KE. It may be that MVIC would not confer protective effect for KE. This study investigated whether 60 MVIC performed 2 weeks before 60 MaxEC would attenuate the magnitude of muscle damage of the KE. **Methods** Twenty-six untrained men ( $21.0 \pm 1.2$  y) were assigned to an experimental (EXP) and control (CONT) groups ( $n=13/\text{group}$ ). The subjects in the EXP group performed 6 sets of 10 MVIC at 90° knee flexion 2 weeks before 6 sets of 10 isokinetic (30°/s) MaxEC, but the subject in the CONT group performed MaxEC without MVIC. Maximal concentric strength (MVC-CON) of the KE, range of motion (ROM), upper thigh circumference, plasma creatine kinase activity and myoglobin concentration, muscle soreness (SOR) and echo intensity of B-mode ultrasound images were measured before, immediately after and 1-5 days after MVIC and MaxEC, and the changes in the variables after MaxEC were compared between the groups by a two-way repeated measures ANOVA. Results Significant but small changes ( $P<0.05$ ) in MVC-CON, ROM and CK were evident immediately to 2 days after MVIC, but they returned to the baseline by 3 days after MVIC. No significant differences in the baseline muscle damage markers were found before MaxEC between the groups. All variables changed significantly after MaxEC, but the changes were smaller and the recovery was faster for EXP than CONT group ( $P<0.05$ ). **Discussion** These results showed that MVIC of the KE conferred potent protective effect against muscle damage induced by MaxEC performed 2 weeks later. The magnitude of effect appears to be similar to that has been shown for the EF in the previous study [1], although the changes in the muscle damage markers were much smaller for KE than EF MaxEC. It is important that MVIC was effective for attenuating muscle damage induced by MaxEC, but further studies are necessary to investigate how MVIC produced the protective effect. **References** 1) Chen et al. (2012) *Med Sci Sports Sci*, 44, 2090-8.

### **REHABILITATION AFTER ACUTE HAMSTRING MUSCLE INJURIES AMONG ELITE SOCCER PLAYERS**

Haxhiu, B., Hundozi, H., Murtezani, A.

*University of Prishtina*

**Introduction:** Hamstring muscles injuries among professional soccer players represent a heterogeneous group of damages as far as type, dimension or precise anatomic region. Therefore, these factors can create difficulties during decision-making related to rehabilitation recommendations and healing prognosis. Degree of repeated injuries in soccer is very high and frequently is correlated to inadequate rehabilitation program or early return to training and active playing. The aim of this study was comparison of two rehabilitation programs after acute hamstrings muscles injury among elite Kosovo soccer players, based on necessary time for players to return to training and active playing, and injury recurrence within the first year of returning to sports. **Methods:** Our prospective study was carried out at the Physical and Rehabilitation Medicine Clinic and at the Sports and Recreation Center in Prishtina, for the period of 12 months. Thirty three soccer players with acute hamstrings muscle injuries confirmed with Magnetic Resonance Imaging are divided into two rehabilitation groups. Seventeen players have undergone through muscular traction rehabilitation program (MT) and electrotherapy (ET), whereas the other sixteen players have received flexibility and strengthening exercise program (FSE). All injured subjects are clinically examined twenty four hours after injury, which includes manual flexibility evaluation and muscular strength of the affected and non-affected extremities. Treatment efficiency validation was measured through the necessary days required for safe return to training and active playing. **Results:** Subjects treated with MT and ET had earlier rehabilitation, average 24.6 days ( $ISD \pm 15$ , rank 10.1 – 43.9 days) compared to subjects of the second group treated with FSE rehabilitation program, their return to training and active playing occurred 49.5 days post rehab ( $ISD \pm 15$ , rank 13 – 87 days). Significant difference was acquired,  $p<0.05$ . After 1 year of return to sports, reinjury rate was significantly greater ( $P = .00251$ , Fisher's exact test) in the MT and ET group, where 9 of 17 athletes (52.9%) suffered a recurrent hamstring strain after completing the stretching and strengthening program, as compared to none of the 16 athletes (0%) in the FSE group. **Discussion:** We conclude that MT and ET rehabilitation program is more effective compare to FSE rehabilitation program after hamstring muscle injuries among Kosovar professional soccer players and their safe return to training and active playing. A rehabilitation program consisting of progressive agility and trunk stabilization exercises is effective in promoting return to sports and in preventing injury recurrence in athletes who have sustained an acute hamstring strain. ### **CONCUSSION IN SCOTTISH MOTOR SPORT: AN INITIAL SURVEY OF AWARENESS AND PRACTICE**

Elliot, J., Richards, H., Turner, A.P.

*University of Glasgow and University of Edinburgh*

**INTRODUCTION** Guidelines about concussion in sport (McCrory et al. 2013) are not always known and used by practitioners and participants (White et al. 2014). Lateral and rotational forces that occur in motor sport present a risk of concussion and subsequent impairment of cognitive and physical performance could place competitors, spectators and officials at risk. Therefore, the aim of this study was to explore the occurrence, knowledge and awareness of symptoms, and management of concussion in Scottish motor sport. **METHODS** Scottish motor sport competitors ( $n=28$ ), officials ( $n=20$ ) and medical personnel ( $n=13$ ) completed an online survey regarding occurrence, knowledge and awareness of concussion. Mann-Whitney tests were used to compare groups' knowledge and symptom scores, estab-

lished using Likert scales. Where concussion had occurred participants were asked how it was managed, including open questions used to understand reasons for under-reporting. RESULTS Competitors (60.7%), officials (75%) and medics (100%) reported experiencing or observing concussion at least once at events. Medics reported significantly higher knowledge scores than officials ( $P=0.013$ ) and competitors ( $P=0.001$ ). There were no significant group differences in scores for recognition of concussion symptoms. Across all populations consistent knowledge-gaps included: lack of effectiveness of protective head-gear; longer recovery time required for younger people; and, increased risk of a second concussion. More competitors (75%), than officials (45% -  $P = 0.04$ ) and medics (39% -  $P = 0.013$ ) agreed that competitors could return to normal training/competition when symptom-free, in contrast to recommendations. 25% of competitors with concussion did not seek a medical review, for reasons including "not recognising concussion" and "wanted to race the next day". DISCUSSION This observational research highlights that concussion occurs in Scottish motor sport and that there is a lack of clear understanding about concussion and subsequent management in this environment. Areas of confusion are similar to reported in other sports (White et al 2014). Main areas to be addressed include education regarding staged return to training and competition (McCrory et al 2013) and dangers of competitors not reporting concussion and receiving medical attention. Research is needed to investigate the occurrence of concussion with a broader sample and using a range of methods, and to test the effectiveness of contrasting education strategies to raise awareness in practitioners and competitors (King et al 2014). ### OP-PM51 Training & Testing: Coordination

#### LOWER EXTREMITY CONTROL IN RESPONSE TO 8-WEEK ACL-INJURY PREVENTION TRAINING IN FEMALE ADOLESCENT ATHLETES

Ullrich, B., Pelzer, T., Wöhlken, K., Hartmann, U., Holzinger, S., Pfeiffer, M.

*Olympic Training and Testing Centre of Rheinland-Pfalz/Saarland*

**Introduction** Female adolescent athletes who perform in sports with jump-landing movements suffer anterior cruciate ligament (ACL) injuries at a 4- to 6-fold higher rate compared with males (Hewett, 2000). Impaired lower extremity control is regarded as a key contributor of ACL injuries. More specifically, reduced knee flexion, increased hip adduction, and impaired hamstring activation during landing tasks might enhance the ACL injury risk (Hewett, 2000). Few studies examined the influence of ACL-prevention regimens on lower extremity control in female athletes. **Methods** Twenty-one elite adolescent female track and field athletes (13.9 years, 51.4 kg) participated in either an 8-week ACL-injury prevention program with two weekly sessions ( $n = 11$ ) using jump-landing and stability tasks, rope strengthening of the hip abductors, and Nordic Hamstring exercises or a control group ( $n = 10$ ). Two times before, and after the training period vertical ground reaction force (VGRF), lower extremity 2-dimensional sagittal and frontal plane kinematics and surface EMG activity from the vastus lateralis, medial hamstrings, gastrocnemius lateralis, and tibialis anterior were analysed in the dominant leg during the stance phase of bipedal drop jumping (DJ-dropping height: 40 cm) for both groups. Therefore, a zebris-force plate, SIMI-high-speed videography (100 Hz) and a Noraxon-EMG system were used. VGRF and kinematics were sampled in 10%-intervals of individual stance phase duration. EMG amplitude values (% Max.) of each muscle were divided into three equal sub-phases of DJ stance phase duration. A two-factor ANOVA (time \* groups) with repeated measures was used to analyze temporal changes and between-group effects. **Results** No significant temporal changes in any outcome occurred in controls. Post training, the DJ stance phase was significantly ( $P < 0.05$ ) reduced. Furthermore, hip flexion/extension patterns were significantly shifted in the extension direction and significant shifts towards more abducted hip joint positions occurred post training. However, knee joint sagittal and frontal plane kinematics and all EMG patterns remained constant during the study. **Discussion** Specific ACL-injury prevention training enhanced DJ performance and hip joint stability, but did not change knee joint kinematics and EMG landing patterns. Lower limb EMG landing patterns in well-trained adolescent athletes may show limited plasticity after short-term interventions. **References** Hewett, TE. (2000). Sports Medicine, 29 (5), 313-327.

#### COMPARISON BETWEEN THE STATIC BALANCE OF PRACTITIONERS FROM DIFFERENT SPORTS AND NON-ATHLETES

Gateva, M.I, Gospodarski, N.I, Treneva, V.I, Avramov, D.2, Ivanov, N.I, Andonov, K.I

*National Sports Academy*

**Introduction** Compared to the vast number of publications concerning the balance in regards of the health aspect, balance as one of the main components of coordinative abilities has not been thoroughly investigated in the field of sport (Solan et al., 2007). Some sports require high level of balance to be developed. What is still interesting is what part of this ability is genetically determined and what depends on training and improvement. **Methods** 60 high level athletes from rowing, canoeing, rhythmic gymnastics, taekwondo and acrobatic gymnastics and 12 non-athletes were tested. All subjects were aged 13-14. Four tests, 30 seconds each, were performed on a force-platform: Test 1 – double leg stance with eyes open; Test 2 – double leg stance with eyes closed; Test 3 – single leg stance with eyes open and Test 4 – single leg stance with eyes closed. The parameters measured were average deviation of the centre of pressure (COP), the maximal deviation of COP and sway velocity. Descriptive statistics and ANOVA were used. **Results** The COP varied between 0,9 to 1,5 cm for Test 1 and Test 2. Significant differences between the groups and tests were not found. In test 3 values were between 1,3 to 2,8 cm deviation of COP and in test 4 values increase from 3,3 to 6,0 centimetres. **Results** from single leg stance with eyes open and eyes closed showed differences with the lowest results from the group of non-athletes and taekwondo and the best score of acrobat gymnast and kayakers. Maximal deviation of the COP showed significant difference in every test between the non-athletes (with lowest results) and all of the sport groups. Some differences between the sports were also observed. Better results were shown by the kayakers, rowers and rhythmic gymnasts compared to the acrobat and taekwondo athletes. The frequency analysis showed that rowers and kayakers (speed varied between 4,5 to 5,8 Hz) restore their balance quicker than the rest of the tested athletes and the non-athletes (0,7 to 2,4 Hz). **Discussion** We defined significantly greater difference in balance ability of the athletes aged 13-14 compared to the non-athlete children of the same age. An advantage in values was also detected in the athletes on small boats in the water, followed by the rhythmic gymnast, taekwondo athletes and acrobat gymnasts. Some studies (Hrysomallis, 2011; Bressel et al., 2007) also compared the level of balance of different sport competitors but found different results. **References** Bressel E, Yonker J, Kras J, Heath E. ### THE EFFECT OF MENTAL TRAINING ON MOTOR PERFORMANCE OF TENNIS AND FIELD HOCKEY STROKES IN NOVICE PLAYERS

Hegazy, K.1, Sherif, A.2, Houta, S.3

1: KIT (Karlsruhe, Germany), UA (Alexandria, Egypt) 2: UA (Alexandria, Egypt), 3: UA (Alexandria, Egypt)

**Introduction** Mental training techniques have been largely used by psychologists, coaches and athletes as a tool for improving learning and performance in sports (Hall & Fishburne, 2010). Forehand and backhand in tennis are the most common used in the field, similarly push pass and hit in field hockey. Therefore, the aim of this study was to examine the effects of mental training on learning ground strokes in tennis and field hockey. **Methods** 24 university students participated in the study. The experimental group received pre-test – mental training program – post-test. Students were taught tennis and field hockey strokes based on mental training, specifically relaxation, visualization and concentration-attention control. Measurements were conducted with the use of motor evaluation tests and questionnaires, once before the implementation of the program and once after the completion. **Results** Wilcoxon results revealed statistically significant differences between the initial and the final measurement for the performance ( $P=.004$ ) and the ability of concentration ( $P=.021$ ) for the forehand, backhand ( $P=.007$ ); ( $P=.033$ ) in tennis and push pass ( $P=.003$ ); ( $P=.008$ ) in field hockey. In addition a significant difference was found for the ability of concentration of the hit stroke ( $P=.005$ ) and similarly for the visualization in tennis and hockey ( $P=.003$ ); ( $P=.032$ ). However, no significant difference has been found regarding to the performance of the hit stroke. **Discussion** The results of the present study revealed that the use of mental training, combined with physical practice, contributes to the optimization of motor performance, which corroborates with the results found in previous studies (Jones & Stuth, 1997; Weinberg & Gould, 2014). Furthermore, researchers have shown that mental training is suitable for beginners as well as for performance optimization in intermediates and experts, also for children and youths for the optimization of precision and quality of movement (Immenroth et al., 2003; Mayer & Hermann, 2009). As a conclusion, a combination of mental and practical training promises the greatest improvement in performance and learning, because it involves all senses. **References** Hall, N., & Fishburne, G. ### GENDER AND PERFORMANCE LEVEL SPECIFIC DIFFERENCES IN BALANCE ABILITY OF ELITE AUSTRIAN ALPINE SKI RACERS

Raschner, C., Müller, L., Starker, T., Patterson, C., Hildebrandt, C.

*University Innsbruck*

**Introduction** The relationship between balance ability (BA) and injury risk has been established in many sports, but the relationship between BA and performance level is less clear (Hrysomallis, 2011). In alpine ski racing a high level of BA is fundamental. Consequently, tests analyzing BA of alpine ski racers are performed (Raschner et al., 2013). The aim of the study was to analyze gender and performance level specific differences in BA of elite Austrian ski racers. **Methods** 109 female ski racers (F-SR) [50 Junior team (F-JT), 30 European Cup (F-EC), 29 World Cup (F-WC)] and 115 male ski racers (M-SR) [55 Junior team (M-JT), 40 European Cup (M-EC), 20 World Cup (M-WC)] underwent two tests on the Biodex Stability System. The first test measured the athlete's ability to maintain postural stability (index) on the unstable tilting platform on one leg (oL-T). The objective of the second test, performed on both feet, was to move the cursor into nine blinking boxes as fast as possible (time in seconds), through tilting the platform (dL-T). Gender specific differences were calculated with the Welch-test. An ANOVA with Scheffe post-hoc-tests analyzed differences in BA between the performance levels of Junior, European Cup and World Cup teams. A criterion of  $p \leq 0.05$  defined significance. **Results** F-SR performed significantly better in oL-T Index [F-SR: 2.1 (95% CI: 2.0-2.6); M-SR: 3.2 (95% CI: 3.0-3.5)] and dL-T time [F-SR: 77s (95% CI: 75-79); M-SR: 88s (95% CI: 85-91)] compared to the M-SR. ANOVA indicated significant differences in oL-T and dL-T between female performance levels. Post-hoc-tests showed that both F-WC and M-WC as well as F-EC and M-EC performed significantly better than F-JT and M-JT. There were not any significant differences in BA between World Cup and European Cup teams in both genders. **Discussion** Ski racing requires perfect technical skills and a high level of physical fitness. Unexpected changes in terrain and high speeds challenge the athlete's balance; hence, it should be trained and tested. As expected, elite female athletes showed a better BA than elite male athletes. Furthermore, racing and training experience explain the enhanced BA of the F-SR and M-SR who were qualified for World and European Cup teams. An important aspect was analyzed by Noe et al. (2009), who showed that the mechanical effects of wearing ski-boots during balance tests of ski racers were compensated by changes in postural strategy through the reorganization of muscle coordination. **References** Hrysomallis C. ### BALANCE: SET OF SPECIFIC SKILLS OR GENERAL ABILITY?

Kramer, A., Gruber, M., Giboin, L.

*University of Konstanz*

**Purpose:** Although there are many studies exploring the mechanisms of postural control and the adaptations in response to balance training, it is still under debate whether balance is a set of specific skills or a general ability, and consequently whether balance training leads to task-specific rather than general non-specific adaptations. To shed light on this issue, we devised the following experiment. **Methods:** Forty participants were assigned to one of two training groups or a control group. One training group completed six sessions on one balance training device, the other training group trained for the same time on a different balance training device. Before and after the training, they performed tests on both devices and had to perform two additional balance tasks on these devices but with a different direction of perturbation. **Results:** Analyses of variance showed that the training groups outperformed the other groups only in the task they had trained (significant group x time interaction effects,  $p < 0.001$ ). This means that there was no transfer even to very similar tasks. **Conclusions:** We conclude that training a balance task has mostly specific rather than general effects. Thus, we propose to view balance rather as a set of specific skills. Therefore, the selection of balance exercises should be executed with great care, regardless of whether

this is in studies exploring the underlying physiological mechanisms of postural control or balance adaptations, in studies quantifying the effects of balance training or when issuing recommendations for rehabilitation or fall prevention training regimens.

#### APPLICATION OF HYPOXIC TRAINING IN TECHNICAL SPORTS.

Zelenkova, I.I, Zotkin, S.I, Korneev, P.I, Koprov, S.I, Almiyashev, D.I, Grushin, A.I

1: *Russian Olympic committee innovation center (Moscow, Russia).*

Currently altitude/hypoxic training is used by elite endurance athletes in summer and winter sports in year-round training plan. Nevertheless there is not widespread use of altitude/hypoxic training in technical sports which is also demanding in multifaceted cognitive and physical abilities. The main characteristic of professional drivers is the reaction time. Also fatigue related crashes due to safety errors are common in professional drivers, furthermore if the competition are carried out in altitude the reaction time is slowing down in a dose-dependent manner. The aim of the present study was to investigate the influence of altitude/hypoxic training in cognitive and physical abilities of professional truck drivers. Twelve male athletes (177 (175.7-182)cm, 82.4 (75.4-85.6)kg, body mass index 25.4 (24.6-26.78)kg/m<sup>2</sup>, 32.5(29-39.5) years) members of the Russian truck team participated in the study. Before and after the hypoxic program each subject underwent body mass composition analysis (InBody), determination of total hemoglobin mass (tHb-mass) using optimized CO-rebreathing method (Bloodtec spirometer, ABL80 FLEX CO-OX analyzer), hemoglobin (Hb) and ferritin (Fe) concentration (from capillary blood, BTS-350). Incremental test for anaerobic threshold determination (Biosen C-Line lactate analyzer) on a stationary cycle ergometer (Ergoselect 200) in hypoxic (at 4000 m; Hypoxico Everest Summit II) and normoxic conditions with the determination of reaction time (Fitflight trainer) were performed. During 21 days each subject participated in "Live high – train low and high" hypoxic program. For rating sample characteristics, median and interquartile dispersion was used. Non-parametric Wilcoxon tests were applied for referencing bound samples. Significance level P was rated at 0.05. Prior the program the significant decrease in visual reaction time in hypoxia 12,7% was found in drivers (P<0.01) and 23,5% decrease in power output on anaerobic threshold (P<0.01) comparing with normoxia. After the program a significant increase in muscle mass weight (P<0.01), decrease in fat weight (P<0.01), significant decrease in time of reaction in hypoxic (P<0.01) and normoxic (P<0.05) condition and increase in power output in incremental test in hypoxic (P<0.01) and normoxic (P<0.01) were found. The difference in time of visual reaction between hypoxia and normoxia after the program was 2,1% and wasn't significant. There was no significant difference in absolute values of tHb-mass, blood volume and Hb concentration but there was significant increase in reliable tHb-mass (P<0.01) and blood volume (P<0.05). The increase of visual-motor response in technical sports can provide the "competitive edge" to succeed at high level events, mostly, if competitions are carried out at altitude and probably decrease fatigue related safety errors.

## Oral presentations

### OP-BN06 Muscle function

#### FREQUENCY OF REGULAR EXERCISE AFFECTS THE TIME UNTIL CHANGE IN MUSCLE VISCOELASTICITY DURING STATIC STRETCHING

Okamura, N., Tsukune, M., Kobayashi, Y., Fujie, M.G.

*Waseda University*

**INTRODUCTION** Static stretching is used to decrease muscle tone. However, the optimal length of time to hold a stretch is unclear, since continuous measurement of muscle tone during static stretching is difficult. We previously described a new method for evaluating muscle tone using a spring-pot viscoelastic model, and demonstrated a change in viscoelastic ratio during 1 min of static stretching (1). In this study, we used this method to investigate the time required to change muscle viscoelasticity in people with different exercise habits. **METHODS** Nine healthy university students aged 20-22 yr (8 males, 1 female) participated in this study. Participants were divided into three groups (n = 3/group) based on their regular exercise frequency: (A) more than once per week, (B) more than once per month, and (C) less than once per month. To measure muscle viscoelasticity, a semispherical indenter tip including a force sensor was fixed to the skin over the center of rectus femoris with an inextensible band. Each subject did 1 min of static stretching using arbitrary strength and we measured the reaction force at the indenter. Using this method, the viscoelastic ratio appears as the slope of the reaction force model. We calculated the time until change in viscoelasticity by plotting slope versus time during static stretching. **RESULTS** On the slope versus time graph, there was a negative peak when the muscle viscoelasticity changed and a positive peak when the subject bent their leg to begin stretching. We calculated the time between the two peaks, and the mean values and standard errors of the time until change in viscoelasticity were (A) 23 ± 2.5 sec, (B) 25 ± 1.8 sec, (C) 34 ± 2.1 sec. **DISCUSSION** The time required to change muscle viscoelasticity by static stretching tended to increase with a decrease in the frequency of regular exercise. When muscle is stretched for a prolonged period, stretch receptors react and cause Ib inhibition that allows muscle tone to decrease (2). More frequent exercise may enhance stretch receptor sensitivity and affect the time needed to change muscle viscoelasticity. When measurements were taken from the opposite leg of the same person, the intraindividual standard deviation of most subjects was less than that of each group. This suggests that muscles in similar condition such as fatigue degree need similar amounts of time to be affected by static stretching. Therefore, the time spent stretching should be changed as muscle condition changes. Future studies will investigate the effects of intraindividual changes in exercise habit and difference in target muscles. **REFERENCES** (1) Okamura, N. et al. (2014). #### ACUTE EFFECTS OF MUSCLE LENGTH DURING THE CONTRACTION PHASE OF CONTRACT-RELAX STRETCHING ON MUSCLE-TENDON MECHANICS

Kay, A.I, Dods, S.I, Blazeovich, A.2

1: *UoN (Northampton, UK), 2: ECU (Perth, Australia)*

**Introduction:** Proprioceptive neuromuscular facilitation (PNF) stretching frequently results in the greatest increases in range of motion (ROM), with contract-relax (CR) being a common variant of the PNF technique. However, despite its efficacy to increase ROM, the underlying mechanisms are poorly understood; furthermore the contractions performed in a highly stretched position during CR stretching can

be painful and induce muscle tissue damage, thus its use is somewhat limited in athletic environments. Therefore, the acute effects of CR stretching and a modified CR (MCR) stretching technique (with the contraction phase performed 'off stretch') were studied in 14 healthy human volunteers. Methods: Passive ankle joint moment and dorsiflexion ROM were recorded on an isokinetic dynamometer with electromyographic (EMG) monitoring of the triceps surae, whilst simultaneous real-time motion analysis and ultrasound imaging recorded gastrocnemius medialis muscle and Achilles tendon elongation. The subjects then performed either CR (4 x 10 s stretches + 5 s contractions) or MCR stretches randomly on separate days before reassessment. Results: Significant increases in dorsiflexion ROM (4.0-4.1°;  $P < 0.01$ ) and decreases in the slope of the passive moment curve (13.3-19.1%;  $P < 0.01$ ), muscle stiffness (21.3-21.7%;  $P < 0.01$ ) and tendon stiffness (15.7-20.4%;  $P < 0.01$ ) were observed in both conditions. A significant increase in peak passive moment (stretch tolerance) occurred after MCR (8.8%;  $P < 0.05$ ) with a similar mean increase after CR (8.9%;  $P = 0.053$ ); significant correlations ( $r = 0.70-0.75$ ;  $P < 0.01$ ) were observed between the changes in peak passive moment and ROM. No differences in between-condition changes were found in any measure ( $P > 0.05$ ). Conclusion: Similar mechanical and neurological changes were observed between conditions, indicating that identical mechanisms explain the analogous ROM improvements, regardless of muscle length during the contraction phase. Importantly, performing the contractions 'off stretch' removes the need for partner assistance, and reduces the potential for microtrauma, likely minimising the risk of inducing muscle strain injury. Thus, the modified CR stretching technique represents an equally effective, simpler, and yet potentially safer, stretching paradigm. Contact: tony.kay@northampton.ac.uk

### COMPUTED PASSIVE TENSILE TEST TO FAILURE OF THE MUSCLE-TENDON COMPLEXE USING A DISCRETE ELEMENT MODEL

Roux, A., Lecompte, J., Iordanoff, I., Laporte, S.

*Arts et Metiers ParisTech*

**Introduction** Muscle tears are common sports-related injuries, the majority of which occur whilst eccentric exercises when muscle contraction is combined with excessive stretching (Uchiyama et al., 2011, Pétillon et al., 2005). A clear understanding of the mechanical conditions that cause the muscle-tendon complex (MTC) to fail as well as structures involved are required to prevent the risk of tear and/or improve rehabilitation specificity (Uchiyama et al., 2011). New numerical approach using discrete element method (DEM) could be the most appropriated to take the architecture and the complex behavior of MTC into account. The aim of this study was therefore to first model and then investigate mechanical elongation response of MTC until rupture. Methods Numerical model was complete in DEM using GranOO software ([www.granoo.org](http://www.granoo.org)). Mechanical properties of MTC were based on literature values (Matschke et al., 2013, Regev et al., 2011). Fibers were built with spherical discrete elements linked with springs (stiffness was related to elastic modulus (EM) (EM=37.44 kPa). The extracellular matrix was computed using springs between fibers. Tendon's fibers were built with respect to muscle fibers architecture (EM=800 MPa). The myotendinous junction (MTJ) was represented by multi-links between tendon and muscle. MTC stress-strain relationship was fitted during a computed tensile test. MTC was fixed on its lower extremity and the upper extremity was subjected to a linear displacement. Elongation was chosen as rupture's criterion, i.e. when spring's lengths overreach 30% of strain (Noonan et al., 1994). Results and Discussion The computed stress-strain relationships display a classical hyper-elastic shape in agreement with in vitro experimental data of Gras et al. (2012). The use of linear springs, added to the MTC's structural effect, leads to a hyper-elastic behavior for the MTC's response in tensile test. Values of mechanical properties of extracellular matrix (EM=100 kPa) and MTJ (EM=400MPa) had to be adjusted in order to fit with experimental data due to the lack of data in the literature. As attending, rupture appeared at the MTJ (Pétillon et al., 2005). MTJ was at the interface between the stiff tendon and the soft muscle, leading to a stress concentration. MTC was broken by fibers' delamination, in agreement with in vitro data (Ilaslan et al., 2007). Conclusion DEM seems to be a promising method to model the hyper-elastic macroscopic response of MTC and investigate the rupture. In order to model MTC's tear, muscle's contraction will be implemented. References Gras et al. (2012). *J Mech Behav Biomed Mater* 15,131-140 Ilaslan et al. ### LATERALITY OF THE MORPHOLOGICAL PROPERTIES OF THE VASTUS LATERALIS MUSCLE IN NON-UNILATERAL SPORT ACTIVITIES

Marzilger, R.1, Bohm, S.1, Schroll, A.1, Legerlotz, K.1, Arampatzis, A.1

*1: HU (Berlin, Germany)*

**Introduction** Vastus lateralis (VL) morphological properties like muscle fascicle length (FL) and cross-sectional area (CSA) have been shown to differ between athletes and non-active persons (Kearns et al., 2000; Abe et al., 2000). In unilateral sport events (e.g. soccer) a leg specific hypertrophy has been reported (Kearns et al. 2001) resulting in an asymmetric morphology between dominant (DL) and non-dominant leg (NDL). Most studies investigating morphological muscle properties focused only on one leg, assuming muscle symmetry between both legs. Therefore the purpose of the present study was to compare the morphological properties (i.e. FL and CSA) of the VL muscle between the DL and NDL of persons involved in non-unilateral sports (2-5h sport/week). Methods The FL and the CSA of the VL muscle of both legs were measured in 18 participants. To determine the VL FL, the participants were seated in a dynamometer (Biodex) and their knee joint was passively moved from 0°-100° with 10°/s while the FL was captured with a 10cm ultrasound probe (Esaote) at the mid portion of the muscle belly. The VL FL was calculated from the captured ultrasound videos with a self-developed semi-automated tracking algorithm. To determine the VL CSA, magnetic resonance images (Turbo 3D T1, TE=16ms, TR=39ms, slice thickness 3.1mm, no gaps between slices) of the thigh were obtained and the transversal pictures were then manually analyzed in Osirix (Pixmeo SARL). For statistical analysis the maximum CSA of both legs was evaluated and the FL of DL and NDL was compared every 5° from 20° to 80° of knee joint angle. Results The average CSA of the DL and NDL were 32.7±4.0cm<sup>2</sup> and 32.5±4.6cm<sup>2</sup> respectively. The average fascicle length ranged from 101.9±13.1mm (20° knee joint angle) to 131.2±16.0mm (80°) in the DL and from 103.8±12.2mm (20°) to 134.6±14.5mm (80°) in the NDL. There were no statistically significant differences between the DL and NDL, neither in FL nor in CSA. Discussion The results show that in moderately active persons that are not involved in unilateral sports, the FL and the CSA of the VL do not differ between the DL and NDL. These findings indicate that moderate non-unilateral sports activities do not lead to side asymmetries in morphological properties of the VL. We conclude that the examination of the VL muscle from one leg would be enough in cross-sectional studies investigating the morphological properties of the VL between groups without specific unilateral mechanical loading. **DIFFERENTIAL TENDINOUS TISSUE ADAPTATIONS AFTER CONVENTIONAL VS. EXPLOSIVE STRENGTH TRAINING**

Massey, G.J.1,2, Balshaw, T.G.1,2, Maden-Wilkinson, T.M.2, Tillin, N.A.3, Folland, J.P.1,2

1: Arthritis Research UK, Centre for Sport, Exercise and Osteoarthritis, 2: Loughborough University, UK, 3: University of Roehampton, UK

**Introduction** Conventional strength training, with an emphasis on sustained high loads, increases muscle tendinous-tissue (aponeurosis and tendon) unit (MTU) stiffness, with some evidence for modest tendon hypertrophy. Explosive training, with an emphasis on rapid force development, may elicit similar changes in MTU mechanical stiffness in a substantially shorter period of time (Tillin et al., 2012). However the efficacy of explosive training to elicit tissue adaptation requires a direct, detailed comparison. This study aimed to assess the mechanical adaptations of the MTU (stiffness) and patellar tendon (stiffness, young's modulus) to conventional and explosive strength training, as well as the changes in tendon cross-sectional area and thus hypertrophy. **Methods** Following familiarisation, young healthy untrained males were matched for maximal voluntary force (MVF) and randomised to 12 wks (3 x per wk, 4 sets, 10 reps) of either maximal (MST, n =10: 1 rep = 1-s up to ~75% MVF, hold ~3-s, rest 2-s) or explosive (EXP, n = 11: 1 rep = fast and hard [>80% MVF] ~1s, rest 5-s) isometric knee extension strength training. Simultaneous force and ultrasound recordings of both vastus lateralis aponeurosis and patellar tendon elongation during constant loading-rate ramp contractions were used to derive MTU and PT stiffness respectively, at a common tendon force level. Mean tendon cross-sectional area was measured from magnetic resonance images (Pre and Post). Tendon stress was calculated and young's modulus estimated over a common stress range. Time [pre-post] x group [MST-EXP] interaction effects were assessed with two-way ANOVA. Results MTU stiffness increased after MST (pre 561 ± 101 vs. post 732 ± 217 N.mm; +30.9%, P = 0.014), but not after EXP (pre 579 ± 105 vs. post 588 ± 86 N.mm; +4%, P = 0.772), resulting in an interaction effect (ANOVA, P=0.02). After both types of training PT stiffness (MST, +22.1%, EXP +20.5%; ANOVA, P=0.888) and young's modulus (MST, +14.5%, EXP, +20.5%; ANOVA, P=0.359) increased similarly. No tendon hypertrophy was observed in either group. **Discussion** Our data indicate that conventional strength training induced a more pronounced increase in MTU stiffness than explosive training. In contrast both interventions elicited equivalent increases in tendon stiffness and young's modulus. These results suggest a differential adaptive response of the tissue components within the MTU (muscle-aponeurosis vs tendon) according to the strength training regime. **References** Tillin NA, Pain MTG, Folland JP. **Oral presentations****OP-SH20 Philosophy & Ethics II****HUMAN PRACTISING - TOWARDS AN ASCETOLOGICAL UNDERSTANDING OF SPORT**

Aggerholm, K.

*University of Southern Denmark*

Within the philosophy of sport the phenomenon of practicing (asceticism) has received very little attention, whereas other related aspects of sport such as excellence (aretism) and competition (agonism) have been subjected to many and thorough studies. Departing from my own studies on talent development in sport (Aggerholm, 2015) and drawing on anthropological and philosophical accounts of practising (Foucault, 2005; Sloterdijk, 2009), I will attempt to clarify this particular phenomenon and interrogate the potential relevance of it for the sport sciences by highlighting central aspects such as repetition, verticality and effort. I will in particular use it to challenge existing accounts of sport within the philosophy of sport, e.g. formalism, conventionalism and internalism, to suggest that human practising can inform a supplemental ascetological account of sport. **References:** Aggerholm, K. 2015. *Talent Development, Existential Philosophy and Sport: On Becoming an Elite Athlete*. **THE AESTHETIC EXPERIENCE IN THE COMBAT SPORTS: A STUDY IN TAEKWONDO**

Coelho, R.C.1, Kreft, L.2, Lacerda, T.3

1: CEFET/RJ (Rio de Janeiro, Brasil), 2: UNI-LJ (Ljubljana, Slovenia), 3: FADEUP (Porto, Portugal)

**Introduction** The investigation on sport's aesthetic experience is still limited, especially regarding the athlete's point of view. The aim of this study was to understand the aesthetic experience lived by senior athletes from Taekwondo Portuguese National Team, in poomsae and combat practice, focusing on reveal the elements which may contribute to the enlargement of the knowledge in this domain. This study started from the literature on general aesthetic, sport aesthetic, and Taekwondo, considering the peculiarities and personal experience of the object. **Methods** The research of qualitative nature, with a phenomenological approach, had an exploratory and a descriptive character. The speech of twenty- two athletes was collected in semi-structured interviews. The information was treated through content analysis of the athletes' speech. **Results** For the poomsae athletes was manifest that the elements, technique, tactical/game, affection/taste, aggressiveness, transcendence/overcoming and kihap (yell), are significant to an understanding of the aesthetic experience of these individuals. In relation to the combat athletes was observed that the elements, technical, tactical/game, affection/taste, aggressiveness, risk, transcendence/overcoming, victory and kihap, were found to be the most significant for the understanding of aesthetic experience in this context. **Discussion** From the analysis and interpretation of this information, it was concluded that the athlete of Taekwondo, in search for the perfect techniques and tactics execution, with the constant support of his/her fellows, adopting an aggressive/assertive posture, surpassing risky situations, and in some moments externalizing his/her inner energy through kihap, overcoming limits, winning, is able to live harmonious, beautiful, ludic, affective experiences, that is, aesthetic experiences. **References** Iseminger, G. ## USING TRADITIONAL GAMES TO PROMOTE SUSTAINABILITY & PEACE IN THE ARCTIC

Killbourne, J.

*Grand Valley State University*

With climate change expanding trade routes in the Arctic and the resultant pursuit of oil, gas, mineral deposits, and fish, it is imperative that the eight Arctic countries find paths towards sustainability and peace in the region. Revisiting and understanding the traditional games of the indigenous people of these regions can go a long way towards helping those determining the region's future to work cooperatively towards these goals. Throughout history the games we have played have been a testament about who we were, and are. From early Inuit bone and hunting games, to the gladiator contests of Ancient Rome, to the modern American game of baseball, the games we play have served as a statement of and a rehearsal for the life-world of that period and place. By reconnecting with and understanding the games of our past, we can build meaningful bridges between our past and present, and hopefully gain a better understanding of our modern world. The aforesaid are timely and important, especially as they relate to indigenous people throughout the world who are trying to preserve their traditions in a fast changing modern world. Israel Ruong (1953) called the preservation of indigenous Sámi traditions, "active adaptation." He said, "Active adaptation means that Sámi cannot alone and without criticism adopt modern culture, casting aside their culture's irreplaceable values, but that they hold fast to their cultural traditions in the new conditions (Ruong cited in Lehtola, 2004: p. 60). This presentation/paper will be divided into two parts. The first part will provide a discussion on the importance of play and games. Section two will offer, based on my research and experiences in the Arctic, lessons learned from traditional Arctic games that may help promote sustainability and peace in the Arctic world. Hopefully by acknowledging these lessons we can pursue a path forward, together reconnecting with the traditional games of the Arctic with the hope of building meaningful bridges between the past and present and moreover, helping to enhance our understanding of the important role traditional games can play in shaping an Arctic where sustainability and peace flourish. ## A STUDY OF "UNIVERSAL SPORTS": THROUGH THE PHENOMENOLOGICAL PERSPECTIVE IN RELATION TO VARIETIES OF HUMAN BODIES

Tanaka, A.

*Musashi University*

Introduction It is essential for modern sports to be competitive to ensure improvements in the skills and training practices of athletes. If competition escalates further, however, there will be problems such as violence, doping and the forced manipulation of persons (Eichberg H (2010)). In addition, weaker players tend to be excluded from sports competitions by the 'win at all costs'. To enable a greater number of people to become attracted to sports and grasp its essence, it is necessary to consider and embody the idea of "universal sports" so that more people can be included. Therefore, the purpose of this presentation is to examine and clarify the concept of "universal sports" through the phenomenological perspective in relation to varieties of human bodies. Procedure of consideration I use the term "Universal sports" to mean inclusive sports related to the diversity of player's bodies. It refers to the opportunity for people with physical strength or potential as well as people with limited physical strength or advanced age to participate. In competitive sports for disabled people, issues of categorization are considered to be significant (Francis, 2005). From an educational viewpoint especially in Japan, simple and easy games are often proposed as teaching materials at school. However, "universal sports" are not typically realized from those games because such activities generally lack interest, a sense of achievement, and growth. Players would find it difficult to enjoy such games. Thus, it would be helpful to define "universal sports", which requires the following discussions: 1) What are the barriers to embodying the idea of "universal sports"? 2) What are the varieties of human body? 3) Are there ways to achieve universality? Discussion Based on the examination of the above questions, the idea of universality can be clarified by some inclusive sports cases. For example, sitting volleyball enables the disabled and the healthy to participate together (Tanaka, 2010). The conclusion is as follows: although the idea of universal sports is to relativize the physical gap in sports abilities of people, it must also promote personal growth through improving movement skills and engaging in appropriate training. It should contain new type of movements and pliable rules so that anyone can change aspects of his/her body by practicing sports movements. ## BASKETBALL WAS INTRODUCED TO JAPAN AT FIRST AS A SPORT FOR WOMEN RATHER THAN FOR MEN

Kakiyama, T.

*Fukuoka University*

Introduction In Japan, the first person who introduced the basketball to Japan is generally believed to be Mr. Hyozo Omori, who graduated from the International YMCA Training School in 1908 and went on to become Sports Director at Tokyo YMCA. This commonly accepted view has also been adopted by the International Basketball Federation (FIBA). However, in a photograph taken in 1902 in the outdoor playing field at Nagasaki Kwassui girl's school, I found a basketball goal behind the schoolgirls who were practicing a new style of gymnastics. The purpose of this study is to determine whether or not basketball had been played in Nagasaki Kwassui girl's school before Mr. Hyozo Omori introduced the sport for the first time in 1908. Methods I visited Springfield College (The birthplace of basketball) to identify the basketball goal of Nagasaki Kwassui girl's school, and extracted a description about the revisions rules for the basketball goal by tracing Amateur Athletic Union (AAU) Official Basket Ball Rules housed at the Archives Center, Springfield College. Results Ms. Mariana Young introduced American-style physical education at Nagasaki Kwassui girl's School. They used wooden circles, sticks and dumbbells, and every word of command was spoken in English in tune with the music by training Japanese women as physical education instructors. In the meantime, looking specifically at the revisions of the rules for the basketball goal by tracing AAU Official Basket Ball Rules housed at the Archives Center, Springfield College, the birthplace of basketball, all they had in the year 1895-96 was the basket, and then in the year 1896-97 and after, a wire mesh called a SCREEN was placed behind each basket as was also shown in the court plan. It was also revealed that the currently used flat-board-style backboard was first adopted in the 1904-05 rules. By magnifying and observing the picture of a basketball goal installed at the outdoor playing field of Nagasaki Kwassui girl's school, it was confirmed that wire mesh was fitted onto a wooden frame. Thus, the basketball goal of Nagasaki Kwassui girl's school that had been photographed in 1902 was identified as a SCREEN before the backboard was adopted. Discussion The possibility has been suggested that basketball was

introduced by Ms. Young at Nagasaki Kwassui girl's school before the time when, according to the accepted view, Mr. Hyozo Omori was said to have introduced the sport to Japan for the first time (i.e. 1908), and hence it seemed likely that basketball was introduced to Japan at first as a sport for women rather than for men. #### **COMPARISON OF COLD COMPRESSION THERAPY WITH OTHER RECOVERY METHODS IN ELITE JUNIOR CYCLIST IN HEAT**

Chan, Y.

*Hong Kong Sports Institute*

**INTRODUCTION** Cryotherapy is one of the recovery methods commonly used after sporting events. Cold water immersion (CWI) is a common and effective form of cryotherapy, by inducing vasoconstriction, stimulate venous return, aid metabolite removal after exercise, reduce swelling and muscle soreness (Bleakley et al., 2010; Vaile et al., 2008; Vaile et al., 2011). However, CWI may not be possible without large amount of ice and pool. Cold compression therapy (CCT) can be simply implemented by applying a cold compression wrap on an injury or major exercised muscles. Little scientific evidence exists yet to proof its effectiveness. **METHODS** Eight elite male junior cyclist (mean age 15.5, height 167.7cm, body mass 57.3kg, peak oxygen uptake 64.7ml/kg/min) completed a maximal cycling test to determine their peak power output (PPO) and oxygen uptake. Subjects then completed 3 tests on separated days with randomized recovery strategies of CWI, CCT and active recovery (ACT) for 15 mins at 31.4C and 74% relative humidity. Each test consists of two 35-min exercise bouts. Each exercise bout included 5 mins warm up, followed by 15 minutes 75% PPO and 15 mins maximal effort time trial. There was 55 mins rest between two exercise bouts, which included 5-min active cool down, 10-min treatment preparation, 15-min randomized recovery strategy and 30-min passive recovery in heat. **RESULTS** No significant differences were observed between average power output, blood lactate, rating of perceived exertion and heart rate for all recovery strategies. However, core temperature decreased significantly before the start of the second exercise bout for CWI. The core temperature also coincides with the mean thermal sensation scale, ranges from 0 (unbearably cold) to 8 (unbearably hot), during recovery strategies for CWI, CCT and ACT (2.64, 3.25 and 4.31 respectively). **DISCUSSION** The current findings suggest that all CCT, CWI, ACT are useful recovery strategies to allow athletes preparing for the next training bouts. CWI may cause thermal discomfort and lower the core temperature to below pre-exercise values; active recovery causes progressive glycogen in muscle fibers (Stamford et al., 1981); while CCT needs special equipment. To find the best recovery strategy, athletes' preferences, duration of exercise, facilities available and rest duration should all be taken into account. **REFERENCES** Bleakley CM, Davison GW. #### **INCREASED PAIN PRESSURE THRESHOLD FOLLOWING ROLLING MASSAGE MAY BE, IN PART, DUE TO CENTRAL NERVOUS SYSTEM MODULATION OF PERCEIVED PAIN.**

Behm, D.

*Memorial University of Newfoundland*

Self-massage using roller massagers are often used to promote soft-tissue extensibility and optimal muscle functioning, subsequently reducing pain. However, the underlying mechanisms for pain reduction following self-massage is not fully understood. The aim of the present study was to quantify and compare the acute effect of rolling massage and manual deep tissue massage on pressure pain threshold (PPT) in individuals with tender spots in their plantar flexor muscles. In a randomized control trial study, tender spots were identified in 150 participants' plantar flexor muscles (gastrocnemius or soleus). Then participants were randomly assigned to one of five intervention groups (n = 30): 1) heavy rolling massage on the calf that exhibited the higher tenderness (Ipsi-R), 2) heavy rolling massage on the contralateral calf (Con-R), 3) light stroking of the skin with roller massager on the calf that exhibited the higher tenderness (SHAM), 4) manual massage on the calf that exhibited the higher tenderness (Ipsi-M) and 5) no intervention (Control). PPT was measured 30s (75 participants) and 15 minutes post-intervention (75 participants) via a pressure algometer. At 30s post-intervention, the Ipsi-R (24%, p=0.006) and Con-R (21%, p=0.02) demonstrated higher PPT values compared with Control and SHAM while Ipsi-M showed higher values than SHAM (31.27%, p<0.001). At 15 minutes post-intervention, PPT was higher following Ipsi-R (19.2%, p<0.001), Con-R (15.9%, p=0.002) and Ipsi-M (10.9%, p=0.05) compared with Control. With all groups combined, PPT declined at 15 minutes post-intervention compared to 30s post-intervention (12.3%, p=0.03). There was no difference between the effects of three deep tissue massages (Ipsi-R, Ipsi-M and Con-R) on PPT. Whereas the increased PPT following ipsilateral massage (Ipsi-R and Ipsi-M) may be attributed to the release of fibrous adhesions; the non-localized effect of rolling massage on the contralateral limb suggests that other mechanisms such as a central pain-modulatory system play a role in mediation of perceived pain following brief tissue massage.

#### **EFFECTS OF HALLIWICK TECHNIQUE ON PHYSICAL FITNESS OF CHILDREN WITH SPASTIC CEREBRAL PALSY IN SCHOOL AGE**

Xiaohui, H., Min, H., Xiaodong, Y., Yu, W., Yonghui, F.

*Guangzhou Sport University*

**Purpose:** To discuss the hydrokinesitherapy for the school-aged cerebral palsy and explore the suitable hydrokinesitherapy method for school-aged children with cerebral palsy by observing the effect of Halliwick technique on physical fitness. **Method:** Twenty-four spastic cerebral palsy children of Guangzhou Cerebral Palsy Rehabilitation School were selected as subjects. These subjects were divided into

the control group (regular rehabilitation therapy, n=12) and the experimental group (regular rehabilitation plus swimming training, n=12). The physical fitness of the subjects was assessed before and after the treatment. Results: Half of experiment group can swimming 50-100m independently after 4 months training. Lung's capacity, sit and reach of swimming group were significant higher after treatment than before ( $P < 0.05$ ). The control group's were no significant difference at the same time ( $P > 0.05$ ). There was no significant difference of BMI, sit and reach between two groups after treatment ( $P > 0.05$ ), except lung's capacity of swimming group was significant higher than the control group ( $P < 0.05$ ). Conclusion: Halliwick technical is an effective method to guide swimming training for school-aged children with cerebral palsy. Swimming can effectively enhance the flexibility and respiratory capacity and it could be an effective method for school-aged children with cerebral palsy to achieve life-long sport and rehabilitation. Keywords: Hydrokinesitherapy; Halliwick technique; Spastic cerebral palsy; Physical fitness

#### EFFECTS OF CONVENTIONAL RESISTANCE TRAINING AND RESISTANCE TRAINING WITH INSTABILITY ON PHYSIOLOGICAL RESPONSES TO MAXIMAL CARDIOPULMONARY EXERCISE TEST IN PATIENTS WITH PARKINSON'S DISEASE

Kanegusuku, H., Silva-Batista, C., Peçanha, T., Costa, L.A.R., Silva Jr, N.D., Miyasato, R.S., Mello, M.T., Piemonte, M.E.P., Ugrinowitsch, C., Forjaz, C.L.M.

1.University of São Paulo / 2.Federal University of São Paulo

Introduction: Parkinson's Disease (PD) is a neurological disease characterized by motor disturbances and cardiovascular autonomic regulation impairments. Conventional resistance training (CRT) and resistance training with instability (RTI) improve motor functions in this population. However, their effects on cardiovascular system are unclear. Thus, this study evaluated the effects of these training regimes on physiological responses to a maximal cardiopulmonary exercise test in patients with PD. Methods: Thirty eight patients with PD (Hoen & Yarh stages II and III, "on" state) were randomly assigned to three groups: Control (C, n=11, 62±3 years – regular care), CRT (n=13, 67±2 years – 2 sessions/week, 5 resistance exercises, 2-4 sets, 12-6 RM) and RTI (n=15, 65±2 years – same protocol as CRT, adding instability accessories at the bases of body support). Before and after 12 weeks, all the patients underwent a maximal cardiopulmonary exercise test conducted on a cycle ergometer (ramp protocol). Heart rate (HR), oxygen uptake (VO<sub>2</sub>) and systolic blood pressure (SBP) were assessed at rest, anaerobic threshold (AT), respiratory compensation point (RCP) and peak exercise. HR decay at 1 min of recovery ( $\Delta$ HRR1) was also measured. Data were compared by a 2-way ANOVA ( $P \leq 0.05$ ) and are presented as means±SE. Results: After 12 weeks, VO<sub>2</sub>peak increased similarly in all the groups (C: 17.8±1.7 vs. 18.6±1.8 ml.kg<sup>-1</sup>.min<sup>-1</sup>, CRT: 18.0±1.2 vs. 18.8±1.2 ml.kg<sup>-1</sup>.min<sup>-1</sup>, RTI: 19.0±1.3 vs. 20.3±1.2 ml.kg<sup>-1</sup>.min<sup>-1</sup>,  $p \leq 0.05$ ). HR and SBP measured at rest and during exercise did not change in any group (HRpeak, C: 146±6 vs. 142±6 bpm, CRT: 126±7 vs. 128±8 bpm, RTI: 131±4 vs. 133±4 bpm, respectively,  $p > 0.05$  / SBPpeak, C: 171±7 vs. 169±8 mmHg, CRT: 160±5 vs. 167±6 mmHg, RTI: 167±4 vs. 168±6 mmHg, respectively,  $p > 0.05$ ).  $\Delta$ HRR1 also did not change in any group (C: 13±3 vs. 12±3 bpm, CRT: 7±2 vs. 8±2 bpm, RTI: 11±3 vs. 14±2 bpm,  $p > 0.05$ ). Conclusion: None of the training regimes (CRT and RTI) promoted any adaptation on cardiovascular and metabolic responses at rest, during and after a maximal cardiopulmonary exercise test in patients with PD. Financial support: CNPQ. CAPES and CEPID-SONO.

#### IS PHYSICAL FITNESS ASSOCIATED WITH FIBROMYALGIA SEVERITY? THE AL-ÁNDALUS PROJECT

Soriano-Maldonado, A.1, Herrador-Colmenero, M.1, Estévez-López, F.1, Segura-Jiménez, V.1, Álvarez-Gallardo, I.C.1, Aparicio, V.1,2, Carbonell-Baeza, A.3, Henriksen, M.4, Amris, K.4

1,2 University of Granada (Spain), 3 University of Cádiz (Spain) and 4 Frederiksberg Hospital (Denmark)

Objective: Fibromyalgia represents a burden for the health care system, with the highest unemployment rate (6%), claims for disability benefit (up to 30%), and greatest number of days of absence from work in Europe (Leadley et al., 2012; Rivera et al., 2009). Physical fitness is a powerful marker of health and disease and could potentially be associated with a lower disease severity in this population. The aim of this study was to assess the association between physical fitness and fibromyalgia severity in women. Methods: This cross-sectional study involved 444 patients with a diagnosis of fibromyalgia according to the American College of Rheumatology criteria. Fibromyalgia severity was assessed with the Revised Fibromyalgia Impact Questionnaire (FIQR). Aerobic fitness (6-minute walk test), muscle strength (handgrip strength, chair-stand, and arm-curl tests), flexibility (chair-sit-and-reach and back-scratch tests) and motor agility (8 feet-up-and-go test) were measured with the Senior Fitness Test battery and digital dynamometry. A standardized composite fitness score ('global fitness profile') was calculated and divided into quintiles. Results: Overall, higher physical fitness was significantly associated with lower fibromyalgia severity, regardless of the fitness test evaluated (all,  $P < 0.05$ ). Participants in quintile 5 (highest 'global fitness profile') had 16% (95% CI: 8.8% to 22.1%;  $P < 0.001$ ) lower fibromyalgia severity than participants in quintile 1 (lowest 'global fitness profile'). Conclusion: Our results suggest that higher physical fitness is consistently associated with lower fibromyalgia severity in women with fibromyalgia. Women with the highest fitness levels had significantly lower fibromyalgia severity (-16%) than participants with the lowest fitness levels, which surpasses the minimal clinically meaningful difference in fibromyalgia. These results might have important implications for the rehabilitation of women with fibromyalgia. References: Leadley, R. M., Armstrong, N., Lee, Y. C., Allen, A., & Kleijnen, J. (2012). ##### THE RELATIVE AGE EFFECT AND INJURIES IN CHILDREN'S FOOTBALL

Rössler, R.1, Junge, A.2,3, Chomiak, J.4, Faude, O.1

Department of Sport, Exercise and Health, University of Basel, Basel, Switzerland

1Department of Sport, Exercise and Health, University of Basel, Basel, Switzerland 2FIFA-Medical Assessment and Research Centre and Schulthess Clinic, Zurich, Switzerland 3Medical School Hamburg, Germany 4Department of Orthopaedics, Charles University and Hospital, Prague, Czech Republic Introduction Physical fitness determines performance in football. Hence, maturation status may be relevant

for succeeding and relatively younger children may refrain from sport participation. The relative age effect (RAE) is known as the circumstance of being selected into a representative team with increased likelihood when born early in the year.<sup>1</sup> We analysed if "RAE" is present in children's football (average level of play). As maturation status may also affect injury risk,<sup>2</sup> we were interested if injury risk and injury severity differ between relatively younger and older children. Methods In a prospective observational cohort study over 2 years we collected injury and exposure data in 7 to 12 years old football players. In total we recorded 6038 athlete seasons. Players were divided into 4 birth quarters (BQ). Number and severity of injuries (lay off time in days) and anthropometric data were analysed. One-way ANOVA was used to compare anthropometrics between BQ. Chi2-statistics were used to compare injury data between BQ. Results Players' mean age was 9.5 yrs (SD 2.0). Mean height and weight were 1.36 m (0.12) and 31.0 kg (7.7), respectively. In total 417 injuries occurred. Average lay off time was 18.9 days (27.1). Players were more often ( $\chi^2=152.26$ ;  $P<0.001$ ) born early in the year (BQ1: 29.4%; BQ2: 28.5%; BQ3: 24.0%; BQ4: 18.2%) and also injured players were more often ( $\chi^2=27.86$ ;  $P<0.001$ ) born early in the year (BQ1: 32.6%; BQ2: 29.7%; BQ3: 21.1%; BQ4: 16.5%). BQ-distribution of the whole sample did not differ ( $p=0.29$ ) from injured players. Relatively older players were taller and heavier ( $P<0.001$ ;  $\eta^2\geq 0.01$ ) but there were no differences in height and weight of injured children between BQ ( $P\geq 0.26$ ;  $\eta^2\leq 0.14$ ). In all four BQ injured players were taller and heavier ( $P<0.001$ ;  $\eta^2>0.02$ ) compared to non-injured players. There was no difference in injury severity between BQ ( $P=0.69$ ;  $\eta^2=0.04$ ). Discussion RAE is especially known from high-level youth sport.<sup>1</sup> RAE was reported for 10-15 years old injured ice hockey players in higher levels of play but not for low or intermediate levels.<sup>3</sup> In our study, RAE was present in the whole sample and in injured children with no differences between BQ in injury risk and severity. Increased height and weight might be risk factors in children's football. ### INCREASED PHYSICAL ACTIVITY IN CHILDHOOD REDUCES ADOLESCENT FRACTURE RISK - AN EIGHT-YEAR INTERVENTION STUDY IN 3 534 CHILDREN

Cöster, M.E., Fritz, J., Nilsson, J-Å., Dencker, M.D., Rosengren, B.E., Karlsson, M.K.

*Clinical Sciences*

Introduction Physical activity (PA) in childhood is associated with higher bone mass and better neuromuscular function, but the effect on fracture risk is not clear. Methods We conducted an intervention program with 40 minutes of moderate PA per school day for eight years in 1339 children aged six to eight years at study start. As controls served 2195 age matched children who continued with the national standard of 60 minutes of physical education per week. We registered objectively verified fractures in all these participants. In a sub-cohort of 234 children we also measured bone mineral content (BMC) and bone mineral density (BMD) at the total spine with dual energy X-ray absorptiometry, and muscle strength in knee extension and flexion by a computerized dynamometer (Biodex®). We calculated annual fracture risk ratios (RR) as well as changes in bone mass and muscle strength. Results The RR of fractures decreased with each year of extended PA ( $r=-0.86$ ,  $p=0.007$ ) so that the RR after eight years [RR 0.48 (0.25, 0.91)] was lower in the intervention than in the control group. The gains in BMD and knee extension and flexion were greater in the intervention than in the control group (all  $p<0.001$  to  $<0.05$ ). Discussion A population-based pediatric PA intervention program reduces adolescent fracture risk, probably due to PA-induced benefits in BMD and muscle function. Contact marcus.coster@med.lu.se

### SOCCER INJURIES IN SWITZERLAND

Gebert, A.1,2, Pühse, U.2, Gerber, M.2, Gassmann, P.3, Lamprecht, M.1

1: Lamprecht und Stamm Sozialforschung und Beratung (Zürich, Switzerland) 2: DSBG (University of Basel, Switzerland) 3: Suva (Swiss National Accident Insurance Fund)

Introduction Soccer injuries are financially relevant and therefore constitute an important public health issue. According to the study „Sport Schweiz“ (Lamprecht et al., 2014) approximately 480'000 persons aged between 15 and 74 years are playing soccer in Switzerland. All in all, every third of them is licenced (SFV, 2013). The large number of players leads to a lot of soccer related injuries. For methodical reasons a lot of studies about the injury risk in soccer concentrate on professional soccer and a few studies focus on amateur soccer. As a consequence, there is incomplete knowledge about the context of injury events when soccer is played informally. Therefore, the aim of this study was to learn more about the context and characteristics of all soccer injuries in Switzerland to provide a basis for further improvements in injury prevention. Methods The support of the Suva allowed us to retrospectively consult a random sample of persons insured by Suva who had sustained an injury while playing soccer between July 1, 2013 and June 31, 2014. A total of 822 persons participated in the standardised telephone survey which took 16 minutes on average. Results Around 30% of the injuries occurred in informal soccer (free time with friends/family, informal tournaments etc.) whereas 70% came up in formal soccer (50% game, 20% practice). In addition to the injured body region and injury type, the collected data include details concerning the injury severity, previous injuries, rehabilitation and the injury situation (such as player to player contact, foul play, referee's response). Furthermore the interviewed persons provided information about their fitness levels and preventive behaviour, their soccer skills and tackle behaviour as well as about the ground conditions, footwear and shin guards. Discussion This study will provide new findings regarding the settings in which soccer injuries occur, different injury types and injury mechanisms. According to the literature, a previous injury (Hägglund et al., 2006) and player to player contact (Schmikli et al., 2011) are regarded as important risk factors for suffering another injury. Additionally, about 20% of injuries occurring during an official game are caused by foul play punished by the referee (Aoki et al., 2012). ### CHARACTERISTICS AND RISK FACTORS OF SPORT INJURIES IN PHYSICAL EDUCATION STUDENTS: PRELIMINARY RESULTS

Blikendaal, S., van Beijsterveldt, A.M.C., Richardson, A., Stubbe, J.

*Amsterdam University of Applied Sciences*

Introduction Sport injuries can have a major impact on the career of Physical Education (PE) students. They can lead to physical limitations, absence from sport classes and study delay. This study aims to investigate the magnitude of the injury problem and to explore the risk

factors for sustaining an injury in PE students. Methods Dutch first-year PE students are followed during the academic year 2014-2015. Prior to the start of the academic year, all PE students underwent a sports medical exam, performed a maximal Interval Shuttle Run Test (ISRT) and filled in a baseline questionnaire. During the follow-up period students fill in an online questionnaire every 5 weeks for retrospective registration of time-loss injuries. Results In total, 292 students were included in this study (70% men and 30% women) with a mean age of 19.6 ( $\pm 2.1$ ) years. During the first 15 weeks of the study 670 follow-up questionnaires were returned and 247 injuries were registered by 174 students (59%). Students reported on average 267 ( $\pm 205$ ) minutes of extracurricular sporting time per week. On average, 690 minutes of intracurricular sport classes were scheduled. Preliminary results show an average time loss duration of 17 ( $\pm 17$ ) days, with a range of 1-85 days and a median of 10 days. Most injuries occurred during intracurricular sport classes (56%) and were acute (64%). Injuries occurred most frequently during soccer (27%), gymnastics (23%), other activities (21%) and martial arts (6%). The most common localizations were knee (15%), ankle (15%), lower leg (12%) and lower back (9%). Significant risk factors for sustaining an injury are an injury in the previous year ( $p < 0.01$ ) and an injury at the start of the academic year ( $p < 0.01$ ). Other possible risk factors were not significantly associated with sustaining an injury: gender ( $p = 0.06$ ), chronic illness ( $p = 0.21$ ), age ( $p = 0.43$ ), sporting hours prior to the start of the academic year ( $p = 0.10$ ), ISRT score ( $p = 0.44$  for men and  $p = 0.42$  for women) and extracurricular sporting time ( $p = 0.92$ ). Discussion The risk of sustaining an injury is high for first-year PE students and this can be considered as an extensive problem. Intracurricular sport classes are a substantial cause of sport injuries. Injuries most often involved the lower extremities. Important risk factors are an injury in the previous year and an injury at the start of the academic year. Contact s.bliekendaal@hva.nl

### EFFECTS OF WEIGHT LOSS AND ISOTONIC CORE EXERCISE OF 8 WEEKS ON PAIN, STRENGTH AND BALANCE IN OBESE MIDDLE AGED WOMEN WITH LOW BACK PAIN

Kim, A.R., Lee, H.S.

*Dankook university*

Introduction Low back pain (LBP) is a common musculoskeletal disorder (Alexopoulos et al., 2003), LBP is caused by obesity, poor muscle strength, and reduced spinal mobility (Bayramoglu et al., 2001). LBP has been not only pain and trunk muscle weakness, but also poor balance control caused of deficit in proprioception in the spine and alter muscle control (Bouche et al., 2006). Therefore, the purpose of this study was to determine the effects of weight loss and isotonic core exercise on low back pain, core muscle strength/body weight, and balance strategy in obese middle aged women with LBP. Methods Eighteen obese middle aged women with low back pain (waist-hip ratio; WHR  $\geq 0.85$ ) were divided to weight loss and isotonic core exercise group (WL+CE,  $n = 6$ ), isotonic core exercise group (CE,  $n = 6$ ) and control group (CON,  $n = 6$ ). The goal of the weight loss was set loss of 0.5 to 1 kg body mass/week and, isotonic core exercise was performed for 1 hour, three times a week, for 8-week at 50 % their individual core muscle strength. Physical characteristics (body mass, BMI, % body fat, muscle mass, WHR), low back pain (ODI, VAS), core muscle strength/body mass (trunk extensor, trunk flexor, hip flexor) and balance strategy (balance, reaction time, adaptation) were measured before (pre), after 4-week (post) and 8-week exercise (post 1) each groups. Results WHR was significantly decreased in WL+CE after post and post 1 than pre ( $p < 0.05$ ). ODI and VAS were significantly decreased in WL+CE after post and post 1 than pre ( $p < 0.01$ ). Trunk extensor strength/body mass was significantly increased in WL+CE at 146° ( $p < 0.01$ ), 158° ( $p < 0.01$ ), 170° ( $p < 0.01$ ) and 182° ( $p < 0.05$ ) after post 1 than pre, Trunk flexor strength/body weight was significantly increased in WL+CE at 146° ( $p < 0.01$ ), 158° ( $p < 0.05$ ) and 182° ( $p < 0.01$ ) after post 1 than pre. Hip flexor strength/body weight was significantly increased in the WL+CE after post 1 than pre ( $p < 0.01$ ). However, weight, BMI, % body fat, body mass, reaction time, and adaptation were not significantly different between time and groups. Discussion Generally, acute weight reduction leads to decrease lean body mass such as decrease muscle mass, consequentially decrease strength and physical fitness (Elfhag & Rossner, 2005). However, the present study showed that weight loss and isotonic core exercise reduced low back pain, improved core muscle strength and balance compared with isotonic core exercise only, probably due to increased muscle strength and decreased body mass. Therefore, we suggest that obese patients with LBP need to performing combination of core muscle strengthening and weight loss in order to effectively decrease low back pain. ### OP-PM45 Training & Testing: Teamsport III

#### THE EVALUATION OF VALIDITY AND RELIABILITY OF A NEW SOCCER SPECIFIC TEST

Tunar, M., Cetinkaya, C., Gumus, H., Gencoglu, C., Unal, B., Kayatekin, B.M.

*Dokuz Eylul University*

Introduction Maximal oxygen uptake is largely associated with match activity profile of soccer players (Helgerud, 2001). Therefore, maximal oxygen uptake is one of the most important indicator of physical performance in soccer. Soccer Specific Modified 1.5 Mile Run Test is a new field test which improved by modifying "Cooper 1.5 mile Run Test" with soccer specific movement pattern. The aim of this study was to evaluate the criterion and construct validity and reliability of Soccer Specific Modified 1.5 Mile Run Test. Methods Totally 48 athletes were participated in the study. To evaluate the construct validity, 16 athletes from other team sports (handball, basketball and volleyball) were recruited in the study in addition to 32 soccer players. Participants visit the laboratory once. Height, weight, body fat percentage and maximal oxygen uptake were measured during laboratory session. In subsequent 2-7 days, Soccer Specific Modified 1,5 Mile Run Test is performed two times in the soccer pitch with 2-7 days apart. Results Soccer players completed the field test in a shorter time, significantly ( $p < 0,001$ ). There is a significant, strong and positive correlations between maximal oxygen uptake and time to complete Soccer Specific Modified 1,5 Mile Run test in soccer players ( $r = 0,83$ ). However, there is no significant correlation between maximal oxygen uptake and time to complete Soccer Specific Modified 1,5 Mile Run test for athletes from other team sports. There is a significant, strong and positive correlations between two field test both groups ( $r = 0,91$ ;  $r = 0,87$  respectively). Discussion Soccer Specific Modified One and Half Mile Run Test is a valid test only for soccer players unlike the athletes from other team sports. Such a result may be caused according to soccer

specific movement pattern. So, criterion and construct validity and reliability of this new field test were shown in this study. References Helgerud J, Engen LC, Wisloff U, Hoff J. (2001). *Med Sci Sports Exerc.* 2001 Nov;33(11):1925-31. Contact mertunrar@gmail.com

### TIME-MOTION DATA ANALYSIS OF A SMALL-SIDED GAME PERFORMED BY YOUNG ELITE MALE SOCCER PLAYERS

Wenker, C.T., Stevens, T.G.A.

*MOVE Research Institute Amsterdam, VU University Amsterdam, The Netherlands.*

**Introduction** Small-sided games (SSGs) are frequently used in soccer training to improve sport-specific fitness of players. Time-motion data analysis has previously shown that distance and high speed running decrease during SSGs, most likely due to fatigue. Recently, it has been argued that including acceleration, deceleration and metabolic power estimations could improve the quantification of training load (1). The aim of the present study was to investigate whether distance covered at high acceleration (HA), high deceleration (HD), and high metabolic power (HP) show a similar fatigue related decrease during an intense SSG compared to the traditionally reported parameters total distance covered (TD) and high-speed running (HSR). **Methods** 47 young elite male soccer players (18±2 years) performed a 6v6 (including goalkeepers) 4x5 min SSG with 2 min passive recovery between game parts (pitch size: 40x34m). Time-motion and heart rate (HR) data were collected using a LPM system (Inmotio, Amsterdam, The Netherlands). Metabolic power was estimated with the 'di Prampero' equation (2) with 1.1 as terrain constant and 4.15 J/kg/m for energetic cost of constant running (1). HR, TD, distance ran above HSR (> 14.4 km/h), HA (> 2.0 m/s<sup>2</sup>), HP (> 20 W/kg), and distance below HD (< -2.0 m/s<sup>2</sup>) during the subsequent game parts were analyzed with a repeated measures ANOVA (level of significance p=.05). The study was approved by the local ethics committee and players signed informed consent. **Results** HR slightly increased from first (175±10 bpm) to second game part (177±10 bpm) and subsequently stabilized. In contrast, decreases were demonstrated from the first to the fourth game part for TD (659 to 588m; -11%), HSR (135 to 107m; -21%), HA (63 to 52m; -18%), HD (59 to 48m; -18%), and HP (156 to 127m; -19%). This decrease was greater for HSR and HP compared to TD, while the decline for HA and HD was not significantly different from TD. **Conclusion** Young elite soccer players demonstrated decreases for TD, distance above HSR, HA, HP, and distance below HD from the first to the fourth game part of the 6v6 SSG. Since the HR remained at a high level (constant from game part 2 to 4), it is likely that these reductions are associated with peripheral fatigue rather than a decrease in motivation. The greater decline for HSR and HP compared to TD suggests that fatigue may affect these measures differently. **References** 1. Stevens TGA, de Ruijter CJ, van Maurik D, van Lierop CJ, Savelsbergh GJ, & Beek PJ. Measured and Estimated Energy Cost of Constant and Shuttle Running in Soccer Players. *J. Biol.* 2005. 208, 2809-2816.

### SALIVARY BIOMARKERS ACROSS A YOUNG SOCCER SEASON

Rama, L., Teixeira, A., Figueiredo, A., Capranica, L., Cortis, C., Tessitore, A., Lopes, R.F.

*Faculty of Sport Sciences and Physical Education of Coimbra*

**Introduction** The aim of this study was: 1) to examine monthly immunological and hormonal adaptive response to training in young soccer players across during an entire competitive season; and 2) to verify the relationship between the immune parameters and the incidence of upper respiratory symptoms (URS - Rama et al, 2013; Spence et al, 2007). **Methods** Players of three soccer teams belonging to the same Portuguese club Under-15 (n=17, age:14.8±0.2yrs, height:170.8±6.6cm, body mass:60.1±9.5kg, body fat:14.8±3.8%), Under-17 (n=22, age:16.1±0.4yrs, height:174.4±6.7cm, body mass:67.0±8.1kg, body fat :14.1±3.0%), Under-19 (n=18, 18.8±0.2yrs, height:177.5±6.9cm, body mass:70.9±8.1kg, body fat:13.3±4.9%), were monitored from the beginning (July 2013) to the end (April 2014) of a competitive season. Monthly, after a rest day and before the first weekly training session, saliva samples were collected at rest and analyzed for immunological (S-IgA concentration, S-IgA secretion rate, S-alpha amylase) and hormonal (cortisol C, testosterone T, T:C ratio) biomarkers. Signs and symptoms of URS were assessed through the WURSS-21 month log (Barret et al, 2005). Anova for repeated measures (p<0.05) was applied to investigate in season differences. **Results** No seasonal significant changes were found in cortisol, testosterone and T:C ratio. Regardless by age groups, a lower (p<0.05) in S-IgA secretion rate emerged at the end of the season. Moreover, while the Under-19 group showed increases in cortisol (p<0.05, ES=1.3) from February to March, the Under-15 group reported more cases of URS (+50% in December). **Discussion** The increased cortisol values in under-19 could reflect cumulative effects of training and competitions, which are similar to those of professional players. In addition the lower values of S-IgA secretion rate observed at the end of the season could be explained as an effect of training loads accumulation and may lead to a higher incidence of URS, especially in the youngest athletes. Thus, monitoring of salivary IgA could provide a useful and noninvasive tool to predict decreases in mucosal immunity (Mortatti et al, 2012), mainly in the younger athletes. **References** Barret, B, Brown, R et al. (2005). *Journal of clinical epidemiology*, 58 (6), 609-617 Mortatti AL, Moreira A, Aoki MS et al (2012). *J Strength Cond Res.* 26(5), 1396-401 Rama, L, Teixeira, AM, Matos et al (2013). *Eur J Appl Physiol* 113: 859-868 Spence, L, Brown, WJ, Pyne, DB et al (2007). *Med Sci Sports Exerc* 39(4): 577-586 not insert authors here

### PHYSICAL DEMANDS DURING VARIOUS TYPES OF CONSTRAINTS-LED CRICKET TRAINING

Vickery, W.1, Dascombe, B.2, Duffield, R.3

*1: Northumbria University; 2: University fo Newcastle; 3: University of Technology Sydney*

**Introduction** Constraints-led training involves modifying the training environment to specifically tailor training sessions to focus on specific physical or skill demands. Constraints that can be modified include field size, player number and playing rules; all of which are suggested to be effective at promoting improved conditioning status within game simulations (Gabbett et al, 2009). This study aimed to examine the physical demands placed upon cricket players when modifications were made to the number of players, field size and playing rules during game simulation cricket training sessions. **Methods** The movement patterns and characteristics of 11 amateur, cricket players (batsmen, fast bowlers, spin bowlers, fielders, and wicketkeepers) were recorded via 10 Hz global positioning devices worn whilst performing four modified constraints-led cricket sessions. Modifications to training sessions included 1) reducing the field size, 2) decreasing the number of fielders, 3) a combination of reduced field size and fielder number and 4) altered playing rules (hit-and-run, continuous rotation of bowlers and all throws back to the wicketkeeper). Comparison of movement demands of each playing position between training sessions were determined using one-way ANOVA with Fisher's LSD post hoc (P<0.05). **Results** For batsmen, a main effect was evident for increased mean speed, total sprinting distance and a decreased work-to-recovery ratio (P<0.05) when playing rules were changed. For fast bowlers, the movement patterns did not differ between sessions (P>0.05), with the exception of increased walking distance (P<0.05) during the rule change session. No significant difference in physical demands were evident between sessions for spin bowlers or fielders (P>0.05). Wicketkeepers covered significantly greater striding distance and high-intensity efforts (P<0.05) combined

with a shorter work-to-recovery ratio during the rule change session. Discussion The use of modified constraints-led cricket training was able to influence the physical demands of amateur cricket players to varying degrees, depending on the session and playing position. Specifically, modification of the playing rules had the greatest influence on the movement patterns of the players, particularly for batsmen and wicketkeepers. The different constraints presents coaches with methods of providing sufficient training stimulus to maintain or improve the physical capacity of players, without compromising the amount of time spent in game-specific skill sessions. ### ACUTE EFFECTS OF TWO DIFFERENT RESISTANCE CIRCUIT TRAINING PROTOCOLS ON PERFORMANCE AND PERCEIVED EXERTION IN BASKETBALL PLAYERS

Freitas, T.T., Calleja, J., Alarcón López, F., Alcaraz, P.E.

*San Antonio Catholic University of Murcia; University of Basque Country*

Introduction In basketball, shooting is the most important technical skill and vertical jump, agility and repeated sprint ability are amongst the main determinants of high performance. Resistance training, for strength/power development, is a common practice in this sport but little is known about the effects of different strength/power protocols on performance and post-resistance training fatigue. Hence, this study aimed to investigate the acute effects of two different resistance circuit training protocols on basketball players' physical and technical performance and rate of perceived exertion. Methods An intra-individual, crossover experimental design was used. Nine basketball players performed, on consecutive weeks, a Power Circuit Training (PCT; 45% 1RM) and a High Resistance Circuit Training (HRC; 6RM) (1). Vertical and horizontal jumps performance, 3-points shooting accuracy, repeated sprint ability (RSA), agility and upper body power output were measured the week before the first training session and following both circuit protocols. RPE was assessed 20 min post-resistance training. Results One-way rmANOVA showed performance decrements in vertical jump height and peak power, horizontal jump distance, 3-points shooting percentage, bench press power output, RSA total and ideal time and agility T-Test total time, following HRC but not PCT ( $p \leq 0.05$ ). RPE was higher in HRC compared with PCT ( $p \leq 0.05$ ). Discussion Results indicate that high intensity resistance training protocols are perceived as harder and result in higher levels of fatigue, which is in accordance with Linnamo's (2) findings. Moreover, HRC leads to acute physical and technical performance declines (3). Low-to-moderate intensity loads, however, don't affect negatively performance. Hence, PCT may be an appropriate option prior to a practice/game as it avoids acute resistance training-induced performance decrements but HRC may be a suitable alternative to develop/perfect technical skills under fatiguing conditions similar to that of competition. Nonetheless, strength and conditioning coaches should carefully plan strength sessions as augmented fatigue levels may lead to an increased risk of injury (4). References 1. ### PROPRIOCEPTION TRAINING: BEFORE OR AFTER REGULAR BASKETBALL TRAINING SESSION?

Pojškic, H., Levic, E.

*Tuzla University*

Introduction It is a common practice among strength and conditioning coaches to conduct proprioception training before a regular training session when athletes are in a rested state, but it is known that the majority of injuries occurred at the end of the training session, or competition, when athletes are fatigued (Hawkins and Fuller, 1999). Therefore, the aim of this study was to investigate the effects of basketball training on single-leg balance ability in rested and fatigued state and assess whether the efficiency of a proprioception program is affected by its performance before or after a regular basketball training. Methods Thirty-three female basketball players were randomly divided into three subgroups ( $n=11$  each). Experimental groups E1 and E2 performed the same proprioception program (8 weeks, 3 times per week, 15-20 minutes per session), but E1 performed before, and E2 after regular basketball training session. A control group performed only the regular basketball training. The Biodex Balance System was used to assess single-leg balance ability, overall stability index (OSI) prior to the utilization of the program (in rested and fatigued state), as well as after the program. General fatigue was induced by the beep test protocol. Two separate 3-way repeated measures ANOVA (time x group x condition) and multiple pairwise comparisons were used to test the differences in the single-leg balance ability between and within the groups pre- and post-proprioception program, and to determine if the timing of the proprioception training (pre-training vs. post-training) affected the balance ability in rested and fatigued state. Results The enhancement in single-leg balance ability for both dominant and non-dominant leg was higher in the experimental groups than in the control group ( $> 15\%$ ). Greater improvement was in a dominant leg's OSI in the fatigued and non-fatigued state in E2 group. E1 group showed similar improvement in the rested state for non-dominant leg compared to E2 group. Discussion We found that a basketball training improved single-leg ability, but greater enhancement was observed when the proprioception training was added. Additionally, we found that the post-training proprioception program positively affected balance ability in rested and fatigued state. These findings are in accordance with Gioftsidos et al. (2006). It seems that training in the fatigued state (post-training) has a positive transfer on single-leg ability in the fatigued state, so it is recommended to conduct it after training session or after exhausting exercises. ### OP-PM58 Health & Fitness: Children II

#### DETECTION OF MUSCLE IMBALANCES IN LOWER LIMBS STRENGTH AND POWER IN YOUNG CHILDREN AND ADOLESCENTS, AS AN INDICATOR IN THE PREVENTION OF INJURIES

López del Amo, J.L.1, Portas Uviña, A.2, Flores Fagnani, P.L.2, Moreno Galceran, D.2, Rovira Riba, N.2, Alba Jiménez, C.3, Padullés Riu, J.M.2

1: SPARG, UVIC (Vic, Spain), 2: UB-INEFC (Barcelona, Spain), 3: UVIC (Vic, Spain)

**Introduction** Functional assessment in young children and adolescents to detect muscle imbalances involving force and power in the lower limbs is a basic factor in injury prevention and in designing rehabilitation programmes to improve the health and performance of young people. New neuromuscular analysis technologies permit highly accurate and non-invasive clinical-functional assessment of human body movement. **Methods** This research used state-of-the-art technology to conduct tests on 177 subjects aged 12 to 17 at a Spanish secondary school (44.6% male and 55.4% female). This included Casio Ex F1 high-speed cameras, the Optogait platform of infrared rays for a treadmill, a vertical jumps platform connected to the Chronopic device, linear encoder connected to the MuscleLab device and Kinovea image analysis software. For the purpose of comparisons, the sample was divided into 4 sub-groups: males aged 12-13 (n=34), males aged 16-17 (n=45), females aged 12-13 (n=42) and males aged 16-17 (n=56). Kinanthropometric assessment tests, vertical jump and horizontal single-leg penta jump tests, walking analysis and tests to evaluate the strength of knee flexor and extensor muscles were conducted. Unilateral deficits, bilateral deficits and the conventional index for flexor and extensor muscles (Hamstring/Quadriceps Ratio) were calculated. **Results** The results detected muscle imbalances in 16.4% of students (those with muscle imbalances in 4 or more of the 9 tests conducted). The prevalence of muscle imbalances was significantly greater ( $p < 0.001$ ) in 12 year-old students than 16-17 year-old ones. Likewise, there were more cases of muscle imbalances in female students, with significant differences ( $p < 0.05$ ). The test with most differences, for both ages and sex, was the horizontal single-leg penta jump. The tests with most muscle imbalances were walking at 4 km/h (32.7%) and the Abalakov jump (28.8%). In groups, in all tests for which the bilateral deficit was calculated, the latter appeared more than bilateral facilitation did. **Discussion** Muscle imbalance, based on force and power performance, involves asymmetry of the agonist and antagonist muscles of a limb (Flexor-Extensor Deficit of the knee joint), asymmetry between the limbs (Unilateral Deficit) or a difference from an expected normal value (Bilateral Deficit). The calculation of these deficits generated around the knee joint may help identify risk factors for injury of the anterior crossed ligament and of the hamstring muscles (Croisier, 2004), the function of the knee joint and its dynamic stability (Aagaard et al., 1998; Gerodimos et al., 2003). **References** Aagaard, P.; Simonsen, E.B.; Magnusson, S.P.; Larsson, B & Dyhre-Poulsen, P. #### PARENTAL AND CHILD SPECIFIC FACTORS ASSOCIATED WITH PHYSICAL ACTIVITY IN FIRST GRADE SCHOOL CHILDREN.

Dreher, M., Hoffmann, S., Brendel, C., Simon, P.

*Johannes Gutenberg-University Mainz*

**Background:** Physical activity in children is known to be associated with the child specific factors overweight, TV viewing, computer use<sup>1</sup>, and the parental factors parental physical activity, overweight, smoking, and social status<sup>2, 3</sup>. Here we additionally studied the association of parental psychosocial inactivity, indecisiveness and sloth – here altogether termed idleness - with the physical activity of young children. **Methods:** 428 first grade school children were characterized with regard to anthropometrics and finished a German-Motor-Coordination test at 11 elementary schools in Mainz. In addition 316 of the respective parents responded to a self-administered paper and pencil questionnaire. Questions were asked about physical activity using the Baecke Questionnaire, idleness behavior factors, anthropometrics and social indicators. Contingency analysis and logistic regression analysis were used to estimate the association between physical activity of the children with the other parameters. **Results:** 4 of the 11 tested parameters were significantly and independently from each other related to physical activity of children. Child related factors associated with inactivity turned out to be watching TV for more than 30 minutes during a weekday, 3.19-fold (CI 1.86 – 5.57,  $p = < 0.0001$ ) or spending time in front of the computer and internet surfing during the weekend, 2.0-fold (CI 1.06 – 3.87;  $p = 0.034$ ). Parental factors were physical activity, 2.3-fold (CI 1.37 – 3.73;  $p = 0.0014$ ) and social activity/ idleness, 2.3-fold (CI 1.40 – 3.81;  $p = 0.0011$ ). **Conclusion:** Neither migration background, smoking habits and weight of parents nor on the weight of the child were associated with physical activity. Surprisingly both, idleness and physical inactivity of the parents but also media consumption of the children appear to be highly related to physical inactivity. All of these factors are principally amenable to be altered by targeted prevention intervention. **Literature:** 1: Marshall, S.J., Biddle, S.J.H., Gorley, T., Cameron, N. & Murdey, I. (2004). #### A SYSTEMATISED REVIEW OF PRIMARY SCHOOL WHOLE CLASS CHILD HEALTHY WEIGHT INTERVENTIONS

Brown, E.C., Baker, J.S., Wyatt, F.B., Buchan, D.S., Kilgore, J.L.

*University of the West of Scotland*

**Background** Childhood obesity is increasing at an alarming rate with projections suggesting that prevalence rates will continue to rise in developing countries.<sup>1</sup> School-based interventions for improving child healthy weight (CHW) are becoming more popular, but the degree of effectiveness remains unclear.<sup>2</sup> Therefore, a systematised review was conducted to determine the effectiveness of school-based interventions in reducing or stabilising BMI and to better inform the strategies and characteristic associated with interventions successful in improving BMI in primary school children. **Methods** A search of databases (PubMed, Health Source: Nursing/Academic Edition, MEDLINE, PsycBOOKS, Psychology and Behavioral Sciences Collection, PsycINFO, SocINDEX with Full Text, SPORTDiscus) for relevant publica-

tions was conducted and the data from included articles was synthesised. Studies selected for inclusion were school-based, whole class (all weight categories) with aims to improve BMI through increasing PA and improving dietary habits. Studies must have included BMI or BMI z-scores in pre and post analyses. This review included randomised and non-randomised controlled trials from years 2004 - 2014. Results Of the 1172 potentially relevant articles we identified, 18 studies met the inclusion criteria. From these 18 studies, 7 yielded a reduction or stabilisation in BMI or BMI z-score in the entire intervention group. Intervention durations ranged from 5 – 36 months. Five of these 18 studies used a combination of environmental, educational, and physical components, 5 combined educational and physical, 2 combined environmental and physical, 2 combined environmental and educational, and 4 used education only. Conclusions School based interventions that involve multiple environmental, educational, and physical strategies and not education only appear to be most likely to result in BMI or BMI z-score improvement. Moderators likely to influence BMI include increased physical activity (PA), decreased sedentary behaviours, lowered sugar sweetened beverages (SSBs), and increased fruit intake. REFERENCES 1. ### **EFFECTS OF 12 WEEKS OF AEROBIC PLUS RESISTANCE TRAINING WITHOUT CALORIC RESTRICTION ON INFLAMMATORY MARKERS IN ADOLESCENT OBESE GIRLS**

Lopes, W.A., Leite, N., Silva, L.R., Brunelli, D.T., Radominski, R.B., Cavaglieri, C.R.

*State University of Maringá*

**Introduction** Exercise has been shown to be effective in reducing chronic inflammation associated with obesity. However, most research has been conducted in adults, so little is known about the anti-inflammatory effects of exercise in the pediatric population. Therefore, the aim of this study was to investigate the effects of 12 weeks of aerobic plus resistance training without caloric restriction on inflammatory markers in adolescent obese girls. **Methods** Thirty-three overweight adolescent girls (14.4±1.1 y; 1.61±0.05 m; 76.3±12.0 kg; 29.1±3.3 kg/m<sup>2</sup>) were randomly assigned to experimental (EG, n=17) and control group (CG, n=16). Body composition, aerobic fitness, muscular strength, dietary intake, glucose, insulin, lipid profile and inflammatory markers were measured before and after 12 weeks of intervention. The intervention program consisted in aerobic exercise (3 days/wk, 60 min, walking or running for 30 min, 50-80% VO<sub>2</sub>max) plus resistance exercise (3 sets of 6-10 reps at 60-70%1-RM). **Results** There was significant decrease in body fat (45.2±4.8 to 43.5±4.6 vs 45.4±5.9 to 46.0±6.3), and increase in VO<sub>2</sub>peak, 1-RM on leg press and 1 RM on bench press in the EG when compared to the CG. The insulin resistance by HOMA-IR reduced significantly in the EG (3.58±1.4 to 2.84±1.5 vs 3.69±1.9 to 3.64±1.4). In relation on inflammatory markers, there was significant decrease only in leptin levels (53.4±20.5 to 44.0±19.5 vs 58.6±26.9 to 63.5±24.0). CRP, IL-6, IL-10, TNF-α, resistin and adiponectin remained unchanged. **Discussion** Aerobic plus resistance training without caloric restriction was able to reduce body fat, insulin resistance and leptin levels in obese adolescent girls. These results corroborate Lemura & Maziekas (2002), who proposed that the combination of aerobic exercise and strength training is effective to decrease fat mass. Also, our results corroborate, in parts, Dãmaso et al. (2014), who showed that the combined aerobic training associated with multidisciplinary intervention was more effective in reducing leptin and increasing adiponectin levels than aerobic training alone. The absence of changes in some inflammatory markers in our study can be attributed to baseline value or to the small body fat reduction (Tam et al, 2010). **References** Lemura LM, Maziekas MT. ### **CARDIORESPIRATORY FITNESS AND PHYSICAL ACTIVITY ON A MULTIDISCIPLINARY SCHOOL-BASED INTERVENTION IN CHILDREN : A RANDOMIZED CONTROLLED TRIAL.**

Batalau, R.1,2, Cabrita, P.2, Cruz, J.1, Gonçalves, P.1, Guerreiro, T.1, Santos, M.1, Gonçalves, R.1, Leal, J.3, Palmeira, A.2,4

*Lusófona University*

**Introduction** Most European children do not meet physical activity (PA) recommendations (Verloigne et al., 2012). So, obesity programmes focusing on PA have been suggested (WHO, 2009). This study is a part of Project PANK, a 6 months school-based multidisciplinary intervention to improve variables associated with cardiovascular and metabolic risk factors (CMRF). The main purpose is to analyse the impact of the intervention on PA and cardiorespiratory fitness (CRF) among Portuguese children. **Methods** Overweight and obese children (n=77, 7-10 y, both genders) were recruited. Intervention group (IG=40) had a PA intervention with 3 meetings for children and parents, an additional PA class (1h) and 6 educational sessions related to PA. At the same time, IG had a nutrition intervention with 3 meetings for children and parents and 6 educational sessions. Control group had no intervention. In IG, the CRF was assessed at baseline, after 3 and 6 months (20m shuttle run test). VO<sub>2</sub>max was estimated by Fernhall et al. (1998) (Fer) and Matsuzaka et al. (2004) (Mat) models. PA was assessed 6 times by accelerometers (GT3X) during 7 days. Evenson et al. (2008) cut-points were used. In CG, CRF and PA were assessed at baseline and after the program. **Results** The IG performed a higher amount of moderate PA (p=.014). Similar results were found in vigorous PA (p=.003). IG presented a higher number of moderate-to-vigorous PA bouts of 1-5 minutes when compared to CG (p=.008). No differences were found between groups in sedentary behaviours breaks. The IG shows higher levels of CRF when compared with CG (Fer Model: p<.001; Mat Model: p<.001). Partial correlation shows a positive association between the variance in vigorous PA since baseline to the end of intervention performed by IG and the variance of the CRF (Fer: p=.021; Mat: r=.42, p=.010). **Discussion** The PANK was effective in improving PA. Our results corroborate that it is possible to achieve improvements in CRF by increasing PA. The results in PA confirm that to achieve health benefits, the PA should be of at least a moderate intensity, but vigorous intensity activities may provide even greater benefit for children (Janssen and Leblanc, 2010). Considering the suggested independent impact of PA on metabolic syndrome and insulin resistance, alternatively or simultaneously mediated by the CRF and adiposity of youth (Guinhouya, et al., 2011), we will explore the possible influence of these results in the several CMRF studied. ### OP-SH11 Sport Statistics & Analysis

#### THE INFLUENCE OF PERFORMANCE LEVEL, AGE, AND GENDER ON PACING STRATEGY DURING A 100KM ULTRAMARATHON

Renfree, A.1, Crivoi, E.2, Martin, L.1

1: *University of Worcester (UK)*, 2: *Universidade de Sao Paulo (Brazil)*.

**Purpose:** To analyse the influence of performance level, age, and gender on pacing during a 100km ultramarathon. **Methods:** Results of a 100km race incorporating the World Masters Championships were used to identify differences in relative speeds in each 10km segment between participants finishing in the first, second, third, and fourth quartiles of overall positions (Groups 1,2,3, and 4 respectively). Similar analyses were performed between the top and bottom 50% of finishers in each age category, as well as within male and female categories. **Results:** Pacing varied between athletes achieving different absolute performance levels. Group 1 ran at significantly lower relative speeds than all other groups in the first three 10km segments (all  $P < 0.01$ ), and significantly higher speeds than Group 4 in the 6th and 10th (both  $P < 0.01$ ), and Group 2 in the 8th ( $P = 0.04$ ). Group 4 displayed significantly higher relative speeds than Group 2 and 3 in the first three segments (all  $P < 0.01$ ). Overall strategies remained consistent across age categories, although a similar phenomenon was observed within each category whereby 'top' competitors displayed lower relative speeds than 'bottom' competitors in the early stages, but higher speeds in the later stages. Females showed lower relative starting speeds and higher finishing speeds than males. 'Top' and 'bottom' finishing males displayed differing strategies, but this was not the case within females. **Conclusions:** Although pacing remained consistent across age categories, it differed with level of performance within each, possibly suggesting strategies are anchored on direct competitors. Strategy differs between genders, and differs depending on performance level achieved in males but not females. Contact: a.renfree@worc.ac.uk

#### EXPLORING SOME OF THE MYSTERIES OF COLLECTIVE COORDINATION IN FOOTBALL: EFFECTIVE PLAYING SPACE AND THE NUMBER OF PLAYERS.

Sampaio, J.1,2, Gonçalves, B.1,2, Folgado, H.1,3, Marcelino, R.1,2

1 *CreativeLab, Research Center for Sports, Health and Human Development (CIDESD)*, 2 *University of Trás-os-Montes e Alto Douro, Vila Real*, 3 *University of Évora, Évora*

**Introduction** To achieve collective behaviour that boosts high-level performances, football players are required to coordinate themselves into smaller sub-groups. The key variables that determine this optimal coordination are likely related to space, time and speed. This study aimed to identify how the number of players that constitute these sub-groups affects team coordination, as measured by the effective playing space (EPS, the smallest polygonal area delimited by the peripheral players, also providing information about the surface that is being effectively covered). **Methods** Twenty outfield football players from a Portuguese first league team participated in this study (age,  $24.8 \pm 3.9$  yrs; professional playing experience,  $7.1 \pm 4.0$  yrs). Positional data were collected using a 5Hz non-differential GPS during six pre-season matches. The EPS was calculated for sub-groups of 3, 4, 5, 6, 7, 8, 9 and 10 players, using the smallest inter-player distance as the selection criteria, i.e., the EPS from the sub-group of 3 players was constituted by the smallest polygonal area delimited by the 3 players who were nearer to each other. The results from these partial EPS situations were calculated in absolute values ( $m^2$ ) and also considering the amount of regularity (approximate entropy). The average speed of the players who formed each partial EPS was also calculated. The statistical comparisons were assessed via standardized mean differences and non-clinical magnitude-based inferences. **Results** The results from each of the six analysed matches were similar. The EPS area was higher with the increase in number of players, especially in the transition from 8 to 9 and 9 to 10 players. The correspondent regularity presented a most likely decrease trend (EPS3 vs. EPS4: difference in means:  $-25.5$ ;  $\pm 3.9\%$ ; mean,  $\pm 95\%$  confidence limits, to EPS9 vs. EPS10:  $-11.0$ ;  $\pm 3.1\%$ ), with magnitudes ranging from moderate to large. The predictability of EPS was especially higher in the transition from 8 to 9 and 9 to 10 players. The average speeds for each sub-group showed trivial/small differences (from EPS3 vs EPS4:  $7.06 \pm 0.22$  km/h, mean  $\pm$  sd, to EPS9 vs EPS10:  $6.86 \pm 0.21$ ). **Discussion** Collective coordination can be seen as a dynamic network that is formed by emergent behaviour originated in local sub-group relations. Current results allowed identifying how the increase in the number of players had the consequence of increasing predictability in EPS areas (as shown by approximate entropy). In addition, average speed results suggest that players achieve an optimal state of collective coordination between 6.5 to 7.5 km/h. The transition from 8 to 9 and 9 to 10 players were particular different from other EPS situations and should require extra attention when planning for representative tasks at the level of playing space and other environmental constraints such as game pace manipulation or player overloading/underloading.

#### TACTICAL METRICS DISTINGUISHING WINNERS, DRAWERS AND LOSERS IN UEFA EURO 2012®

Winter, C., Pfeiffer, M.

*Johannes Gutenberg University Mainz*

**Introduction** Recently, research concerning observational performance analysis in soccer has increased significantly. Nonetheless, most investigations neglect constituent properties of sports games (MacKenzie & Cushion, 2013). An alternative approach for notational analysis is presented that meets requirements for a meaningful analysis (especially the permanent procedural interaction). To create information crucial for coaches, a connection between the observations and success is established by means of artificial neural networks. **Methods** To gather meaningful tactical metrics, an observation model developed by Optikick® was used. Here, the main idea is to understand a soccer match as a system that is always in a certain state (Pfeiffer, Zhang & Hohmann, 2010). To score a goal the attacking team has to solve four different successive objectives: (1) Control the ball, followed by (2) a spatial progression and (3) the preparation of a scoring opportunity leading to (4) the shot on goal. Depending on the behaviour of the attacking team, the defence faces four corresponding tasks in addition to the omnipresent task to win control over the ball. The referees' decisions (interruptions, set plays and goals) complete the states. During a match a timestamp is recorded for each state transition and based on this data tactical metrics are calculated. For the study, 27 of the 31 games played at the UEFA Euro 2012® were analysed. The missing games included preliminary and final round matches of different teams, so that a systematic error is not expected. An artificial neural network (IBM SPSS 22) was used to classify if a team won, lost or drew depending on their tactical metric values. The data of 54 teams were divided into 75% training, 15%

testing and 10% hold-out. Training and classification process was calculated 20 times to reduce the possibility of a classification by chance. Results Inter-rater reliability showed excellent results (Cohens Kappa = .89;  $p < .05$ ). The artificial neural networks lead to 72.13% correct classifications. Only 7.84% of the winners were assigned to losers and 10% of the losers were assigned to winners. Discussion The successful classification reveals a connection between match success and the presented metrics. It should be highlighted that a wrong classification between winners and losers was very unlikely to occur. Tactical metrics describe different types of behaviour and, therefore, hold the opportunity to conduct meaningful recommendations for the training and coaching process. ## FACTORS AFFECTING PERFORMANCE TIMES IN INTERNATIONAL LONG-TRACK SPEED SKATING

Noordhof, D.A.1, Mulder, R.C.M.1, de Koning, J.J.1, Hopkins, W.G.2

(1) VU University, Amsterdam, The Netherlands (2) Victoria University, Melbourne, Australia

**Introduction** Analysis of competition performances of elite athletes can provide not only the effects of environmental and other venue-specific factors but also estimates of within-athlete variability between competitions, which determines smallest important and other magnitude thresholds for studies of factors affecting performance. An analysis of speed-skating performance times is available only for elite 1000-m races over a season (1). The purpose of this study was therefore to analyze all six international long-track speed-skating events, focusing on short-term variability between races (2). **Methods** Official performance times in international elite events were downloaded from speedskatingresults.com for one Olympic cycle and analysed with a mixed linear model. The fixed effects were altitude (numeric linear), barometric pressure (numeric linear), type of rink (closed vs open), and competition importance (World Championships or Olympics vs World Cups). Random effects provided estimates of residual venue-related variability of mean performance times between races and of within-athlete variability between races within clusters spanning ~8 d. Effects were assessed with magnitude-based inference. **Results** The within-athlete race-to-race variability expressed as coefficients of variation ranged from 0.5% to 1.3%. There was a small difference in within-cluster variability between male juniors (0.8%) and female juniors (1.0%) but no difference between male and female seniors (both 0.6%). In relation to thresholds defined by these variabilities (0.3x through 4.0x for small through extremely large respectively), the effects of altitude per 1000 m were very large mean improvements in performance of 2.5% in juniors and 1.9% in seniors. An increase in barometric pressure of 100 hPa resulted in a large reduction in performance of 2.0% for juniors and an unclear effect for seniors. Only juniors competed in open rinks, where there was a very large reduction in performance of 3.2%. Junior and senior skaters showed a small increase in speed (0.5% and 0.3%) at the more important competitions. Residual venue-related variability was generally moderate to large. **Conclusions** The variability in performance times of speed skaters is a little less than that of elite track cyclists, another sport performed against air resistance. Converted to units of mean power (by multiplying by 2-3), the variability is about twice that of elite track runners, presumably reflecting variability in technique and power output between races. Interactions between athletes and the large environmental and venue effects may also contribute to the variability. These findings will be useful for researchers investigating strategies to enhance performance of elite speed skaters. **References** 1. Muehlbauer et al. *Res Q Exerc Sport* 2010;81:1-6. 2. ## DOPING IN MASS SPORT: IN INEXPLICABLE PHENOMENON?

Pitsch, W.

Saarland University

Doping in mass sport is mostly understood within an (implicit) rational choice explanation, assuming that athletes try to maximize their benefit from engaging in elite sport by increasing their probability to reach high placements. At present, the phenomenon of doping in mass sport is increasingly focused by social scientific research as well as by Anti Doping Organizations although there is only little knowledge about the prevalence and the determinants of doping in this segment of sport. We conducted three empirical studies, investigating in the prevalence of doping in three different settings: (1.) among university students in four different European countries ( $n=8,224$ ), (2.) among sportsmen and -women in Palatinat (a region in Germany,  $n=1,930$ ) and (3.) among amateur cyclists, licensed by USACycling ( $n=3,756$ ). The research in all these studies was conducted using the Randomized Response technique in a webbased survey. This technique allows interviewees to answer embarrassing questions honestly without fear from social sanctions. The overall analysis showed that about 5 % of the participants in all these studies deliberately used forbidden substances or methods in order to increase their sporting performance. This percentage is somewhat lower than comparable results in elite sports but among the huge number of recreational sportsmen and -women we will nevertheless find a large number of deviators. The challenging issue for social sciences as well as for any Anti Doping measures is, that this behaviour cannot easily be explained by using similar patterns as in elite sport. Especially the influence of a monetary or non-monetary utility from high placements cannot be hypothesized as a driver for doping decisions in mass sports. By conducting comparative analyses over the three independent studies, we will describe which determinants are stable or unstable predictors of different doping prevalences. From these data, we will be able to formulate first assumptions, concerning the drivers for doping in recreational sport.

## PERCEPTIONS OF UK OLYMPIC AND PARALYMPIC SPORTS TOWARD ATHLETE SUPPORT SERVICES DELIVERED BY HIGHER EDUCATION INSTITUTES

Thompson, K.G.1, Allen, C.2, Taylor, G.2, McLeay, F.3

1:UCRise (Canberra, Australia), 2:TASS (Newcastle, UK), 3:Northumbria Uni (Newcastle, UK)

**Introduction** This study was part of a research project, funded by TSB, ESRC and ONE, which aimed to assess the requirements of sports for athlete support services based in Higher Education Institutes (HEIs) after the 2012 Olympic Games. **Methods** A questionnaire was developed containing a mix of 68 open and closed questions and administered to Performance Directors and High Performance Managers in summer and winter Olympic/Paralympic sports ( $n=55$ ) with 37 responding (62.7% return rate). **Results** Over 70% of respondents wanted to access facilities, athlete academic support and scholarship agreements with HEIs, although only 33-50% did. 75% were willing to receive more sport science support services from HEIs but only 47% did. Sports did not agree that HEI staff possessed adequate expertise in sports medicine, sports science, strength and conditioning, performance lifestyle, talent ID and research and innovation support services (5 point Likert scale 1=strongly disagree 5=strongly agree: mean values 2.31 to 3.13 SD 0.88-1.09). Sports reported that HEI sup-

port services would be worse than those delivered by the Home Country Institutes of Sport who employed specialised support staff (5 point Likert scale 1=a lot worse, 5=a lot better: mean 2.18, SD 0.87). Respondents agreed that practitioners based at HEIs had too much conflict with other University commitments (5 point Likert Scale 1=strongly agree, 5=strongly disagree: mean 2.15 SD 0.93). Non-the-less 88% of respondents indicated that they would be interested in joint funding a support post with a University due to: cost effectiveness (65%), sustainability (44%), staff development (42%), maintaining athlete support (38%) and staff retention (20%). Sports reported research collaboration as being beneficial (mean 4.08 SD 0.9; 5=large benefit, 1=no benefit at all) in terms of a performance (enhancing) impact (78%), with 44-50% also perceiving a benefit from the additional sport science testing support and educational impact involved for athletes and coaches. However only 45% of sports indicated they would actually like to see research and innovation provided by HEIs. When choosing an HEI to work with, sports reported in rank order of importance: location, cost, facilities, staff members, sporting reputation, academic reputation and being campus-based. Discussion Most sports perceived benefit from HEIs providing athlete support services, facilities, scholarships, academic support and research collaboration and would consider joint funded posts, however they had concerns regarding dedicated staffing and the quality of support services on offer; subsequently take-up of HEI services was less than 50%.

### OP-SH09 Psychology (Challenges within Sport Psychology II)

#### BREATHING EFFORT MORE THAN FLOW LINKS MUSIC TO AUTONOMIC HEALTH

Blasco-Lafarga, C.I, Monteagudo-Chiner, P.I, García-Soriano, C.I

*University of Valencia, Spain*

Introduction: Breathing efforts act upon the mechanism of the Respiratory Sinus Arrhythmia (RSA), an autonomic reflex which links respiration, blood pressure and cardiac regulation (Elghozi, Girard, Fritsch, Laude, & Petitprez, 2008), thus enhancing parasympathetic responses. Music and physical activity share other features such as Flow, an intrinsically enjoyable state that happens when there is a perceived balance between one's competencies and the demands of the task (Jackson & Roberts, 1992). Recent studies propose the use of Heart Rate Variability (HRV) (e.g. RMSSD), to quantify Flow (e.g. the challenge-ability balance dimension) (Keller, Bless, Blomann, & Kleinböhl, 2011; de Manzano, Theorell, Harmat, & Ullen, 2010), but to our knowledge, no study has analyzed the association between Flow and RSA in wind instrument players. Objectives: The present study aims to analyze the association between Flow and RMSSD changes in response to 2 wind instrument performances, different in terms of perceived difficulty. Methods: 8 male wind musicians (29.13±7.33 years; 69.36±10.31 kg) answered a questionnaire of flow "FSS-2" (Jackson & Eklund, 2002) following the 2 performances rated as difficult and easy, played on 2 alternate days with no audience. 2 segments of 20 minutes (Per1 & Per2), with 5 min of break, were retained for HRV analysis. The last 500 beats within each 20 min were analyzed (Kubios 2.1 software). Results: Opposite to RMSSD, which increased and even showed significant differences in the 2nd part of the hard performance ( $p < 0.05$ ), all Flow indexes went down as the difficulty increased, but not significantly (Wilcoxon test). Moreover, Challenge-hability balance showed a negative correlation with RMSSD at Per1 (Spearman,  $r = -0.752$ ;  $p = 0.032$ ) Discussion: Our results confirm the parasympathetic rebound due to the higher respiratory demands in the difficult performance, but suggest that this harder effort may become uncomfortable, and thus, related to the decrease in Flow, although not significantly. The autonomic benefits attributed to playing wind instruments through the RSA improvement, remain despite the fact that higher respiratory demands may lead musicians out of their comfort zone. #### THE VALIDITY AND RELIABILITY OF THE BEHAVIOURAL REGULATION IN EXERCISE QUESTIONNAIRE-2 AMONG RHEUMATOID ARTHRITIS PATIENTS

Yu, C.I, Rouse, P.C.2, Kitas, G.D.3, Duda, J.L.1

*1: University of Birmingham, UK, 2: University of Bath, UK, 3: Dudley Group of Hospitals NHS Trust, UK*

Introduction Rheumatoid Arthritis (RA) is a chronic inflammatory disease that causes pain, stiffness and joint swelling. Health benefits of regular physical activity (PA) have been demonstrated for RA patients however their PA uptake is low (Yu et al., in press). Thus, it is important to examine the motivation for PA in RA patients. Grounded in Self-determination Theory (Deci & Ryan, 2000), the Behavioural Regulation in Exercise Questionnaire (BREQ-2) (Markland & Tobin, 2004) was developed to assess autonomous and controlled regulations (and amotivation) for PA and validated in healthy populations. It is often errantly assumed that questionnaires designed for such populations are appropriate for clinical groups. This study adopted a mixed methods (qualitative and quantitative) approach to examine the validity and reliability of the BREQ-2 in RA patients. Methods Study 1: the 'think aloud' procedure and a focus group were employed to examine the content validity of the BREQ-2 (n=6; M age=65 yrs). Study 2: 325 RA patients (96 (m), 229 (f); M age=57 yrs) completed the BREQ-2. The internal reliability of the subscales was assessed and the factorial validity was determined via confirmatory factor analysis (CFA). To examine criterion related validity, bivariate correlations were calculated with scores on the Subjective Vitality Scale and a measure of perceived capability and quality of life (ICECAP-A). Results RA patients reported no difficulties comprehending the BREQ-2 items and found the content suitable. Results of the reliability test and CFA suggested two items be removed and the fit of the data to the measurement model was improved (Chi square=225.05, CFI=.96, RMSEA=.057). Subscales exhibited acceptable internal consistency (alpha =.75-.93). As hypothesised, autonomous motivations positively correlated with subjective vitality and reported QOL. Controlled regulations and amotivation were either negatively or not correlated with these variables. Discussion Findings provide support for the internal reliability and factorial and criterion-related validity of a 17 item BREQ-2 when administered to RA patients. The BREQ-2 could be employed in future studies examining (a) the determinants of and outcomes associated with PA motivation, and (b) the impact of SDT-based PA promotion interventions in this clinical population. ## ASSESSMENT OF THE RECOVERY-STRESS STATE IN SKYDIVERS

Finkenzeller, T., Löberbauer, M., Amesberger, G.

*University of Salzburg*

Introduction Skydivers are faced with a high amount of mental and physical demands (Chatterton et al., 1997). The ability to cope successfully with stress and to recover effectively is of great importance, especially in periods of intensive training such as a training camp. Heart rate variability (HRV) reflects autonomous nervous system activity and might be sensitive to indicate alterations in the stress-recovery state of skydivers caused by a high training load. Thus, aim of this study was to analyze i) alterations in the sympathovagal balance and ii) changes in the assessed actual recovery-stress state during the time course of a training camp. Method A sample of five male professional skydivers (age  $M = 30.2$  years,  $SD = 6.3$ ) completed a training camp in Florida that lasted 17 days. An electrocardiogram of the sleeping phase was recorded seven days before the camp in Austria and four times during the camp (day 2, 7, 12 and 16). A time segment of six hours (from 0:00 to 6:00 a.m.) was selected for analyzing HRV parameters. Additionally, the athletes filled out the stress-recovery questionnaire for athletes (REST-Q Sport; Kellmann & Kallus, 2000) three weeks before the camp and on the second and 16th training day. RM-ANOVA's (factor: time) were calculated with the values of HRV and REST-Q-scales. Results The mean of all normal beat-to-beat-intervals and the HRV parameters RMSSD, pNN50 und HFnu (normalized high-frequency power) demonstrated significant ( $p > .05$ ) or ten-dential ( $p < .08$ ) time effects ( $\eta^2$  between .47 and .69). The above mentioned values decrease from baseline to the second training day and show an increase to the 7th day. Subsequently, the parameters steadily decrease until the end of the camp. Significant or ten-dential time effects were obtained for the REST-Q-scales „general stress“, „lack of energy“, „physical recovery“ and „being in shape“ ( $\eta^2$  between .52 and .67) showing a decrease from baseline to the second day and an approximation to the baseline on the 16th training day. Discussion The decline in HRV from baseline to the second day reflects a reduced vagal activity that could be evoked to a large part by the jetlag. The temporal adaptation seems to be overcome until the 7th day expressed by an increase in vagal activity during night. The subsequent decreases in HRV may be caused by the mental and physical stress of the training. It is concluded that HRV is a sensitive indicator of the stress-recovery state in skydivers. ### OP-PM46 Training & Testing: Fatigue I

#### THE UTILITY OF THE MULTI-COMPONENT TRAINING DISTRESS SCALE TO MONITOR SWIMMERS DURING PERIODS OF TRAINING OVERLOAD

Main, L.C., Warmington, S.A., Korn, E., Gastin, P.B.

*Deakin University*

Introduction Athlete monitoring for optimising performance remains one of the greatest challenges for sport scientists and coaches alike. While strong and consistent relationships have been observed between self-report measures and performance, their use is not without limitations; such as timeliness of administration, and the potential time burden for athletes. Given the widespread use of the Recovery-Stress Questionnaire for Athletes – Sport (REST-Q), and its reported ability to show significant changes concurrently with training loads in swimming (González-Boto, et al., 2008), the aim of the present study was to assess the utility of the shorter MTDS (Main & Grove, 2009), compared with the REST-Q-Sport, to monitor swimmers preparing for the national championships. Methods Twenty-one national level adolescent swimmers completed eight weeks of testing. Once a week participants completed an 8 x 50 m sprint test, vertical jump test, sit-and-reach test, the MTDS and the REST-Q. All testing was incorporated into the swimmers' normal training program. Sequential regression was employed to determine if addition of the MTDS improved prediction of athlete performance beyond that afforded by the REST-Q. For exploratory purposes, a second sequential regression was performed where the order in which the two questionnaires were entered was switched to determine if the MTDS on its own provided greater predictive ability of performance than the REST-Q. Results On its own, the REST-Q accounted for the following variances in performance: flexibility (14.6%,  $p < 0.01$ ), power output (17.7%,  $p < 0.01$ ), swimming speed (15.5%,  $p < 0.01$ ) and swimming endurance (17.5%,  $p < 0.01$ ). In comparison, on its own the MTDS accounted for the following variances in performance: flexibility (12.1%, NS), power output (16.4%,  $p < 0.05$ ), swimming speed (20.5%,  $p < 0.01$ ) and swimming speed endurance (23.8%,  $p < 0.001$ ). Discussion The findings of the current study suggest that both the REST-Q and the MTDS have the capacity to predict performance on a range of fitness components associated with swimming. The REST-Q was more sensitive to predictions associated with swimmer flexibility and power output, while the MTDS was more sensitive to predicting actual swimming performance. #### AQUA EXERCISE DOES NOT AFFECT RECOVERY OF PERFORMANCE, DAMAGE MARKERS, THE IMMUNE-STATUS AND SENSATION OF PAIN AFTER MUSCLE-DAMAGING EXERCISE.

Wahl, P., Sanno, M., Ellenberg, K., Frick, H., Boehm, E., Haiduck, B., Mester, J., Bloch, W.

*German Sport University Cologne*

Introduction Aqua exercise might be an effective method of recovery from muscle damaging exercise, as the water resistance might induce mild massaging effects and hydrostatic pressure, and the exercise itself might increase muscle blood flow without inducing further eccentric actions, all reducing the oedema and inflammation. Therefore, the aim of the present study was to investigate the effects of passive recovery vs. aqua cycling on isometric and dynamic strength, markers of muscle damage, the immune status, muscle soreness and the perceived physical state (PEPS) after muscle damaging exercise. Methods 20 male subjects (age:  $24.4 \pm 2.2$ , weight:  $81.6 \pm 7.6$  kg) completed 300 maximal-effort counter movement jumps (CMJ) (one jump every 8 sec.). Afterwards, they were randomly assigned to either a passive recovery group (P) or an aqua-bike (AB) group, which performed 30 min of cycling in a pool. Before, directly

after the 300 CMJ, directly after the recovery session and up to 72h post, isometric and dynamic strength of leg extensor muscles, creatine kinase (CK), lactate dehydrogenase (LDH), and the immune status were measured. Furthermore, questionnaires on muscle soreness (visual analog scale (VAS)) and PEPS were completed. Results Maximal isometric and dynamic strength showed significant decreases in both groups of up to -20%. Number of repetitions at 30% of maximal isometric strength even decreased up to -35%, but showed a faster recovery than maximal performance. However, no significant differences were found between both groups in all measures of performance. Each of the four dimensions of the PEPS (health, flexibility, fitness, energy) and the VAS showed significant changes over time, however, no differences were found between groups. CK and LDH significantly increased over time and both parameters increased higher in the AB-group (CK: AB: +1325% vs. P: +864%; LDH: AB: +157% vs. P: +131%), but again no significant differences were found between AB and P. Also, measures of the immune status showed significant effects over time, but no significant differences between groups. Discussion The results of the present study showed, that a single 30min session of aqua exercise after 300 CMJ did not affect the recovery of muscle power, muscle soreness, the persons perceived physical state, markers of muscle damage and the immune status compared to passive rest. These results are in contrast to previous studies investigating the effects of aqua exercise on recovery (Takahashi et al. J Sport Sci. 2006), although aqua exercise was repeated on consecutive days in this study. Therefore, it might be concluded, that this kind of recovery intervention needs to be repeated more frequently to generate effects. Contact Wahl@dshs-koeln.de

### ACUTE FATIGUE OF LOWER LIMB AND TRUNK MUSCLES IMPAIRS STRENGTH, BALANCE AND SPRINT PERFORMANCE IN ACTIVE YOUNG ADULTS

Faude, O., Donath, L., Lustenberger, K., Furer, T.S., Zahner, L., Roth, R.

*University of Basel*

Introduction Balance, strength and sprint abilities are important performance prerequisites in various sports. Trunk and lower limb muscles are both considered relevant to control and maintain body functioning. To date there is scarce data available on the impact of either trunk or lower limb musculature on functional performance. We conducted a randomized controlled cross-over study to quantify the impact of isolated trunk muscle fatigue in comparison to isolated lower limb fatigue on strength, balance and sprint performance. Methods Twenty-four sport students (12 women; 23 (SD 3) y; 59 (10) kg; 1.65 (0.09) m; 12 men; 23 (3) y; 78 (9) kg; 1.81 (0.06) m) completed on three different days in randomized order either a trunk fatigue protocol, a lower limb fatigue protocol or a passive control condition. Before and after each fatigue protocol and the control condition, several performance tests were conducted in the following order: isokinetic strength (trunk as well as knee flexion and extension); static (tandem stance on a force plate) and dynamic (Y-balance test) balance; 20 m-sprint; agility and a prone plank test. The trunk fatigue protocol comprised repetitive trunk extension and flexion as well as loaded Russian twists. The fatigue protocol for the lower limbs included unilateral leg press (both legs), seated leg-curls and repeated counter-movement jumps. Exercises were repeated as circuit training for 20 min. Results Compared to the control condition, trunk fatigue resulted in impaired isokinetic trunk flexion strength (probability for the effect being practically meaningful: 100%; standardized mean difference: 1.13), prone plank (100%; 0.74), Y balance (87%; 0.31), agility (83%; 0.28) and tandem stance (89%; 0.45) performance. Lower limb fatigue negatively affected Y balance (100%; 0.64), agility (100%; 0.58), sprint (100%; 0.36), tandem stance (100%; 0.92) and prone plank (95%; 0.39) performance as well as trunk flexion (81%; 0.24) and knee extension (89%; 0.29) strength compared to control. Trunk flexion (100%; 0.93) and prone plank performance (97%; 0.37) were impaired after trunk fatigue relative to lower limb fatigue. Greater impairments after lower limb fatigue were observed for Y balance (87%; 0.33), agility (96%; 0.32), sprint (76%; 0.24) and tandem stance (78%; 0.38) performance as compared to trunk fatigue. Discussion We observed that a 20 min fatigue protocol, focusing either the legs or the trunk, impaired balance, strength and sprint performance. Particularly, balance and sprint performance were affected by lower limb fatigue. Although to a lower extent, isolated trunk fatigue also deteriorated these functional performance measures. ### THE EFFECT OF POST-EXERCISE CRYOTHERAPY ON RECOVERY CHARACTERISTICS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Hohenauer, E., Taeymans, J., Baeyens, J.P., Clarys, P., Clijisen, R.

*University of Applied Sciences and Arts of Southern Switzerland*

Introduction The effectiveness of cryotherapy on post-exercise recovery is predominantly described as the ability to decrease the inflammatory processes through reducing the local cell metabolism by inducing vasoconstriction. The aim of this review and meta-analysis was, to critically determine the possible effects of different cooling applications compared to non-cooling, passive post-exercise strategies on recovery characteristics after various, exhaustive exercise protocols. Methods A systematic literature search was conducted in the databases MEDLINE (PubMed), SportDiscus and PEDro between. A total of n = 36 articles were processed in this study. To establish the research question, the PICO-model, according to the PRISMA guidelines was used. The Cochrane's risk of bias tool was used for the quality assessment. Meta-analyses of subjective characteristics like delayed-onset muscle soreness (DOMS) and ratings of perceived exertion (RPE) and objective characteristics like blood plasma markers and blood plasma cytokines during a 96 hours (hrs) recovery period were performed. Results The overall risk of bias, especially for performance bias and detection bias, was high. Pooled data from 27 articles showed, that cooling and especially cold water immersion affected the symptoms of DOMS (up to 96 hrs) and RPE (up to 24 hrs) significantly compared to the control conditions. There was no evidence, that cooling affected objective recovery variables significantly. Discussion The majority of the studies had a high risk or an unclear risk of bias, which made the interpretation of the results uncertain. The main bias was produced with the blinding procedure. One main finding of this study was, that cold therapy (CWI) significantly alleviated the symptoms of DOMS 24 hrs, 48 hrs and 96 hrs after the cooling application. In this context it can be advised to take the amount of adipose tissue over the affected cooling area into account, because it can significantly affect the rate of intramuscular cooling. These findings are important for further studies because the effect of cooling could be highly influenced by the amount of adipose tissue. We had to spend much time for extracting data out of graphs or to contact researchers to obtain their data. Future studies should present their data e.g. as mean  $\pm$  SD and not only as graphs, without detailed description. References Moher D, (2009), J Clin Epidemiol, 62(10): p. 1006-12. ### OP-PM73 Molecular Biology and Biochemistry: Age

#### EFFECTS OF DIFFERENT TYPES OF CHAIR BASED EXERCISE PROGRAMS ON HORMONAL, FUNCTIONAL AUTONOMY AND PHYSICAL FITNESS IN PRE-FRAIL ELDERLY WOMAN.

Furtado, G.1,2, Uba-Chupel, M.1,2, Rama, L.1, Rieping, T.1, Sousa, N.1, Direito, F.1, Pedrosa, A.F.1, Ferreira, J.P.1, Teixeira, A.M.1

1:Coimbra University, Faculty of Sport Sciences and Physical Education (Coimbra, Portugal), 2: CAPES - CsF (Ministry of Fundation, Brazil)

**Introduction :** The main consequence of the immunosenescence is the decline of the functional autonomy (FA) and a satisfactory physical fitness (PF) state (Milte & Crotty, 2014). These factors are associated with elderly-frailty, whose common characteristic is psychophysiological stress. Cortisol (COR) is an essential hormone in the regulation of the stress response but recently, salivary alpha-amylase (sAA) has also emerged as a novel biomarker for evaluating stress (Maruyama et al., 2012). The aim of this study is to analyse the effects of different chair-based group exercise class programmes (CBE) on salivary COR and sAA levels, PF and FA in pre-frail elderly woman. **Methods:** The sample consisted of 61 female participants (age =  $82 \pm 7.30$ ) from four elderly care institutions. The participants were stratified according to the Frailty Phenotype developed by Fried et al., (2001) and divided into an four groups: a) aerobic 'walking' (AWE, n=23); b) Yoga/ flexibility (YTF, n=24); Elastic-band (E-BR, n=21) and control group (CG, n=21). To measure FA the Tinetti Falls Efficacy Scale (FES), Katz Index of Independence (ADL) and The Lawton Instrumental Activities of Daily Living (IADL) Scale were used. For measured PF, the Rikli & Jones 'Senior Fitness Test Battery' was used. The salivary levels of sCOR were measured by ELISA and sAA by a kinetic assay. All the tests were applied before and 14-weeks after the exercise CBE programme intervention in all the groups. **Results:** Our study revealed that cortisol levels increased slightly ( $p=.72$ ), but not significantly, unlike the alpha amylase activity, that decreased substantially in all the intervention groups ( $p=0.12$ ). No changes in the perception of the IDL and IADL were reported, however a significant decrease in RF, except for the CG was reported. The levels of physical FP improved substantially, except for the CG and the YTF groups. **Discussion:** The effectiveness mediation of the CBE programmes aiming at substantial improvements in overall health and PF of frail-elderly is scarcely present in the scientific literature (Robinson et al., 2014). A short increased in COR response is characteristic of the hormonal adaption to exercise (Maruyama et al., 2012). Moderate exercise programs in elderly populations may induce a lower sympathetic influence, which may explain the decrease in the alpha-amylase secretion. The decrease in the sAA activity could also be associated with an anti-inflammatory state through the increment on the para-sympathetic activity. The improvement in FP and the decrease in the RF show that even in this pre-frail old population, is possible to gain muscle strength and balance with CBE. **References** Fried, L. et al. (2001). #### MICRORNA PROFILES OF SUBCUTANEOUS FAT TISSUE AND SERUM IN WOMEN – ASSOCIATIONS WITH AGE AND POSTMENOPAUSAL HORMONE REPLACEMENT THERAPY

Kovanen, V.1, Lanzarini, C.2, Kangas, R.1, Alen, M.1, Kaprio, J.3, Kujala, U.1, Sipilä, S.1, Franceschi, C.2, Pöllänen, E.1, Capri, M.2

1: GEREK and Dept. of Health Sciences, University of Jyväskylä (Jyväskylä, Finland), 2: Dept of Experimental Pathology, University of Bologna (Bologna, Italy) 3: National Institute for Health and We

**Introduction** After menopause, women tend to gain weight due to accumulation of fat. Fat tissue is secretory organ contributing to inflammation. However, little is known about the contribution of fat to the circulating microRNA (miR) pool. This study aimed to investigate the similarities and differences of fat and serum miR pools in premenopausal women and in postmenopausal hormone replacement therapy (HRT) users and non-users. **Methods** Subcutaneous fat tissue and serum were used from a subsample of the SAWEs Study. It includes postmenopausal HRT discordant MZ twin pairs (Ronkainen et al 2009) and a cohort of premenopausal women with no hormonal treatment (Pöllänen et al 2011). Mature miR profiling was performed using an Applied Biosystem's human MicroRNA Array pool A. Target genes and pathways of specific miRs were identified using the DIANA-microT 3.0 (<http://diana.cslab.ece.ntua.gr/microT/>) as in Olivieri et al (2014). **Results** We found 11 miRs to be up- and 25 down-regulated in fat and 5 up- and 38 down-regulated in serum when postmenopausal women not on HRT were compared to premenopausal women (aging-effect). Only three of the identified miRs were found in both fat and serum. Most highly affected pathway by this miR profile was steroid hormone biosynthesis. When comparing MZ twins having used several years' HRT with their non-user co-twins, 13 miRs were found to be up- and 22 down-regulated in fat and 36 up- and 10 down-regulated in the serum of HRT users (HRT effect). Four miRs were found in both fat and serum samples. One of the significantly affected KEGG pathways was WNT signalling. We also compared the fat and serum miR profiles between premenopausal women and postmenopausal HRT users and found 12 up- and 26 down-regulated miRs in fat, 12 up- and 15 down-regulated miRs in serum and three shared miRs down-regulated both in fat and serum (anti-aging effect of HRT). Most significantly affected pathway was the TGF-beta signalling pathway. **Discussion** Fat and serum miR profiles and the potentially affected KEGG pathways showed both age and estrogen status related differences. These results emphasize the importance of miR-mediated regulation of aging process in fat. Furthermore, the role of circulating miRs in serum, as potential diagnostic markers of aging or hormonal status warrants further studies. **References** Ronkainen PH et al (2009) J Appl Physiol. 107:25–33. #### EFFECTS OF ELASTIC-BAND RESISTANCE TRAINING AND NUTRITIONAL SUPPLEMENTATION ON CIRCULATING MYOKINES AND MUSCLE QUALITY OF INSTITUTIONALIZED ELDERLY - THE VIENNA ACTIVE AGEING STUDY

Hofmann, M., Halper, B., Oesen, S., Franzke, B., Wagner, K.H., Wessner, B.

University of Vienna

**Introduction** Ageing is associated with reduction of muscle mass and physical function, whereby strength training and adequate nutrition have revealed beneficial effects [1]. However, studies in very old people including mechanistic explanations are scarce. Therefore, the aim

of this study was to investigate whether circulating myokines (myostatin (MST), GDF-15, activin A, follistatin (FST), IGF-1), muscle quality (MQ) and functional parameters would be altered in response to resistance training with or without protein supplementation in institutionalized older people. Methods A total of 117 participants (103 females aged 82.5±5.9; 14 males aged 84.7±6.4) were randomly assigned to 3 groups (RT=resistance training, RTS=elastic-resistance training combined with protein supplementation, CT=cognitive training) and examined before, after 3 and at the end of 6-months of intervention with 2 sessions per week in each of the 3 groups. MQ was determined as the ratio of muscle strength or power and muscle mass [2]. Serum MST, FST, GDF-15, IGF-1 and activin A were measured by ELISA. Physical function was analysed using handgrip strength, chair rise test, arm lift test and 6 minute walking test (6MWT). To assess changes over time within the single study groups Friedman-tests were used. Results MQ increased in response to RT (+13%, p=.002) and RTS (+15%, p=.040). Additionally, performance improved in RT and RTS for chair rise test (RT +28%, p=.001; RTS +25, p=.003), arm lift test (RT +23%, p=.002; RTS +51%, p=.000) and 6MWT (RT +14%, p=.021; RTS +10, p=.015). These changes were accompanied by changes in FST (RT: +12%, p=.028; CT: -7%, p=.030) and activin A (RTS: +52%, p=.042; CT: -10%, p=.011), while IGF-1, MST and GDF-15 levels were not affected. At baseline, MQ correlated positively with all physical parameters and negatively with GDF-15 (p<0.05). Discussion Our data confirm that MQ and physical performance is increased by strength training even at an older age, whereas protein supplementation seems to be ineffective in further enhancing performance. As FST blocks the activation of activin A (and MST) [3] we hypothesize that the positive effects of strength training in elderly could be mediated by blocking muscle degradation pathways rather than inducing muscle growth, usually induced via IGF-1. However, this needs to be confirmed in further studies investigating the cellular mechanisms directly in skeletal muscles. References [1] Peterson MD, et al. ### HORMONE STATUS DEPENDENT DIFFERENCES IN MUSCLE PROTEOMICS: A STUDY WITH PREMENOPAUSAL WOMEN AND POSTMENOPAUSAL TWIN SISTERS DISCORDANT FOR THE USE OF HORMONE THERAPY

Pöllänen, E., Soliymani, R., Lalowski, M., Niskala, P., Sipilä, S., Kaprio, J., Kujala, U., Baumann, M., Kovanen, V.

1: Department of Health Sciences, University of Jyväskylä, Finland, 2: University of Helsinki, Finland, 3: National Institute for Health and Welfare, Helsinki, Finland.

Introduction. We studied the effects of menopausal status (pre/post) and effects of postmenopausal use of hormone replacement therapy (HRT) on skeletal muscle proteomics. Methods. The 24 female study participants were 6 healthy premenopausal women and 9 postmenopausal monozygotic twin sister pairs. Homogenized m. vastus lateralis samples were solubilized in 2D conditions using modified FASP protocol. The protein digests were separated and analysed using label-free nano-liquid chromatography tandem mass spectrometry (nano-LC-MS/MS) on a Synapt G2-S mass spectrometer (or ProteomicsTM Informatics software) were limited by including only those quantified with ≥2 unique peptides and p≤0.05 by ANOVA. The filtered lists of proteins with up/down-regulated expression were subsequently used in the Ingenuity Pathways Analysis (IPA, www.ingenuity.com). Results. In total, 918 proteins were identified, of which 662 were quantified and used in IPA comparisons. Of them, 223 were significantly differentially expressed in post- vs. premenopausal subjects (age-effect) and 136 in comparisons between postmenopausal HRT-users with their non-using co-twins (HRT-effect), p≤0.05 in both comparisons. Four most significantly associated canonical pathways revealed by IPA searches included: Mitochondrial dysfunction, Oxidative phosphorylation, Glycolysis and Calcium signaling (p-values ranging from 1E-8 to 2E-24). Analysis of downstream effects predicted an increase in the activity of Cell death and survival and decrease in Small molecule biochemistry pathways, portrayed as an age-effect, which were found to be reversed in HRT users. Discussion. We were able to identify proteome-wide differences in skeletal muscle of pre- and postmenopausal women and in HRT-users compared to non-using genetically identical twin sister. Our results indicate that both age and HRT associate with alterations in muscle energy metabolism. One of the major changes predicted to be increased in postmenopausal as compared to premenopausal state were related to cell death, while in HRT-use showed the opposite trend. These results indicate that estrogen exerts a regulatory role on muscle metabolism and processes of cell survival. However, it cannot be completely ruled out that the observed differences in post- vs. premenopausal state are due to aging per se and not due to difference in hormonal status. ### OP-PM52 Health & Fitness: Lifestyle I

#### INFLUENCE OF GENETIC POLYMORPHISMS ON RESPONSE TO PHYSICAL TRAINING IN HEALTH PARAMETERS

Bueno Junior, C., Frattini, I.R., Ferrari, G.D., Chiaratto, T., Ferezin, L.P., Trape, A.A., Hott, S.C.

University of Sao Paulo

Introduction The dramatic increase in average life expectancy highlights the importance of promoting a healthy aging and regular practice of physical exercise (Fried, 2004). It is also known that genetic polymorphisms may act in the expression of proteins and change features that modify the response to a practice of physical exercise (Ostrand et al., 2009). In this context, the purpose of this study was to analyze the effects of ACE I/D and ACTN3 R/X genetic polymorphisms on response to physical training in health parameters in women at the end of adulthood and early in the old age. Methods Fifty four women were genotyped (ACE I/D and ACTN3 R/X genetic polymorphisms) and based on these genetic characteristics they were shared in groups and trained during 12 weeks in an indoor sports court (two days a week and 90 min per day, mainly doing aerobic and strength exercises at level 13 to 15 on the Borg Scale). They also were submitted to measurements of height, body mass, body mass index, waist circumference, blood pressure and answered questionnaires related to quality of life (Short Form - 36 - Health Survey), levels of depression (Geriatric Depression Scale - GDS), psychological stress (Stress Symptoms Inventory - SSI) and sleep quality (Epworth Sleepiness Scale - ESS) immediately before and after this intervention period. The comparison between the averages of the different groups was performed by two-way repeated measures ANOVA and the significance level adopted was 5%. Results Related ACTN3 only the RR/XX group presented a reduction in body weight and systolic blood pressure after training, as well an improvement in quality of life and daytime sleepiness - and among these four variables the RR/XX group was only different of the XX group at the beginning (before training) in systolic blood pressure. On the other hand, despite only the II ACE have shown a reduction in body weight and body mass index after training, this group had presented at the beginning of training

higher values of body weight and body mass index. Discussion This is the first study related ACTN3 and ACE polymorphisms and the analysed variables. Regarding blood pressure, for example, there are some studies related NOS polymorphisms (Sponton et al., 2014). In conclusion, the RR/XX ACTN3 group presented better response to the exercise than the XX group, as well as the II group, despite its worse initial values when compared to the other groups. ### STABILITY OF LEISURE-TIME PHYSICAL ACTIVITY AND ALL-CAUSE MORTALITY IN TWINS DURING 23-YEAR FOLLOW-UP

Waller, K., Kaprio, J., Kujala, U.M.

*University of Jyväskylä*

Introduction Many observational studies have reported that leisure-time physical activity has protective effect on all-cause mortality, however no randomized controlled trials conform this. As observational studies are not able to adjust for genetic selection, the aim of this twin study was to find out whether long-term (15 years) leisure-time physical activity, adjusted for genetic liability and childhood experiences, protect against all-cause mortality. Methods The prospective Finnish Twin Cohort includes all same-sex twin pairs born in Finland before 1958. Physical activity was measured with structured questionnaire. The stability and change in vigorous and volume of physical activity during 15-year baseline (activity measured in 1975, 1981 and 1990) were used as the baseline predictors. Altogether 11 325 twin individuals, including 4 190 complete twin pairs, had answered required physical activity questions in all three baseline time points. Cox proportional hazards model was used for mortality analysis starting from the 1990 response date until July 31, 2013. Results During follow-up period 1 478 individuals died. Decreased mortality was observed among individuals with continues vigorous physical activity (active in 1975, 1981 and 1990); age and sex adjusted hazard ratio (HR) of death was 0.55 (95 % CI 0.46-0.64) and full covariate adjusted HR including health status was 0.73 (0.61-0.88), while the fully adjusted HRs for activity increasers and decreasers were 0.86 (0.75-0.99) and 0.95 (0.78-1.16) respectively compared to individuals who had no vigorous activity during baseline years. Within pairwise analyses HR for continues vigorous activity was 0.65 (0.46-0.91) and fully adjusted was 0.72 (0.48-1.07). Also belonging to the highest third in volume of physical activity during 15 year baseline was associated with decreased mortality even in fully adjusted pairwise model (0.73, 0.54-0.98) when compared to the lowest third. No differences were seen in any of the analyses within MZ pairs with cotwins differing in physical activity profile. Discussion Continues vigorous physical activity and high volume of activity decreased mortality during a 23-year follow-up even among individuals without clinically overt disease. However, genetic selection may play a role in this as no difference was seen within MZ pairs. Contact katja.waller@jyu.fi

### POINTS-BASED PHYSICAL ACTIVITY: A NOVEL APPROACH TO PHYSICAL ACTIVITY PROMOTES IMPROVED BODY COMPOSITION IN OVERWEIGHT, INACTIVE WOMEN.

Holliday, A.1,2, Vargas, E.1, Burgin, A.1, Blannin, A.1

*University of Worcester*

1 U. of Birmingham, UK. 2 U. of Worcester, UK. Introduction: Fifty-eight percent of women in England are overweight or obese (Health and Social Care Information Centre, 2013). In addition, only 29% of women in England meet the recommended level of physical activity (Townsend et al., 2012), despite the health benefits of exercise being widely acknowledged. The aim of the current study was to investigate the effect of a points-based exercise intervention, offering greater flexibility and autonomy, on changes in cardiovascular fitness (CVF), body-weight (BW), and body composition (BC) in overweight, inactive women. Method: Seventy-six overweight, inactive women were randomly assigned to one of three groups: point-based exercise (PB; n=24, 40±7 yrs, 28.7±3.2 kg•m<sup>-2</sup>), traditional prescribed exercise (Pres; n=26, 41±7 yrs, 29.9±3.3 kg•m<sup>-2</sup>) or control (CONT, n=26, 42±7 yrs, 28.6±3.3 kg•m<sup>-2</sup>). Pres completed 30 minutes of moderate-intensity exercise, 5 times per week. PB attained 35 "Physical Activity Points" (derived from MET scores) each week, awarded for exercise and non-exercise physical activity of varying intensity and duration. CONT maintained sedentary behaviour. All participants were asked not to alter dietary habits. Measures of BW, waist and hip circumferences were obtained and BC was measured using Dual-X-ray Absorptiometry. A treadmill incremental exercise test to exhaustion was completed for the measure of maximal aerobic capacity (VO<sub>2</sub>max) and maximal fat oxidation (MFO). All measures were obtained at baseline, weeks 4, 12 and 24. Results: BW was significantly lower in PB at 24-weeks compared with baseline (74.2±8.7 kg vs. 77.7±9.3 kg, p=0.004). Change in BW was significantly greater in PB at 24-weeks (-3.3±5.9 kg) than in CONT (+0.7±2.6 kg, p=0.020). No change in BW was observed in Pres. Total fat mass was significantly lower at 12-weeks compared with baseline in PB (27.6±5.99 kg vs. 29.2±6.54 kg, p=0.005). Reduction in fat mass was significantly greater in PB compared with CONT at 24-weeks (-1.93±4.75 vs. +0.92±2.33 kg, p=0.045). Neither lean mass nor body fat percentage changed significantly in any condition. VO<sub>2</sub>max and MFO were unaltered with training. Discussion: A point-based approach to physical activity interventions may prove beneficial for improving BC, compared with traditional exercise programs. However, more strenuous exercise may be necessary to elicit improvements in CVF and increase lean mass to further enhance BC. ### THE EFFECT OF INTELLIGENT PHYSICAL EXERCISE TRAINING ON SICKNESS ABSENCE AND JOB PERFORMANCE AMONG OFFICE WORKERS: A RANDOMIZED CONTROLLED TRIAL

Christensen, J.R., Sjøgaard, G., Sjøgaard, K., Justesen, J.B.

*University of Southern Denmark*

Introduction Physical training may improve health and decrease the risk of sickness absence and low job performance. The aim of this paper was thus to investigate the effect of individually tailored intelligent physical exercise training (IPET) on sickness absence and job performance among office workers. Methods In a randomized controlled trial employees from six companies located across Denmark were allocated to a training group, TG, (N = 194) or a control group, CG, (N = 195). The TG received one-hour high intensity IPET every week within working hours, and was recommended to perform 30 minutes of moderate intensity physical activity six days a week during leisure time. The principles of IPET have previously been described in details (Sjøgaard, Justesen et al. 2014). Before and after the one-year intervention the office workers answered a questionnaire on work ability (ten-step ordinal scale), productivity (ten-step ordinal scale),

and health (five-step ordinal scale). These data were analyzed with ITT. Only short term absence in spells of 1 to 10 days were included in the sickness absence data. Adherence was calculated as the number of completed training sessions out of the total possible training sessions, which ranged from 34 - 37 between the six companies within the one-year time-period. For the per protocol analysis, we set a cut-point of  $\geq 70$  % for adherence. Results At baseline, there were no differences between training and control group. The participants were on average  $44 \pm 10.4$  years old, 75% were female and had an average BMI of  $25.4 \pm 5.1$  kg/m<sup>2</sup> and an average percentage body fat of  $29.1 \pm 8.8$ %. After one year, an ITT analysis showed that TG had a significant increase in workability from 8,7 to 9,0 ( $p = <0.001$ ), productivity from 8,2 to 8,6 ( $p = 0.054$ ) and general health from 3,5 to 3,8 ( $p = <0.001$ ) compared to the CG but there was no change in sickness absence between the two groups. A per protocol analysis, where 89 (46%) office workers participated  $\geq 70$  % showed a significant 6% improvement in job performance ( $p = <0.001$ ), and 56 % decrease in sickness absence ( $p = <0.001$ ) compared to the CG from baseline to one-year follow-up. Sickness absence were at baseline mean 4,4 days in TG and 3,5 days in CG. Discussion One-hour high intensity IPET in working hours combined with recommendations of 30 minutes daily leisure time moderate intensity physical activity improved job performance and decreased sickness absence if adhering to the intervention protocol. Overall, these results underline the effectiveness and corporate incentives of implementing IPET at the workplace. Reference Sjøgaard G., Justesen JB, Murray M, Dalager T, Sjøgaard K. (2014). ### OP-PM25 Physiology: Mixed session

#### FAT OR FIT: DOES BODY COMPOSITION OR FITNESS AFFECT IMMUNE AND INFLAMMATORY CHANGES OF FIREFIGHTERS IN THE HEAT?

Walker, A.1,2, Keene, T.2, Argus, C.1, Driller, M.3, Rattray, B.1

*University of Canberra*

1: UCRISE (Canberra, Australia) 2: ESA (Canberra, Australia) 3: UW (Hamilton, NZ) Introduction When firefighters work in the heat, changes in immunity (Smith, DL et al., 2005) and inflammation (Wright-Beatty et al., 2014) occur, possibly increasing the risk of immunothrombosis. However, a risk profile for individuals regarding these changes is largely unknown. The present study aimed to establish whether differences in body composition and fitness affect the magnitude of immune and inflammatory changes of firefighters following work in a hot environment. Methods Forty-five urban firefighters (42 male, 3 female;  $40.1 \pm 8.6$  yrs,  $178.8 \pm 7.5$  cm,  $83.3 \pm 9.4$  kg) completed a standardised work task in the heat ( $100 \pm 5^\circ\text{C}$ ) consisting of two 20-min periods separated by a 10-min rest. Prior to heat testing, individuals were assessed using DXA for body-fat (BF) ( $20.8 \pm 7.2$  %), lean-mass (LM) ( $65.6 \pm 7.4$  kg) and anthropometric determination of BMI ( $26.2 \pm 2.2$  kg.m<sup>-2</sup>). Further, aerobic capacity (VO<sub>2</sub>) was assessed via open-circuit spirometry using the Bruce treadmill protocol ( $56.2 \pm 8.6$  ml.kg.min<sup>-1</sup>). Participants were separated based on each characteristic into tertiles for analysis (Low, Mod, High). Blood was collected at 4 time points (pre-work, post-work, post+1hr and post+24hrs). Participants completed a self-selected recovery protocol following the work task. Differences in Leukocytes, platelets, TNF $\alpha$  and LPS were then compared based on those tertiles. Results Overall increases in immune and inflammatory markers were observed following the work period, with platelets remaining elevated 24-hrs into recovery. Participants with higher levels of BF had significantly higher levels of leukocytes ( $p=0.01$ ) and TNF $\alpha$  ( $p=0.03$ ) at the four time points. Further, LPS was affected by differences in LM alone with the high tertile group demonstrating lower values than the low ( $p=0.04$ ). Platelet numbers were not affected ( $p>0.05$ ) by tertiles for any variable. Likewise, neither BMI nor VO<sub>2</sub> tertile distinguished levels of any immune or inflammatory variable. Discussion Differences in body composition, particularly BF and LM may play a predictive role in changes to immunity and inflammation in firefighters following work in the heat. On the other hand, neither BMI nor VO<sub>2</sub> played a role in the immune and inflammatory response of this cohort. Firefighters demonstrating high BF and/or low LM may experience higher levels of immune and inflammatory activity, which may be predisposing them to a greater risk of a thrombotic event. Focusing on improving body composition, independent of BMI may improve the safety of firefighters when they work in the heat. References Smith DL et al., (2005). Ergonomics, 1, 55-65. #### GALECTIN-3 AND SUPPRESSION OF TUMORIGENICITY 2 MEASUREMENT IN PARTICIPANT AT THE "TOR DES GÉANTS"

Le Goff, C., Kaux, J.F., Gergelè, L., Millet, G.P., Viallon, M., Croisille, P., Cavalier, E.

*University Hospital of Liège*

Introduction: Gal-3 is a carbohydrate binding lectin produced by macrophages, upregulated in hypertrophied heart, emerging as a mediator for fibrosis development and cardiac remodeling. ST2 is a family member of IL-1 receptors initially known for its role in immunological processes. It has a potential role in the cardiac pathogenesis. These receptors are led in cardiomyocytes and fibroblasts due to a mechanical stress. We aimed to examine the evolution of Gal-3 and ST2 in trailers who ran one of the most challenging ultra-marathon in the world: the Tor des Géants (330 km, altitude range: 24000m). Methods: Levels of plasma Gal-3 and ST2 were determined at 4 times: before the start, after 158km, at the end and 3 days after the end of the race in 33 trailers. Samples were directly centrifuged and frozen at  $-80^\circ\text{C}$ . Gal-3 measurement was performed on the VIDAS (Biomérieux) and ST2 was analyzed with the Presage ST2 Assay (Critical Diagnostic). The reference values are  $<17.8$ ng/mL for Gal-3 and  $<35$ ng/mL for ST2. Statistica was used for the statistical analysis (ANOVA). We calculated the difference between the different time and expressed in delta:  $\Delta 1=(T2-T1)/T1*100$ ,  $\Delta 2=(T3-T2)/T2*100$ ,  $\Delta 3=(T4-T3)/T3*100$ ,  $\Delta 4=(T3-T1)/T1*100$ ,  $\Delta 5=(T4-T1)/T1*100$ . After that, we tried to correlate the delta between them (results= R(p-value)). Results were considered as significant with  $p<0.05$ . Results: Plasmatic levels of Gal-3 did never exceed the cut-off of 17.8ng/mL, except for 1 trailer in T2. A slight increase of levels of Gal-3 was observed at T2 (min-max:7.5-17.6ng/mL). These ones did not vary a lot at T3 (min-max:7.0-18.8ng/mL) but return to normality at T4 (min-max:6.0-12.8ng/mL). For ST2, at T1, 12 subjects had plasmatic levels above the reference value of 35ng/ml. At T2, only 2 trailers blood samples were still in the reference interval. Indeed, a great increase of ST2 plasmatic levels observed (min-max:18.8-158.8ng/mL). A slight decrease of ST2 levels was observed at T3, but only one subject had a value below 30ng/ml (min-max:20.1-182.7ng/mL). However, a subject had still plasmatic levels above T2 values. A return to normality was observed at T4 with 16 trailers blood levels in the reference interval (min-max:12.0-56.4ng/mL). We observed an increase for Gal-3 and ST2, above the reference values only for ST2. We noted for both a decrease up to the normal values 3 days after the trail. For the correlation between deltas, we observed that Gal-3 and ST2 are correlated for each delta. Discussion: A logical correlation is observed between Gal-3 and

ST2 as they are involved in cardiac fibrosis and inflammation. But we do not know why it is not in the same proportion. We know that some trailers take NSAIDs and painkillers during the race. The results of this study demonstrate that this exercise was associated with biochemical abnormalities that may reflect adverse consequences on cardiac structure as fibrosis. However, ST2 values were higher, perhaps due to a mechanical stress more than a cardiac stress. Gal-3 is perhaps then more cardio-specific than ST2.

### EFFECTS OF PROLONGED LOW INTENSITY EXERCISE WITH ENERGY DEFICIT ON MARKERS OF MUSCLE PROTEIN TURNOVER.

Mattsson, C.M., Flockhart, M., Söderlund, K., Hendo, G., Jakobsson, M., Pontén, M., Ekblom, B.

*Åstrand Laboratory of Work Physiology*

**Introduction** It is well known that ultra-endurance exercise, such as Adventure racing and military operations, often induce substantial energy deficits. This suggests a catabolic state, but the exact effects on protein turnover have not yet been sufficiently investigated. The aim of this study was to examine several markers involved in muscle protein turnover before and after a multi-day physically demanding military training operation. **Methods** Seven female (age  $21 \pm 5$  years, weight  $71.2 \pm 6.6$  kg) and seventeen male (age  $20 \pm 1$  years, weight  $76.6 \pm 6.2$  kg) performed a 185 hours military training operation. Energy intake was estimated from food supply and energy expenditure was calculated from continuous heart rate and accelerometer recordings. Muscle biopsies were taken from M Vastus Lateralis before and after the operation. **Results** A negative energy balance of 1,500-2,000 kcal/24 hours was estimated. Body weight declined 3.4 (95% CI 3.0-3.8) kg and muscle explosive strength, evaluated from squad and counter movement jumps, was reduced 5 and 6 %, respectively, after the operation with no difference between genders. Muscle glycogen content was reduced from  $269 \pm 58$  to  $181 \pm 44$  mmol/kg dry muscle ( $p < 0.05$ ) with no difference between genders. Muscle content of mTOR and p70 as well as MAFbx were unchanged while the protein content of MuRF-1 was significantly down regulated in both genders. **Discussion** The study indicated that prolonged low intensity exercise with substantial energy deficit reduces muscle function and muscle glycogen content. Proteins for muscle synthesis mTOR and p70 were unchanged while the down regulation of MuRF-1 indicates a protection against muscle break down during the energy deficit situation, preserving the muscle mass.

### INFLUENCE OF ANGIOTENSIN-CONVERTING ENZYME GENE I/D GENOTYPE AND REST INTERVAL BETWEEN SETS ON EXERCISE-INDUCED MUSCLE DAMAGE

Andrade, H.1, Silva, D.2, Curty, V.3, Zovico, V.4, Cardoso, B.4, Machado, R.4, Pereira, R.1, Machado, M.4,5

1: UESB (Jequié, Brazil), 2: UFRJ (Rio de Janeiro, Brazil), 3: FASAP (Santo Antônio de Pádua, Brazil), 4: UNIG (Itaperuna, Brazil), 5: FUNITA (Itaperuna, Brazil)

**Introduction** It is reported in the scientific literature that the insertion/deletion polymorphism of Angiotensin-converting enzyme gene (ACE) is associated to an increased susceptibility to Exercise-Induced Muscle Damage (EIMD), but there is no reports about the influence of the performance of resistance exercise with varied rest intervals between sets above susceptibility to the EIMD among subjects with different ACE gene genotypes. **Objective** The aim of this study is to evaluate the influence of I/D genotype of the ACE gene and the rest interval between sets, as well as, the interaction between these variables above the susceptibility to the EIMD. **Materials and Methods** Twenty seven healthy male performed two resistance exercise sessions one week apart. Exercise sessions consisted of 4 sets with 85% of 1 repetition maximum (1RM) for each exercise, which was carried out in the following order: bench press, lat pull down, shoulder press, elbow extension and elbow flexion. Each exercise was performed until the concentric failure and the rest interval between sets was randomly defined as 1 or 3 minutes for each session. Venous blood samples were taken previously and 24, 48 and 72 hours after each exercise session to measure the serum creatine kinase (CK) activity and to genotype subjects for ACE gene through the Polymerase Chain Reaction (PCR) technique, what allowed gathering the subjects according to the genotypes: II, ID and DD. The peak of serum CK activity, that is a muscle damage indicator, was used as dependent variable. The ANOVA two-way (3 genotypes x 2 rest intervals) was used to compare genotypes and exercise sessions with different rest intervals between sets, as well as the interactions between them. The  $p < 0.05$  significance level was adopted. **Results** There was significant difference in the serum CK peak between the genotypes ( $p = 0.041$ ), with bigger CK peak values in subjects with II genotype when compared to the others. There was not difference between the sessions with 1 and 3 minutes rest intervals ( $p = 0.863$ ). Similarly, there was not significant interaction between the genotypes and rest intervals to serum CK peak measurements ( $p = 0.969$ ). **Conclusion** The subjects with II genotype of the ACE gene are more susceptible to the EIMD, characteristic that is independent of the rest interval between sets adopted during resistive exercise sessions.

### FUNCTIONAL AND METABOLIC CHARACTERIZATION OF EXERCISING MUSCLE IN A MOUSE MODEL OF SICKLE CELL DISEASE

Chatel, B.1,2, Gondin, J.1, Le Fur, Y.1, Vilmen, C.1, Bernard, M.1, Messonnier, L.2, Bendahan, D.1

1: Aix-Marseille University, 2: University Savoie Mont Blanc

**Introduction** Sickle cell disease (SCD) is an inherited disorder resulting in the synthesis of an abnormal hemoglobin (HbS) leading to painful vaso-occlusive crisis (VOC). Given that SCD is mainly considered as a hemoglobin and hemorheological disorder, its impacts at the muscle level have been scarcely studied. Yet, fatigue is a major symptom of the disease (Ameringer et al. 2013). Recent studies have disclosed a significant muscle remodeling in SCD indicating a potentially impaired supply and use of oxygen (Ravelojaona 2014). However, the metabolic translation of this remodeling process in exercising muscle is still unknown. The aim of this study is to characterize the potential functional and metabolic abnormalities in a mouse model of SCD. **Methods** Healthy (HbAA,  $n=11$ ), heterozygous (HbAS,  $n=10$ ) and sickle cell (HbSS,  $n=10$ ) mice were studied. The anesthetized mice were placed in a home-built device designed for a strictly non-invasive study of the gastrocnemius muscle by NMR (Giannesini et al. 2010). Information on muscle function, volume and metabolism were collected during a rest-stimulation-recovery protocol that was repeated twice 48 hours apart, for two exercise intensities (2 Hz and 0.5 Hz). **Results** On the contrary to the low-frequency protocol, HbSS mice displayed a reduced total force production (-46 and 25% compared to HbAA and HbAS, respectively) and a larger force reduction (-71  $\pm$  9%, -56  $\pm$  9% and -58  $\pm$  11% for HbSS, HbAA and HbAS, respectively) during the high-frequency protocol. At the metabolic level, HbSS mice exhibited a larger acidosis during the low- (+72 and 42% compared to HbAA and HbAS, respectively) and high-intensity protocols (+21% compared to HbAA and HbAS). **Discussion** We demonstrated in the present study that SCD was associated with an impaired muscle function and to a more pronounced exercise-induced intracellular acidosis. Both an increased non-oxidative glycolytic energy production and an altered protons handling might account for this larger acidosis. This alteration of muscle function and acidosis may represent degradation factors of quality of life (Ameringer et al.

2013) and a risk of triggering VOC (Ueda and Bookchin 1984) that could be deleterious for SCD patients. References Ameringer S, Elswick RK, Jr., Smith W (2013). *J Pediatr Oncol Nurs.* 31:6-17. ### EFFECT OF LONG-HAUL AIR TRAVEL EAST AND WEST ON RECOVERY OF TEAM SPORT PERFORMANCE.

Duffield, R.1, Fowler, P.2, Crowcroft, S.1, Mendham, A.1, Halson, S.3, Vaile, J.3, Knez, W.2

1: *University of Technology Sydney (Australia)*, 2: *Aspetar (Qatar)*, 3: *Australian Institute of Sport (Australia)*

Introduction Though international travel is a requirement for elite team-sport athletes, limited information is available on the post-travel recovery timeline(1). Moreover, whilst it is proposed that jet-lag symptoms are worse following eastward compared to westward long-haul air travel(2), this is yet to be confirmed from relevant physical performance measures. Consequently, the present study determined the effects of eastward and westward long-haul air travel on physical performance relevant to team-sports. Methods Data was collected from 19 trained males at 09:00(AM) and 17:00(PM) for 4 days one week prior to (Baseline) and immediately following (Post 1-4) 21 h air travel west across eight time-zones from Australia to Qatar. Following a six day wash-out and 21 h return travel east, data was collected at the same times of day for a further four days (Post 1-4). Testing included a countermovement jump (CMJ), 20-m sprint and agility test, followed by the Yo-Yo Intermittent Recovery level 1 (YYIR1) test. Analyses were performed by fitting a linear mixed model to the absolute change from Baseline. Furthermore, standardised effect size (Cohen's d) analysis assessed the magnitude of differences between travel directions. Results CMJ peak power ( $P=0.01$ ;  $d=2.19$ ) and velocity ( $P=0.02$ ;  $d=1.91$ ) were lower at Post2 AM following westward compared to eastward travel. In addition, 5m sprint times were slower at Post2, 3 and 4 PM ( $P<0.05$ ;  $d>0.90$ ), 10m sprint times were slower at Post1, 3 and 4 PM ( $P<0.05$ ;  $d>0.90$ ), and 20m sprint times were slower at Post4 PM ( $P=0.01$ ;  $d=1.51$ ) following westward compared to eastward travel. Conversely, distance covered in the YYIR1 was significantly reduced at Post1 PM ( $P=0.01$ ;  $d=2.57$ ), and large effect sizes indicated reduced performance at Post2, 3 and 4 ( $d>1.00$ ) PM following eastward compared to westward travel. Discussion Long-haul transmeridian air travel can impair maximal lower-body power and intermittent-sprint performance for up to four days post-travel. Furthermore, a greater disruption of intermittent-sprint performance may occur following eastward compared to westward air travel. Conversely, westward air travel could have a greater impact on lower-body power. These contrasting results may relate to differences in arrival times and ensuing testing times. Thus, specific tailoring of recovery interventions may have merit based on travel direction and arrival time. Further research is required to articulate the specifics of such factors on team sport performance. References 1. Leatherwood et al. (2013) *Br J Sports Med*, 47(9):561-67. 2. Waterhouse et al. ### OP-BN07 Gender II

#### TECHNIQUE DIFFERENCES BETWEEN MALE AND FEMALE CROSS-COUNTRY SKIERS WHILE WHOLE BODY, UPPER BODY AND ARM POLING IN A SKI ERGOMETER

Bucher, E.1, Danielsen, J.2, Hegge, A.M.2, Faude, O.1, Ettema, G.2, Sandbakk, Ø.2

1: *University of Basel (Basel, Switzerland)* 2: *Norwegian University of Science and Technology (Trondheim, Norway)*

Introduction: The anthropometric and physical differences between men and women should not only influence the capacity to generate power and energy, but may also lead to differences in technique in a whole-body endurance sport like cross-country skiing. Since the upper body plays a crucial role in this sport, specific training of the arms and trunk is of importance. However, little is presently known concerning gender differences in the technical execution of the double-poling movement and how this coincide with variations in exercise efficiency. Purpose: To characterize gender differences in the technical execution of upper body poling and exercise efficiency between whole-body (WP), upper-body (UP) and arm poling (AP) among elite cross-country skiers. Methods: Ten male and ten female elite cross-country skiers, matched for international performance level, completed three incremental submaximal tests and a 3-min all-out test on a Concept2 SkiErg in all poling modes. Power output was measured with the ergometer's internal software. Respiratory variables were assessed employing open-circuit indirect calorimetry. Movement data from eleven passive reflective markers on the ergometer and body was captured by the Qualisys motion capture system. The regression lines of submaximal oxygen uptake on power output were used to compare exercise efficiency. Results: When producing the 87% ( $152\pm 28$  vs  $285\pm 34$ W in WP), 97% ( $110\pm 19$  vs  $216\pm 34$ W in UP) and 103% ( $69\pm 12$  vs  $140\pm 20$ W in AP) higher power outputs during the 3-min test, men exhibited shorter poling times and used greater shoulder and elbow extension at the start of poling (all  $P<0.05$ ). There were no gender differences in the shoulder and elbow angles at the end of the poling phase. The hip angles did not differ between the men and women at the start of poling, but were significantly smaller for the men at the end of the poling phase, resulting in a larger trunk range of motion for the men (all  $P<0.05$ ). The relationship between oxygen uptake and power output during the three submaximal sessions did not differ between the men and women for any of the poling modes. Conclusions: The higher power outputs of the men coincided with significant gender variability in the technical execution of all poling modes and a favourable distribution of muscle mass in arms. The tendency towards greater angular range of motion of the trunk shoulder and elbow joints executed over relatively less time among men indicate a more explosive poling technique compared with female skiers. However, the energetic cost of a given power was independent of gender for all modes.

#### SEX DIFFERENCES IN COMPENSATION STRATEGIES FROM EXPERIMENTALLY REDUCED MUSCLE FUNCTION

Benoit, D.L., Flaxman, T.E., Alkjaer, T., Simonsen, E.B., Krogsgaard, M.R.

*University of Ottawa*

Females have greater incidence of traumatic knee joint injury compared to males [1]. Reduced muscle strength and varied activation patterns observed in females compared to males is suggested to contribute to the injury mechanism [2]. Yet it remains unclear if decreased stability is a direct result of the reduced muscle function or a more complex issue. Experimental reductions in quadriceps muscle function may provide more valuable insight into the effects of muscle weakness on joint stability. Young healthy adults (12 males, 10 females) participated in this study. Hypertonic saline (causing a perception of pain and a centrally mediated reduction in muscle activa-

tion [3]) was injected into VM of the dominant leg. Subjects performed 2 sets of 20 squats during 2 conditions: baseline and experimental pain. Kinematics, kinetics and surface EMG of 10 muscles were recorded. Squats were time normalized to 100%. Linear envelopes of the EMG were integrated for the descent and ascent phases (determined by peak knee flexion angles). Preliminary results are presented. Time to peak knee joint angle and joint flexion and extension velocities did not significantly differ between conditions (T-test  $p > 0.05$ ). Knee extension moment and power of the test leg was reduced with pain in both groups (-10.2% and -8.1%); however, only females demonstrated increased peak knee extension moments and power (+8.3% and 6.9%) in the contralateral limb. Integrated VM was reduced during both descent and ascent phases. Average peak VM activation was reduced by 43% in males and 40% in females. During ascent, a reduction in integrated vastus lateralis (VL) of both groups (~21%) and biceps femoris (BF) of females (~30%) was also observed. The hypertonic saline injections caused a reduction in voluntary muscle activation to both the VM and VL in males and females, thus reducing test leg knee extensor moments and power. However, a compensation strategy, evidenced by increased moment contribution in the contralateral limb, was only observed in females. Also, a reduction in vastii and hamstring activation was only observed in females which may decrease joint stiffness and increase the risk of anterior tibial translation and ACL strain [4]. Further investigation on muscle weakness and its effect on knee joint stability between sexes as well contributions from adjacent hip and ankle joints are warranted. ### SEX DIFFERENCES IN MUSCLE ACTIVATIONS IN ASSOCIATION WITH ANTERIOR CRUCIATE LIGAMENT INJURY

Smale, K.B., Flaxman, T.E., Alkjaer, T.E., Simonsen, E.B., Krogsgaard, M., Benoit, D.L.

*University of Ottawa*

The incidence of knee injuries has been recorded to be as high as 4.6 times greater in females than in males [1] and the underlying cause for this disparity is still relatively unknown. Since muscles are the only active contributors to dynamic knee joint stability, it is quite feasible that the observed injury differences could be attributed to varying muscle activations between males and females. Therefore the objective of this study was to compare the muscle activations produced by males and females during countermovement jumps. This sub-study arises from a larger longitudinal study that tracks the functional ability of individuals who have torn their anterior cruciate ligament (ACL). To date, this sub-study consists of 10 healthy (5 male:  $30 \pm 8$ y; 5 female  $28 \pm 8$ y) and 10 ACL deficient (5 male:  $30 \pm 6$ y; 5 female  $28 \pm 6$ y) participants who completed three successful, two-footed countermovement jumps for maximum height. Trials were considered successful if the hands were kept on the hips, each foot landed entirely on a force plate, and balance was maintained. Linear envelopes were normalized to maximum voluntary isometric contractions and to 200 ms before and after foot contact at landing. Significant differences were tested using independent t-tests through statistical parametric mapping with a Bonferroni multiple comparisons correction for a final  $\alpha = 0.0125$ . In healthy young adults, all three (rectus femoris (RF), vastus medialis, and vastus lateralis) of the measured quadriceps muscles exhibited significantly greater activation in females pre-impact (0-20% of the cycle) than males. In ACL deficient, the RF was recruited more in males from the time of impact onwards ( $P = 0.001$ ) while the lateral gastrocnemius (LGAS) activation was greater in females than in males from 0-20% ( $P = 0.001$ ) and 40-80% ( $P = 0.000$ ) of the jump cycle. Timing of peak activation in the gastrocnemii showed no differences in the healthy controls, but after ACL rupture, female ACL deficient consistently took longer to reach their peak than healthy females in the LGAS ( $P = 0.001$ ) and significantly longer than male ACL deficient ( $P = 0.006$ ) and healthy females ( $P = 0.011$ ) in the medial gastrocnemius. The greater activation of quadriceps observed in healthy females than males pre-landing was not observed after ACL injury. Compared to injured males, injured females switched to a greater activation of the LGAS throughout a majority of the jump cycle and specifically at time of impact. At low flexion angles similar to those that occur at jump landing, the gastrocnemius acts as an antagonist to the ACL [2] due to the production of an anterior tibial shear force. Therefore, this higher LGAS activation at impact in females would generate a greater anterior shear force in an already unstable knee, which may contribute to the increased incidence of knee injuries seen in females. ### LEG DOMINANCE AND ACL INJURY RISK IN ELITE AUSTRALIAN FEMALE FOOTBALLERS

Hill, C., Donnelly, C., Lloyd, D.

*1 Centre for Musculoskeletal Research, Griffith Health Institute, Griffith University, Gold Coast, Australia. 2 School of Sport Science, Exercise and Health, University of Western Australia, Australia*

Introduction: Leg dominance may be a possible aetiological risk factor in non-contact Anterior Cruciate Ligament (NC-ACL) injury. Female athletes, particularly in football (soccer), have a higher rate of ACL injury to their non-dominant leg (NDL). Muscles play an important role in stabilising the knee to prevent ACL injury. Therefore, this research examines leg dominance in the isokinetic strength of the knee flexors (KF) and knee extensors (KE) of elite female footballers. Methods: Fifty-five athletes were recruited from the elite Australian W League and national age football players ( $18 \pm 3$  yrs;  $59 \pm 8$  kg;  $165 \pm 8$  cm) without a history of knee injury. The dominant leg (DL) was the participants' preferred kicking leg. Knee muscle strength assessments were performed using multi-velocity isokinetic concentric and eccentric dynamometry. Results: Participants demonstrated differences in the joint angle at which peak torques were generated. NDL peak concentric KF torque was achieved at a greater flexion angle ( $47 \pm 13^\circ$ ) compared to the DL ( $39 \pm 15^\circ$ ) ( $p = 0.012$ ), where as peak NDL concentric KE torque was achieved at more extended knee angles ( $55 \pm 14^\circ$ ) than the DL ( $62 \pm 9^\circ$ ) ( $p = 0.002$ ). However, the participants demonstrated no differences between DL and NDL in peak torques, time to peak torque, rate of torque development and hamstring to quadriceps ratios. Discussion: This study demonstrated that leg dominance exists in female footballers though this may be difficult to identify using traditional isokinetic methodology and outputs. Importantly, contralateral differences exist in the joint angles at which peak KF and KE torques are generated. The results suggest quadriceps dominating the knee flexors at extended knee angles of the NDL compared to the DL. The quadriceps dominance, and the decreased ability of the KF to adequately resist rapid anterior shear forces, may be the reason for greater risk of NC-ACL injuries in the NDL of female athletes. This necessitates further research.

### SEX DIFFERENCES IN THE BIOMECHANICS OF BODYWEIGHT SINGLE-LEG SQUAT VARIATIONS

Chapman, C.J.1,2, Khoo, S.1, Beach, T.A.C.1

*(1) Faculty of Kinesiology and Physical Education, University of Toronto, Toronto, Ontario, Canada. (2) Canadian Sport Institute Ontario, Toronto, Ontario, Canada.*

Introduction Single-leg squats (SLS) are commonly used to make exercise recommendations and assess injury risk, but it is unknown whether the location of the elevated foot should be controlled to interpret performance. In a previous pilot study wherein a small sample

(N=12) of mostly men (N=10), we found that stance-leg net joint moment magnitudes did not differ within subjects who performed SLS with the elevated foot behind, beside, and in front of the planted foot (Chapman et al. 2014). Given that between-sex differences in SLS performance have been reported (Graci et al. 2012, Zeller et al. 2013), we were motivated to extend our initial pilot work to include a larger sample comprised of an equal number of men and women. Methods Thirty-two recreationally active volunteers who are injury- and pain-free have agreed to participate. Rigid clusters of markers will be attached to the feet, shanks, thighs, pelvis and trunk and three SLS variations (i.e., elevated foot front, side, back) will be performed. Marker positions will be recorded at 200 Hz, and ground reaction forces (GRFs) at 2000 Hz. Kinematic signals will be smoothed and input with the GRF data into an inverse dynamical linked-segment model of the body to yield body size-normalized estimates of the net joint sagittal and frontal moments about the hip, knee, and ankle. A general linear model ANOVA with one within- (SLS variation) and one between-subject (sex) factors will be used together with a least squares mean procedure to assess main/interaction effects. Biomechanical analyses will be completed using Visual3D, and statistical procedures will be conducted in SPSS. Results Data collection and analyses are currently in progress. Given previous research findings (Chapman et al. 2014, Graci et al. 2012, Zeller et al. 2013), we hypothesize that the position of the elevated foot during the SLS will not affect stance-leg net joint moment magnitudes within-subjects, but that these magnitudes will differ between men and women within SLS variations. ### ENERGY EXCHANGE IN FEMALE POLE VAULT

Russomanno, G.T., Misuta, S.M., Brenzikofer, R.

*UnB Universidade de Brasilia*

Introduction Pole vault is one of the most technical events in athletics, the knowledge of the mechanical energy exchange behind this event is essential to improve the performance of the athlete. It is already known the importance of run-up velocity and energy exchange in pole vault; however, some athletes' technical individualities directly affect the jumping mechanics. Thus, the aim of this study was to analyze the energy exchange during a female jump. Methods A female pole-vaulter (1.72 m, 57 kg) with a personal best of 4.85m took part in the study. The data acquisition was performed in the women's pole vault final at a national championship. Eleven jumps from 4.30 m to 4.91 m were recorded by 4 Basler (model A602fc) cameras synchronized (genlock) with a frequency of 100 Hz, positioned on the right side of the runway corridor. A 5 meters long rod was used for calibration. The video sequences here digitalized using the Dvideow system [1]. 3D coordinates of 18 points of interest were calculated by using the DLT method. The kinematic data were softened by 3rd order Butterworth digital filter with a cutoff frequency of 6 Hz for each one of the points of the model. The total energy of the athlete's center of mass (CM), over the time, was calculated as the sum of the potential energy plus kinetic energy. [2] Results Approach velocity had a CV 1.2%, with a takeoff average velocity of  $7.72 \text{ m/s} \pm 0.20 \text{ m/s}$ . The values of  $E_{\text{Initial}}$  and  $E_{\text{Final}}$ , were respectively  $45.96 \pm 0.82 \text{ J/kg}$  and  $47.14 \pm 0.71 \text{ J/Kg}$ . The variables of decrease and increase of energy were  $18.45 \pm 1.39 \text{ J / kg}$  and  $19.63 \pm 1.51 \text{ J / kg}$ . The gain of energy was  $1.18 \pm 0.83 \text{ J / kg}$ . The maximum height reached by the athlete's CM was significantly correlated with Final total energy ( $r = 0.82$ ,  $P < 0.01$ ). The athlete also has a higher grip position when compared with the best athletes in the world. Discussion Although the low values of  $E_{\text{gain}}$ , the athlete showed high values of  $E_{\text{Initial}}$  and  $E_{\text{Final}}$ ,  $45.96 \pm 0.82 \text{ J/kg}$  and  $47.14 \pm 0.71 \text{ J/Kg}$  respectively independent of the height jumped. Unlike other athletes, she has a higher Grip, which gives her an advantage over the other vaulters. This higher grip is due to the distinguished jump technique and it may be a good indicator of performance in pole vault as Angulo-Kinzler et al. (1994) observed in male athletes, confirming the findings in this study. When compared to the other vaulters she is one of the fastest with an average velocity of  $7.72 \text{ m/s} \pm 0.20 \text{ m/s}$ . The results of this study are relevant for women's pole vault improvement. References 1. Figueroa, P. J., Leite, N. J., Barros, R.M.L. ### OP-SH24 Sociology (Sport and gender)

#### "SPORTS DON'T LAST A LIFETIME, BUT I WANT TO LIVE WITH HIM FOREVER": FUNCTIONS AND DYSFUNCTIONS OF SEXUAL RELATIONSHIPS BETWEEN FEMALE ELITE-ATHLETES AND COACHES

Johansson, S.

*The Swedish School of Sport and Health Sciences*

Introduction Coach-athlete sexual relationships (CASR) have been suggested to harm athlete welfare, sport performance, and to inherently constitute an abuse of power, trust and professional ethics by coaches (e.g. Brake & Burton Nelson, 2012; Toffegaard-Nielsen, 2001). However, very little is known about CASR, especially consensual romantic relationships between athletes and coaches of legal age (Johansson, 2013). The purpose with this research is to explore female elite-athletes' stories of CASR, emphasizing functional and dysfunctional aspects associated to athlete wellbeing and sport performance. Methods In-depth interviews included five female elite-athletes aged 23-30 with experience of CASR, i.e., boyfriend/girlfriend relationships and unattached sexual relations. Readings of interview transcripts and coding into functional and dysfunctional themes were conducted to generate the stories. Storying the athletes' experiences thus served to contextualise functions and dysfunctions on a within-case basis. Results The athlete's stories yield insights of qualitatively different functions and dysfunctions of CASR. Functional elements include specific components such as care, trust, sense of value and security, and a unique support and understanding. These elements were described to have a positive effect on the athletes' wellbeing and performance. Dysfunctional elements found in the athletes' stories comprised e.g., a need for secrecy in fear of negative reactions causing unhealthy restraints, career disruption due to break-ups and dependency tied to the partner/coach synthesis. Discussion

The diversity of functions and dysfunctions of CASR addressed in this study dispute the assumptions and normative notions that CASR are inherently harmful and abusive. The stories illustrate that female athletes can recognise consensual, mutually desired CASR. Importantly, functions and dysfunctions are not necessarily distinct, uniform or constant, but can transform and differ before, during and after the sexual relationship. This study emphasises the need to further examine how CASR can affect athlete wellbeing and sport performance in both functional and dysfunctional senses. ### **SPORT AND PEACE BUILDING IN POST-CONFLICT SOCIETIES: THE ROLE OF OPEN FAN FOOTBALL SCHOOLS IN KOSOVO**

Krasniqi, S.

*High School*

**Abstract** The use of sports for purposes of development has been increasingly important topic particularly in post-conflict societies. However, there is a gap in the literature on how the sport can be used more productively as a peace building device in post conflict countries. This is because there is non-agreement in the literature on the role of sports in peace building. First, sport was viewed as mechanism to increase antagonism between rivalry groups and may reinforce division of ethnicities and second the sport could facilitate social inclusion and integration. This thesis uses qualitative research techniques mainly in-depth interviews with trainers, instructors and children in order to investigate how football sport in Kosovo contributed to peace building. In addition, the reflective practice technique was used because the author of the thesis has been involved in implementing Open Fan Football Schools (OFFS) in Kosovo. Based on findings the thesis argues that OFFS has played a vital role in peace building in Kosovo by bringing together and integrating different ethnicities in Kosovo. Findings also suggest that OFFS offer a hope for peace building and if adequately implemented can contribute to peace building in post-conflict societies similar to Kosovo. The study urges the need for more proactive policies and donor support to fund similar sport activities in order to promote peace building. **Keywords:** football, peace building, gender, post conflict countries, multi ethnicity. ert authors here

### **ZLATAN IBRAHIMOVIC – A POST-COLONIAL READ OF AN INDIVIDUAL SPORT TRADEMARK**

Johan, E.

*Malmö University*

**Zlatan Ibrahimovic – A post-colonial read of an individual sport trademark** Introduction In the beginning of October in 2014 a documentary telling the story of prominent Swedish football player Zlatan Ibrahimovic was released. Zlatan has lately taken a great interest in carefully nurturing his trademark with the topic of this piece being one of the latest additions. Just recently, however, Zlatan announced the campaign #805 million names in which he together with World Food Program intends to spread awareness of world hunger. The relevance of this piece, I argue, lays in Zlatan not only being the most published-of individual sport athlete in Sweden, as well as having fans all around the world, but also that he is a very special product of our time where the issues of race and xenophobia are as ever apparent. Method and theory With the documentary as empiricism this paper applies postcolonial theory in order to shed light on aspects which would have been difficult to otherwise acknowledge. In taking the theoretical steps provided by Frantz Fanon, Edward W.Said, Homi K. Bhabha and Gyatri Spivak this paper also attempts to perform what should be referred to as a postcolonial method. The mindset and thoughts provided by each of the above mentioned postcolonial theorists is used as a theoretical lens to reveal how the messages conveyed through the documentary might be analyzed and understood. Discussion Fanon's discussion of self/other is, when it comes to Zlatan, expressed in terms of being Swedish/being other, about him stating himself as different. The empiricism clearly demonstrates that being Swedish cannot be done without also being other. With Said, Zlatan is considered as the oriental in order to reveal the discourse that he, from a Saidian perspective, cannot distance himself from. In difference from Fanon, however, it becomes clear that the construction of other is occurring because of, and within, a discursive system, and that the self is constructed and strengthened by what it is not. It is the knowledge that produces the subject and the knowledge about the oriental and irrational Zlatan is found to be produced in order to find out how he can be what he is. With Bhabha, we will see how the stand initiated by Said (shifting the focus away from the other and turning the gaze on the self) gets expanded into a discussion of stereotypization and the ambivalence that follows. The problems which in this case initially were thought to be found in Zlatan (in Bhabha's case in the colonized) is in fact found in the opposite (the colonizer). The empiricism shows how the ambivalence makes the part in power unsure of where the borders of identity can be drawn. In the line with the Spivak way of thinking, Zlatans expressed collective subjectivity, and his wanted representation of everyone that is also different, is dissected through a discussion of subalternity.

### **ORGANISATION AND LEADERSHIP CHANGES REASONS FOR TEENAGE GIRLS TO DROP OUT FROM SPORT**

Eliasson, I., Johansson, A.

*Department of Education, Umeå university*

**Introduction** Many girls and boys quit sport in their teens and the reasons for this has eluded scientist and sport organisations for many years. This study was initiated by the Swedish Floorball Association with the aim to understand why many teenage girls quit floorball and to increase knowledge about what sport clubs can do to prevent girls from dropping out. A special research focus was directed towards the disengagement process which the girls undergoes when they take the decision to quit their sport. **Methods** The study is based on data from 24 semi-structured interviews with 12 girls aged 13-18 years (n=12) and with one parent from each of the girls (n=12). The girls belonged to three different floorball clubs geographically spread in Sweden and had quit floorball from 6 months to 2,5 years ago. The study draws on Ebaughs (1988) theory of the disengagement process. **Results** The results showed that the disengagement process can take from a few months up to two years before the girl takes the final decision to quit. The process was described by four different phases 1) First doubts 2) Seeking alternatives 3) The Turning point 4) After the decision. While the parents were involved in the process representatives from the sport clubs were almost absent. The longer into the process the girls where the more final their decision became. Six factors were identified as the main reasons for the girls to quit their sport, often a girl quit due to a combination of three to four of these factors. The most salient factors were an increased focus on sport performance and results, changes in the team's formation, new

coaches and changes in the coach attitudes, interest in other activities or sports, lack of time and high demands on themselves. No one of the girls in this study had been contacted from the sport organisations after they quit. Discussion The results point out the impact different changes had for the girls' decision to quit and the importance for the clubs to be aware of this. It also highlights how the absence of the representatives from the sport clubs in the girls' disengagement process led to limited knowledge about the girls' feelings and thought processes which means they were less able to adopt accurate strategies or to implement appropriate interventions to reduce the dropout rate. One message to the sport organisations is therefore to develop strategies for how to gather knowledge of their members' thoughts and feelings about their sport participation and be proactive in their work concerning how to handle changes, group cohesion and coach education. Organisation and leadership in the sport organisations were seen as key areas to develop when the ambition is to lower dropout rates. References Ebaugh, H., R., F. (1988). *Becoming an EX. #### IS-PM05 ROLE OF GLYCOGEN IN SKELETAL MUSCLE REGULATION AND FUNCTION

##### ROLE OF GLYCOGEN IN SKELETAL MUSCLE SR CA<sup>2+</sup> REGULATION

Ørtenblad, N.

*University of Southern Denmark*

**Introduction** Muscle glycogen is the preferential fuel during muscle work and the depletion of glycogen is thought to be a main contributor to muscle fatigue. Already in the beginning of the last century it was revealed that carbohydrate is an important fuel during exercise and pioneering muscle biopsy studies in the late 1960s, demonstrated that muscle glycogen contents is associated with exhaustion and that glycogen changes with exercise, recovery and training (1). Thus, the importance of skeletal muscle glycogen as a fuel during exercise, and fundamental aspects of glycogen regulation is well documented. However, little is known about the precise mechanism that relates skeletal muscle glycogen to impaired muscle function and cell signaling. The use of electron microscopy has revealed that glycogen is not homogeneously distributed in skeletal muscle fibres, but rather localized in 3 distinct pools: i) intermyofibrillar glycogen located between the myofibrils; ii) intramyofibrillar glycogen located within the myofibrils; and iii) subsarcolemmal glycogen located just beneath the surface membrane (3, 5). Further, each glycogen granule has its own metabolic machinery with glycolytic enzymes and regulating proteins. These glycogen granules are connected with the sarcoplasmic reticulum (SR) in close contact with key events in the excitation-contraction (E-C) coupling. In line with this, there has now been provided experimental evidence in favor of a direct role of decreased glycogen, localized within the myofibrils, for the reduction in SR Ca<sup>2+</sup> release during fatigue (2-5). This has been revealed at the level from isolated SR vesicles from human muscle after exercise and in single intact and mechanically skinned muscle fibres. Together, these results demonstrate that distinct subcellular populations of glycogen have different roles in contracting single muscle fibres and this may affect muscle contractility and fatigability. Such an SR-glycogen arrangement may involve a regulation of the cytosolic Ca<sup>2+</sup> levels and, in turn, the activation and energy utilization of skeletal muscle. References 1. ##### SINGLE MUSCLE FIBRE ANALYSIS OF PROTEINS IMPORTANT FOR GLYCOGEN METABOLISM IN SKELETAL MUSCLE FROM TRAINED CYCLISTS FOLLOWING HIGH-INTENSITY AND AEROBIC-INTENSITY BOUTS OF EXERCISE.

Murphy, R.1, Frankish, B.1, Lane, S.2, Areta, J.2, Stapleton, D.3, Hawley, J.1

*(1) La Trobe University, (2) RMIT University, (3) The University of Melbourne*

**INTRODUCTION** Glycogen is an important fuel source, providing energy for contracting skeletal muscle. Skeletal muscle is heterogeneous in nature, comprised of slow-twitch (Type I) and fast-twitch (Type II) fibres, which are distinct in their metabolic and contractile properties. This study investigated the effects of varying glycogen availability by utilizing different exercise modes in humans. We measured the abundance of specific glycogen related proteins as well as their phosphorylation (activation) state where applicable. Uniquely, we determined these changes in individual fibres, thereby addressing muscle heterogeneity. **METHODS** Eight endurance-trained cyclists performed two experimental trials (Low or High glycogen), where glycogen content was manipulated via exercise-diet interventions. Each experimental trial lasted 15 hours, consisting of a high-intensity interval training (HIT, evening of day 1) and aerobic-intensity training (AIT, morning of day 2) bout of exercise. Muscle biopsies from the vastus lateralis were collected Pre- and Post- each exercise bout and individual muscle fibres were immediately collected under paraffin oil, and prepared for western blotting analysis. **RESULTS** Overall, following the HIT bout of exercise, there were fibre type- and trial-specific decreases in glycogen synthase and glycogen phosphorylase, with concomitant increases in their phosphorylated forms. No changes in glycogen branching or glycogen debranching enzymes were seen following HIT in either trial. AIT did not result in any changes seen for those proteins in either the Low or High glycogen trials. **DISCUSSION AND CONCLUSIONS** Glycogen availability influences the expression of various glycogen related proteins, and does so in a fibre specific manner. These findings highlight the complexity of glycogen metabolism and that fibre type needs to be considered when understanding its regulation. Analyses conducted in whole muscle should therefore be interpreted with caution.

##### INTRACELLULAR COMPARTMENTALIZATION AS A REGULATOR OF GLYCOGEN METABOLISM AND INSULIN SIGNALING

Prats, C.

*Core Facility for Integrated Microscopy, Center for Healthy Aging, University of Copenhagen*

During the last decades, visualization of the intracellular dynamics of metabolic events has revealed a key player in the regulation of signalling and metabolic pathways, compartmentalization. Cells are not bags full of metabolites and enzymes, the complexity and the

dynamics of intracellular compartments are finely designed and modulated to host specific cellular processes and regulate them. Several steps in glycogen metabolism and insulin signaling are regulated by intracellular redistribution of key enzymes and local accumulation of metabolites. Furthermore, several studies have reported evidence that indicate that glycogen metabolism is locally regulated; where intermyofibrillar and intramyofibrillar glycogen particles are differentially utilized to fulfill specific energy demands. Here, I will review and summarize what is known and what is still lacking to reach full understanding of the complexity of skeletal muscle glycogen metabolism and insulin signaling.

### IS-PM14 EFFECT OF SCHOOL BASED PHYSICAL ACTIVITY INTERVENTIONS

#### TWO DANISH SCHOOL-BASED PHYSICAL ACTIVITY INTERVENTIONS

Bugge, A., Klakk, H., Wedderkopp, N., Andersen, L.B.

*University of Southern Denmark*

Introduction Schools are potentially effective settings for early public health prevention. The aim of these two studies was to evaluate the effect of additional physical education (PE) lessons in Danish public schools on cardiovascular disease (CVD) risk and body composition. Methods The two quasi experimental studies were; The Copenhagen School Child Intervention Study (CoSCIS) (1) and The Childhood Health, Activity and Motor Performance School Study Denmark (CHAMPS) (2). The increase in PE was two extra lessons in CoSCIS and four extra PE lessons in CHAMPS, both compared to the mandatory two PE lessons in the control schools. CoSCIS involved 18 schools (10 intervention and 8 controls) and included a post-intervention measurement three years after the onset of the intervention and a follow-up four years after the end of intervention. The analyses included 696, 6- to 7-year-old children at baseline. CHAMPS involved 10 public schools (6 intervention and 4 control). Analyses included 1218 children, aged 6–10 years at baseline and here we include the two-year follow-up. Anthropometrics, systolic blood pressure (SBP) and aerobic fitness was measured at baseline and follow up in both studies. Fasting blood samples were analyzed for classic CVD risk factors and a composite risk score was computed from z-scores of CVD risk factors. Results In CoSCIS the intervention did not have a positive effect on the composite risk score or measures of body composition either at post-intervention or the follow-up. The HOMA score of the intervention group boys had a smaller increase from baseline to post-intervention compared with control boys ( $p = 0.004$ ). From baseline to follow-up intervention group boys had a smaller increase in SBP compared with control boys ( $p = 0.010$ ). There were no other significant differences between groups. In CHAMPS the intervention significantly lowered mean of composite risk score with 0.17 SD (95% CI:  $-0.34$  to  $-0.01$ ). Six PE lessons per week had a beneficial effect on triglycerides levels ( $-0.18$  SD, 95% CI:  $-0.36$  to  $0.00$ ), systolic blood pressure ( $-0.22$  SD, 95% CI:  $-0.42$  to  $-0.02$ ) and insulin resistance (HOMA-IR) ( $-0.17$  SD, 95% CI:  $-0.34$  to  $0.01$ ). The intervention did not result in any effects on mean value of BMI. However, a beneficial intervention effect on prevalence of OW/OB based on BMI (OR 0.29, 95% CI: 0.11 to 0.72) was found. Discussion Based in these two studies, there seem to be a threshold for the amount of extra physical activity in school-based interventions to affect CVD risk profile and body composition. Further studies are needed to verify this. References 1. Bugge, A., B.El-Naaman, M.Dencker, K.Froberg, I.M.Holme, R.G.McMurray, and L.B.Andersen. 2012. #### EFFECTS OF A 2-YEAR SCHOOL-BASED DAILY PHYSICAL ACTIVITY INTERVENTION. THE SOGNDAL SCHOOL-INTERVENTION STUDY.

Resaland, G.K., Anderssen, S.A., Andersen, L.B.

*Sogn and Fjordane University College*

Introduction We aim to present parameters of importance to achieve health-improving effects on fitness and cardiovascular risk factors based on a two-year school-based teacher-led 60-minute daily physical activity intervention school that took place over two academic years. Methods A total of 259 children, corresponding to all fourth-graders enrolled in 2004 (born 1995) and 2005 (born 1996) in two elementary schools in two rural municipalities in Western Norway, were invited to participate. Intervention-school children ( $n = 125$ ) carried out 60-minute daily physical activity over two school years. Control-school children ( $n = 131$ ) had 45 minutes of physical education twice weekly. We analyzed serum glucose, insulin, total cholesterol, high density lipoprotein cholesterol and triglyceride. Peak oxygen uptake was directly measured during a treadmill protocol. Also body mass, height, weight, blood pressure and waist circumference were measured. Results We found a significant greater beneficial development in cardiorespiratory fitness, blood pressure, total cholesterol to high-density lipoprotein cholesterol ratio and triglyceride in intervention-school children than in control-school children. Those children in the Intervention-school with the least favorable starting point experienced the most beneficial effect of the intervention. Conclusion In conclusion, a school-based physical activity intervention can beneficially modify children's CVD risk profile if the intervention is of sufficient length and if the physical activity is planned, organized and led by expert physical education teachers. Therefore, this intervention has shown that physical activity can positively modify fitness and cardiovascular risk factors at an early age, and thus might be an important tool in the primary prevention of cardiovascular diseases, and should be given due consideration in the design of school policies. The Intervention school has decided to continue its commitment to the physical activity program, and expand the program to all 330 pupils. The program consists of 30 minutes of daily teacher-led physical activity. Also other schools in the area have established physical activity as part of the school curriculum.

#### EFFECTS OF SCHOOL-BASED PHYSICAL ACTIVITY INTERVENTIONS: THE KISS STUDY

Kriemler, S.1, Zahner, L.2, Meyer, U.3

*1;3University of Zürich; 2University of Basel*

Introduction We aim to present parameters of importance to achieve health-improving effects on physical activity level, fitness and cardiovascular risk factors based on a physical activity intervention in elementary school that took place over one academic year and with a follow-up 3 years off intervention. Methods Twenty-eight classes from two of 26 provinces in Switzerland were cluster randomized to the

intervention (16 classes, n=297) and control (12 classes, n=205) groups. The intervention consisted of a multi-component PA intervention including daily physical education, short activity breaks, and education of classroom teachers. Primary outcomes included body fat (skin-fold thickness), aerobic fitness (shuttle run test), PA (accelerometry), and quality of life (questionnaires), secondary outcomes included a composite cardiovascular risk score (blood samples). Children and parents in the control group were not aware of the existence of an intervention group. Results Of 502 children, 498 provided baseline and post-intervention data and 58% of those who took part at baseline participated at the follow-up 3 years off intervention. At post-intervention, children in the intervention compared to the control group showed statistically significant decreases in the sum of four skinfolds (adjusted difference (AD) -2.10mm; 95%-CI -3.48 to -0.90), and significant improvements in aerobic fitness z-score (AD 0.22; 95CI 0.01 to 0.42), MVPA at school (AD 1.19 z-score units; 95CI 0.78 to 1.60) and over the day (0.44 z-score units; 95CI 0.04 to 0.82), corresponding to 11-14 min of differences among groups per day, and a more favourable composite cardiovascular risk score (AD -0.18; 95CI -0.29 to -0.06). Quality of life and total PA did not change. At the 3-year follow-up, children in the intervention arm compared with controls had a significantly higher aerobic fitness (AD 0.373 z-score units; 95CI 0.157 to 0.59) corresponding to a shift from the 50th to the 65th percentile between baseline and follow-up, while the immediate beneficial effects on the other primary outcomes were not sustained. In conclusion, body composition, aerobic fitness, moderate-vigorous PA in school, and cardiovascular risk factors can be significantly improved in primary school children by a multi-component PA intervention, provided by experts and with compulsory elements within one school year. However, a continuous intervention or an adaptation of our school system with the provision of daily PE taught preferably by experts seems necessary to maintain overall beneficial health effects as reached at the end of the intervention.

### IS-PM07 LIFELONG ENDURANCE TRAINING: MAINTENANCE OF HIGH CARDIOVASCULAR AND OXIDATIVE METABOLIC PERFORMANCE WITH AGING: IN HONOUR OF BENGT SALTIN \*

#### LONGITUDINAL PUMPING IS PRESERVED WITH LIFELONG ENDURANCE TRAINING AND IS AN INDEPENDENT PREDICTOR OF MAXIMAL CARDIAC OUTPUT

Steding-Ehrenborg, K., Boushel, R.C., Calbet, J.A., Åkeson, P., Mortensen, S., Saltin, B.  
*Copenhagen Muscle Research Centre, Denmark and Hvidovre Hospital, Denmark*

Background: Ageing decreases cardiac volumes and function, and lifelong endurance training has been shown to prevent or postpone some of the deteriorations. The effects of normal ageing as well as of lifelong endurance exercise on longitudinal and radial contribution to stroke volume are unknown. The aim of this study was to determine longitudinal and radial pumping at rest in healthy untrained and well trained elderly. Furthermore, we aimed to investigate the relationship between cardiac output during maximal exercise and longitudinal and radial pumping. Methods: Eight male elderly athletes (age 63±4 years) and seven matched control subjects (age 66±4 years) underwent cardiac magnetic resonance imaging (CMR). Athletes and controls also underwent maximal exercise testing to determine peak oxygen uptake (VO<sub>2</sub>peak) and exercise cardiac output was determined using dye dilution technique. Results: Left ventricular longitudinal and right ventricular longitudinal contribution to stroke volume (%) was higher in athletes compared to controls (65±13% vs 52±13%, p=0.06 and 87±13% vs 78±11%, p=0.13, respectively). Radial contribution (%) was similar in both athletes and sedentary controls (8.1±1.8% in athletes, 8.6±1.4% in controls, p=1.0). Left ventricular atrio-ventricular plane displacement was an independent predictor of maximal CO (R<sup>2</sup>=0.89, p<0.0001, β=0.89). Conclusion: Elderly athletes have preserved longitudinal function at a level similar to young untrained subjects. Longitudinal function is the main contributor to ventricular ejection and is an important factor to achieve a cardiac output that meets the increased metabolic demands with increased activity and exercise.

#### ENDOTHELIAL-MEDIATED VASODILATION AND MUSCLE VASCULAR CONDUCTANCE DURING EXERCISE

Mortensen, S.P.  
*University of Southern Denmark*

Exercise training is known to alter the responsiveness and capacity of the vasculature to dilate in response to vasodilator stimuli including signals induced during muscle contraction. In this talk, the influence of lifelong physical activity on vascular function will be presented. Blood flow responses to femoral arterial infusion of dilator substances will be compared between lifelong trained elderly and sedentary young and older individuals. These responses will be related to the vascular conductance responses during exercise involving a small and large muscle mass measured together with arterial and venous blood pressures. The role of local vasodilator signals for regulating muscle vasodilatation will be integrated with measures of tonic regulation of blood flow by vasoconstrictor signals from the sympathetic nervous system in contracting muscle and in inactive vascular beds. The interplay between local mediators of muscle vasodilatation such as ATP, adenosine, nitric oxide and prostacyclin and their sympatholytic influence in the control of muscle blood flow with lifelong physical activity will be discussed.

#### LIFELONG TRAINING KEEPS MITOCHONDRIA YOUNG

Boushel, R.  
*The Swedish School of Sport and Health Sciences*

Ageing is associated with diminished cardiovascular function, and loss of muscle oxidative capacity is also considered a salient feature. While moderate-to-high intensity training increases O<sub>2</sub> delivery to muscle and induces mitochondrial biogenesis, it remains unclear to what extent ageing in itself, or a lower training level with age contributes to loss of skeletal muscle oxidative capacity. Leg O<sub>2</sub> delivery and VO<sub>2</sub> were determined during incremental exercise on a cycle ergometer in 8 men (67±2 yrs) who maintained road cycle training >200 km/week for >40 years (Lifelong-Trained -LT) and compared to age-matched sedentary (UT) controls (67±1 yrs). Mitochondrial respiratory capacity was measured in permeabilized fibres from biopsies of the quadriceps using respirometry (Oxygraph, Oroboros, AT). Peak VO<sub>2</sub> across the legs measured by the Fick method was 36% higher in LT (2693±186 ml.min<sup>-1</sup>) compared to UT (1981±166 ml.min<sup>-1</sup>) with a 12% higher leg O<sub>2</sub> extraction in LT. V<sub>max</sub> of mitochondrial respiration with mixed substrates was ~2-fold higher in the ET (109±6 pmol.sec<sup>-1</sup>.mg<sup>-1</sup>) compared to UT (60±4 pmol.sec<sup>-1</sup>.mg<sup>-1</sup>, p<0.01). Excess capacity of mitochondria over O<sub>2</sub> delivery was larger in the LT compared

to UT resulting in lower relative ADP activation of mitochondria in-vivo at peak exercise, accompanied by a lower in-vivo mitochondrial p50. The findings reveal that skeletal muscle mitochondrial respiratory capacity of lifelong trained males is retained at a level comparable to trained young individuals, and indicate that decrements in aerobic performance with age are primarily attributed to diminished oxygen delivery.

### **CENTRAL HAEMODYNAMICS DURING EXERCISE**

Calbet, J.A.

*University of Las Palmas de Gran Canaria*

Maximal oxygen uptake (VO<sub>2</sub>max) is the main determinant of the exercise capacity and is a good predictor of life expectancy. VO<sub>2</sub>max is progressively reduced with ageing. Since VO<sub>2</sub>max is primarily determined by maximal oxygen delivery and secondary by the muscular capacity to extract oxygen, the factors determining maximal oxygen delivery become critically important to understand how exercise capacity is limited with ageing. Maximal systemic oxygen delivery depends on maximal cardiac output (Q<sub>max</sub>) and arterial oxygen content. Q<sub>max</sub> explains most of the reduction in VO<sub>2</sub>max with ageing. However, the limiting role of Q<sub>max</sub> has been reported to be more important in trained than in untrained elders. This could indicate that other factors apart from maximal systemic oxygen delivery may have a greater role in untrained elders. For example, it has been reported that peak leg blood flow (LBF<sub>peak</sub>) during upright whole body exercise is reduced with ageing. However it remains unknown whether the reduction of the maximal muscular perfusion is proportionally greater than the reduction of Q<sub>max</sub> due to reduced vascular conductance. Moreover, it remains unknown what factor limits VO<sub>2</sub>max in world level elite endurance elderly athletes. Here we present central and peripheral haemodynamic data obtained in 6 young (Y) (21±2 years), 8 lifelong sedentary elderly (LSE) (66±5 years) and 4 elite endurance elderly athletes (EEA) (65±6 years) men during incremental cycling to exhaustion. EEA achieved a greater VO<sub>2</sub>max than LSE, due to higher cardiac output (+45-55%) explained by a much higher stroke volume in EEA than Y and LSE. Peak leg blood flow (LBF<sub>peak</sub>) was 25% lower in LSE than in Y and 48% higher in EEA than in LSE. Thus, ageing is associated with reduced Q<sub>max</sub> and LBF<sub>peak</sub>, while lifelong participation in elite endurance events maintains LBF<sub>peak</sub> at levels similar to those observed in young sedentary men. The remarkably higher Q<sub>max</sub> in EEA than Y or LSE (25±3, 21±2, 19±2 L/min, respectively) is associated to a higher central blood volume and preload at W<sub>max</sub> in EEA, for a similar afterload in the three groups. The main reason why LBF<sub>peak</sub> is reduced with ageing appears to be the reduction of Q<sub>max</sub>, since the three groups directed a similar amount of blood flow to perfuse the trunk. Supported by the Lundbeck Foundation and Augustinus Foundation

### **IS-PM15 RECENT DEVELOPMENTS IN ALTITUDE AND HYPOXIC TRAINING SPONSORED BY ASPETAR**

---

#### **DOES ALTITUDE TRAINING ACTUALLY IMPROVE ENDURANCE PERFORMANCE IN ATHLETES? A CRITICAL REVIEW OF THE DIFFERENT METHODS**

Robach, P.

*Ecole Nationale des Sports de Montagne, site de l'Ecole Nationale de Ski et d'Alpinisme*

Endurance athletes often use altitude training in an attempt to enhance exercise performance. Evidence suggests that altitude training may be useful for some athletes, and the accepted underlying mechanism is an increase in total hemoglobin mass and thus oxygen carrying capacity. However, a crucial question remains unanswered: is altitude training beneficial for endurance champions? The traditional Live high – train high (LHTH) method is somewhat “paradoxical” since 1) controlled studies failed to demonstrate any clear impact on physical performance in highly-trained individuals, but 2) LHTH remains the most popular altitude-training method, likely due to numerous anecdotal reports from world-class athletes showing outstanding competitive results following LHTH. Here the gap between science and practice highlights the need for further research on highly-trained individuals. The effectiveness of Live high – train low (LHTL) on exercise performance was demonstrated in well-trained individuals using natural altitude. Insights from LHTL using simulated altitude show marginal performance improvement in highly-trained individuals, suggesting that the effectiveness of this method in athletes with high total hemoglobin mass and maximal oxygen uptake is limited. It may be that LHTL using hypobaric hypoxia does promote stronger adaptive responses and therefore performance enhancement, however this hypothesis must be further verified. Live low – train high (LLTH), i.e. hypoxic training, yields conflicting results in untrained and trained individuals, suggesting no consistent advantage for sea-level performance for elite athletes in particular. It may be that high-intensity interval training or even repeated sprint-training coupled with hypoxia has a positive effect on performance. Whether this benefit extends to elite athletes is however unclear. In summary, altitude training methods based on hematological changes (LHTH and LHTL) seem more certain than those based on within skeletal muscle changes (LLTH). Living and/or training in a natural hypoxic environment might be the best option for elite endurance athletes, both with respect to adaptive responses and motivational aspects. More controlled studies investigating highly-trained individuals are necessary.

#### **SANGUINE ALTITUDE – OVERLY OPTIMISTIC OR DOES THE EVIDENCE STACK UP?**

Gore, C.

*Australian Institute of Sport (Canberra)*

Introduction Altitude/hypoxic training remains popular despite the challenge of demonstrating performance advantage (3). There are a variety of hypoxic modalities used ranging from living and training at altitude (live high:train high - LHTH) (8), to live high:train low (LHTL) (8), live low:train high (10) and resting in hypoxia (12). Despite encouraging results for several of these modalities to increase haemoglobin mass (Hbmass), the associated logistics has caused a search more time efficient protocols, which may be less disruptive to training and competition (2; 10). My aim is to review data for (Hbmass) to identify the minimum useful dose. Discussion Critical to interpreting changes in Hbmass is minimising sources of error associated with the technique, therefore I will review data to quantify the imprecision of Hbmass and how to minimise it. Estimates of within subject standard deviation of Hbmass derived ~10 years apart indicate a value of ~2% (4; 5). Two recent meta-analyses (5; 11) will be used to attempt to answer the questions of “How high and how long is required to increase Hbmass”, “What is the minimum time-effective dose?”, “How long do the effects last?”, and “Will altitude training work for me?”. Confounders that can blunt an increase in Hbmass at altitude include illness (9), negative energy balance (9) and lack of iron. The latter

will be explored in terms of a retrospective analysis of the dose of oral iron relative to ferritin iron stores (7). Despite there being a clear relationship between increased Hbmass and VO<sub>2</sub>max (14), the strength of this relationship in athletes after altitude training is less clear, with an ~1% increase in Hbmass resulting in a 0.6–0.7% increase in VO<sub>2</sub>max (13). A meta-analysis of natural altitude interventions concludes that the mean performance benefits are of the order of 2–4% among elite athletes (1), but this is not always the case in athletes despite increased Hbmass (6). In conclusion, LHTH and LHTL altitude training is likely worthwhile but there are often many mitigating factors to overcome. References 1. Bonetti DL & Hopkins WG. *Sports Med* 39:107-27, 2009. 2. ## **INNOVATIONS IN HYPOXIC TRAINING TO MAXIMIZE PHYSICAL PERFORMANCE: FROM ENDURANCE ATHLETES...TO TEAM-SPORT PLAYERS...TOWARD PATIENTS**

Millet, G.

*University of Lausanne*

Twenty years ago, the main altitude training method used was "live high - train high" (LHTH) [1] in hypobaric hypoxia by endurance athletes. It was modified mid-90s by the development of "live high - train low" (LHTL) [2]; sleeping at altitude to gain the hematologic adaptations (Hbmass) while training at sea level to maximize performance (maintenance of sea level training intensity). This LHTL method can be accomplished via a number of methods and devices: natural/terrestrial altitude (HH) or in "simulated altitude" (normobaric hypoxia, NH) using nitrogen dilution or oxygen filtration [3]. Another hypoxic intervention is "live low - train high" (LLTH) mainly in NH, including intermittent hypoxic exposure at rest (IHE) or during intermittent hypoxic training sessions (IHT). Noteworthy, most of the available studies were conducted with endurance athletes. Recently, our research group challenged two points (1) that normobaric and hypobaric hypoxia can be used interchangeably, both in medicine and in sport (2) that altitude training benefits are limited to Hbmass and to aerobic sports. 1. Based on the existing data [4] relating to differences in ventilatory responses, fluid balance, acute mountain sickness severity and/or nitric oxide metabolism, it is likely that HH induces different physiological responses than NH. Recently, we reported that both 24 h [5] and 18 days [6] of LHTL in either NH or HH differentially affect oxidative status of athletes. Furthermore, Saugy et al. [7] reported that LHTL (2250 – 1100 m) while sleeping in HH versus NH induced different responses and a larger performance enhancement. Sleeping pattern also differs between NH and HH [8]. 2. Recently, we [9-11] defined a new hypoxic method (RSH, repeated sprint training in hypoxia) leading to improved repeated-sprint ability (RSA). Therefore, we logically proposed [9] to divide the LLTH paradigm in four subsets; i.e. IHE, CHT (continuous training in hypoxia), IHT and RSH since each method is likely based on different mechanisms. Faiss et al. showed larger improvements in cycling [12] or cross-country skiing [13] RSA following few (6-8) RSH sessions compared to similar training in normoxia. Finally, Brocherie et al. [14] reported that in elite team-sport players, the combination of LHTL and RSH ("live high train low and high", LHTLH) enhances both Hbmass and RSA. 1. ## **Invited symposia**

### **IS-BN08 MENTAL AND COGNITIVE TRAINING: IMPORTANCE FOR SKILL LEARNING, REHABILITATION AND SPORTS ACTIVITIES– MECHANISMS AND APPLICATIONS**

#### **MENTAL TRAINING OF FINE MOTOR SKILLS**

Leukel, C., Lauber, B., Kurz, A., Niemann, N., Gollhofer, A., Taube, W.

*University of Freiburg*

Fine motor skills are unique in humans compared to other species (Porter R and RN Lemon 1993). They are relevant in everyday life as well as in sports (e.g. dart throwing, shooting, basketball shots, etc.) and great effort is made to rehabilitate these functions in case of an injury. Therefore, new approaches seek to find better ways to effectively train these functions. In this context, we recently performed experiments asking whether mental training is able to improve motor performance. We concentrated on two types of fine motor skills, movement accuracy and movement speed (Lundbye-Jensen J et al. 2011). Furthermore, as subsequent training of both types was shown to cause interference (i.e. the performance improvements of one skill is reduced by subsequent training of the other skill) (Lundbye-Jensen J et al. 2011; Lauber B et al. 2013) we asked whether mental training would prevent interference. The present talk therefore addresses how fine motor skills, but not ballistic contractions, can be improved by mental training and how mental training may prevent interference. Some of the underlying neural principles will be presented and the potential consequences of these findings for training interventions are discussed. Lauber et al. 2013. *PLoS ONE* Lundbye-Jensen. *PLoS ONE* Porter R, Lemon RN. 1993. *Monographs of the Physiological Society*, No. 45. New York: Oxford University Press.

#### **IMPACT OF COMPUTERIZED COGNITIVE TRAINING DURING PERIODS OF INACTIVITY**

Marusic, U.

*University of Primorska*

The talk will briefly present the effects of prolonged inactivity (immobilization) on the human body such as impaired cardio-vascular, skeletal and muscular systems (Pavy-Le Traon et al., 2007) with additional evidence of potential deficits in sensorimotor functioning (Car-

penner et al., 2010), cognition (Lipnicki & Gunga, 2009) and brain functioning (Marusic et al., 2014). Several studies have shown the close interrelation of physical activity and cognitive function (Kramer & Erickson, 2007). This talk will briefly present the efficacy of cognitive interventions for the enhancement of sports performance and highlight the importance of developing new interventions for staying cognitively active during physical inactivity in order to maintain sensorimotor function. For this purpose, studies targeting and improving specific cognitive domains will be presented (Tardif & Simard, 2011). Verghese et al. (2010) have demonstrated that cognitive training can even lead to improved mobility performance in sedentary seniors due to a close link between these areas of cognition and motor control. To illustrate this close link, we will present behavioral adaptations in gait parameters as well as neural adaptations assessed by multichannel EEG. Furthermore, the importance and effectiveness of cognitive training in a virtual environment (targeting spatial navigation, executive functions, working memory and attention) while being physical inactive will be highlighted and effects after 28-days of rehabilitation and after 400-days after completion of rehabilitation will be presented.

### **EFFECT OF MOTOR IMAGERY AND MOVEMENT OBSERVATION ON POSTURAL CONTROL AND SENSORIMOTOR FUNCTION OF THE CERVICAL SPINE**

Taube, W.

*University of Freiburg*

Studies indicate that motor imagery (Hallett et al. 1994) and observation of movements (Neuper et al. 2005) activate brain regions that are also active during the actual task performance. Based on these findings it is assumed that activation of (motor) representations is responsible for behavioral adaptations after mental training. With respect to postural control, Hamel & Lajoie (2005) and Tia et al. (2010) reported improved performance after motor imagery and movement observation, respectively. Thus, motor imagery and observational training seem to have the potential to improve postural control. However, no previous study has ever tested whether mental non-physical training can improve posture in an unstable, dynamic environment, where sensory feedback is essential in order to counteract external perturbations that cannot precisely be anticipated. Furthermore, it is not known whether these forms of non-physical training can improve sensorimotor function of the cervical spine that is also considered to rely strongly on sensory feedback. The present talk highlights the potential of motor imagery and observation to improve performance in tasks that strongly rely on afferent feedback and displays brain activity (assessed by fMRI and TMS) associated with mental training of different postural tasks. Furthermore, comparisons between young and elderly subjects are made. It will be demonstrated that elderly subjects demonstrate greater cortical activity when mentally simulating postural tasks than young adults. Furthermore, they seem to rely more strongly on visual input in order to activate subcortical brain areas associated with postural control. This might be an important aspect when applying mental simulation techniques in order to maintain or restore sensorimotor function during periods of immobilization. ### **MINOR EFFECTS OF A FATIGUING RECUMBENT CYCLING TASK ON FATIGABILITY OF A HAND MUSCLE**

Zijdwind, I.1, Gringhuis, R.1, Hettinga, F.2, Bakels, R.1

*\*UMC Groningen, \*\*University of Essex*

Introduction Muscle fatigue is defined as an exercise-induced reduction in the force generating capacity. Fatigue can be due to changes in the central nervous system (central fatigue) and the peripheral nervous system or muscle (peripheral fatigue; Gandevia, 2001). There is some debate whether muscle fatigue is confined to active muscle groups or that quiescent muscles also show fatigue-related changes in force (Elmer et al., 2013; Rattey et al., 2006). We hypothesized that if fatigue-related changes would manifest themselves in quiescent muscles, that these muscles would show greater fatigability during a sustained contraction following (fatiguing) exercise. Methods Twenty young participants (10 females, 21-26 years) performed a maximal (Bike\_Max, until exhaustion) and a submaximal (Bike\_submax, minor or no fatigue) recumbent cycling exercise test, on two separate occasions separated by 1 week. Before (MVC\_1) and after (MVC\_2) this exercise test, brief maximal voluntary contractions (MVC) of the left index finger abductor (FDI) were assessed. These were immediately followed by a 2-minute sustained index finger abduction and another final brief FDI contraction (MVC\_3). Results The MVC\_1 of the FDI did not differ between the two occasions (56.9N, SD 9.4). MVC\_2 directly following the exercise test was significantly smaller after Bike\_max (86% initial MVC) than after Bike\_submax (94% MVC,  $P=0.04$ ). However, no significant difference was observed after the 2-minute sustained contraction (MVC\_3, Bike\_max: 55% initial MVC; Bike\_submax, MVC\_3, 57% initial MVC,  $P=0.41$ ). During the sustained contraction the force declined significantly ( $P<0.001$ ). No main or interaction effect, however, was found between the two occasions ( $P>0.1$ ). Conclusion Our data only show a small effect of a fatiguing recumbent cycling task on hand muscle force. However, the lack of an effect on the fatigability of this hand muscle suggests that this effect is only short-lasting and of minor importance. ### **IS-BN01 DIGITAL SUPPORT SYSTEMS IN RECREATIONAL AND ELITE SPORTS**

#### **TECHNICAL SUPPORT SYSTEMS IN SPORTS: ADAPATED TO INDIVIDUAL NEEDS**

Wolf, P., Rauter, G., Gerig, G., Sigrist, R., Riener, R.

*ETH Zurich*

Introduction A human trainer adapts training to the athlete's individual learning stage, skills, and personality. However, a human cannot observe all physiological and biomechanical variables characterizing the motor task, neither at the same time nor at a high precision. In addition, complex motor tasks may benefit from concurrent multisensory feedback, a type of feedback a human trainer can hardly provide. To overcome these limitations of a human trainer, we developed a technical system that supports a comprehensive assessment of the current performance in rowing, namely the M3-Rowing Simulator (Rauter et al., 2013), and that features concurrent uni- and multi-

modal feedback strategies (Sigrist et al., 2013 & 2014). Besides exemplifying challenges and solutions on how feedback strategies can automatically be selected, we will present results on motor learning experiments where subjects trained either with or without individualized feedback. Methods Sixteen non-rowers were randomly assigned either to an experimental or to a control group. Subjects were requested to learn a typical oar movement in upper body-arm rowing. After a baseline test, subjects trained on two days including five 180s lasting trials with feedback each followed by a 60s lasting non-feedback trial. On a third day, another non-feedback trial (retention test day 3) was measured (protocol similar to Sigrist et al., 2013 & 2014). The experimental group received automatically selected feedback. Therefore, in the non-feedback trials, the most dominant error out of five errors (four spatial and one velocity error) was determined. In the subsequent training a feedback was provided which has been demonstrated to reduce this error. The resulting individual feedback protocol was also presented to one subject of the control group, i.e., the control group was provided with the same feedback, however, the currently most dominant error was not necessarily addressed. Results In contrast to the control group, the experimental group significantly reduced the normalized overall error from baseline to retention tests on day 2 and day 3. The velocity error was significantly reduced by both groups. The experimental group reduced the velocity error significantly more than the control group from baseline to retention on day 2. Discussion One of the largest potentials of technical support systems in sports was explored: Continuously monitored data was used to switch online between feedback strategies. The technical system developed was able to accelerate motor learning when compared to unsupervised provision of concurrent feedback (We also tested a group receiving no feedback – the group did not learn at all). Therewith, a basis is given to explore further features of technical support systems in sports. References Rauter G, Sigrist R, Koch C, Crivelli F, van Raaij M, Riener R, Wolf P (2013). ### WEARABLE COMPUTING SYSTEMS FOR RECREATIONAL AND ELITE SPORTS

Eskofier, B.

*Friedrich-Alexander-Universität Erlangen-Nürnberg*

Wearable computing systems play an increasingly important role in recreational and elite sports. They comprise of two important parts. The first are sensors embedded into clothes and equipment that are used for physiological (ECG, EMG, ...) and biomechanical (accelerometer, gyroscope, ...) data recording. The second are signal processing and data mining algorithms implemented on wearable computers (smartphones, watches, ...) that are used for analysis of the recorded data. Wearable computing systems can provide support, real-time feedback and coaching advice to sportsmen of all performance levels. In order to implement these systems, several challenges have to be addressed. Our group works on four of the most prevalent of these: - Integration: sensors and microprocessors have to be embedded unobtrusively and have to record a variety of signals. - Communication: sensors and microprocessors have to communicate in body-area-networks in a secure, safe and energy-saving manner. - Interpretation: physiological and biomechanical data have to be interpreted using signal processing and machine learning methods. - Usability: interaction with the systems is provided by human-computer-interfaces (HCIs) that have to be intuitive and adapted to several use cases. The talk presents the named challenges and technological solutions to overcome them. The talk is relevant and targeted to researchers aiming to: - include embedded physiological and biomechanical sensors in their studies, - obtain information about secure and energy-efficient communication strategies, - get examples of fundamental concepts of signal analysis and machine learning, - interact with and present information to sportsmen using intuitive HCIs.

### TOWARDS INTELLIGENT FEEDBACK SYSTEMS

Baca, A.

*ISW at the University of Vienna*

Introduction: Technological systems are getting increasingly important for physical activity monitoring and assessment in general and for supervising load and performance in particular. Miniature sensors and computing devices are attached to the athletes or integrated into the sports equipment in order to acquire and process performance or load related data. Ubiquitous computing technologies are thus applied to implement systems, which provide athletes with feedback information on the quality of the motion just performed. The current challenge lies in the development of intelligent systems that cannot only analyse the data but suggest strategies and interventions. One specific concept shall illustrate the potential of such systems. The idea is to provide interactive communication technology in order to assist athletes (recreational and elite sports) in adapting certain performance parameters with respect to the individual performance level. Based on the collected data, which are wirelessly transferred to a server, feedback instructions from (remote) experts having internet access may be given during exercising. Moreover, intelligent algorithms may be integrated into the server application in order to generate feedback instructions automatically. Practical implementations of this concept will be illustrated on the example of long distance running and exercising on weight training machines.

## Invited symposia

### IS-SH07 Lars Magnus Engström Memorial Session

#### A PHILOSOPHICAL PERSPECTIVE ON THE RELATIONSHIP BETWEEN THE LOGIC OF SPORT AND THE ETHICS OF SPORT.

Schneider, A.

*Western University*

What does sport mean? A philosophical perspective on the relationship between the logic of sport and the ethics of sport. A philosophical account will be given about of the meaning and logic of sport in contemporary society, in particular put in relation to ethical issues. More specifically, the question of whether the ethics of sport is tied to the logic of the practice of sports will be addressed. Philosophical analysis of the key concepts of sports, games and play has been declining in more recent years, while much more momentum has developed in the area of ethics in sport. The progress of important ethical positions and concepts has proceeded somewhat independently from careful explanation of exactly what those concepts logically entail. This presentation will be about an examination of whether or not there is a relationship between the two areas of study and if so, what kind of relationship that may be and to what degree. A clearer under-

standing of the potentially diverse logic in various conceptualizations of sport may help to clear the perspectives on some seemingly intractable ethical issues.

### THE LOGICS OF PRACTICE IN SPORTS – OUTLINE OF A THEORY

Larsson, H.

*The Swedish School of Sport and Health Sciences*

Invited symposium. The logics of practice in sports – outline of a theory In 1968, Lars-Magnus Engström started to follow the physical activity patterns of over 2000 Swedes who were born in 1953. This study is still ongoing. In his analyses, Engström found it difficult to analyze his material according to sport concepts or rational motives for doing sports (e.g. health). However, he found useful tools in the work of French cultural sociologist Pierre Bourdieu. Over the years, Engström devoted much attention towards chiseling out a framework for understanding the logics of sport practice, and how these logics can be used to analyse participation patterns and the social stratification of sport. What does sport mean? A philosophical perspective on the relationship between the logic of sport and the ethics of sport The first paper will give a philosophical account of the meaning of sport in contemporary society, in particular put in relation to ethical issues. More specifically, the question of whether the ethics of sport is tied to the logic of the practice of sports will be addressed. The progress of important ethical positions and concepts has proceeded somewhat independently from careful explanation of exactly what those concepts logically entail. This presentation will be about an examination of whether or not there is a relationship between the two areas of study and if so, what kind of relationship that may be and to what degree. A clearer understanding of the potentially diverse logic in various conceptualizations of sport may help to clear the perspectives on some seemingly intractable ethical issues. What does sport mean? Outline of a theory of a logic of sports practices When sports practices and patterns of participation are analysed in research, a common approach by researchers is to understand what people do from the point of view either of what motives that individuals ascribe what they do, or what function the activity might have in relation to, in the case of sport and physical activity for instance, educational or health benefits, or sport performance. This seems, however, to be a way of subjecting practice to a rational logic. Instead, this presentation takes the logic of practice of sport, as it is theorized by Bourdieu, as its starting point. The presentation will outline a number of logics of sports practices that Lars-Magnus Engström has explored, using data from his longitudinal study. The Logic of Sport and the Practice of Sport The third paper will examine the logic of (competitive) sport, in order to illustrate the contribution to this foundational issue that can be made by analytical philosophy. The paper will employ the techniques of conceptual analysis, in suggesting logically necessary conditions for the use of the word 'sport'; and will try to show how the resulting criteria can act both as a demarcation device (between sport and non-sporting activities), and as a source of value prescriptions for sporting practice.

### THE LOGIC OF SPORT AND THE PRACTICE OF SPORT

Parry, J.

*Charles University in Prague*

I will examine the logic of (competitive) sport, in order to illustrate the contribution to this foundational issue that can be made by analytical philosophy. The paper will employ the techniques of conceptual analysis, in suggesting logically necessary conditions for the use of the word 'sport', and will try to show how the resulting criteria can act both as a demarcation device (between sport and non-sporting activities), and as a source of value prescriptions for sporting practice.

### OP-SH10 Psychology (Training and Exercise)

#### PERSPECTIVES ON TRAINING APPLIED SPORT PSYCHOLOGISTS IN AUSTRALIA

Marchant, D.

*Victoria University*

In this presentation, I reflect on critical perspectives in developing competence with early career applied sport psychologists from a trainers' perspective. The underlying theme will be looking in and looking out to denote the significance of reflective practice, personal insight and the capacity to adapt. In relation to working with neophyte ASPs the broad objective is developing service-delivery competence (SDC) defined by Tod, Andersen and Marchant (2009) "as the application of suitable psychological theory through the use of appropriate skills and interventions, in a therapeutic relationship to meet a client's needs and expectations, with routine reflection by the practitioner on how they have influenced the process of service provision." For this presentation white water kayaking terminology (e.g., Eddy, Eskimo roll, Feather, Keeper hole, Rapids) will be used as a metaphor for the challenges of assisting neophyte ASPs in 'staying afloat' while they move toward functional competence. In terms of the necessary skills to work successfully over a sustained period in applied sport psychology we focus heavily on eight development themes with neophyte sport psychologists; 1) Intake and counselling skills 2) assessment skills; 3) rapport building; 4) relational skills; 5) domain specific knowledge; 6) knowledge transfer and exchange 7) listening and attending and 8) business skills. Finally, I will draw heavily from the work of Michael Franz Basch (1980, 1988) in describing methods used over a 20 year period to assist young ASPs bridge the gap between theory and practice. Basch, M. F. (1980) *Doing psychotherapy*. New York: Basic books. Basch, M. F. (1988). *Understanding psychotherapy: The science behind the art*. New York: Basic Books. Tod, D., Andersen, M. B., & Marchant, D. B. (2009). A longitudinal examination of neophyte applied sports psychologists' development. *Journal of Applied Sport Psychology*, 21(Suppl. 1), S1-S16. doi:10.1080/10413200802593604

### 10-YEAR CUMULATIVE AND BIDIRECTIONAL ASSOCIATIONS OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR DOMAINS WITH HEALTH-RELATED QUALITY OF LIFE IN FRENCH ADULTS

Omorou, A., Menai, M., Lata arche, C., Kesse-guyot, E., Oppert, J.M., Hercberg, C., Briançon, S., Vuillemin, A.

*University of Lorraine*

Background: The causality and directionality of the associations of domains of physical activity (PA) and sedentary behavior (SB) with health-related quality of life (HRQoL) in adults remain to be defined. This study investigated the longitudinal association of 10-year cumulative levels of PA and SB with HRQoL and the reverse association. Methods: A sample of 2,093 individuals from a 10-year cohort of French adults (SU.VI.MAX trial) was included. Data were collected at three time points (1998, 2001 and 2008) using the Modifiable Activity Questionnaire (MAQ) for PA and SB and the DUKE Health Profile for HRQoL (physical, mental, social and general health dimensions). PA domains corresponded to occupational and leisure-time while SB domains corresponded to leisure time spent screen-viewing, reading or sitting. The cumulative level (from 0 to 3) referred to the number of time points where a high PA level (> 2h30min/week for leisure-time PA and > 7h/week for occupational PA), high SB (> 2h/day for screen-time, > 1/day for reading and > 4h/day for total sitting time) or good HRQoL (greater or equal to French adults normal values) was reported. Regression analyses first examined the cumulative level of high PA, high SB as predictors of HRQoL at 10-year follow-up and reverse associations. Results: The 10-year cumulative level of high leisure-time PA predicted a high HRQoL score in the four dimensions while occupational PA predicted a high score in only physical and general health. Cumulative level of high screen-viewing time and high total sitting time was associated with lower HRQoL score respectively for physical health dimension and physical and general health dimensions. The cumulative level of high reading-time was associated with high mental and social health scores. In the reverse association, cumulative level of good HRQoL predicted more leisure-time PA, less screen-viewing time and less total sitting time but was not related to occupational PA. Only good social health predicted more reading-time. Conclusion: Cumulative and bidirectional PA-HRQoL associations were observed for leisure-time PA and time spent screen-viewing with most HRQoL dimensions. Other associations were less consistent. Relationships between PA, SB and HRQoL are complex and should not be oversimplified in one or the other direction. Taking into account the specific domains of PA and SB in health promotion programs appears of importance to design interventions aiming at improving HRQoL in adults.

### INVESTIGATING THE INTERACTION BETWEEN THE BIG-FIVE AND DISPOSITIONAL COPING IN SPORT

Kaiseler, M., Levy, A.

*Leeds Beckett University; Edge Hill University*

Introduction It has been recommended (Allen, Greenlees, & Jones, 2011) that future research should consider how personality traits interact in determining specific types of sport related coping. Accordingly, this study aimed to explore what combinations of the Big-Five personality taxonomy are associated with sport-related coping. Methods Data was collected among four hundred UK athletes (male n = 237, female n = 163), aged between 18-48 years (Mage = 22.97 SD =7.0). Participants completed the Big-Five Inventory (BFI; John, Donahue, & Kentle, 1991) and the 37-item Dispositional Coping Inventory for Competitive Sport (DCICS; Hurst, Thompson, Visek, & Gaudreau, 2011). Results Hierarchical multiple regressions were conducted for each coping subscale. At step one demographic variables were entered, at step two the Big-Five personality traits were added, and at step 3 two-way interaction effects were included. For task-oriented coping, the inclusion of a two-way interaction effect (R<sup>2</sup>adj = .255) showed a significant effect for the interaction between extraversion and neuroticism ( $\beta = -.19, P < .001$ ), alongside neuroticism and openness ( $\beta = .15, P < .01$ ). For distraction coping, the inclusion of a two-way interaction showed a significant interaction (R<sup>2</sup>adj = .380) for agreeableness and conscientiousness ( $\beta = .20, P < .001$ ). Finally, for disengagement coping a significant two-way interaction effect (R<sup>2</sup>adj = .403) was found for extraversion and neuroticism ( $\beta = -.10, P < .05$ ). Discussion Findings revealed that athletes who were low neurotic in conjunction with high extraversion and openness were more likely to report task-oriented coping. Distraction-oriented coping was preferred by athletes low in both conscientiousness and agreeableness traits. Finally, low extraversion and high neuroticism was associated with greater use of disengagement-oriented coping. The current findings reinforce the need to investigate the interactive effects of personality dimensions upon sport-related coping. Doing so would assist applied practitioners to maximise the potential of coping-related interventions by targeting particular personality profiles. References Allen, M.S., Greenlees, I., & Jones, M. (2011). An investigation of the five-factor model of personality and coping behaviour in sport, *Journal of Sports Sciences*, 29, 841-850. ### COMPETENCES REQUIRED BY ELITE ATHLETES IN TERTIARY EDUCATION

De Brandt, K., Wylleman, P., Van Rossem, N.

*Vrije Universiteit Brussel*

Introduction. Student-athletes perceive challenges in different domains when they make their transition into higher education. To cope with these transitional challenges, student-athletes require specific competences to optimize their preparation for and their development throughout their dual career 'elite sport and higher education' pathway. While past research has focused on structural and organizational initiatives in the topic of dual careers, there is a lack of knowledge with regard to the competences athletes require to successfully combine elite sport and higher education. Theoretical framework. This study used the Holistic Athletic Career model from Wylleman, Reints, & De Knop (2013) to explore the competences needed by student-athletes to successfully initiate their combination of elite sport and higher education. Methodology. Using a retrospective design, semi-structured interviews were conducted with nine elite student-athletes who 'successfully' initiated their elite sport and higher education pathway. 'Successfully' means that all participants had academic success rates above university average and competed at international level. Results. Elite student-athletes require skills, attitudes, knowledge and experiences at the athletic, psychological, psychosocial, academic and financial level in order to successfully initiate a dual career in higher education. These include, amongst others, coping with athletic and academic related pressure, goal setting, effective use of time, prioritizing tasks, being able to live alone in a student house, and self-discipline. Further detailed results will be presented. Practical implications. In order to optimize the transition and integration of athletes into higher education, structural and organizational initiatives together with dual career support services need to be complemented with athletes having sufficient, effective and transferable competences in order to be able to take full responsibility for developing their own dual career pathway. Support services should be aware of the competences that student-athletes require so they can provide their athletes with tailor-made support (e.g. teaching them

time management and self-regulatory skills) prior to and during the transition into higher education. References. Wylleman, P., Reints, A., & De Knop, P. (2013). A developmental and holistic perspective on the athletic career. Abstracts of the ISSP 13th World Congress of Sport Psychology. (p. 2). Beijing.

### OP-PM47 Training & Testing: Fatigue II

#### THE IMPACT OF A 3 WEEKS DETRAINING PERIOD ON FOREARM MUSCLE PERFUSION AND OXYGENATION IN MALE AND FEMALE ROWERS DURING INCREMENTAL HANDGRIP EXERCISE

Celie, B., Dumortier, J., Boone, J., De Backer, T., Verbelen, D., Bourgois, J.

*Ghent University*

**Introduction** The purpose was to study the effect of a 3 weeks detraining period on forearm blood flow (FBF) and muscle oxygenation (deoxy[Hb+Mb]) during an incremental cyclic contraction protocol (ICCP) in oarsmen. **Methods** A population of 11 rowers (8 ♂, 3 ♀) from the Belgian national team were selected to perform ICCP after a 10 weeks training period (pre-test) and after 3 weeks of detraining (post-test). Before ICCP, maximal voluntary contraction (MVC) was determined for each individual, whereas FBF (ml/min) and deoxy[Hb+Mb] (expressed in % towards the arterial occlusion maximum value) were measured during ICCP using Doppler US and NIRS respectively. Peak force during ICCP was determined and ICCP peak FBF and peak deoxy[Hb+Mb] were divided by this peak force. **Results** The results showed a higher MVC during post-test ( $605,5 \pm 88,0$  N) compared to the pre-test ( $556,6 \pm 110,8$  N) ( $p=0,009$ ). However, absolute peak FBF was decreased during the post-test ( $664,9 \pm 303,6$  ml/min) compared to the pre-test ( $803,8 \pm 370,8$  ml/min) ( $p=0,030$ ). Furthermore, the ratio peak FBF on peak force showed lower values during the post-test ( $1,7 \pm 0,83$  ml/min/N) in comparison with the pre-test ( $2,1 \pm 0,82$  ml/min/N) ( $p=0,043$ ). No significant differences were found in relative peak values of deoxy[Hb+Mb] during the post-test ( $55,8 \pm 23,0$  %) compared to the pre-test ( $51,9 \pm 23,8$  %) ( $p=0,725$ ). The ratio peak deoxy[Hb+Mb] on peak force showed no significant differences ( $p=0,377$ ) between both test moments. **Discussion** To conclude, firstly, we observed an increased MVC after 3 weeks of detraining. The higher MVC could be an effect of a decreased fatigue (due to an intensive training schedule) relative to the fitness of the athletes. Secondly, a decreased peak FBF and a decreased peak FBF on peak force ratio were observed after a 3 weeks detraining period. This can be partly explained by the loss of training induced physiological adaptations during short term detraining [2].

#### MUSCLE TISSUE DESATURATION IN TRAINED MALE AND FEMALE CYCLISTS

van der Zwaard, S., Jaspers, R., de Haan, A., de Ruiter, C.

*MOVE Research Institute Amsterdam, VU University Amsterdam (Amsterdam, Netherlands).*

**Background:** At high exercise intensities, physical performance may be limited by insufficient oxygen supply to the muscle fibers. Whether there is a (mismatch between oxygen demand and supply may be assessed measuring the muscle tissue oxygen saturation (TSI), which reflects the dynamic balance between oxygen supply and utilization. Oxygen saturation is generally measured by near infrared spectroscopy (NIRS). However, these measurements are likely affected by adipose tissue thickness (ATT) and therefore do not fully resemble physiological saturation values. Therefore, untrained or female subjects are usually excluded from analyses and rather slim males have been studied. **Purpose:** Determine whether there is a difference in measured oxygen desaturation throughout maximal incremental exercise between trained female and male cyclists. **Methods:** Twenty trained cyclists (10 male, 10 female) completed a maximal incremental cycling test 30-45W:3min<sup>-1</sup> at 90 rpm. TSI was obtained from mm. vastus lateralis (VL) and medialis (VM) by continuous-wave NIRS. Adipose tissue thickness (ATT) was determined by skinfold measurements. Ventilatory threshold (VT) was assessed by V-slope and respiratory compensation point (RCP) by ventilatory equivalents. Differences in ATT and maximal desaturation were analyzed by independent t-tests and TSI desaturation by mixed design ANOVAs (gender x threshold (VT-RCP-MAX)). **Results:** Both sexes showed significant desaturation throughout incremental exercise (Rest/M,  $p<0,001$ ). Women showed lower desaturations during incremental exercise compared to men (VL: 10.5 vs. 30.2%,  $p<0,001$ ; VM: 8.6 vs. 20.7%,  $p<0,01$ ) and higher ATT levels (VL: 8.4 vs. 3.3mm,  $p<0,001$ ; VM: 8.6 vs. 4.4mm,  $p<0,01$ ). The desaturation during incremental exercise was negatively related to ATT ( $n=20$ ;  $r_{VL}=-0,81$  and  $r_{VM}=-0,76$ ,  $p<0,001$ ). **Conclusion:** ATT confounds NIRS measurements of physiological oxygen desaturation throughout incremental exercise, resulting in higher measured saturation levels and smaller desaturations as well as smaller signal-to-noise ratios in trained female compared to male cyclists. Therefore, comparison of (de)saturation profiles in athletes needs to take into account differences in ATT. Even though the trained female cyclists present higher ATT levels, they still show significant measured oxygen desaturations during incremental exercise as well. **Funding:** Technologiestichting STW

#### MAXIMAL AEROBIC POWER ASSESSMENT FOR PERFORMANCE: SHOULD WE CONSIDER SKELETAL MUSCLE OXYGENATION AND MINUTE VENTILATION?

Lajoie, C., Gendron, P., Laurencelle, L., Trudeau, F.

*Université du Québec à Trois-Rivières*

Time and again, exercise specialists are faced with test results and try to contrive a better physiological rationale for determining maximal aerobic power (MAP). This is especially true when a subject, at the end of a graded exercise testing (GXT) cannot complete a full step or consumes less oxygen than that required by the imposed workload. The purpose of this study was to arrive at a more accurate MAP test, by looking deeper into the data, exploring the concomitant behaviour of  $\dot{V}O_2$  against pulmonary minute ventilation ( $\dot{V}_E$ ), skeletal muscle oxygenation and  $O_2$  pulse. Twenty nine active to world class male cyclists (age =  $28,8 \pm 9,2$  years, height =  $177,1 \pm 6,0$  cm, weight =  $70,8 \pm 7,3$  kg, mean  $\dot{V}O_{2max}$  of  $65,8 \pm 7,9$  ranging from 52.6 to 80.2 ml $O_2$ •min<sup>-1</sup>•kg<sup>-1</sup>) of different training status took part in the study. All participants performed a MAP test starting at 130 W and successively stepped up by 30 W increments. The duration of the step efforts was 5 minutes, cushioned by 3 minutes recovery periods at 1 W per kg of body weight. We compared the gain obtained in  $\dot{V}O_2$ ,  $\dot{V}_E$ , ventilatory equivalent ratio for oxygen ( $\dot{V}_E/\dot{V}O_2$ ), skeletal muscle oxygenation by NIRS (deoxyhemoglobin; HHb), heart rate (HR) and oxygen pulse ( $O_2$  pulse) at the last step of the GXT, versus the average gain registered at the preceding steps. Results show that the gain obtained at the last completed step of the GXT and the average gain in  $\dot{V}O_2$  ( $381,16 \pm 131,2$  vs.  $372,19 \pm 56,5$  ml $O_2$ •kg<sup>-1</sup>•min<sup>-1</sup>) were

similar ( $p = 0.71$ ). However, 14 of the 29 subjects did not show a higher gain in  $\dot{V}O_2$  at the last completed step as compared to the average gain ( $-101.07 \pm 82.9$  ( $n=14$ ) vs.  $+98.38 \pm 79.7$  ( $n=15$ )  $\text{mlO}_2 \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ ). In particular, the gain in HHb was lower ( $p < 0.001$ ) in 24 of the 29 subjects ( $-1.23 \pm 0.70$ ;  $n=24$  vs.  $1.11 \pm 0.66$ ;  $n=5$  arbitrary units) at the last step of the GXT. The gain in Ve at the last completed step was increased ( $p < 0.001$ ) by 147% ( $32.92 \pm 10.01$  L/min) as compared to the average gain of the preceding steps ( $13.31 \pm 2.9$  L/min). The mean gain in  $\dot{V}E/\dot{V}O_2$  during the GXT ( $1.15 \pm 0.7$  L/ $\dot{V}O_2$ ) was also increased at the last completed step ( $4.81 \pm 2.3$  L/ $\dot{V}O_2$ ,  $p < 0.001$ ). No significant changes were observed between steps for HR and O<sub>2</sub> pulse. Twenty six subjects attempted a final uncompleted step, but only two were able to show a higher gain in  $\dot{V}O_2$  as compared to their preceding average gain. In conclusion, a subject may, partially or successfully, reach a higher power output, but he may not necessarily consume more oxygen in the skeletal muscle. This disproportionate increase in ventilation and the corresponding decrease in HHb suggest that aerobic power assessment needs to be adjusted for estimating a 'true aerobic power' for exercise prescription. ### USING DIFFERENTIAL RATINGS OF PERCEIVED EXERTION TO MEASURE INTERNAL LOAD

McLaren, S.J., Graham, M., Spears, I.R., Weston, M.

*Teesside University*

**Introduction** Differential ratings of perceived exertion (dRPE) enhance the precision of internal load measurement by discriminating between central (e.g. breathlessness, RPE-B) and peripheral (e.g. leg, RPE-L) perceived exertion (Weston et al., 2014). A more detailed analysis of dRPE with physiological measures collected during contrasting exercise modes is required, however. Further, the influence of post-session timing when collecting dRPE is as yet unexplored. Our aim was to investigate the sensitivity of dRPE as measures of internal load and to explore the effect of timing on dRPE. **Methods** Twelve university male soccer players performed 2 maximal incremental exercise protocols (Treadmill, Cycle) in a counterbalanced manner, separated by 3-7 days. Maximal heart rate (HRmax), maximal oxygen uptake ( $\dot{V}O_{2\max}$ ), peak blood lactate (BLa) and pre-post protocol change in countermovement jump height (CMJ) were measured for each protocol. Players provided dRPE (CR100) immediately upon exercise termination (RPE-B0, RPE-L0) and 30-minutes post exercise (RPE-B30, RPE-L30). Data were analysed using magnitude-based inferences. **Results** The between protocol differences were most likely large for HRmax (Treadmill  $197 \pm 8$  b.min vs Cycle  $186 \pm 12$  b.min, mean difference 5.9%;  $\pm 90\%$  confidence limits 2.3%) and CMJ ( $1.4 \pm 4.5$  cm vs  $7.4 \pm 4$  cm,  $-24.9\%$ ;  $\pm 7.4\%$ ), likely moderate for  $\dot{V}O_{2\max}$  ( $52.1 \pm 4.8$  ml.kg.min vs  $49.2 \pm 6.9$  ml.kg.min, 6.1%;  $\pm 5.0\%$ ) and likely small for BLa ( $8.5 \pm 2.2$  mmol vs  $9.4 \pm 1.8$  mmol,  $-12.3\%$ ;  $\pm 16.3\%$ ). There was a very likely large difference (17.5%;  $\pm 6.8\%$ ) in RPE-B0 between Treadmill ( $95.4 \pm 7.5$  AU) and Cycle ( $79 \pm 13$  AU) and likely small difference in RPE-L0 ( $-10.1\%$ ;  $\pm 10.5\%$ ) between Treadmill ( $86 \pm 12$  AU) and Cycle ( $94 \pm 11$ ). The difference in RPE-B30 was likely small (11.4%;  $\pm 13.9\%$ ) between Treadmill ( $80 \pm 16$  AU) and Cycle ( $71 \pm 13$  AU) and very likely moderate for RPE-L30 ( $-34.1\%$ ;  $\pm 27.1\%$ ) between Treadmill ( $68 \pm 21$  AU) and Cycle ( $87 \pm 13$  AU). The effect of timing for RPE-B was likely large for Treadmill ( $-17.7\%$ ;  $\pm 9.6\%$ ) and trivial for Cycle ( $-11.6\%$ ;  $\pm 6.1\%$ ). For RPE-L, the timing effect was very likely large for Treadmill ( $-23.9\%$ ;  $\pm 11.1\%$ ) and very likely moderate Cycle ( $-7.3\%$ ;  $\pm 4.6\%$ ). **Discussion** Our small to large differences between RPE-B and RPE-L collected following maximal exercise performed on different modes support that dRPE represent different dimensions of effort, thereby supporting their usefulness as measures of internal load. The intensity of activities completed during the final stages of a maximal exercise protocol does influence dRPE, although this appears to be dependent on exercise mode. We recommend that further investigations concerning dRPE and potential timing effects be undertaken during regular training sessions. **References** Weston et al. *J Sci Med Sport* 2014. In press.

### FASTER HEART RATE RECOVERY WITH INCREASED RPE LEVELS AFTER AN 87 KM ULTRA-MARATHON: PARADOXICAL FINDINGS WITH IMPLICATIONS FOR MONITORING ATHLETES

Lamberts, R.P.1,2, Mann, T.N.1, Lambert, M.I.1

*Stellenbosch University*

**Introduction** Changes in heart rate recovery (HRR) are generally associated with changes in training status and this measurement shows potential as a valuable monitoring tool (Capostagno et al.). Faster HRR has been linked with an improvement in training status whereas slower HRR has been linked with a decrease in training status. However, two recent studies have found faster HRR after a significant increase in training load (Dupuy et al., Lamberts et al.), suggesting that faster HRR may not always reflect an adapted state. In order for day-to-day changes in HRR to be interpreted accurately, further clarity on the relationship between HRR and day-to-day changes in training status is required. With this in mind, the aim of this study was to determine the relationship between HRR and an acute training "overload" by comparing HRR responses before and after an ultra-marathon road race. **Methods** Ten runners completed a standardized laboratory protocol ~7 days before and between 2 and 4 days after participating in the 87 km Comrades Marathon. The protocol included muscle pain ratings, a 5 bound test and 20 min of treadmill exercise at 70% of maximal oxygen uptake followed by 15 min of recovery. Respiratory gases and heart rate measurements were used to calculate steady state exercise responses, HRR and excess post-exercise oxygen consumption and participants also provided a rating of perceived exertion during exercise (RPE). **Results** All participants completed the 87 km race with finishing times of between 8 h 11 min and 11 h 39 min. A strong correlation was found between PTRS and race finishing time ( $r = -0.89$ ,  $p = 0.0005$ ), suggesting that all runners attempted to complete the race in the fastest possible time. During the post-race submaximal exercise test, RPE was significantly higher ( $13 \pm 2$  vs.  $11 \pm 1$ ;  $p < 0.01$ ) while HRR was significantly faster ( $35 \pm 5$  vs.  $29 \pm 4$  beats;  $p < 0.01$ ). No other significant changes in respiratory or heart rate parameters were observed. **Discussion** This study found faster HRR along with increased RPE levels in runners who completed an 87 km ultra-marathon. These findings are paradoxical, as a faster HRR is often associated with positive training adaptation. However, our findings are in line with the work of Dupuy et al. and Lamberts et al. who reported a faster HRR in functionally overreached athletes. The current study emphasises that changes in HRR should always be interpreted in the light of changes other parameters. As submaximal parameters, as HRR and RPE, are able to reflect changes in training status (Daanen et al.) and a state of overreaching, they are promising parameters to monitor and fine tune training prescription in athletes. **References** Capostagno B. et al (2013) *Int. **MEASURING THE FATIGUE EFFECT ON ICE HOCKEY SKILLS DURING A TESTING PROTOCOL CONDUCTED AMONG ELITE HOCKEY PLAYERS**

Lemoine, J., Martini, G., Trudeau, F., Brunelle, J.F.

*Université du Québec à Trois-Rivières*

**Introduction** In ice hockey, most testing procedures refer to physiological parameters, without taking consideration of multiple technical skills (Behm et al., 2005; Burr et al., 2008). In this regard, more complete testing protocol seems to be optimal to verify about the impact of fatigue on performance. This study aims to measure the impact of fatigue during a multi-dimensional (i.e. physiological and technical) ice hockey testing protocol among a group of elite hockey players. **Methodology** Six males, university level hockey players ( $21.8 \pm 0.55$  year) accepted to take part to an on-ice testing protocol. The suggested protocol is in its pilot phase for further testing among other sub-populations. Each player had to complete a repetitive testing circuit six times, with a work-rest ratio of 1:2, as it is recommended by Cox et al (1995). Speed, acceleration, decision making, agility, shooting abilities and rated perceived exertion (RPE) were measured at each repetition. Repeated measures ANOVAs were conducted to verify the evolution of each of the protocol's component. Post hoc analyses were conducted to identify specific variations in performance. **Results** Results revealed a significant diminution of performance in shooting abilities ( $F = 4.52$   $p = .005$ ). Speed and acceleration declined, but not significantly ( $p > .10$ ). Agility and decision making were improved during the protocol, but not significantly ( $p > .15$ ). However, RPE increased over the protocol ( $F = 3.52$   $p = .015$ ). In summary, post hoc analyses revealed that most of significant differences appeared at the fifth and sixth repetition. **Discussion** In general, fatigue seems to affect acuity skills such as shooting precision. In general, players adapted well to most tasks especially in agility and decision making. The performance level of players and timing of assessment (i.e. mid season) could explain small effects of fatigue on most hockey skills. Further research should be conducted among players of multiple competition levels. **References** Behm, D. G., Wahl, M. J., Button, D. C., Power, K. E., & Anderson, K. G. (2005). **Oral presentations****OP-PM75 Molecular Biology and Biochemistry****RELIABILITY OF TRUNK MUSCLE ELECTROMYOGRAPHY DURING LOADED BACK SQUAT EXERCISE.**

Clark, D., Lambert, M., Hunter, A.M.

*Irish Rugby Football Union*

**Introduction.** Surface electromyography (sEMG) has recorded trunk muscle activation (TMA), during back squat exercise (Clark et al. 2012). However, the inter day reliability and sensitivity to different loads, of sEMG from such exercise alongside kinematic measures, has not been reported. **Aims:** to determine the inter day reliability and load sensitivity of TMA sEMG and kinematics during back squats **Methods.** Ten males performed 3 test sessions: 1) back squat 1RM was determined; 2) and 3) 3 repetitions at 65, 75, 85 and 95% of system mass max (SMmax) (Brandon et al. 2011). Kinematics were measured from an electrogoniometer and linear transducer and sEMG were recorded from vastus lateralis (VL), rectus abdominus (RA), external oblique (EO), upper lumbar erector spinae (ULES) and lumbar sacral erector spinae (LSES). sEMG amplitude was determined by Root Mean Squared (RMS). Mean RMS for test loads 75, 85 and 95% SMmax was normalized to the mean RMS at 65% SMmax for each phase of the squat respectively. **Results.** No differences ( $p > 0.05$ ) existed between tests for any kinematics and intra subject CV% for all data ranged from  $1.2 \pm 0.7\%$  to  $11.7 \pm 12.6\%$ . Eccentric power increased ( $p < 0.05$ ) with each load increment and concentric power followed established load, power relationship (Cormie et al. 2007). Between test differences in mean RMS for each muscle in each squat phase ranged from  $-26.6 \pm 25\%$  to  $26.1 \pm 26.3\%$  and intra subject CV% for all EMG data ranged from  $29.4 \pm 1.2\%$  to  $12.6 \pm 7.2\%$ . ICC for all loads demonstrated fair relative reliability for just RA (0.60) and EO (0.71) in the eccentric and the LSES (0.60) in the concentric phase. RMS significantly ( $p < 0.05$ ) increased alongside load for all muscle sites in the eccentric phase and in the concentric phase for ULES, LSES and EO only ( $p < 0.05$ ). **Discussion.** TMA increased linearly across load in all muscles in the eccentric phase and the posterior stabilizers in the concentric phase; therefore, the loaded squat is an effective training stimulus for the trunk stabilizers. However, researchers and practitioners should only record sEMG from certain trunk muscles, depending on the contraction phase, for reliable and repeatable measurement. **References** Brandon, R., Howatson, G., & Hunter, A. **NEUROMUSCULAR FATIGUE DURING LOW-INTENSITY ISOMETRIC EXERCISE WITH BLOOD FLOW RESTRICTION**

Brandner, C.1,2, Rantalainen, T.1, Page, B.1, Warmington, S.1

*1: Deakin University, School of Exercise and Nutrition Science, 2: Aspire Academy (Doha, Qatar)*

**Introduction:** Light-load resistance exercise with blood flow restriction (BFR) has been shown to increase muscle strength and mass similarly to heavy-load resistance exercise. Since fatiguing exercise is suggested as a potent stimulator to increase muscle mass, it is important to characterise the rate of fatigue with BFR during resistance exercise. Therefore, the purpose of this study was to determine the effect of BFR on muscle fatigue via the decline in force of maximal voluntary contractions (MVCs) during isometric knee extension exercise. **Methods:** A randomized, counterbalanced, within-subject design was used to investigate the effect of BFR on muscle fatigue during unilateral isometric knee extension exercise (Biodex 4, USA). Untrained male participants ( $n=12$ ;  $24 \pm 1$  yrs) completed four testing sessions separated by one week: four sets (30 repetitions, followed by 3 sets of 15) at 20% MVC with BFR (BFR20) or without (CON20), and two conditions that excluded the 20% MVCs (BFRX and CONX). To evaluate fatigue each trial, a baseline MVC prior to beginning each trial (MVC1) was compared with an MVC completed for every 7th repetition (4 during the first set, followed by 3 in sets 2-4). MVC force, surface electromyography (EMG) and peripheral nerve stimulation (M-Wave) were recorded during each MVC. **Results:** MVC1 (baseline) was not different between trials ( $284 \pm 30$  N). There was a trial x time interaction for MVC force ( $P \leq 0.05$ ). MVC force decreased significantly from

MVC1 to end of set 1 (MVC5) for all trials (~235 N; 11%;  $P \leq 0.01$ ), however there were no differences between trials. Following this, MVC force returned to baseline level for both CON20 and CONX during all subsequent MVCs (6-14). However, in comparison with MVC1, force continued to decrease throughout all subsequent sets for both BFR20 (MVC14; 199 N; 25.0%;  $P \leq 0.01$ ) and CONX (214 N; 22.8%;  $P \leq 0.01$ ). In addition, MVC force was significantly lower for both BFR trials compared with both CON trials ( $P \leq 0.05$ ). There were no trial x time interactions, or main effects for trial or time for EMG activity during MVCs and 20% contractions. Discussion: Previous investigations have shown a decrease in force immediately post-exercise, and at 24- and 48-hours post-exercise. This was the first study to demonstrate a decline in MVC force throughout a standard BFR resistance exercise protocol (i.e. 30/15/15/15 repetitions). Of note, BFR was shown to be more fatiguing than LLRE regardless of an exercise intervention being performed. It is possible that different mechanisms are responsible for the decline in MVC force for both BFR trials, but might be due to an increase in metabolic by-products, hypoxia, and overall a decrease in central drive from higher brain centres. ## LONG-RANGE CORRELATIONS IN THE FLUCTUATIONS OF STANCE, SWING AND DOUBLE-SUPPORT TIMES IN NORMAL WALKING

Mickel, C., Kollegger, G.

*Institute for Sports Science*

Introduction: Plenty of research documents long-range correlations in stride interval fluctuations under different conditions for healthy subjects, while it has been shown that this structure breaks down with aging and several pathologies [1-8]. But are there also long-range correlations in the fluctuations of stance, swing and double-support-times? Methods: 48 students of the Institute for Sports Sciences (height 178cm  $\pm$  11.3, weight 72,1kg  $\pm$  12, age 23,5 years  $\pm$  3,92) that had no acute or chronic lesions or diseases of the lower extremities carried four 3D accelerometers (Analog Devices ADXL 326), which were mounted to the distal end of Os metatarsale III and below the Malleolus lateralis of each foot. Sampling frequency was set to 2000 Hz. Subjects were instructed to walk at PWS for consecutive 20 to 25 minutes. Two double-photoelectric barriers measured locomotion velocity several times during the trial. Average locomotion velocity for the group was 1,57 m/s  $\pm$  0,16 with an average SD for the single subject of 0,02 m/s. Results: After separating the accelerometer time-series into stride intervals, stance, swing and double-support time (=DST) their duration was selected resulting in a total of 13.552 step cycles that could be included in the analysis. Detrended fluctuation analysis (=DFA) was performed and compared to a surrogate-data test (thousandfold randomization). DFA resulted in  $\alpha = 0,86$  for stride interval,  $\alpha = 0,78$  for stance,  $\alpha = 0,66$  for swing and  $\alpha = 0,62$  for DST. All of them showed significant differences to the surrogates we can, therefore, deduce that those are long-range correlations. Discussion: The  $\alpha$  of the single phases show long-range correlations that are below the ones for stride interval. One suspects to find a synergy between stance and swing that sum up to stronger long-range correlations for stride interval. Testing this with a technique similar to the uncontrolled manifold hypotheses did not provide clear results. It is further still unknown, what the physiological mechanisms are that underlie the production of long-range correlations. References [1]. ## CORTICAL CONTROL OF GAIT FUNCTION IN PEOPLE WITH PARKINSON'S DISEASE: A PILOT STUDY

Roeder, L.1, Boonstra, T.2, Smith, S.1, Stewart, I.1, Kerr, G.1

*1: Queensland University of Technology, Brisbane; 2: University of New South Wales, Sydney*

INTRODUCTION Gait difficulties (e.g. small steps, freezing) are common symptoms of Parkinson's disease (PD) [1]. Neuroimaging studies suggest that alterations in the structure and function of basal ganglia and cortico-frontal networks contribute to gait disorders in PD [1,2]. However, the exact neural mechanisms are not well understood [1]. In this study we compare corticomuscular coherence (CMC) during treadmill and natural overground walking to investigate the contribution of motor cortical activity to gait control in people with PD. METHODS Four PD individuals (61.1 $\pm$ 9.3 years; H&Y 1.2 $\pm$ 0.45) performed overground and treadmill walking at a comfortable, self-selected pace (3.4 $\pm$ 0.6 km/h). EEG was recorded from 12 sites; bipolar EMG was recorded bilaterally from 4 leg muscles (Tib. Ant. (TA), Sol., lateral & medial Gastroc.). Pooled coherence was computed between the Cz EEG electrode and the TA muscle of the right leg using the MATLAB toolbox NeuroSpec 2.0. Time-dependent coherence was calculated relative to the heel strike of the right foot. RESULTS During overground walking, CMC was significant at 1-5Hz from -800 to -350 ms prior to heel strike and at 3-11Hz from -350 to 0 ms prior to heel strike. During treadmill walking, CMC was significant at 1-9Hz from -800 to -350 ms prior to heel strike. When comparing both gait modalities, CMC in the 5-9 Hz range was significantly higher during treadmill walking from -750 to -350 ms prior heel strike and during overground walking from -350 to 0 ms prior to heel strike ( $p < 0.01$ ). In the 1-4Hz range, CMC was significantly higher during overground walking at most times of the gait cycle ( $p < 0.01$ ). DISCUSSION For people with PD overground walking may utilize different neural circuits than treadmill walking. The significant CMC under 11 Hz prior to heel strike during overground and treadmill walking is lower than reported for healthy people who exhibit significant beta-band coherence (24-40 Hz) [3]. This suggests deficient cortical drive to the muscle in the beta-band in people with PD. However, our findings should be interpreted with caution due to the small sample size and the lack of a control group. Further research is warranted to confirm these deficiencies in cortical control of gait function in people with PD. REFERENCES [1] Maillet A, et al. ## EFFECTS OF ECCENTRIC WORKLOADS ON MUSCLE MICROCIRCULATION AND NEUROMECHANICAL CHARACTERISTICS OF THE KNEE EXTENSOR MUSCLES

Yin, N., Chen, Y., Shih, T., Lin, K., Su, S., Rolf, C., Wang, H.

*School and Graduate Institute of Physical Therapy, College of Medicine, National Taiwan University*

The aim of this study was to evaluate and compare the effects of two eccentric workloads on muscle activation and fast force capacity in quadriceps muscles in asymptomatic players by measuring the muscle activation and fast force capacity both before and after 4 sets of a knee extension exercise. Muscle microcirculation values during the exercise were also compared. Seventeen college tennis players were

randomly assigned to perform 4 sets of either 40 repetitions (n=9, age: 20.0 ± 1.5 y) or 80 repetitions (n=8, age: 21.5 ± 1.0 y) of the eccentric exercises. The muscle activation, measured by rate of EMG rise (RER), and the rate of force development (RFD) in the quadriceps muscles during the isometric knee extensions were measured pre- and post-exercise in all subjects. Muscle microcirculation in the vastus lateralis muscle during the fourth set was also measured. The results revealed that reductions of rectus femoris muscle activation occurred only after eccentric exercises with sets of 80 repetitions; however, reductions in the vastus muscles were observed in both exercise groups. Between-group comparisons showed there was greater oxygen saturation in the group that performed the 80-repetition sets (all  $P < 0.05$ ). Changes in oxygen saturation levels in the vastus lateralis muscle were correlated with the RER reductions ( $\rho = -0.495$ ). Furthermore, The EMG outcomes showed correlations with the absolute RFD ( $\rho$  ranging from 0.363 to 0.566). We conclude that muscle activation and the microcirculation of the quadriceps muscles were differentially affected by the low and high workloads of the eccentric exercise.

### OP-PM53 Health & Fitness: Lifestyle II

#### THE EFFECT OF DIFFERENT EXERCISE TYPES ON BODY COMPOSITION IN YOUNG ADULTS

Drenowatz, C., Hand, G.A., Sagner, M., Shook, R.P., Burgess, S., Blair, S.N.

*University of South Carolina*

**Background.** Despite the widely accepted benefits of exercise on chronic disease risk and mortality, there remains controversy on the role of exercise in weight loss and weight management. The purpose of this study was to examine the effect of different exercise types on measures of adiposity across different fat categories. **Methods.** A total of 348 young adults (49% male, 28±4 years), participating in an ongoing observational study, provided valid data over a period of 12 months. Fat mass (FM) and lean mass (LM) were measured via dual x-ray absorptiometry every 3 months. Percent body fat (BF) was calculated and used to differentiate between normal fat, overfat and obese. At each measurement time point participants reported engagement (min/week) in aerobic exercise, resistance exercise and other exercise during the previous 3 months. Change in exercise participation was calculated using mixed linear modelling. In addition, total physical activity level (PAL) was objectively assessed with the SenseWear Mini Armband. **Results.** Most participants (93%) reported some exercise participation during the observation period. Total exercise or specific exercise types did not significantly affect subsequent BMI after adjusting for sex, ethnicity, age and baseline values of adiposity and exercise. There was, however, a positive effect of total exercise on lean mass ( $p < 0.01$ ) and a negative effect on fat mass ( $p < 0.01$ ). Resistance exercise had a positive effect on lean mass ( $p < 0.01$ ) and a negative effect on fat mass ( $p < 0.01$ ) while aerobic exercise only affected fat mass ( $p < 0.01$ ). Any exercise type positively affected lean mass in normal fat participants ( $p < 0.04$ ). In overfat and obese participants fat mass was negatively affected by resistance exercise ( $p \leq 0.02$ ) but not by aerobic exercise ( $p \geq 0.09$ ). Additionally adjusting for PAL did not change the previously reported results. **Conclusion.** Despite the limited effects on BMI, exercise induces positive changes in body composition. Exercise increases lean mass in normal fat participants while it reduces fat mass in overfat and obese adults. This group may benefit particularly from resistance exercise due to potential problems with achieving a sufficient intensity during aerobic exercise.

#### ADULT PARTICIPATION IN PHYSICAL ACTIVITY AND MUSCLE STRENGTHENING EXERCISES: RESULTS FROM THE AUSTRALIAN NATIONAL NUTRITION AND PHYSICAL ACTIVITY SURVEY

Bennie, J.A.1, Pedisic, Z.2, van Uffelen, J.G.Z.1, Banting, L.1, Vergeer, I.1, Biddle, S.1

*1 Institute of Sport, Exercise & Active Living, Active Living & Public Health Group, Victoria University, Australia, 2 Faculty of Kinesiology, University of Zagreb, Croatia*

**Introduction** The World Health Organization physical activity guidelines recommend that adults aged 18-64 years do ≥150 minutes of moderate to vigorous-intensity physical activity (MVPA) and ≥2 sessions of muscle strengthening exercises (MSE) per week (WHO, 2010). However, population studies rarely report on the prevalence of adults meeting the combined MVPA-MSE recommendations. This paper reports the prevalence and sociodemographic variations in recommended MVPA-MSE participation among Australian adults. **Methods** Data were drawn from the Australian Bureau of Statistics, National Nutrition and Physical Activity Survey and were collected by face-to-face interviews between May 2011 and June 2012. Physical activity was assessed using the previously validated Active Australia Survey (Brown et al., 2004). To assess MSE levels participants were asked if they did MSE in the last week and, if so, how many times they did this. The proportions participating in both ≥150 minutes MVPA and MSE ≥2 sessions were compared by selected socio-demographic and lifestyle variables. **Results** Data were available for 9,345 adults, aged 18-85 years. A total of 14.0% (95% CI 13.5-14.8%) met the MVPA-MSE recommendations. More males than females met the the guidelines (16.2 vs 12.2%,  $p < 0.001$ ). The prevalence of meeting MVPA-MSE guidelines declined with age, with the highest rate observed among those aged 18-24 years (24.5%), and the lowest rate among those aged 65+ years (6.6%). Higher prevalence rates were observed among those who rated their health as excellent (25.4%) and had high education levels (19.1%). Lower prevalence rates were found among those who rated their health as poor (4.1%), had low education levels (4.6%), and were current smokers (8.6%). **Discussion** The vast majority of Australian adults did not meet the combined MVPA-MSE recommendations. Given the use of self-report measures, these population estimates are likely to be conservative. Public health surveillance should continue to monitor combined MVPA-MSE levels. Moreover, future studies should investigate other potential determinants of MVPA-MSE participation, such as health awareness, motivation, perceived barriers, social and environmental support, and access to facilities to engage in MVPA-MSE. **References** World Health Organization (WHO). ## DEVIATION BETWEEN SELF-REPORTED AND MEASURED OCCUPATIONAL PHYSICAL ACTIVITY LEVELS IN OFFICE EMPLOYEES: EFFECTS OF AGE AND BODY-COMPOSITION

Donath, L.K., Wick, L., Zahner, O.

*University of Basel*

University of Basel, Department of Sport, Exercise and Health, Basel, Switzerland University Hospital of the Friedrich-Schiller-University Jena, Institute of Psychosocial Medicine and Psychotherapy, Jena, Germany Introduction The decision to assess occupational physical activity (PA) levels via questionnaires or accelerometry relies on available resources and affects test validity and economy. Although self-reported data collection seems feasible and inexpensive, the obtained information could be biased by demographical determinants. Thus, we aimed at comparing self-reported and objectively measured sitting, standing, and walking time adjusted for age and body composition in office employees. Methods Thirty-eight office employees (8 males, 30 females, age: 40.8±11.4 years, BMI: 23.9±4.2 kg/m<sup>2</sup>) were equipped with height-adjustable desks (HAWD). They were asked to estimate their sitting, standing, and walking time using the Occupational Sitting Physical Activity Questionnaire (OSPAQ). The ActiGraph wGT3X-BT was additionally employed to objectively measure individual physical activity profiles within one week. In order to compare subjectively and objectively measured data, intra-class correlations (ICC) and multiple pairwise t-tests were computed. Additionally, repeated measures analyses of variances (ANOVA) were calculated including age- (<39 years of age vs. >39 years of age) and BMI-groups (underweight, normal weight, overweight) as independent factors. Additionally, Bland-Altman-plots were created in order to evaluate heteroscedacity and the amount of over- and underestimation of self-reported PA assessment. Results The correlation between self-reported and objectively measured PA levels was low for walking: (ICC: 0.04), moderate for sitting (ICC: 0.51) and standing (ICC: 0.64). Self-reported data yielded a significant underestimation of occupational standing time (13.3% vs. 17.9%,  $p < .01$ ) and an overestimation of walking time at work (12.7% vs. 5.0%,  $p < .01$ ). Large interaction effects between "age" and "measurement" of standing time ( $F = 6.0$ ,  $p = .02$ ,  $\eta^2 = .14$ ) and BMI group and measurement of walking time were found ( $F = 3.7$ ,  $p = .04$ ,  $\eta^2 = .17$ ). Especially, older employees (> 39 years) underestimated their standing time, while underweight workers (BMI < 20 kg/m<sup>2</sup>) overestimated their walking time. No significant effects occurred for sitting time. Discussion Self-reported physical activity data differ from objective data. Demographic variables seem to affect the amount of self-reported misjudging of physical activity levels. In order to improve the validity of self-reported data, subjective and objective measures from larger representative samples could be used to develop a correction formula for the economic assessment of physical activity by subjective measures.

## OBJECTIVELY MEASURED PHYSICAL ACTIVITY IN A WEB-BASED INTERVENTION ON PERSONALIZED NUTRITION: FINDINGS OF THE FOOD4ME STUDY

Marsaux, C.

*Maastricht University*

Marsaux, C.1; Celis-Morales, C.2; Woolhead, C.3; Fallaize, R.4; Kolossa, S.5; Navas-Carretero, S.6; Tsigirioti, L.7; Surwillo, A.8; Hoonhout, J.9; Goris, A.10; Walsh, M.3; Manios, Y.7; Traczyk, I.8; Martinez, J.A.6; Lovegrove, J.A.4; Daniel, H.5; Gibney, M.5; Mathers, J.C.2 and Saris, W.H.M.1, on behalf of the Food4Me Study. 1:Maastricht University, The Netherlands, 2:Newcastle University, UK, 3:University College Dublin, Ireland, 4:University of Reading, UK, 5:Technische Universität München, Germany, 6:University of Navarra, Pamplona, Spain, 7:Harokopio University of Athens, Greece, 8:National Food & Nutrition Institute, Warsaw, Poland, 9:Philips Research, Eindhoven, The Netherlands, 10:Philips Consumer Lifestyle, Amsterdam, The Netherlands Introduction Physical inactivity is a leading risk factor for mortality. Several web-delivered physical activity (PA) interventions have reported positive behavioral outcomes, but evidence supporting the maintenance of PA changes is lacking; larger studies featuring interactive technologies are needed. The Food4Me study was a European web-based randomized controlled trial investigating whether a personalized intervention is more effective than the conventional "one size fits all" approach in changing nutritional and PA behaviors. Methods 1,607 participants from 7 European countries were randomly assigned to either a control or 3 personalized nutrition (PN) groups. PA was measured objectively (TracmorD accelerometer, Philips) during the 6-month intervention. Controls were given general PA advice, whereas PN groups received personalized PA advice at several time points. Changes in PA patterns were analyzed at months 3 and 6 of the intervention. Results At baseline, participants in the Food4Me study had relatively high PA levels (PAL), men being slightly but significantly more active than women ( $1.75 \pm 0.02$  vs.  $1.72 \pm 0.01$ , mean  $\pm$  95%CI;  $p < 0.05$ ); however 60% of women and 42% of men did not meet the WHO recommendation to accumulate weekly 150 minutes of moderate-equivalent PA (MEPA) in 10-min bouts. Adherence differed significantly by country for women and was lowest in Greece. Preliminary analyses show a significant increase from baseline in MEPA at month 3 for both control ( $62.6 \pm 30.6$  min/wk, mean  $\pm$  95%CI;  $p < 0.001$ ) and PN groups ( $46.4 \pm 16.3$  min/wk, mean  $\pm$  95%CI;  $p < 0.001$ ), but not at month 6. No significant differences in PA between PN and control groups were found. Compliance in wearing the accelerometer decreased markedly during the study; only half of participants had sufficient valid data at month 6. Conclusions Using accelerometers to assess PA is feasible in a web-based intervention study. Both conventional and personalized approaches effectively increase MEPA in European adults, but long-term engagement of participants is a challenge. Contact c.marsaux@maastrichtuniversity.nl

## STUDY ON INNOVATIONS OF SPORT FOR ALL MANAGEMENT IN CHINA

Wang, Y.

*China Sport Information Center*

Introduction After the Beijing Olympics, the Chinese government has been attaching greater importance to sport for all development. The opening date of the Beijing Olympic Games has been named as the "National Fitness Day". The first administrative regulation on the development of national fitness undertaking-"Regulations on National Fitness"-was issued, and the National Fitness Program (2011-2015) was formulated. The past few years have witnessed big progress in the development of sport for all, but some problems still exist. For example, more and more of the Chinese population is becoming overweight and elderly, and the physical conditions of young people are constantly declining. To address these issues, the sport for all administration in China has been carrying out a series of innovative initiatives. Methods This paper tries to summarize and analyze the measures and benefits of these innovations. The methods of literature research, expert interviews and comparative analysis are applied in this paper. Results Firstly, from the conceptual perspective, the focus of Chinese government has turned from mere establishment of sports facilities to comprehensive provision of sports public service. Secondly, the management pattern has been innovated. The sport for all development used to rely on government bodies. Now the efforts of governments, enterprises and social sectors have all been encouraged. Thirdly, the ways of managing sport for all programs have been different. The sport for all administration has been putting more attention on formulating policies and regulations rather than

directly organizing sports activities. Discussion As a result of these innovative initiatives, the public sport awareness in china has been increasing remarkably in recent years. The facilities for sport for all have been significantly improved and a more energetic mechanism of sport for all has been established. And lots of Olympic champions and world champions have been encouraged to participate in sport-for-all voluntary service. To sum up, the management of sport for all in China has been going through a lot of innovations after 2008 Olympics. And Beijing's bidding for the 2022 Winter Olympics will further push forward the national fitness undertaking to a new stage. References The State Council of China. ### OP-PM55 Health & Fitness: Obesity

#### EFFECTS OF LIFESTYLE INDUCED WEIGHT LOSS ON MAXIMAL FAT OXIDATION

Skovborg, C.

*University of Copenhagen*

Do not insert authors here! Introduction Maximal fat oxidation (MFO) is increased after an exercise-intervention at low-moderate intensities (1), whereas weight loss decreases MFO (2). Exercise in combination with diet induced weight loss is a common clinical intervention for the treatment of obesity. The aim of this longitudinal study was to examine whether MFO is enhanced with intensive lifestyle intervention (ILI) and at 3 months follow up. We hypothesized that the increased physical activity and hypocaloric diet would enhance MFO in obese subjects. Methods Obese participants (BMI:  $37 \pm 2$  kg/m<sup>2</sup>) enrolled in a 12-week ILI were recruited to the study. The ILI consisted of daily exercise (1-3 hrs.) of different intensities and a hypocaloric diet composition according to Nordic Nutritional Recommendations (CHO: 45-60%, Fat: 25-40%, Protein: 10-20%). Measurements were performed before ILI (B) and right after ILI (A) and again after 3 months of free living (3 MTH). MFO was determined from measurements of gas exchange using indirect calorimetry during a progressive, graded exercise test on a cycle ergometer until RER > 1.0 as previously described (3). After a 1 min break graded exercise was continued until exhaustion to determine VO<sub>2</sub>max. Results Participants (n = 46) were divided in two groups. One group who had lost >10% of initial body weight (WL; n = 23,  $16 \pm 1\%$ ) and the other who had lost <10% of initial body weight at 3 MTH (NL, n = 23;  $5 \pm 1\%$ ). Both groups achieved significant weight loss from B to A ( $p < 0.001$ ,  $11 \pm 1\%$  and  $7 \pm 1\%$ , respectively). VO<sub>2</sub>max (l/min) improved from B to A (avg.  $2.8 \pm 0.2$  and  $3.0 \pm 0.1$ ) and decreased during follow up (avg.  $2.6 \pm 0.2$ ). There was no difference in VO<sub>2</sub>max and MFO between groups at any time. MFO (g/min) was unchanged after ILI (B:  $0.48 \pm 0.04$  and  $0.54 \pm 0.03$ ) and (A:  $0.44 \pm 0.03$  and  $0.42 \pm 0.04$ ) and decreased ( $p < 0.001$ ) at 3 MTH ( $0.39 \pm 0.03$  and  $0.32 \pm 0.04$ ) in WL and NL, respectively. Discussion In the present study the difference in weight loss between groups did not influence the MFO or the increase in VO<sub>2</sub>max after ILI or significantly influence the magnitude of decrease observed in both VO<sub>2</sub>max and MFO after 3 months follow up. The unchanged MFO after ILI was in contrast to our proposed hypothesis and we speculate that the negative energy balance induced by ILI may attenuate the effect of increased physical activity. #### CUT-OFF POINTS OF HEALTH-RELATED FITNESS ASSOCIATED WITH METABOLIC SYNDROME IN KOREAN MEN AND WOMEN

Park, S.1, Ko, B.G.1, Jung, J.W.1, Kim, S.H.1, Kim, K.J.2, Jae, S.Y.3, Jun, J.4, Kyun, J.S.5, Yum, J.S.6, Kim, W.J.

*Korea Institute of Sports Science1, Kemyung Univ. (Daegu, Korea)2, UOS (Seoul, Korea)3, Yonsei Univ. (Seoul, Korea)4, SNUH (Seoul, Korea)5, SNUBH(Bundang, Korea), KNSU(Seoul, Korea)*

Introduction Cardiorespiratory fitness (CRF) is known to attenuate the risk of chronic conditions such as metabolic syndrome (MetS), cardiovascular disease (CVD), and type 2 diabetes. Thus, the cut-off points of CRF associated with health has been reported for men. However, the minimal thresholds of other health-related fitness components including muscular fitness for health have been limited, specifically for women. Therefore, the purpose of this study was to determine the thresholds of associated with MetS in Korean men and women. Methods A total of 1,378 adults (54.6% women) between 19 and 64 years participated in this study. All the participants performed health-related fitness (HRF) of Korean National Fitness Award Program (KNFA) tests, which composed of CRF (maximal oxygen uptake, VO<sub>2</sub>max), grip strength, sit-ups, and, sit-and-reach. FasMetS was defined as the NCEP ATP-III criteria. Using HRF and the MetS as the criterion, receiver operating characteristic (ROC) curves analyses were used to identify cut-off points for HRF. Relative risk Results The cut-off points for HRF associated with the MetS were as follows: 39.33ml/kg/min (11.2 METs) for CRF, 53% for grip strength, 38 rep for sit-ups, 9.5cm for sit-and-reach, and 28.95ml/kg/min (8.3 METs) for CRF, 41.29% for grip strength, 17 rep for sit-ups in Korean men and women respectively. And, the odds ratio for the over CRF thresholds were 0.32 (95%CI: 0.178-0.573) for Korean men and 0.50 (95%CI: 0.289-0.864) for Korean woman when compared with the under CFR thresholds, independent of age, smoking, alcohol intake and body mass index. Discussion This study is the first to identify thresholds of HRF associated with an increased likelihood of MetS in women as well as men. In the study CRF and muscular fitness were significantly related to the prevalence of MetS in men and women. In our ROC analysis, the optimal CRF threshold associated MetS was 11.2 METs in men, which is similar to ones by Kawakami et al (2014) and Katzmarzyk et al. (2007), 10.8 METs and 11.3METs, respectively. This study was designed to provide the cut-off points of HRF throughout adulthood even though fitness is known to decrease with aging. Since this is the first year of the KNAF study, we plan to identify age- and sex-specific thresholds for HRF. Reference Katzmarzyk PT, Craig CL, Gauvin L. (2007). Diabetologia 50,538-544. ## IMPROVEMENT IN QUALITY OF LIFE AFTER INTENSIVE LIFESTYLE INTERVENTION IS RELATED TO MAINTENANCE OF WEIGHT LOSS

Nielsen, M., Dandanell, S., Skovborg, C., Dela, F., Helge, J.W.

*University of Copenhagen*

**Introduction** Obesity can impact negatively on physical health, psychosocial functioning and emotional well-being (1). Intensive lifestyle interventions (ILI) are one approach to combat obesity and our aim was to unravel if weight loss (WL) maintenance 3 months after ILI concur with improvements in quality of life (QoL). We hypothesized that individuals who had a weight loss of >10 % of body weight 3 months after an ILI, would have superior improvements in QoL compared to those who lost <10 %. **Methods** This ILI was undertaken at Usherup Folk high school that runs ILIs of 10-14 weeks that aim to change the dietary habits, physical activity patterns and cognitive understanding of being obese. 60 participants answered a validated questionnaire; Impact of Weight on Quality of Life-Lite (IWQOL-Lite) (2) before and after the ILI and after returning to normal life for 3 months. 44 participants (BMI 37.1 ± 1.5 kg/m<sup>2</sup>) completed the questionnaires. Statistical analysis was performed by 2-way ANOVA (Sigmaplot 12.0) **Results** Based on the relative WL from start to 3 months after the ILI, two groups were established; a WL group (13 w, 9 m) lost > 10 % (13.6 ± 1.0 kg) and a weight regain (WR) group (16 w, 6 m) lost <10 % (6.8 ± 0.6 kg) of body weight. Total score in QoL showed that the WL group (+12.7 ± 2.1%) had a significantly (p<0.001) improved QoL 3 months after the ILI compared the WR group (+5.2 ± 1.6%). In the subcategories of the IWQOL-lite Physical function, Self-esteem and Work there were tendencies towards a difference (+16.9 ± 3.1 vs. +8.5 ± 2.5 % (p=0.08), +23.1 ± 3.1 vs. +10.9 ± 3.2 % (p=0.08) and +15.6 ± 4.8 vs. +1.5 ± 2.4 % (p=0.02)) in WL and WR, respectively. Furthermore, a significant correlation (r<sup>2</sup>= 0.18, p<0.01) was found between relative WL and improvement in QoL 3 months after ILI. **Discussion** In line with our hypothesis subjects who maintain a WL of > 10 % of body weight 3 months after an ILI are rewarded with improvements in QoL compared to those who do not maintain a 10 % WL. The study emphasizes that factors such as physical function, self-esteem and functions in work contexts are interrelated with the maintenance of lifestyle changes and weight loss. Whether these factors are also interrelated with weight loss maintenance over a longer time period still needs to be investigated. **Reference** 1) Danish-Health-and-Medicines-Authority (Updated March 2003) "National plan towards morbid obesity – solutions and perspectives" (In Danish) 2) Koloitkin et al. ## GASTRIC BYPASS PATIENTS DO NOT CHANGE EXERCISE HABITS AFTER SURGERY

Lund, M.T.1, Hansen, M.1, Wimmelmann, C.2, Taudorf, L.1, Helge, J.W.1, Mortensen, E.L.2, Dela, F.1

*University of Copenhagen*

**Introduction** Roux-en-Y gastric bypass (RYGB) leads to a major weight loss in severely obese patients and decrease the risk for developing type 2 diabetes, cardiovascular disease and premature death. Regular exercise has the same beneficial traits as weight loss and will further decrease these risks. Since most patients that undergo RYGB remain obese after the surgery-induced weight loss, regular exercise should be part of a healthier lifestyle. The primary outcome of the present study was the change in cardio-pulmonary fitness after RYGB in severely obese patients. **Methods** Thirty-four (10M/24F, BMI 43 ± 1 kg/m<sup>2</sup>, age 40 ± 2 yrs) subjects scheduled for RYGB had body composition (DXA-scan) and cardio-pulmonary fitness (incremental bicycle test to exhaustion) assessed and completed questionnaires regarding physical activity and function (SF-36 and CAMB (1;2)) twice before (A and B) and 4 (C) and 18 (D) months after surgery. Data was analyzed with mixed-model ANOVA with least squares post hoc test followed by a Tukey-Kramer adjustment. **Results** Cardio-pulmonary fitness (A: 21 ± 1, B: 22 ± 1, C: 26 ± 1 and D: 29 ± 2 ml O<sub>2</sub>/min/kg body weight, p < 0.001) increased with weight loss. However, maximal oxygen uptake (A: 2713 ± 128, B: 2711 ± 125, C: 2584 ± 128 and D: 2609 ± 189 ml O<sub>2</sub>/min, p = 0.02) was lower at C and D compared to B. The number of patients that felt very limited in performing strenuous activities (e.g. running, heavy lifting, strenuous sports) decreased (A: 72 %, B: 54 %, C: 18 %, and D: 4 %, p < 0.001) with weight loss. Finally, self-reported weekly amount of time spent on exercise (e.g. running, soccer, tennis, aerobic) (A: 1.5 ± 0.4, B: 1.5 ± 0.4, C: 1.5 ± 0.4 and D: 2.2 ± 0.5 hrs/week) did not change after RYGB. **Conclusions** After RYGB cardio-pulmonary fitness increases as weight is lost. This decreases the experience of limitations to perform exercise. Nevertheless, questionnaire data and the slight decrease in maximal oxygen uptake show that RYGB patients do not adopt new exercise habits the first years following surgery. **References** 1. ### OP-BN09 Biomechanics Mixed session

#### THE MECHANICAL POWER OUTPUT – VELOCITY CURVE OF THE VELOTRON CYCLING ERGOMETER, AND ITS RELEVANCE FOR CYCLING PERFORMANCE AND PACING RESEARCH.

Schoenmakers, P.P.J.M.1, Smit, A.2, Hettlinga, F.J.1

*University of Essex*

**THE MECHANICAL POWER OUTPUT – VELOCITY CURVE OF THE VELOTRON CYCLING ERGOMETER, AND ITS RELEVANCE FOR CYCLING PERFORMANCE AND PACING RESEARCH.** 1University of Essex, School of Biological Sciences, Centre of Sport and Exercise Science, Colchester, United Kingdom. 2AlbertWOT, Hilversum, The Netherlands. **Introduction** Interaction with the environment is an important determinant of pacing behaviour in athletes (Smits et al., 2014). The Velotron Racermate Dynafit cycle ergometer is introduced to resemble real life situations by allowing on screen opponents, gear changes and the creation of windy and/or hilly conditions. Furthermore, it is claimed that the Velotron incorporates the non-linear relation between mechanical power output and velocity as is apparent in road cycling. This biomechanical aspect is essential in determining successful pacing behaviour and is of influence on the decisions that athletes make during races regarding their energy expenditure (de Koning et al., 1999; Hettlinga et al., 2012). The present study aimed to determine the relation between mechanical power output and velocity of the Velotron cycling ergometer. **Methods** To determine the mechanical power output - velocity curve of the Velotron, a range of velocities and accompanying power outputs were evaluated. The Velotron was propelled using

a calibration rig to simulate a continuous pedalling cadence of 90 RPM. The rig was attached to the crank of the Velotron at the position of the left pedal via a counterbalanced double universal joint. By upshifting gears, while keeping the cadence on 90 RPM, 18 different stages were tested. Power output and speed data were collected over 30 seconds of steady state cycling per stage, resulting in the power (PO) velocity (v) curve. Trendlines were fit and coefficients of determination were obtained. Results 18 Unique samples were taken (PO(W) - v(kmh); 29-14, 35-15, 44-17, 56-19, 63-20, 72-22, 83-23, 100-25, 121-27, 149-30, 189-32, 226-25, 274-38, 355-41, 416-44, 489-47, 601-50, 744-54). Best fits were obtained using a power fit trendline, evidencing the non-linear character of the power velocity curve of the Velotron (PO=0.0453v<sup>2</sup>4,078, r<sup>2</sup>=0.997). Discussion The range of velocities and accompanying power outputs tested on the Velotron showed a clear non-linear curvature, as is apparent in real life outdoor cycling performance. Our findings support the Velotron as a realistic and valid cycle ergometer to study cycling performance and pacing behaviour in a laboratory setting. References Smits B, Popping G, Hettinga F. ## ENERGY COSTS AND LEG MUSCLE ACTIVITIES IN ASCENDING STAIRS

Halder, A.1, Kuklane, K.1, Gao, C.1, Miller, M.1, Noren, J.2, Delin, M.3, Lundgren, K.1, Fridolf, C.1

*Lund University*

1: LU (Lund, Sweden), 2: BRIAB (Stockholm, Sweden), 3: DeBRAND (Stockholm, Sweden) Introduction Repetitive movements and continuous force production through lower limb muscles are required to ascend many flights of stairs on demand especially in an emergency situation. The purpose of this study was to determine the relationship of muscle activity to the oxygen uptake (VO<sub>2</sub>) and the development of leg muscle fatigue from real stair climbing activities. Methods A total of twelve healthy adults (8 men and 4 women) with mean age (±SD) 35.6 (± 9.7) volunteered in the study. Subjects were encouraged to climb 12 floors with 268 steps in their self-selected pace. Oxygen consumption, heart rate (HR) and surface electromyography (sEMG) of the thigh Vastus Lateralis (VL), Vastus Medialis (VM) and Gastrocnemius Lateralis (GL), Gastrocnemius Medialis (GM) from calf muscles as well as ascending speed were recorded. Results The average total time required about 162 (± 38.9) s to reach to the top 12th floor while VO<sub>2</sub>max reached to about 3.0 (± 0.7) l/min corresponding to 40.5 (± 6.5) ml/kg/min. The average HRmax peaked to 170 beats/min and max metabolic rate calculated about 553 W/m<sup>2</sup> from the participants. The main sEMG root mean square (RMS) average median amplitudes (P<0.05) results from GL; RMS average and area amplitudes of (both P<0.02) GM muscles reduced significantly in one-way ANOVA test. Moreover, RMS amplitudes of both thigh and calf muscles showed anticipated progressive reduction at the end. The average climbing speed dropped gradually from .95 to .73 m/s. Discussion However, none of the leg muscles frequency analysis showed significance decrease, thus no indication of muscle fatigue in this self-controlled short duration repetitive activities. This may suggest that subjects tend to adopt some coping strategies that might have changed the sEMG signals (Bigland-Ritchie et al., 1981). The results also showed that sEMG amplitudes reduction might be related to the gradual speed reduction during climbing and to the decrease of leg muscles force production capabilities (Cifrek et al., 2009). Stair ascent is a physically challenging task in terms of leg muscle force production and cardiorespiratory capacities. This may be possible to manage for a shorter duration with tolerable amount of physical stress under self-controlled situations. Future studies with more number of floors and longer ascending duration to evaluate physical evacuation capacity and muscle fatigue are needed. ## MOTOR UNIT FIRING RATE RESPONSES TO ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE

Macgregor, L.

*University of Stirling*

Introduction: Exercise-induced muscle damage (EIMD) has been associated with unaccustomed exercise, particularly eccentric muscle contractions (Warren et al, 1999). EIMD manifests with delayed onset muscle soreness (DOMS) and impaired muscle function. Additionally, decreased motor unit (MU) recruitment threshold and increased MU synchronization, suggesting a centrally mediated response to EIMD (Semmler, 2014). Aim: To investigate centrally driven strategies in MU recruitment following EIMD, specifically concerning MU firing rate and common drive. Methods: Healthy male subjects (mean age 26.2 years) (n=14), performed repeated sets of 12 eccentric knee extension contractions, until failure, on an isokinetic dynamometer. Range of movement and eccentric velocity were 90° and 60°/sec, respectively. Maximal voluntary contraction (MVC), rate of torque development (RTD) and perceived muscle soreness was recorded pre- and 48 hours post- eccentric exercise, as indicators of EIMD. High density electromyography (HD-EMG) was captured, on each day, from the vastus lateralis, during a 12s submaximal (60% of MVC) isometric knee extension. HD-EMG captures were decomposed using a precision decomposition algorithm (PD III), as described by Nawab et al (2010), to detect individual MU firings. The cross-correlation between recruited MUs was compared between pre- and post-exercise as an indicator of the level of common drive to MUs. Identified MUs were also grouped into tertiles, to establish early, middle and late recruitment. Mean MU firing rates within each tertile were compared pre- and 48 hours post-eccentric exercise. Results: MVC and RTD were 28% (p<0.001) and 57% (p<0.001) lower 48 hours post-exercise, compared to pre-exercise. These functional impairments were accompanied by a 50% (p<0.05) increase in perceived muscle soreness. There was no significant alteration in the total number of recruited MUs, detected by HD-EMG, pre- vs. post-exercise. The mean firing rate of late recruited MUs (third tertile) significantly (p<0.05) declined 48 hours post-eccentric exercise. While the MUs located in the second (middle) tertile showed a non-significant (p=0.071) tendency towards slower firing rate 48 hours post-exercise. Although peak cross correlation of recruited MUs did not differ significantly between time points, mean cross correlation of MUs was 41% (p<0.001) higher 48 hours post-exercise. Discussion: This study has shown that 48 hours following EIMD, in the knee extensors, the firing rate of later recruited MUs is impaired, despite force output being maintained. In response, common drive to motor units is increased, as indicated by greater mean cross correlation of MUs. References: Nawab, SH, Chang, SS, De Luca, CJ. ### OP-SH25 Sociology (Sport and gender)

#### TRANSCENDING GENDER HIERARCHIES? YOUNG PEOPLE AND FLOORBALL IN SWEDISH SCHOOL SPORT

Larneby, M.

*Malmö University*

In Swedish organized team sport boys and girls mainly train and compete separately. As Messner (2002) argues, this often reproduces traditional gender hierarchies within sport, in which boys are favored and girls undervalued. However, as a relatively new sport, floorball has "good opportunities to be depicted in a more equal way" (Ljunggren 2013:10). In contrast to floorball practiced during leisure time, in school sport it is often performed in mixed-sex groups. The aim of this study is to explore and discuss young people's construction and displaying of gender in a mixed-sex floorball group, and in what way gendered power relations are exercised within this group. Methodology and theory An ethnographic approach was used to access voices, attitudes and actions on and off the floorball pitch (Ennis & Chen 2012). Young teenagers attending floorball lessons at a sport school from 7th to 9th grade were observed and interviewed. Lorber's (1994) theory of gender as a social institution was used to analyze and interpret their expressions and actions, attitudes and notions of sport. Results The mixed-sex sport setting seems to actualize an unspoken and unquestioned need to dichotomize and construct distinct groups of boys and girls (cf. Lorber 1994). In the studied group, the teenagers talk of themselves as "we" vs the "boys/girls". The girls seem to emphasize that they empower themselves by improving their athletic skills together with boys, and that their strength and ambitions are appreciated. Yet, they are also patronized in various ways by their male peers. The boys reproduce an orthodox masculinity as they perceive that the girls threaten the boys' position in sport. This is complex, as they similarly challenge this masculinity by appreciating the girls as skilled training peers. Conclusion When boys and girls attend a sport school it may be the first time they play floorball with representatives of the other sex, as training during leisure time is usually gender separated. Although the boys and girls constantly emphasize differences due to gender, they strive towards a uniform level of skills and ideal way of play too. Gender seems to lose significance in this common strive for similarity. Despite this, gendered power relations set an agenda based in a notion underlining that "boys' way to play floorball" is the ideal. Thus, a traditional gender hierarchy is rather reproduced than transcended. References Ennis, C. and S. Chen. 2012. Interviews and focus groups. #### THE ROLE OF EMOTIONAL RELATIONS IN ADVANCING GENDER EQUALITY IN SPORT GOVERNANCE

Adriaanse, J.

*University of Technology Sydney*

Introduction Women remain largely under-represented in the governance of sport organisations according to the Sydney Scoreboard global index for women in sport leadership (International Working Group on Women and Sport, 2015). Most research on gender and sport governance focuses on the concept of power. Central to this study was the concept of collaboration between and within men and women. Theoretically the study draws on Connell's (2009) concept of a gender regime, a pattern of gender relations characterised by four interwoven dimensions of social life: production, power, emotions and symbolism. The aim of this paper is to investigate the role of collaborative/emotional relations in advancing gender equality in sport governance. Methods An audit of the gender distribution on boards of 56 Australian National Sport Organisations (NSOs) was conducted followed by 26 semi-structured interviews with CEOs and board directors of five NSOs. Structured on Connell's four-dimensional gender model, case studies with results for each of the five NSOs were drafted and gender regimes identified. This presentation reports on two case studies: Sport boards C and E. Results Sport board C exhibited a gender regime of masculine hegemony in transition. This regime was associated with divisive and hostile emotional relations between and within men and women directors providing limited prospect for gender equality in sport governance. Conversely, sport board E showed a regime of gender mainstreaming in progress which was associated with cohesive and supportive emotional relations on the board. This regime offered positive prospects for gender equality in sport governance. Discussion The study's finding that divisive and hostile emotional relations inhibited prospects for gender equality on sport boards corresponds with results of a 'drop-out' study in German sport organisations (Pfister & Radtke, 2009). Further, the current study found that cohesive and supportive emotional relations were associated with a regime of gender mainstreaming in progress but they need to operate in conjunction with other gender dimensions to achieve gender equality in the governance of sport organisations. The other dimensions were gender parity in numbers (power relations), women and men sharing the most influential roles such as board chair and CEO (production relations), and the adoption of gender equality as an organisational value (symbolic relations). #### THE IMPACT OF GENDER QUOTAS IN SPORT LEADERSHIP IN NORWAY

Sisjord, M.K., Fastang, K., Sand, T.S.

*The Norwegian School of Sport Sciences*

Do not insert authors here The impact of gender quotas in sport leadership in Norway. The paper focuses on gender representation on boards in the Norwegian Olympic and Paralympic Committee (NOC). NOC is the umbrella organization for the 55 individual sport federations. In 1990 the General Assembly of NOC passed paragraph, 2-4 in NOCs rule book, stating that the composition of members to executive boards, councils and committees shall be proportionate to the gender distribution among members, such however, that there shall be at least two representatives from each of the sexes. Annual reports from the sport federations reveal a progressive increase of women on the boards reflects the gender distribution of memberships. The paper highlights how the sport federations are dealing with the issue of gender representation based on qualitative interviews with representatives from 24 individual sport federations primarily with the secretaries general. The results are categorized according to: the awareness of the paragraph among administrators and leaders of

the federation, how the paragraph is put into practice, and particularly the efforts made with the purpose of promoting equal gender representation. The results show that 17 of the federations are aware of, and in general follow the paragraph. All of them follow the rule with regard to the composition of the board, and seven federations have developed specific initiatives in order to promote representation of the underrepresented sex. On the other hand, four federations are aware of the rule but struggle with following it in practice, not having made specific efforts for following it. The latter category includes the three federations apparently ignoring the rule. A couple of the interviewees even spoke against quotas. In the discussion of the results it will be shown that the larger federations are following the rule. The biased gender distribution in memberships in some federations will also be discussed. Furthermore, the results are discussed in relation to gender theory with particular reference to Connell's perspectives of the gender order in society and the concept gender regime.

### **DISTRIBUTIONAL LOGICS OF THE SWEDISH OLYMPIC COMMITTEE**

Hellborg, A.

*Malmö University*

**Introduction** The aim of this presentation is to map out and analyze the Swedish Olympic Committee's (SOC) financial distribution logics. In Sweden, SOC is a key financial actor for many Swedish athletes, others are sponsors and indirectly sport associations. Gender theory will be used as an analytical tool together with an age perspective. This study is part of my thesis which concerns three financial actors (SOC, Swedish sport associations and sponsors) within four different sports (soccer, curling, equestrian sports and golf). **Method** The study is based on interviews with the chair of SOC as well as information on SOC's website and interviews with two sport association representatives (soccer and curling). **Results** Preliminary results suggest that the main criteria for giving an athlete financial aid in the form of scholarships is their international competitive status and their chances of winning a medal at the Olympic Games. In practice, this means that the distribution between different sports can be skewed since some sports have many top athletes while other sports have none. There are no gender equality policies guiding SOC's decisions that affect the distribution in a gender equal manner. There is, however, a logic based on a conception of age. When two equally skilled athletes compete for the same spot the SOC prefer to support the younger athlete. Finally the athletes must be able to train and compete, which means that athletes will not receive financial support during rehabilitation or parental leave etcetera. **Discussion** According to Ridgeway women are often overlooked and viewed as less competent than men (2011; compare Hellborg & Hedenborg 2015). There's a risk that these stereotypical views could affect the distribution of SOC's means if they don't have a gender equality policy. Women may also be more affected than men by disruption in financial support when starting a family since pregnancy affects their ability to train and compete. This is also something that SOC needs to consider as an equality matter. Concerning age, it is problematic to assume that a younger athlete will have a longer development curve since athletes' peaks can alter and some bloom later than others. In some sports, like curling, golf and equestrian sports (which are included in this study), age average of top athletes are much higher than in for example football. **References** Hellborg, A.M. & Hedenborg, S (2015) "The rocker and the heroine: gendered media representations of equestrian sports at the 2012 Olympics" *Sport in Society* 18:2:248 Ridgeway, C.L. ### **EMANCIPATING MOVEMENTS: AN INVESTIGATION OF FEMALE PARTICIPANTS' EXPERIENCES OF FITNESS PRACTICES THROUGH COLLECTIVE MEMORY WORK**

Bladh, G.

*Lund University*

**Emancipating movements: An investigation of female participants' experiences of fitness practices through collective memory work** Bladh, Greta, Lund University, Sweden **Introduction** Research within social science has framed exercise by the ordinary individual as something enmeshed within the subject's negotiations of social structure and discourse as these practices are entangled within social structures of neoliberal expressions of consumerism and individualization (Smith-Maguire 2008, Dworkin 2001). In relation to this, the moving body has been caught as the protagonist of the new morals of health (Metzl 2010). Physical activity has also been comprehended as an emancipatory practice for women by means of transgressing gender stereotypical expectations. However, the results of former analytical work make clear certain constraints, such as a social construction of a glass ceiling in muscle development in women (Dworkin 2001), and the restraining relationship between athleticism and femininity (George 2005). This in turn has an impact on the way and where women exercise and engage in physical activity (Goerge 2005, Dworkin 2001). Hence, the aim of this study is to examine the constraining properties circumscribing female physical activity in an everyday setting of the gym by means of collective memory work and thus further illuminate the potential emancipatory qualities of practices of physical fitness of the female individual. **Methods** Exercise can be comprehended as an action within its narrative. Yet, how and why we tell a story are dependent upon a criteria of relevance, that is, our memories are censored through socialization (Haug 1987: 49). Therefore, by collectively analyzing written down memories of physical activities in a particular setting a critical light will be shed upon female physical fitness in an everyday setting. **Results/Discussion/Hypothesis** As this research process is its initial stage, this paper aims first and foremost to discuss the methodological approach towards a critical perspective regarding physical activity and fitness among women with an ambition to further the research within this area of study within sports science. **References** Dworkin, Shari L. ### PS-PL04 INACTIVITY AND THE AGEING POPULATION

#### INCREASING PHYSICAL LEVELS IS THE KEY COMPONENT TO IMPROVING LIFELONG HEALTH AND WELL BEING

Blair, S.

*University of South Carolina*

Sedentary habits are highly prevalent in most countries of the world. In the U.S. approximately 25-35% of adults are inactive, meaning that they have sedentary jobs, no regular physical activity program, and are generally sedentary around the house and yard. Given that sedentary and unfit individuals are at approximately two-fold higher risk for many health conditions than those who are moderately active and fit, the population attributable risk (PAR) of inactivity is high. In the Aerobics Center Longitudinal Study (ACLS) the PAR for low fitness in more than 50,000 women and men followed for many years is 16-17% of deaths. This is far higher than other putative risk factors for mortality. For example, obesity accounts for 2-3% of deaths in the U.S. In the ACS, 27% of the deaths might have been avoided if none of the men had prevalent cardiovascular disease at baseline whereas 44% of the deaths might have been avoided if none of the men had been unfit. The independent relative risks for death are comparable for prevalent cardiovascular disease (RR=2.4) and for low fitness (RR=2.3). Over the past few decades we have largely engineered the need for physical activity at home, on the job, and during leisure-time out of the daily lives of most people in industrialized societies. To address the major public health problem of physical inactivity we will need to consider and evaluate societal, environmental, and individual approaches to making physical activity more common for more people more of the time.

#### PHARMACEUTICAL DRUG DEVELOPMENT IS THE KEY TO OFFSETTING AGE RELATED DYSFUNCTION AND CHRONIC DISEASE

Evans, W.

*Duke University and KineMed, Inc*

Sarcopenia is a universal phenomenon that results in an increased risk of disability, morbidity, and mortality. While the loss of skeletal muscle mass and function with age is inevitable, the trajectory of loss is highly variable. Regularly performed exercise, particularly resistance exercise, has remarkably positive effects on increasing strength and function in elderly people. Exercise can help to slow the rate of loss of muscle with advancing age and prevent disability and reduce morbidity and mortality. However, the large majority of elderly people do not exercise regularly and inactivity accelerates loss of muscle and function. Skeletal muscle has many roles, besides contractile function. It is the main source of insulin stimulated glucose disposal and serves as a metabolic reserve of amino acids during periods of stress and undernutrition. The pharmacological treatment of sarcopenia rather than exercise is unlikely, however, a new generation of anabolic therapies may be effective to treat the frail and weak elderly patients. Bed rest in older people is associated with a large loss of muscle in a very short period of time and this loss results in greatly reduced physical activity after returning home. Indeed, many older people are unable to return home after hospitalization due to loss of muscle and function. The loss of muscle and function resulting from hip fracture in elderly people occurs most rapidly in the initial period after surgery and rehab therapy is often ineffective in improving function. The use of pro-anabolic therapies either alone or with exercise to prevent immobilization atrophy in these patients has the promise of greatly improved outcomes associated with prevention or increased muscle loss. The use of pharmacological therapy can also improve muscle insulin sensitivity and stimulate protein synthesis, increase muscle blood flow in elderly people with peripheral artery disease and improve function. Anabolic therapies may also help to treat sarcopenic obesity by prevention muscle loss during weight loss in older people. The new generation of anabolic therapies include selective androgen receptor modulators, ghrelin, antagonists of the TGF-beta superfamily hold great promise for treating the most frail and those at greatest risk of late-life disability.

## Adapted Physical Activity

**IMPACT OF AN ADAPTED PHYSICAL ACTIVITY FOR PATIENTS WITH CHRONIC KIDNEY DISEASE**

Frih, B., Frih, A., Bensalah, R., Rjili, H., Bensalah, Z., Bendhia, N., Elmay, M., Hammami, M.

*LabNAFS-LR12E505 – Faculty of Médecine-Monastir (TUNISIE), Departments of Nephrology, Monastir Hospital (TUNISIE), Departments of MPR, CHU Monastir - (Tunisie).*

**Introduction** The success of dialysis treatment and survival of patients depends on several factors, which are mainly; the quality of life and the physical conditions of these patients **Objective:** To evaluate the effects of an adapted physical activity based on flexibility, strength and endurance exercises program. **Patients and methods:** A group of 30 hemodialysis patients recruited from the department of nephrology and hemodialysis. This group was following a physical activity program for a period of 12 weeks, 2 times a week. The evaluation is performed before and after the proposed protocol by two questionnaires: quality of life (SF36) and hospital anxiety and depressive scale (HAD), echocardiogram, electrocardiogram, spirometry, lipidic concentration and six-Minute walk Test (6MWT). **Results:** There was no undesirable event during rehabilitation sessions. The quality of life (physical and mental component) and anxious component (HAD) improved. The distance walked on the 6MWT has increased. The lipid profile was enhanced (HDL and LDL - cholesterol, triglyceride). **Discussion - Conclusion:** Designing an adapted physical activity is highly recommended for the patients with chronic kidney disease. This appears to be a safe and effective alternative for developing functional capacity, laboratory parameters and the psychological profile of hemodialysis patients.

**EFFECT OF BLOOD VOLUME ON PLASMA VOLUME SHIFT DURING EXERCISE**

Ogura, T., Oda, S., Kaida, K., Miyazaki, K., Kawabata, T.

*laboratory for environmental physiology for exercise*

**EFFECT OF BLOOD VOLUME ON PLASMA VOLUME SHIFT DURING EXERCISE** Ogura, T., Oda, S., Kaida, K., Miyazaki, K. and Kawabata, T. Kansai Univ. Graduate School of Health and Well-being (Japan) **Introduction** The maintenance of blood volume (BV) is an important factor for providing circulatory stability, thermoregulatory and maintaining performance during exercise. Hypovolemia from thermal dehydration or progressive pooling of blood in cutaneous blood vessels and the shifts in plasma volume (PV) reduces the central circulating blood volume (I). The aim of the present study is to assess the effect of BV on PV shift during exercise and BV - aerobic work capacity relationship in the difference of fitness levels in individual variations. **Methods** Thirteen healthy (Japanese professional football player) participated in the present study. Their mean (SEM) age, height, weight and peak oxygen consumption (VO<sub>2</sub>peak) were 27.4 (1.5) yr, 178.4 ( 2.6) cm, 71.3 (1.9) kg and 61.5 (1.1) ml kg<sup>-1</sup> min<sup>-1</sup>. Subjects rested in supine posture for 40 min. after the rest period, BV, cardiac output (CO) and stroke volume (SV) were measured by the pulse dye densitometry (DDG-2001, Nihon Kohden, Japan) using the dye Indocyanine green as the indicator in the supine position. And then subjects moved on the treadmill. **Results** The values of VO<sub>2</sub>peak per body weight was 61.5 (1.1) ml kg<sup>-1</sup> min<sup>-1</sup>. Maximal HR during graded exercise was 182.7 (1.6) beats min<sup>-1</sup>. The CO and SV at rest were 4.3 (0.10) L and 88.5 (1.85) ml. BV and PV in the supine posture were 64.7 (3.9) and 38.1 (2.4) ml kg<sup>-1</sup>, respectively. The percentage of changes in PV during graded exercise decreased gradually from 10.7 (0.6) % to 20.7 (0.7) % in exhaustion. The shifts in PV at the point of LT level averaged 16.4 (0.6) % and the range of the PV shift in individual variations were from 12.5% to 19.6%. **Discussion** The relationship of peak VO<sub>2</sub> with BV indicated a significant positive correlation between peak VO<sub>2</sub> and BV. It is well known that during dynamic exercise, BV tends to fall slightly due mainly to decreased PV in proportion to the exercise intensity. In the present study, during exercise PV decreased significantly from an average resting value of 2685.4 ml by 19.6% or 532.4 ml. The shifts in plasma volume at LT averaged 440.4 ml or 16.4% and the relationship of the shifts in PV at LT with total PV indicated a significant negative correlation. However, the relationship of the circulating PV, calculated from the shifts of PV at LT in individuals, with total PV and VO<sub>2</sub> at LT indicated a significant positive correlation between the circulating PV and total PV and VO<sub>2</sub> at LT. These results suggested that the strong positive relation between the shifts in PV and total PV and results in a maintenance of the circulating BV. **References** 1 Fortney SM, Nadel ER, Wenger CB, and Bove JR: Effect of acute alteration of blood volume on circulatory performance in human. *J Appl Physiol* 50: 292-298, 1981 Contact takakaw@kansai-u.ac.jp

**BLOOD VOLUME AND AEROBIC PERFORMANCE IN ELITE SOCCER PLAYER**

Kaita, K., Ogura, T., Miyazaki, K., Oda, S., Kawabata, T.

*Laboratory for environment physiology for exercise*

**BLOOD VOLUME AND AEROBIC PERFORMANCE IN ELITE SOCCER PLAYER** Kaita, K., Ogura, T., Miyazaki, K., Oda, S. and Kawabata, T. Kansai Univ. Graduate School of Health and Well-being (Japan) **Introduction** The maintenance of blood volume (BV) is an important factor for providing circulatory stability, thermoregulatory and maintaining aerobic performance in football game. Hypovolemia from thermal dehydration or progressive pooling of blood in cutaneous blood vessels and the shift in plasma volume (PV) reduces the central circulating blood volume. Under these condition, cutaneous vasoconstriction leads to excessive heat storage in heat stress. Increases in sweat rate and skin blood flow during exercise enhance heat dissipation and prevent hyperthermia. Hyperthermia itself has been suggested to limit aerobic performance. The aim of the present study is to assess the effect of BV on PV shift during exercise and BV-aerobic work capacity relationship in the difference of fitness levels in individual variations in elite football player. **Methods** We measured changes in plasma volume during exercise and blood volume in thirteen professional football players, attached to Japan football league. Blood volume was measured by the pulse Indocyanine green (ICG) dilution method (DDG-2001, Nihon Koden, Japan). Exercise intensity was increased stepwisely until voluntary exhaustion. Blood samples were collected at each stepwisely exercise intensity and at exhaustion. **Results & Discussion** It is well known that during exercise, BV tends to fall slightly due mainly to decreased PV in proportion to the exercise intensity (I). In the present study, in exercise PV decreased significantly from an average resting value of 2685.4 ml by 19.6% or 532.4 ml.

The mean values (SE) of peak VO<sub>2</sub> was 61.5 (1.1) ml kg<sup>-1</sup> min<sup>-1</sup>. BV and PV in the supine posture were 64.7 (3.9) and 38.1 (2.4) ml kg<sup>-1</sup>, respectively. The relationship of VO<sub>2</sub>peak with BV and PV indicated a significant positive correlation. The value of VO<sub>2</sub> at lactate threshold (LT) was 57.5 (1.5) ml kg<sup>-1</sup> min<sup>-1</sup>. The PV shift-LT averaged 440.4 ml or 16.4%. The relationship of the circulating PV, calculated from the PV shift-LT in individuals, with total PV and VO<sub>2</sub>-LT indicated a significant positive correlation. These results suggested that the strong positive relation between the PV shift and total PV, and results in a maintenance of the circulating BV. References 1. Kawabata, T. et al. (2004). *J Therm. ### LONG-TERM ENDURANCE EXERCISE IN MS PATIENTS – IMPACT ON QUALITY OF LIFE AND DEPRESSIVE SYMPTOMS IN RELATION TO BASELINE FATIGUE

Wonneberger, M., Schmidt, S.

Schmidt, S.: *Neurologische Gemeinschaftspraxis Bonn, Gesundheitszentrum St. Johannes, Kölnstr. 54, 53111 Bonn, Germany; 2Ruhr-University of Bochum*

**Introduction** Quality of life (QoL) is substantially impaired in MS patients [1]. In addition to motor and balance disability fatigue and depressive symptoms (DS) also strongly contribute to QoL [2]. The long-term effects of aerobic endurance exercise on QoL and DS remain to be defined, in particular with reference to the baseline fatigue. **Patients and Methods** Prospective, non-randomized, observer blinded cohort study of 89 patients with relapsing-remitting MS and an EDSS of ≤ 3.5. Fatigue was measured by the Fatigue Severity Scale (FSS) with a defined cut-off value of ≥4.0 for a subgroup analysis of fatigue versus non-fatigue. QoL was determined by the SF-36 Health Survey and DS by a German version of the Center for Epidemiologic Studies Depression Scale (CES-D), the ADS-L. An individualized exercise intervention was performed for 12 months with follow-up examinations every three months. The data were explored by per-protocol analysis using ANOVA for repeated measurements. **Results** A significant reduced QoL for all subscales of the SF-36 ( $p < .05$ ) and the ADS-L ( $p < .01$ ;  $\eta^2 = .15$ ) was detectable in MS patients with fatigue in comparison to those without fatigue. However, a significant interaction effect over time was only discernible in the subscale 'general health perception' in patients with fatigue ( $p \leq .01$ ; partial  $\eta^2 = .08$ ). **Discussion** The lack of measurable improvement over the intervention period may be due to (1) the extended study duration of 12 months [3]; (2) the lack of social interaction with other participants and the infrequent contact with study personnel [4]; (3) the possible insensitivity of the SF-36 in MS patients [3]; (4) the overall low scores in the ADS-L of the patients included may have masked possible effects on DS [5]. For further studies assessing the impact of endurance training on QoL and DS in MS patients, the aforementioned methodological shortcomings have to be addressed. **References** 1. ### ASSOCIATION OF PHYSICAL ACTIVITIES AND SEDENTARY BEHAVIORS WITH SLEEP DISTURBANCE BY DIFFERENCE BETWEEN COMMUNITY-DWELLING ELDERLY WITH AND WITHOUT MUSCULOSKELETAL PAIN.

Saito, T., Sakita, M., Kumagai, S.

*Aso Rehabilitation College*

**[Purpose]** Each factor of physical inactivity and pain is associated with sleep disturbance. However, it is not clear whether association of physical inactivity with sleep disturbance is affected by musculoskeletal pain (MSP). This study examined whether some combinations of physical activities (PA) and sedentary behaviors (SB) led to different association with sleep disturbance between person with and without MSP. **[Methods]** Cross-sectional data were collected on 715 elders aged 65 years and over living in Dazaifu, Japan. MSP was defined as pain that sustains more than 1-3 months during the past year and participants were asked to identify pain locations on a body diagram. Sleep disturbance was analyzed by using the Pittsburgh Sleep Quality Index of the Japanese version (PSQI-J). PA and SB were objectively measured using a triaxial accelerometer (Omron Healthcare, Active Style Pro HJA 350IT). Participants were categorized into four groups (2 groups of PA x 2 groups of SB) according to their levels of PA and SB (divided into 2 levels; low and high levels around the median) under MSP and non-MSP groups. Logistic regression analysis was used to examine effect of PA/SB on sleep disturbance under MSP and non-MSP groups. In the analyses, gender, age, body mass index, smoking, educational attainment were treated as potential confounders. **[Results]** The prevalence of MSP was 60.7%. In those with MSP, significantly higher risks of sleep disturbance were showed in high PA/high SB group (odds ratios [OR] 2.76, 95% confidence interval [CI] 1.37-5.53), low PA/low SB group (OR 2.54, 95% CI 1.35-4.78), and low PA/high SB group (OR 2.36, 95% CI 1.28-4.37), compared with that of the reference group (high PA/low SB group). However, each group without MSP was not significantly associated with sleep disturbance. **[Conclusion]** The combination of low PA and high SB might be the risk of sleep disturbance in older adults with MSP. The result of this cross-sectional study indicates that reduction of SB will be as important as progression of PA in older adults with MSP in particular.

### INFLUENCE OF BLINDNESS ON INTERMITTENT RUNNING PERFORMANCE

Hoos, O.1, Ruttman, T.1, Kümmel, M.1, Megerle, F.1, Beneke, R.2

1: *JMU-SS (Wuerzburg, Germany)*, 2: *PUM-DMTH (Marburg, Germany)*

**Introduction** Preliminary data from blind young people reveal a markedly lower aerobic fitness, primarily due to a reduced level of habitual physical activity (Hopkins et al., 1987; Shindo et al., 1987; Aslan et al., 2012). The regular engagement in adapted ball games seems useful in this context (Karakaya et al., 2009). However, data on aerobic fitness and performance of blind adults engaged in adapted ball games is not available. Therefore, the aim of this study was to investigate the influence of blindness on intermittent running performance (IRP) by comparing blind soccer players with physically active PE students under blinded and sighted conditions. **Methods:** n=8 male blind soccer players (BS: age: 29.0±6.7 y) performed an adapted YoYoIR1-test (Bangsbo et al., 2008) with continuous heart rate measurement (Polar RS800) as well as a single leg stance test (max. 120 s) on a balance board (Togu). Additionally, n=11 male PE students (age: 25.1±1.8 y) performed the same tests under both blinded (PE-bl) and sighted (PE-vis) conditions in randomised order. IRP (in m) and exercise heart rate (HR in bpm, HRmax) as well as balance time (in s) were compared between groups by means of mixed ANOVAs. **Results:** Significant group effects were found for IRP (F=40.2; p<0.001;  $\eta^2=0.75$ ) and balance time (F=518.4, p<0.001,  $\eta^2=0.98$ ) with significant lower values in BS (365±165 m; 4±1 s) compared to PE-bl (1069±261 m; 15±15 s) and PE-vis (1378±276 m; 120±0 s), respectively. A significant interac-

tion effect (group x running speed;  $F=19.7$ ;  $p<0.001$ ;  $\eta^2=0.59$ ) was detected for exercise heart rates. While all groups had similar HRmax (BS:  $192\pm 11$  bpm; PE-bl:  $192\pm 7$  bpm; PE-vis:  $193\pm 7$  bpm), PE-bl and BS both exhibited significantly higher HRs at low running speeds compared to PE-vis. Discussion: Similar to a previously reported general reduction in aerobic fitness (Shindo et al., 1987) blind soccer players show a highly reduced (-74%) IRP. Additionally, our data indicate that IRP is directly influenced by the loss of visual control, although to a much lower extent (-22%). Consequently, our results support the notion that blind people should be strongly encouraged to increase habitual physical activity (Hopkins et al., 1987; Shindo et al., 1987; Aslan et al., 2012) in order to reduce the large deterioration in physical fitness and corresponding health prognosis. ### **INFLUENCE OF HIPPOThERAPY ON RESPIRATORY MUSCLE STRENGTH IN INDIVIDUALS WITH DOWN SYNDROME IN THE FEDERAL DISTRICT, BRAZIL**

Barros, J.F., Costa, V.S.F., Silva, H.M., Nunes, R.N., Silva, A.R., Browne, R.A.V., Elsangedy, H.M.

1. *Universidade Federal do Rio Grande do Norte* / 2. *Universidade de Brasília*

Introduction: Down syndrome, from all genetic syndromes are the most common. Individuals who may have decreased respiratory muscle strength mainly due to hypotonia, a common characteristic in this population. Objective: To analyze the effects of a hippotherapy program on the respiratory muscle strength in individuals with DS practitioners (GE) and non-practitioners (GC) in both genders. Material and methods: The study included 41 subjects with 20 in the experimental group (EG) and 21 of the Control Group (CG), of both sexes, aged 7-13 years, all diagnosed with Down Syndrome (DS). Was used to measure the Manovacuometry respiratory muscle strength, following the protocol proposed by Black and Hyatt (1969), where participants were instructed to perform expiratory maneuvers maximum (MEP) and inspirations maximum (MIP). Statistical analysis was given from a distribution specification. We used the Kolmogorov-Smirnov test to assess the normality of the data distribution and the Levene test to verify homoscedasticity of variables assessing equality or not of variances between groups of variables. Accordingly, after these checks, we used the Mann-Whitney test to determine differences between the means of groups (CG and EG) as using the Spearman correlation test to visualize possible relationships with age and practice time hippotherapy. Adopted a significance level of  $p < 0.05$ . Results: The individuals who performed the practice of hippotherapy showed improvements compared to both inspiratory respiratory muscle strength (MIP) when expiratory (MEP), although no significant difference. Conclusion: This study demonstrates that the hippotherapy program has benefits in respiratory muscle strength in individuals with DS and particularly younger did better. Reference: Costa, V.S.F. Influence of hippotherapy on respiratory muscle strength in individuals with Down Syndrome in the Federal District, Brazil. Master's thesis. University of Brazilia, UnB.

### **INFLUENCE ON V-WAVE RECOVERY CURVE DURING SKIN COOLING USING A DOUBLE STIMULATION METHOD**

Yona, M.1, Tadano, C.2, Naito, Y.3, Shimose, R.4, Sugawara, H.5, Sakamoto, M.6, Seki, H.7, Muro, M.2

1: *TUPLS (Japan)* 2: *Toho Univ. Med. (Japan)* 3: *Kokushikan Univ. (Japan)* 4: *Sagami Chuo Hosp. (Japan)* 5: *Tokyo Univ. Tec. (Japan)* 6: *Kitazato Univ. (Japan)* 7: *Niigata Manage. Univ. (Japan)*

Introduction We have demonstrated the effects of skin cooling on the spinal cord by analyzing the H-reflex recovery curve using a double stimulation method. There was a difference in the time it took to attain peak recovery between CS and NCS (CS:250ms, NCS:300ms). These results suggest that the decrease in H2/H1 with skin cooling is related to elevated motoneuron inhibition. However, there is a possibility that input from cold receptors has an influence on central command. The evoked V-wave response could be used to reflect the magnitude of efferent  $\alpha$ -motoneuron output during voluntary muscle activation. Therefore, the purpose of this study was to investigate the effects on V-wave using a double stimulation with skin cooling. Methods Eight healthy adults volunteered for this study. Isometric contraction force and twitch of the triceps surae were measured with a force transducer attached to a footplate apparatus. Electrical signals were picked up by surface electrodes (10mm) on the belly of SOL and MG. This experiment was performed under two conditions that consisted of skin cooling (skin temp. 26 deg.; SC) and control (skin temp. about 33 deg.; NSC). A cooling pad, attached to the skin, was used in the cooling condition. H-reflexes and M-waves were evoked in the SOL and MG muscles by electrical stimulation of the posterior tibial nerve via a cathode ball electrode (5mm in diameter) pressed into the popliteal fossa. V-waves evoked with a double stimulation (conditioning V-wave: V1, test V-wave: V2) were obtained under the two conditions during 30%MVC. Time intervals between conditioning and test stimulation ranged between 10 and 800ms ( $n=2$ ) and 100 and 300ms ( $n=6$ ). The data analyzed was V-wave peak-to-peak amplitude (V2/V1). Results and Discussion There was no significant difference in Hmax, Mmax and H/M ratio between CS and NCS. There was no significant difference between the amplitude of the control V-wave and V1. Regarding the rate of V2/V1, there was an initial complete depression within several tens of milliseconds and an early recovery attaining a peak at about 150ms under both conditions. The two peaks of recovery at around 100-300 ms has been used as an optimal point for measuring central command excitability in the double V-wave test. However, there was no difference in the time it took to attain a peak recovery between CS and NCS (first peak: 150ms, second peak: 250ms) in SOL and MG. Furthermore, there was no difference in the rate of V2/V1 between CS and NCS. These results suggest that the level of MVC was low therefore high threshold motor units were not recruited at 30%MVC.

### **LIFE QUALITY OF SPINAL CORD INJURED**

Silva, A.R.1, Oliveira, P.F.A.1, Benito, L.A.O.1, Santos, J.A.T.1, Barros, J.F.2, Browne, R.A.V.2, Magalhães, G.L.3, Alves, E.D.1

1. *Universidade de Brasília* 2. *Universidade Federal do Rio Grande do Norte* 3. *Instituto Federal de Brasília*

Introduction The spinal cord injury is one of the most disabling syndromes that affect not only young adults with significant social and financial repercussions. People with have partial or total loss of motor, sensitive, autonomous function and complications in their organic system (Maynard et al., 1997). The outcomes of this trauma interfere in the quality of life and the functional capacity of these people, characterizing a dependence on other people's care and limitations that will go on for the rest of their lives (Caffer et al., 2005). Therefore, the aim of this study was to check the level of quality of life in men with spinal cord injury that practice or not physical activity in institutions of the Federal District-Brazil. Methods Data was collected from 30 men with of traumatic etiology, divided in active ( $N=16$ ) and sedentary ( $N=14$ ), ranging from 20 a 60 years old. To collect data, instruments like the SF-36 (medical Outcomes study 36-Item short-Form Health Survey) (Ciconelli et al., 1999) and the survey for the diagnosis of the level of physical activity of the aim population (Matsudo et al., 2000) were used. To the data analyses the frequency, charts, central tendency measurements (average) of dispersion (standard deviation) were

realized. For the tests, levels of significance of 5% were used. Results The age range was 41-50 years old (36,6%) and the average time of injury was 20-30 years (36,6%); As the cause of the injury, the prevalence is fire guns (40%), in its vast majority of injury are total (73,3%) with the predominance of the thoracic level of injury (76,6%). Discussion In relation to the survey the mean domain scores of the SF-36 of spinal cord injuries are presented low values, however, the dominance of functional capacity of the SF-36 of the medullar disabled people that practice physical activities is significantly higher than in relation to sedentary ones. The quality of life is closely related to the lifestyle of the person with cord injury, thus, interventions like physical activity can promote the improvement of the functional independency and quality of life. ### **METABOLIC CHANGES IN HUMAN MUSCLE WITH 90 DAY BED-REST AND RESISTANCE EXERCISE**

Cussó, R.1, Guerrero, M.1, Irimia, J.M.2, Cadefau, J.A.1, Fernandez, R.3, Tesch, P.3

*University of Barcelona*

Introduction Spaceflight is a unique environment that poses several physiological challenges to the human body. 90 days of immobility was a good approximation to experience muscle degeneration that occurs with such a long-term immobility (1). Exercise performance during this period was a good test to counteract those effects. The aim of the study was to observe how the glucose metabolism was modified during this period. The assay was performed on muscle biopsies to measure activities of the enzymes controlling glucose metabolism and changes in the expression of corresponding mRNAs before and after starting the experiment. Methods 21 participants performed 90 days of bed rest. They were divided into two groups: group 1. (BR) 12 participants rested, group 2. (BRE) 9 participants exercised. The BRE group trained a concentric-eccentric resistance protocol. Muscle biopsies were obtained from the Vastus Lateralis before and after finish the experience. Glycogen synthase (GS), glycogen phosphorylase (GPh), hexokinase (HK), phosphofructokinase (PFK-1), citrate synthase (CS) activities and their corresponding mRNAs were assessed. Results BR causes a decrease in GS, GPh, HK and CS activities. This decrease is also accompanied by a decrease of mRNAs being significant in their single HK mRNA and CS mRNA. In hiring BR slightly increases the PFK-1 activity accompanied by an important but not significant increase of its mRNA. Exercise training increases the activities of all enzymes being particularly significant the GPh and HK. These increases in activity also correspond to increases in expression of the mRNAs. Discussion In summary, the decrease in energy metabolic capacity provided by the oxidation of glucose that occurs during muscle degeneration caused by prolonged immobility corresponds to a decreased activity of regulation key enzymes that it is controlled by expression of the synthesis of the enzymes involved. These results would be related with the decrease in slow-twitch fibres and an increase of hybrid fibres showed by Trappe et al (2). Exercise training counteracts these losses, increasing the new synthesis of mRNA and so does the protein expression of these enzymes. References 1. Edgerton VR, Roy RR. 1995: NASA 2003. ### **DO CANCER PATIENTS RE-CALL PHYSICAL ACTIVITY FROM LAST WEEK?**

Vassbakk-Brovold, K.1,2, Kersten, C.1, Fegran, L.1,2, Mjåland, S.1, Seiler, S.2, Berntsen, S.2

*1) Southern Hospital Trust, 2) University of Agder*

Background: Feasible, valid and reliable measures are important when quantifying physical activity (PA) level in cancer patients. The short form of the International Physical Activity Questionnaire (IPAQ-sf) is a validated and commonly used questionnaire to assess PA in adults. However, the IPAQ-sf has not previously been validated in cancer patients undergoing oncologic treatment. Objective: The objective of the present study was to compare IPAQ-sf with objective measures of physical activity in cancer patients receiving chemotherapy with curative or palliative intent. Materials & Methods: The present study was part of a 12-month prospective individualized lifestyle intervention focusing on diet, PA, stress management and smoking cessation in 100 cancer patients undergoing chemotherapy with curative or palliative intent. During the first 2 months of the lifestyle intervention, participants were instructed to wear a SenseWear™ Armband (SWA) for 5 consecutive days before completing the IPAQ-sf at the cancer center while receiving chemotherapy. From SWA, PA of moderate- or vigorous intensity (MVPA) >10 min duration were compared with self-reported values from the IPAQ-sf. Walking was included in MVPA from the IPAQ-sf. Results: 66 patients both completed IPAQ-sf and wore the SWA over 5 days. MVPA was 844 and 181 min/week with the IPAQ-sf and SWA, respectively. IPAQ-sf significantly overestimated MVPA by 663 min/week, or 366% compared to SWA (p=0.001). Comparing MVPA, IPAQ-sf and SWA, the mean difference and limits of agreements from the Bland-Altman plots were 662 (±1707) min/week. Discussion: Using the IPAQ-sf, cancer patients participating in an individualized comprehensive lifestyle intervention while undergoing curative or palliative chemotherapy overestimated MVPA by almost 100 min/day. The size of overestimation made over 7 days is larger than the American Cancer Society's PA guidelines for cancer patients of minimum 150 min/week of moderate PA. Conclusion: Based on the present finding of a large overestimation of PA, the IPAQ-sf cannot be recommended as an assessment tool addressing PA level for cancer patients undergoing oncologic treatment.

### **COMPARISON OF PHYSICAL ACTIVITY BETWEEN ADOLESCENTS LIVING IN A COASTAL AREA AFFECTED BY THE GREAT EAST JAPAN EARTHQUAKE AND TSUNAMI AND THOSE OUTSIDE AN AFFECTED AREA**

Okazaki, K.1, Suzuki, K.1, Sakamoto, Y.2, Sasaki, K.1, Suzuki, H.3

*1 Tohoku Gakuin University (Sendai, Japan), 2 Tohoku Institute of Technology (Sendai, Japan), 3 Okayama University (Okayama, Japan)*

Introduction The 2011 Great East Japan Earthquake and Tsunami had a significant effect on the lifestyle of Japanese adolescents; in particular, the physical activity of victims from the submerged coastal areas seems to have been considerably deteriorated. This study aimed to compare the physical activity between middle school students living in an affected coastal area and those living outside an affected area. Methods A total of 418 middle school students in seventh and ninth grades from an affected coastal area (N = 222) and outside an affected area (N = 196) were enrolled at 2 years after the earthquake. Students were asked to report their personal and demographic characteristics and their activities by using World Health Organization's Health Behaviour in Schoolchildren (HBSC) questionnaire (Booth et al., 2001) and time spent sitting during weekdays and weekends. In addition, the number of daily steps was assessed using an accelerometer. Results Independent t-test (t = -2.2, df = 297, p < 0.05) revealed that students living outside an affected area

(530 ± 263 min/day) spent significantly more time sitting per day during weekdays than did those living in the damaged coastal area (461 ± 293 min/day). In contrast, the number of daily steps (in affected coastal area 7,020 ± 2,687 vs outside the area 7,304 ± 2,371 steps/day) and activity as per HBSC questionnaire (in affected coastal area 64% vs outside the area 68% active) were not significantly different. Discussion Our study results indicated that the daily steps of students in both areas were lower than those of previous studies (Tudor-Locke et al., 2011; Adams et al., 2013); however, the daily steps did not significantly differ among the two student groups. Moreover, time spent sitting during weekdays among the students living in the damaged area was lower than those of living outside the damaged area. It seemed that school-based interventions taken by the teacher reduces the time spent sitting during weekdays. Specifically, club activities after class in the school may be important for improvement of their activities. Further studies are needed to examine their personal and demographic characteristics longitudinally. References Booth ML, Okely AD, Chey T, Bauman A. (2001) *Br J Sports Med*, 35, 263-267. ## PHYSICAL ACTIVITY AND OBESITY IN DOWN'S SYNDROME

Joffroy, S.1.2, Garnier, S.1, Geneau, S.1, Lemoine-Morel, S.3, Sanguignol, F.4, Mauriege, P.5

*Université Paul Sabatier 1; ITO-CEOPS 2; Université Rennes 3; Clinique Bondigoux 4; Université Laval 5*

Introduction Down syndrome is known to be a chromosomal condition that is associated with intellectual disability, a characteristic facial appearance, and weak muscle tone in infancy. Children with Down syndrome have a higher risk for developing obesity. Because of the negative consequences associated with obesity, prevention and interventions in children with Down syndrome should be a major health priority. In our study, to find out the prevalence of overweight and obesity in Down's syndrome, 578 french children and adults living in communities were studied. Body Mass Index (BMI) and its relationship with environmental factors as dietary habits and physical activity were studied. Methods We analyzed 239 women (27.5 ± 14.5 years-old) and 339 men (29.2 ± 13.7 years-old) located in 3 social medical centers in France. A questionnaire was used via the National file of the sanitary and social establishments (FINESS) and anthropometric measures (weight, height and BMI calculated), demographic data (age) and different indicators: diet program, physical activity (endurance, continuous exercise) were determined. Results It was found that 45.4% of males and 61% females were categorized as overweight and obese. The middle BMI in our population was 25.4 kg/m<sup>2</sup> but the prevalence of obesity and overweight is 52,4% in contrast to the one of the French population which is 39%. 1,9 % of subjects are thin and 6,2 % are in severely or massively obese. The middle BMI increases from 41-50 years and decreases after 60 years. Overweight and obesity affect 61 % of the women against 44,5 % of the men. We observed that physical activity is associated with a lower category of BMI about 4 kg/m<sup>2</sup>. The age, the interaction of sex and diet and physical activity are significant according to the BMI category. Even if the cause of obesity in people with Down syndrome is unknown and probably multifactorial, it would include the food habits, depressed metabolic rate, reduced exercise and endocrine abnormalities (Bricout, 2007; Fernhall, 2009; Mendonca, 2013). Discussion-Conclusion Physical activity alone is associated to a decline of BMI (p < .05) while, interaction of dietary and physical activity has no influence in the decline of BMI. ### EFFECTS OF TENNIS ON PARASPINAL MUSCLES IN PREPUBESCENT AND PROFESSIONAL PLAYERS: A VOLUMETRIC MRI STUDY

Dorado, C., Calbet, J.A.L., Idoate, F., Sanchis-Moysi, J.

*Instituto Universitario de Investigaciones Biomédicas y Sanitarias (IUIBS), Las Palmas de Gran Canaria University, Spain; Radiology Department, Clínica San Miguel, Pamplona (Spain)*

Introduction. Tennis practice imposes a great stress in the lumbar spine musculature [1]. In children and professional tennis players, the upper extremity muscles are hypertrophied asymmetrically [2, 3]. The purpose of the present study was to assess if tennis induce the asymmetric hypertrophy of paraspinal (PSP) muscles in prepubescent (PRE) and professional (PRO) tennis players. Methods. Magnetic resonance imaging (MRI) was used to determine the volume of PSP in 8 male PRO (21.9 years), 7 male PRE (11.0 years, Tanner 1-2) and 16 male non-active controls (10 prepubescents: 11.0 years, Tanner 1-2; and 6 adults: 23.5 years). The MRI images (L1-L2 intervertebral disc to pubic symphysis), were used to calculate the volume of PSP (iliocostalis lumborum, multifidus, longissimus thoracis, spinalis thoracis analyzed conjointly). Differences between sides were assessed using Student's paired t-tests. Significant differences were assumed when P<0.05. Results PSP had similar volumes in the non-dominant and dominant sides in PRE (214.8±49.1 vs 215.7±45.7 cm<sup>3</sup>, respectively, P=0.93), PRO (495.7±97.5 vs 476.5±108.3 cm<sup>3</sup>, respectively, P=0.12) and control subjects, children (194.0±41.8 vs 186.9±37.6 cm<sup>3</sup>, respectively, P=0.08) and adults (458.1±77.9 vs 442.0±69.5 cm<sup>3</sup>, respectively, P=0.20) Discussion The present study shows that tennis induces a symmetric development of PSP muscles at prepubertal age. Also, that side-to-side symmetry in the muscle volume of PSP remains at a professional level. In addition, our results show that daily living activities during childhood and adulthood also induce a symmetric degree of hypertrophy of PSP muscles. Conclusion The muscle volume of paraspinal muscles (analyzed conjointly) is similar in the dominant and non-dominant sides, in tennis players and in physically non-active population, children and adults. ## THE CHARACTERISTICS OF LOWER LIMB MOTOR FUNCTION AND KINEMATICS OBSERVED IN 2 STEP TEST: FOCUS ON THE DISTINCTION AMONG THE RISK OF FALLING.

Miyamoto, R.1, Muranaga, S.1, Jinji, T.2, Osawa, Y.1, Ino, Y.1, Higashi, T.1

1:Kameda Medical Center (Chiba, Japan) 2: IBU (Chiba, Japan)

Introduction 2 step test (2ST) is known to measure the walking ability. This calculates the 2 step value (2SV), which standardize the maximum distance of 2 strides divided by their height (Muranaga, 2003). Moreover, This 2ST can conveniently evaluate the walking ability unlike other methods measuring it. However, it has not validated the characteristics of lower limb kinematics in 2ST. The purpose of this study is to reveal the characteristics of lower limb kinematics dependent on the risk of falling from the 2SV. This can be useful to prevent the falling. Method Subjects were 18 elderly (Age:  $74.7 \pm 3.3$  years old). 2ST was performed twice bilaterally and analyzed the reflective markers applied on body landmarks by using Vicon MX. The 2SV is divided into 3 groups (Poor: P which is above 1.25, Normal: N which is 1.26-1.50, and Good: G which is above 1.51). In this study, the analysis of lower limb kinematics was only on the initial side and categorized 3 stages; the 1st stage is from the start to the initial foot contact, the 2nd stage is from the initial foot contact to the second foot contact, and the 3rd stage is from the second foot contact to the finish, which gathers the both feet. In addition, lower limb ROM and both isometric and isokinetic muscle strength of the knee were also evaluated. One Way ANOVA ( $P < 0.05$ ) was used for the statistical processing and Benferroni Method was used for a multiple comparison. Result The statistically significant was shown next. In G, the knee flexion angle at the mid phase of the 2nd stage, the ankle plantar flexion angle, and hip extension angle at the initial phase of the 3rd stage were statistically significant compared with P. Furthermore, isometric knee extension strength, as well as knee flexion strength, were statistically significant at angler velocity  $0^\circ$  and  $60^\circ$ . Regarding lower limb range of motion, both hip extension and flexion were also statistically significant in G compared with P. Conclusion This study showed that G possesses the strides by flexing knee deeply first followed by extension. It is assumed that greater muscle strength is necessary to manage the deep knee flexion and propel the lower limb farther in this stage and the results of isometric knee strength supported this finding. Furthermore, the knee joint movement at the mid phase of the 2nd stage will affect the angler difference in hip and ankle at the initial phase of the 3rd stage. For the lower limb ROM, the hip extension ROM after the initial knee flexion phase could be the key component. This suggested that the knee movement at the mid phase of the 2nd stage greatly influences the difference in 2SV.

## MUSCLE ACTIVATION OF WORLD-CLASS BREASTSTROKE SWIMMERS

Olstad, B.H.1, Vaz, J.R.2, Zinner, C.3, Cabri, J.1, Kjendlie, P.L.1

1: NSSS (Oslo, Norway), 2: UoL (Porto, Portugal), 3: GSU (Cologne, Germany)

Introduction Quantification of muscle activity can provide coaches and athletes with a better understanding of coordination, co-activation, muscle intensity and the relative muscle contribution to the overall propulsion in complex dynamic movements such as breaststroke (BR) swimming. It is also important in order to understand movement economy at the muscular level with increasing intensity. Therefore, the aim of this study was to investigate muscle activity with surface electromyography (EMG) in world-class (WC) BR swimmers performing at 60% and 100% of maximal effort. Methods Four WC BR swimmers (FINA points  $998 \pm 19$ ) with medalist at Olympic Games, World- or European-championship within the past two years participated; two females (age  $25.5 \pm 4$  yrs; height  $167 \pm 1.4$  cm; weight  $66.2 \pm 10.1$  kg) and two males ( $27.3 \pm 1.7$  yrs;  $188 \pm 2.8$  cm; weight  $86.6 \pm 0.8$  kg). They performed 25 m of BR at 60% and 100% of maximal effort. The muscle activity was recorded using waterproof electrodes and active sensors and recorded according to Olstad et al. (2014a) during 5-10 stroke cycles in triceps brachii (TB), biceps brachii (BB), trapezius (pars descendens) (TR), pectoralis major (pars clavicularis) (PM), gastrocnemius med. (GM), tibialis anterior (TA), biceps femoris (BF) and rectus femoris (RF) at 1000 Hz. Each stroke cycle was divided into three phases based on the leg kick; propulsion (PP), glide (GP) and recovery (RP). Paired t-tests were used for peak amplitude EMG, integrated EMG (iEMG) and average EMG per cycle/phase. Results The swimmers showed high reproducibility in terms of EMG peak value and time between two consecutive EMG peaks. At 60% intensity peak EMG amplitude was found during the PP for GM, TA, BF and RF, in GP for TB, and in RP for BB, TR and PM. At 100% the peak EMG amplitude changed for BB, TR and PM to the GP. The amplitude peak as well as iEMG was significantly higher for all muscles at 100% compared to 60% ( $p < 0.01$ ). Average EMG per phase showed the lowest activity during the GP for TR, GM, TA, BF and RF at 60% and 100%, except for GM showing least activity during the RP at 100%. The same muscles showed the highest activity during the PP. TB, BB and PM had the lowest activity during the PP at both 60% and 100%, and the highest activity during the GP. Discussion World-class BR swimmers show a very consistent EMG pattern across multiple stroke cycles and different velocities. The change in peak EMG amplitude for the upper body at 100% towards the GP of the legs can be used to reduce the intra-cyclic velocity variations in the stroke. Low EMG activity of the leg muscles during GP indicates an economical use of the muscles with relaxation during the GP as well as upper body at the PP. An increase for GM in GP at 100% can indicate a more active use to create a better streamline position of the feet. References Olstad BH, Zinner C, Cabri J, Kjendlie PL (2014a). ## MUSCLE ACTIVATION AND KINEMATIC DIFFERENCES BETWEEN FEMALE AND MALE ELITE BREASTSTROKE SWIMMERS

Grydeland, M., Olstad, B.H., Cabri, J., Kjendlie, P.L.

Norwegian School of Sport Sciences

Introduction Studies on muscle activation in swimmers are almost exclusively performed irrespective of sexes. In breaststroke (BR), potential differences in muscle activation between sexes are unknown. The aim of this study was to investigate muscle activity during the stroke cycle and different phases in BR at three levels of intensity (60, 80 and 100% of maximal effort) in female and male elite swimmers. Methods Nine elite breaststrokers (FINA points  $844 \pm 150$ ) participated; five females (age  $20.3 \pm 5.4$  yrs; height  $168.5 \pm 3.7$  cm; weight  $64.3 \pm 5.4$  kg) and four males ( $27.7 \pm 7.1$  yrs;  $186.5 \pm 2.9$  cm; weight  $84.8 \pm 2.2$  kg). The swimmers performed 25 m of BR at 60, 80 and 100% of maximal effort. Muscle activity was recorded using waterproof electromyography (EMG) electrodes and active sensors according to Olstad et al. (2014a) during 3-5 stroke cycles in triceps brachii (TB), biceps brachii (BB), trapezius (TR), pectoralis major (PM), gastrocnemius medialis (GM), tibialis anterior (TA), biceps femoris (BF) and rectus femoris (RF) at 1000 Hz. Each stroke cycle was divided into three phases based on the leg kick; propulsion (PP), glide (GP) and recovery (RP). Kinematics was recorded using 3D automatic motion tracking (Olstad et al., 2014b). Independent samples t-tests were used to compare integrated EMG (iEMG), cycle/phase and stroke length, stroke rate, velocity and knee angles during the different phases and the full stroke cycle. Results In a total of 96 iEMG measurements, significant differences ( $p < 0.05$ ) were only found for RP GM 100% and GP BF 80% where females had higher values than males, and for total iEMG in TA at 60%, RP TA 60% and 80%, and PP BB 80% where males had higher values. Of 51 kinematic measurements, differences were found in cycle

length at 60%, knee angle during GP for all effort levels (females higher), velocity during GP and time in PP at 100%. At 60-80-100% effort males had higher velocity in all three phases compared to females. Males had longer stroke lengths, but females had longer PP. Female swimmers spent more time in PP and RP while males had a longer GP at 60% effort. At 80 and 100% males decreased their GP time significantly more than females. At 60% effort females had higher stroke rate, but not at 80 and 100%. Males had significant larger knee angles in PP and RP, but not in GP. Discussion Significant differences in velocity and stroke-length were demonstrated between female and male BR swimmers. However, only few significant differences were found in muscle activity during the stroke cycle and the phases in BR. This indicates that factors other than muscle activation, contribution and interplay during the stroke cycles explain the sex differences in performance of elite breaststrokes. ### DEPENDENCE OF SPORTS RESULT IN JERK OF THE BAR FROM THE LEVEL OF PHYSICAL READINESS OF SPORTSMEN AND BIOMECHANICAL PARAMETERS OF MOVEMENT

Sivokhin, I., Fyodorov, A., Tapsir, M.

*Kostanay State Pedagogical Institute*

Introduction The sports result in weight lifting is substantially determined by a level of technical skill and physical readiness. Revealing of the most significant and informative parameters of technical and special physical readiness of sportsmen allows to obtain the objective data for development of more effective models of preparation and improvement of quality of work the account of correction of an orientation, structure and the contents of training employment, and also selection of more effective means of technical and physical preparation at various stages of becoming of sports skill. The purpose of research – definition of biomechanical parameters of technical equipment of jerk of a bar and parameters of special physical readiness, revealing of features of interrelation, and also studying of joint influence of parameters of readiness on result in jerk. Methods For achievement of an object in view research in which weight-lifters of various qualification in the age of 20-23 years (n=10) have taken part is carried out. Biomechanical parameters of technical equipment of jerk of a bar were determined with the help of the complex tool technique. The standard methods of mathematical statistics were applied to the analysis of results of research. Results The result in jerk has a high degree of interrelation with a parameter of the maximal force of muscles of the bottom extremities to what high factors of correlation between results in knee-bend and competitive results in jerk ( $r=0.85$ ) testify. The analysis of interrelation of result in jerk and in jumping tests testifies that the greatest sizes of factors of correlation have parameters in such tests as a jump upwards without burdening with fast switching in work of muscles of the bottom extremities from a conceding mode on overcoming ( $r=0.80$ ). This test allows to estimate a level of explosive force in a combination to ability of the sportsman effectively to use in movements of a similar sort energy of elastic deformation of the muscles-copular device. Discussion / Conclusion The analysis of results of research testifies to presence of close and significant interrelation of results in jerk and test exercises with dynamic characteristics of movement which are connected to performance of draft and undermining. So, value of the maximal effort on which efficiency of performance of undermining and as a whole productivity in jerk ( $r=0.86$ ) depends, has high positive connection as with the explosive force determined in jumping test ( $r=0.76$ ), and with the maximal any force determined in knee-bends with a bar of limiting weight ( $r=0.82$ ).

### COMPARISON OF CONCENTRIC FORCES BETWEEN TWO VERTICAL JUMPS ON LAND OR IN WATER

Chen, W.C., Chien, K.Y., Cheng, F.Y.

*Graduate Institution of sports equipment technology*

Introduction Water is an ideal environment for carrying out jumps, reducing impact force through buoyancy, but it could also provides a floating interface may affecting the force production during takeoff when bounce followed by dynamic squatting. Therefore, the purpose of this study was to investigate the peak ground reaction forces (GRF) during takeoff of squat jump (SJ) or countermovement jump (CMJ) between on land or in pool of water. Methods 14 male minor-league college volleyball players were recruited in this study (average height was  $175.68 \pm 3.90$  cm, the average body weight (BW) on land was  $64.14 \pm 4.72$  kg, and the aquatic BW was  $36.30 \pm 3.20$  kg). Before conducting the experiment, they were all measured the length from malleolus lateralis to trochanter major of the dominate leg for the water level in the swimming pool by an adjustable underwater platform. Then participates were asked to perform two jumps on land or in water randomly on an AMTI water-proof force measurement device. We recorded three successful SJ and CMJ in land and aquatic based condition and analyzed the peak GRF during takeoff of each jump. The force data were normalized by the BW in the condition. Furthermore, the condition-difference was calculated by water value divided by land. Repeated measures two-way ANOVA (analysis of variance) method was used to exam peak GRF of two jumps in two conditions and a pair t test was carried out for the ratio of jump forces between land and water conditions. Results The results were showed no significant interaction between jumps and conditions. The peak GRFs of SJ are  $3.16 \pm 0.37$  BW on land and  $4.93 \pm 0.83$  BW in water as well as those of CMJ are respectively  $2.51 \pm 0.28$  BW and  $3.93 \pm 0.51$  BW. The SJ forces are significantly higher than CMJ in both conditions. However, the GRF ratio of different conditions were no difference between SJ and CMJ ( $1.57 \pm 0.26$  vs  $1.59 \pm 0.31$ ). Discussion Although the BW in water is approximate 56.63% on land because of the buoyancy, the aquatic GRFs during takeoff are higher of SJ and CMJ by 1.56 and 1.57 times respectively. The concentric GRF usually refers exercise intensity. Therefore, that means jumping in water needs more force production to overcome water drag resistance than the gravity on land. However, the difference between land or water condition among SJ and CMJ are the same. Therefore, this finding suggests that aquatic jump regardless types are an alternative to exercise training on land. References Donoghue OA., Shimojo H, Takagi H. ### DIFFERENT ATTACHMENT POINTS OF RESISTED METHODS AND ITS CONSEQUENCES IN VELOCITY TRAINING: A DYNAMOMETRIC STUDY

Lemos, L.1, Martins, C.2, Silva, G.3, Conceição, F.3

1: UFPB, UNIPÊ (Brazil); 2: UFPB (Brazil); 3: FADEUP (Portugal)

Introduction: The use of special means and methods in order to improve the speed and acceleration has become a common practice in Athletics. However, few studies have analyzed the changes of different resisted means in relation to dynamic parameters and its consequences for competitive performance. The aim of this study is to determine the dynamometric variables from resisted methods when

athletes reach their maximum speed and to check whether the use of different attachment points induce changes in the pattern of the curves of the ground reaction force. Methods: From a force platform, 11 sprinters performed 3 speed exercises, in order to assess the ground reaction forces. Data were analyzed in Matlab and the time of the relevant moments in the force curves, forces magnitude, angles and ground reaction impulses of the support phase of the athletes were determined. Results: The observed results indicated that: (i) the use of resistive exercise time favors the increase in the propulsive phase, decrease in the braking phase and advance of the moment at which the local maximum peak braking and propulsive horizontal (ii) the use of the belt promotes increased propulsive impulses and shows to be the most suitable for the acceleration phase, (iii) the application of the vest promotes increased magnitude of the vertical force active and appears to be the most suitable for middle weathered the phase of maximum speed; (iv) the increase of vertical forces were more relevant to the distinction between elements faster and slower the normal race. Conclusion: In the studied sample, the use of resisted methods induced changes in the patterns of the curves of the ground reaction force. Contact: luis.training75@gmail.com

### MUSCLE ACTIVITIES IN LOWER LIMB AFFECT TO THE CRANK FORCE DURING MAXIMAL PEDALING

Tanaka, S.1, Hiratsuka, K.1, Tsunoda, N.2

1: Kokushikan University (Tokyo, Japan) 2: Graduate of Sport System, Kokushikan University (Tokyo, Japan)

Introduction The anaerobic power generation capacity during maximal pedaling affected by work load and pedaling frequency. It has been reported that muscle activity level was effected to the pedaling frequency. However, the characteristics of crank force due to the muscle activity in maximal pedaling with different work load is not clear. Therefore, the purpose of this study was to investigate the crank force and efficiency of pedaling produced by the muscle activities in lower limb during maximal pedaling. Methods Subjects were 21 collegiate males. The anaerobic power, crank force and angular velocity were measured using a cycling ergometer and a custom-made measurement system. Subjects performed maximal pedaling for 10s with loads of 5%kp (light load) and 10%kp (heavy load) to body weight. In addition, ratio of anaerobic power per crank force (AP/CF ratio) was calculated in all the subjects. Lower limb muscle activities of rectus femoris, vastus medialis, vastus lateralis biceps femoris, tibialis anterior and gastrocnemius were measured by surface electromyography (EMG). Moreover, crank force per integrated EMG ratio (CF/iEMG ratio) as an efficiency of pedaling was calculated for all subjects. Results The crank force was closely related to the anaerobic power in light and heavy loads. The AP/CF ratio on heavy load was significantly higher than that of light load. The muscle activity pattern of the rectus femoris and biceps femoris under both loads were significant difference in up stroke phase. Moreover, under the light load, CF/iEMG ratios of all muscles were significantly lower value due to increased crank angular velocity. On the other hand, no significant difference was observed in the CF/iEMG ratio of the knee extensors muscles. Discussion In this study, the crank force was closely related to the anaerobic power in maximal pedaling with light and heavy loads. A significant difference of muscle activity pattern were observed in hip and knee flexion phase in spite of work load. And also, efficiency of pedaling was differed by work load. From these results, it was suggested that the crank force produced by muscle activity may affected to the pedaling efficiency during maximal pedaling. References Hug F, Dorel S. (2009), J. ### STRUCTURAL AND CONTRACTILE PROPERTIES OF THE THIGH MUSCLE IN SPRINTER AND LONG DISTANCE RUNNERS

Hiratsuka, K.1, Miyazaki, D.1, Shimojyu, S.1, Okada, M.1, Simunic, B.2, Djordjevic, S.2, Tsunoda, N.3

1: Kokushikan University (Tokyo, Japan) 2: University of Primorska (Koper, Slovenia) 3: Graduate of sport system, Kokushikan University (Tokyo, Japan)

Introduction It is well known that structural and functional characteristics of the lower limb muscle was affected by specific training mode. Especially, in muscle fiber properties, sprinter has exceed fast twitch fibers, muscle contraction velocity of sprinter was higher than long distance runners. However, contractile property and size of the belly in thigh muscle were not cleared. Therefore, the purpose of this study was to clarify the muscle structure and contractile properties of the thigh muscle in sprinters and long distance runners. Methods Subjects were 20 sprinters (SP; aged 20.3±1.9yrs, height 171.4±4.8cm and weight 62.8±5.4kg), 14 long distance runners (LDR; aged 19.6±1.0yrs, height 170.7±4.6cm and weight 55.7±3.8kg) and 9 collegiate students of physical education (CON; aged 20.7±1.3yrs, height 176.5±3.7cm and weight 72.6±13.5kg) as control group. Muscle belly in Rectus femoris (RF), Vastus medialis (VM), Vastus lateralis (VL) and Biceps femoris (BF) were measured by ultrasonic scanning method. Contractile response of the muscle belly was recorded by TMG method. The displacement sensor was positions at the surface of the belly in each muscles. Single twitch stimuli with two surface electrodes were used to obtain the dynamic response. Three contractile parameters of delay time (Td), contraction time (Tc) and maximal displacement of the muscle belly (Dm) were analyzed by TMG method. Results Muscle thickness of RF, VM and VL were not significant difference among the groups. Whereas, Thickness of the BF in LDR showed significant lower values than SP and CON groups. In SP, the Td of the muscle belly twitch response of RF (22.9±2.6ms), VM (19.7±1.7ms) and BF (22.1±2.0ms) were significant lower than that of LDR and CON groups. Td of LDR was observed highest values in VL (22.6±1.9ms). Tc value of RF in SP (25.3±4.9ms) was lower than that of LDR (29.4±3.2ms). Also, same tendency was observed in VM (21.8±2.8ms) and BF (27.6±10.4ms). Dm of muscle belly of each muscles were not differed among the groups. Discussion In this study, it is cleared that muscle thickness as a structural characteristics was significant differed between SP and LDR in BF. Whereas, Td and Tc as a contractile properties of muscle belly except for VL in thigh were significant shorter in SP than other groups. From these results, it was considered that contraction parameters using TMG method may evaluate the muscle contractile properties due to athletic training modes. ### CHANGES IN BILATERAL ASYMMETRY OF PEDALLING POWER AND MUSCLE ACTIVITY DURING 30 SECONDS ISOKINETIC SPRINT CYCLING

Rannama, I., Pedak, K., Port, K., Bazanov, B.

Tallinn University

Introduction Notable asymmetry in bilateral biomechanical patterns of the pedalling has been declared by earlier studies. It seems that effort increase, due to higher power output or accumulated fatigue, improves the pedalling symmetry of the crank torque production (Carpes et al., 2010), but there are also opposing findings (Bini and Hume, 2014). It is noted that pedalling kinetics asymmetry may not be related to bilateral differences in the muscle activation magnitude and its variability (Carpes et al., 2011). The purpose of present study

was to compare muscle activity and pedalling power patterns between dominant (DO) and no dominant (ND) leg and examine the changes in asymmetry during fatiguing. Methods The pedalling power (POW) and force production smoothness (PS- mean and peak effective force ratio in %) and EMG of VL, RF and BF of seventeen competitive cyclists were measured bilaterally during maximal 30s isokinetic seated cycling test with the cadence of 100 rpm. Asymmetry index (AI%) between DO and ND side in normalized RMS EMG amplitude, EMG median frequency (MF), POW and PS of first and last 5 second period were computed and statistical significance of differences between DO and ND side and AI% in start and end part of the test were examined. Results The DO side POW and PS values were significantly ( $p < 0.05$ ) higher than ND in start (POW:  $524 \pm 96$  v  $466 \pm 81$ ; PS:  $33.8 \pm 2.9$  v  $30.7 \pm 4.2$ ) and end (POW:  $349 \pm 56$  v  $335 \pm 48$  W; PS:  $32.3 \pm 3.7$  v  $29.8 \pm 4.5\%$ ) of the test. Lateral POW AI was reduced from  $11.4 \pm 13.2$  from start to  $3.9 \pm 5.8\%$  in the end, PS AI did not change. No dominance dependent differences were found in normalized EMG amplitude and MF values in initial part of the test, but at the end of the test was noted significantly lower EMG amplitude in BF of DO leg. No significant changes were found in AI of EMG parameters between start and end part. Discussion The results of present study indicate that asymmetry in pedal force patterns is leg dominance dependent and decrease with fatiguing, this is in line with previous findings (Carpes et al., 2010). At the same time no directional asymmetry and significant systematic change in AI was found in EMG patterns. It supports Carpes et al. (2011) findings that in incremental and constant load tests pedalling force asymmetries in favour of the preferred leg during pedalling are not directly related to the magnitude of muscle activation. ## THE DIFFERENCING OF STRING TENSION ON HITTING PERFORMANCE IN BANMINTON ATHLETE

Vanasant, T.

*Sports Authority of thailand*

THE DIFFERENCING OF STRING TENSION ON HITTING PERFORMANCE IN BANMINTON ATHLETE Introduction String tension is very important during badminton game because it is a last part of the racquet to be contact a shuttlecock and. The tension will result directly to bouncing and landing target of the shuttlecock. So, appropriate string tension would result in a more effective in badminton game. The purpose of this study was to investigate the effect of string tension on hitting performance in badminton athlete. Methods Three reflective markers was attached on dominant arm of athlete's skin: Shoulder, elbow and Wrist. Marking a reflective tape on shuttlecocks base to determine velocity. Athlete selected a racquets randomly with a different in string tension (22, 26, 30 pounds / ft<sup>2</sup>) that confirmed tension after stringing by using sound frequency analysis. Then, athlete was request to hitting 10 times for each tension by using jump smash skill. The data was recorded via 4 high speed cameras that operating at 500 Hz. Screening 5 times as a perfect hitting to analyze arm angular velocity and shuttlecock velocity when passing a reference position. All Data were digitized and smoothed by using cut of frequency at 200 Hz. A one-way ANOVA (1x3) design with repeated measure was applied to examine the possible interaction between each string tension. Results The results showed that an average arm angular velocity increased when using higher string tension. (average velocity  $742.29 \pm 5.71$ ,  $770.96 \pm 4.58$ ,  $797.97 \pm 7.59$  deg/sec. respectively). However, there was no significant difference in the speed of the shuttlecock at a reference position. Discussion Our study showed a relationship when the tension was changed higher, it will be effect athlete increased their angular velocity respectively to maintain a speed of the shuttlecock. This result is based on the theory and research in practice that has previously said that the less tension will provide faster speeds than the higher tension (Brody, 1979; Brannigan & Adali, 1980; Bower & Cross, 2005;). In competition, this factor may have effect on achievement or make an advantage for athletes. References Brody, H. ## KNEE INJURY ASSESSMENT USING SUBJECT-SPECIFIC BIOMECHANICAL MODELS OF HUMAN KNEE JOINT

Goebel, R.1, Orsi, A., Hashemi, H.N.2, Vaziri, A.2

*1 Qatar University, Doha-Qatar, 2 Northeastern Univeristy Boston-USA*

Introduction: Finite element (FE) models of the knee joint were developed to study the mechanics of soft tissue injury. The main tissues of interest are ligaments and articular cartilage. An ACL tear occurs over 250,000 times annually; costing over \$1 Billion in the U.S (1). Theories surround how these injuries occur, such as motion combinations, unbalanced musculature, etc. Subject specific injury analysis is a novel method to determine the motions to lead to tissue failure in individuals. Subject specific injury mapping has not been performed using FE modeling. The need for individualized injury detection stems from the unique tissue geometries of each patient. This study describes the technique developed to detect individualized injuries. Method: We developed a robust protocol for building subject-specific biomechanical models of the human knee joint. Magnetic resonance imaging, motion analysis and force platform data in conjunction with detailed 3D finite element models were used in the construction of each biomechanical model. The proposed protocol allows estimation of stresses, forces and contact kinetics in different knee elements during various activities. Results: In this investigation the knee undergoes sudden displacements and rotations, as typical in sports. The posterolateral bundle of the ACL demonstrated higher rupture susceptibility than the anteromedial bundle. The average varus angular displacement of ACL failure was 46.6% lower compared to the average valgus angular displacement. Femoral external rotation (ER) decreased the frontal plane angle required for ACL failure by 27.5% compared to femoral internal rotation. Articular cartilage damage was shown to initiate prior to ACL failure during valgus failure. The simulations demonstrating higher ACL injury susceptibility, ER and valgus, showed cartilage damage in these regions. Conclusion: Our study provides new insight into the mechanisms of tear initiation and propagation in knee ligaments and cartilage damage. The results show the ACL most likely to tear in ER, combined with valgus. Our simulations correlate well with reported ACL/cartilage injury combinations from literature. This increased understanding will improve surgical procedures, and training programs can address the avoidance of harmful knee motions in athletes (2). References: (1) Boden, B. P., Griffin, L. ## RELATIONSHIP BETWEEN MECHANICAL CHARACTERISTICS OF THE PATELLAR TENDON AND BODY SIZE IN HUMAN

Hegyí, A., Péter, A., Ureczky, D., Tihanyi, J.

*University of Physical Education, Budapest, Hungary*

**Introduction.** It was found previously that mammals with larger body size have stiffer tendons connected to extensor muscle groups compared to their smaller companions. The main aim of this study was to investigate the relationship between mechanical characteristics of the patellar tendon and body height and weight in human. **Methods.** 77 young recreational athletes (38 women and 39 men; age=20.95±1.33 yrs) participated to this study. The length of the patellar tendon was measured by ultrasonography (US) at 0, 20, 40, 60, 80 and 100% of the maximal voluntary isometric contraction in a computerized knee dynamometer at 60 degrees of knee joint angle. The length at the end of the toe region was also defined and deemed to be the rest length. Patellar tendon force was calculated by the torque divided by the tendon level arm based on corresponding data in the literature [1]. Stiffness was defined as the slope of the force-elongation curve. Strain value was calculated as a percentage of the elongation relative to the rest length. Length of the patellar tendon was validated by magnetic resonance imaging on 13 subjects. Relationship between the rest length, maximal elongation, body height and weight were tested by Pearson's correlation. Significance level was set at  $p<0.05$ . **Results.** Rest length of the patellar tendon was 49.6±5.0 mm. The use of US to measure patellar tendon length was supported by the validation (ICC=0.93). At maximal voluntary knee extension (193.8±62.1 Nm) the tendon elongated by 6.10±2.43 mm. The strain was 12.8±6.25%. Stiffness of the tendon was 820.5±364.2 N/mm. Rest length showed significant relationship with the body height ( $r=0.58$ ,  $p<0.001$ ). Stiffness correlated with body weight and height ( $r=0.49$ ,  $p<0.01$ ;  $r=0.42$ ,  $p<0.01$ ; respectively). Stiffness was inversely proportional to the maximal elongation ( $r=-0.48$ ,  $p<0.01$ ). **Discussion.** In previous studies the strain of different tendons in human varied between 3% and 13%. It shows that the elongation of the patellar tendon is relative high compared to other tendons in the body. Correlations between stiffness and body size suggest that the tendon adapts to the body weight and height which provide larger inertia at the knee joint. Tendons linked to extensor muscles seem to have larger stiffness that may be due to the continuous load in locomotion. Our results show that patellar tendon characteristics relate to the body size similar to the mammals in general, however the strength of the relationship suggest that other factors such as training can substantially alter the mechanical properties of the tendon. ## KINETIC CHARACTERISTICS OF KICKING MOTION BETWEEN FOOTBALL PLAYERS WITH OR WITHOUT GROIN PAIN – FROM MOTION ANALYSIS OF THE KICKING LEG AND THE TRUNK DURING INSTEP KICK-

Murakami, K.I, Oda, K.I, Yamaguchi, T.I, Takahashi, Y.I, Ogaki, R.I, Shimada, S.I, Miyakawa, S.I, Nagamoto, H.I

*1:Sendai Univ.2:Showa Univ.3:Univ of Tsukuba.4:Tohoku Univ.*

**【Introduction】** Although the incidence rate of groin pain among football players is said to be low, the treatment becomes challenging as it may become chronic once it develops. It has been reported that kicking motion relates to the groin pain. However, its mechanism is still unclear. The purpose of this study was to reveal the characteristic motion of kicking between football players with or without groin pain. **【Methods】** Eight players with the history of groin pain in the past year (GP) and nine players without the groin pain (NP) were included in the study. All the players kicked the ball 3 times to the target, which was 10 m away, by instep kick after total of 39 body markers (based on Plug-in gait maker set) were applied. Kicking motion was analyzed by three-dimensional motion analysis (Vicon T20x20; sampling 250 Hz) and mutually-synchronized force plate (Kistlerx1; sampling 1000 Hz) followed by analysis of the kicking leg and the stance leg using motion analyzing software Vicon Nexus 1.7. Analyzing interval was from the toe off of the kicking leg (TO) through the maximum hip extension of the kicking leg (MHE). **【Results】** The maximum flexion torque of the hip from MHE to BI in the kicking leg was not significant between the GP and the NP group. However, maximum knee extension torque to BI of the kicking leg in the GP group (164.14 ± 46.05 N/kg) was significantly higher than that of the NP group (113.26 ± 90.30 N/kg) ( $p<0.05$ ). Relative rotation angle of the upper and lower trunk in the GP group (9.1±6.4°) was significantly smaller than that of the NP group (19.2 ± 5.7°) ( $p<0.05$ ). Ankle dorsiflexion angle of the pivot leg was significantly smaller in the GP group (FC 13.2 ± 7.0° and BI 7.7 ± 13.2°) than that of the NP group (FC 19.7 ± 10.1° and 16.2 ± 10.2°) ( $p<0.05$ ). Average speed of the translation direction of the body mass center was significantly smaller in the GP group (during FC-BI 2.97 ± 0.30 m/sec) than that of the NP group (during FC-BI 3.19 ± 0.30 m/sec) ( $p<0.05$ ).

**【Discussion】** The distinctive point about instep kick in the GP group was that it depended on knee extension torque of the kicking leg and the rotation angle of the upper and lower trunk was less compared to the NP group. In addition, decreased average speed of FC to BI phase was observed compared to TO to FC phase, although average speed of the same phase increased in the NP group. These results may suspect that the groin pain occurrence may have a relationship with kinetic stress of the knee extensors, and motion depending on the kicking leg because of ineffective motion and decreased speed. Also, the fact that the ankle dorsiflexion angle was smaller in the GP group from FC to BI phase, body mass center maybe leaned backward compared to the NP group. **【Reference】** 1) Hölmich P. et al.(2004). *Br J Sports Med*, 38(4), 446-451. 2) Gilmore J. ## ACCURATE EVALUATION OF JOINT FORCES AND MOMENTS IN WHOLE BODY JOINTS DURING GAIT USING WEARABLE INERTIAL MOTION SENSORS AND IN-SHOE PRESSURE SENSORS

Kim, Y.H.I, Khurelbaatar, T.I, Kim, K.I

*Kyung Hee University*

**Introduction** Integrated systems of optical cameras and force plates have been conventionally utilized for human motion analyses, including joint kinematics and kinetics, due to its accuracy. However, it is limited to the laboratory work space required by the camera and force plate system. To analyze the human motion of daily activities or sports outside of the laboratory, wearable systems consisting of inertial motion sensors and in-shoe pressure sensors have been recently developed. In this study, the joint forces and moments in whole body joints during gait were evaluated using a wearable motion analysis system consisting of an inertial motion measurement system and an in-shoe pressure sensor system. **Methods** Walking motions were captured from 5 healthy male subjects using wearable and conventional systems simultaneously. The wearable system consisted of MVN@ inertial motion capture system (Xsens Technologies, Netherlands) with 17 inertial and magnetic sensors and Pedar-X@ (Novel gmbh, Germany) in-shoe pressure system. The conventional system composed of Hawk@ digital system (Motion Analysis, USA) with 10 cameras and 4 MP4060@ force plates (Bertec Corporation, USA). In the wearable system, the orientations of each body segment, vertical component of ground reaction force and center of pressure data were recorded. The positions of 37 anatomical landmarks were then calculated from the orientations of body segments using the imple-

mented software MVN®. Inverse dynamic analyses were conducted using Matlab® with a dynamics model of the human whole body. Results The joint forces were strongly correlated between the wearable system and the conventional system with small normalized root mean squared error (NRMSE) values in all joints ( $r=0.71-0.99$ ;  $NRMSE=5.5\%-6.2\%$ ). The lower extremity showed significantly higher correlation ( $r=0.99$ ) than the trunk ( $r=0.80-0.81$ ) and the upper extremity ( $r=0.71-0.79$ ). The joint moments showed good agreement with strong correlations ( $r=0.70-0.98$ ) in all joints except the shoulder ( $r=0.49$ ). The NRMSEs of the joint moments were acceptable (8.0%-16.9%) in all joints except the shoulder (24.1%) and elbow (35.2%). Discussion The measurements of both the joint forces and joint moments in human whole body joints using wearable inertial motion sensors and in-shoe pressure sensors were feasible for normal motions with a low speed such as walking, especially in the lower extremity joints. The portability and mobility of this wearable system can provide wide applicability in both clinical and sports motion analyses. Contact [yoonhkim@khu.ac.kr](mailto:yoonhkim@khu.ac.kr)

## BALANCE RECOVERY AFTER RANDOM PERTURBATIONS – INTERACTION EFFECTS OF DIFFERENT STIMULUS VARIABLES

Freyler, K., Ritzmann, R., Gollhofer, A.

*University of Freiburg*

Introduction Setups with translating platforms representing a realistic simulation of slips by generating external perturbations are used in balance research to investigate underlying mechanisms of compensatory responses (Blake et al. 1988). Previous studies have been executed in static, bilateral balance paradigms with predictable, univariate settings. However, most falls happen in transient phases during single limb support, influenced by interdependent variables such as unpredictable amplitude, velocity or direction of stimulus origin (Horak et al. 1997). To detect phasic and segmental neuromuscular characteristics and kinematic strategies of compensatory responses in a dynamic balance paradigm, this study aimed to assess interaction effects of direction, amplitude and velocity during randomly applied perturbations on center of pressure (COP) displacement, joint kinematics and electromyographic (EMG) activity. Methods While balancing on one leg on a free-swinging platform, randomly allocated surface translations varying in direction (anterior-posterior (ap), medial-lateral (ml)), amplitude (2vs.3cm) and velocity (1.1vs.1.8m/s) were analyzed in 20 subjects regarding COP displacement and velocity, ankle, knee and hip joint excursions and EMG activity during short (SLR), medium (MLR) and long latency response (LLR) of selected shank and thigh muscles. Results Phases: SLR and MLR were scaled to increased velocity; LLR was scaled to increased amplitude ( $P<0.05$ ). Segments: Phasic interrelationships were accompanied by segmental distinctions: distal muscles were used for fast compensation in SLR, proximal muscles responded in LLR ( $P<0.05$ ). Kinematics: Ankle and knee joint deflections compensated for ap perturbations, hip joint deflections were used to restore equilibrium after ml perturbations ( $P<0.05$ ). Discussion Outcomes provide evidence that amplitude- and velocity-induced phasic and segmental preferences exist to regain equilibrium after surface translation: muscles of the distal segment govern the quick, non-functional response, whereas muscles of the proximal limb serve as delayed stabilizers to functionally prevent falling (Gollhofer et al. 1989). Regarding the kinematic strategy, dependencies exist concerning perturbation direction: a distal strategy is used for ap stabilizations, whereas the proximal segment is used to compensate for perturbations in the frontal plane. In conclusion, interaction effects indicate that compensatory responses are based on complex processes including different postural strategies characterized by phasic and segmental specifications, precisely adjusted to the type of balance disturbance. ## RESISTANCE TRAINING INDUCES BENEFICIAL BIOMECHANICAL ADAPTATIONS IN OLD TENDON RATS

Marqueti-Durigan, R.C., Almeida, J., Durigan, J.L.Q., Nakagaki, W.R., Guzzoni, V., Boghi, V., Renner, A., Selistre-de-Araujo, H.S.

*Universidade Federal de Mato Grosso do Sul - UFMS; Universidade de Brasília, UnB - University of Western São Paulo*

The ageing process causes significant reductions in functionality, especially the muscular system which in turn also affects the tendons, increasing the chances of injuries. One way to reduce this process is through exercise training. Thus, the aim of this study was to determine the effect of resistance training (RT) in tendons of aged rats. The animals were divided into four groups: young sedentary (YS,  $n = 5$ ), young trained (YT,  $n = 5$ ), old sedentary (OS,  $n = 5$ ) and old trained (OT,  $n = 5$ ). Trained rats were submitted to the climb protocol with progressive load for 12 weeks. After the training period, the calcaneal tendon (CT); superficial flexor tendon (SFT) and deep flexor tendon (DFT) were removed for biomechanical analyses. The results demonstrated that RT may be able to prevent progressive decrease in tendon function during ageing. Although RT has prompted significant biomechanical changes in trained aged rats, there was no increase in cross-sectional area, either a reduction in tendon stiffness. Therefore, the tendons are adapted according to the stimulus, in this case the OT showed better biomechanical responses when compared with OS. Thus, the RT may be an excellent strategy to maintain the tendon properties during ageing.

## THE EFFECT OF LOWER EXTREMITY MASSES AND VOLUMES ON THE BALANCE PERFORMANCE OF ATHLETES

Akil, M.1, Celenk, C.2, Aktug, Z.B.3, Marangoz, I.4, Yilmaz, T.1, Top, E.1

*Uşak University*

1: UUSBF (Usak, Turkey), 2: EUBESYO (Kayseri, Turkey), 3: NUBESYO (Nigde, Turkey), 4: KMSIUMYO (Kahramanmaraş, Turkey) Introduction Balance is a measure of whole body performance, which requires, in addition to motor output, three interacting sensory systems: the vestibular, visual and somatosensory system (Mergner and Rosemeier, 1998). Our study aims to investigate the effects of lower extremity mass and volume characteristics of elite athletes on the balance performances. Methods The study has included 42 elite athletes totally with an average age of  $23.45\pm 2.50$  years, average height of  $173.64\pm 6.96$  cm, average weight of  $79.55\pm 14.19$  kg and average body mass index of  $26.22\pm 3.06$ . The calf, femur, foot and leg volumes of the subjects included in the study have been determined by means of Frustum method (Sukul et al., 1993); however, calf, femur, foot and leg masses of the subjects have been determined by means of Hanavan method (Kwon, 1998). The balance performances of the athletes have been measured by using Biodex Balance System. The balance performances have been scored by double leg (DL) as dynamic and static. Dynamic balance performances have been measured in three levels as good, moderate and low. Results When the balance performances of volumes and masses of calf, femur, foot and leg of the athletes have been compared, a significant difference between oscillation indexes and static balances has not been detected ( $p>0.05$ ). When dynamic balance performances have been evaluated, it has been found that there is a significant difference in low-level balance test ( $p>0.05$ ), and a positive difference has been found between the masses and volumes of calf ( $r= .437$ ), femur ( $r= .609$ ), foot ( $r= .344$ ) and leg ( $r= .607$ ) in terms of good and moderate level of balance performances ( $p<0.01$ ,  $p<0.05$ ). Discussion According to the

results obtained, the masses and volumes of calf, femur, foot and leg of the athletes have affected the balance performances and, as the difficulty level of the balance performance increases, the lower extremity mass and volumes affect the balance performance much more. In conclusion, it has been found that lower extremity masses and volumes affect the balance performance of the athletes positively, and lower extremity mass and volumes are required to be improved enough in the branches that put an emphasis on balance. ### CHANGES IN ENERGY COST AND STRIDE PARAMETERS DURING A LONG DISTANCE EXERCISE IN RUNNING

Deflandre, D.1, Miny, K.1, Dardenne, N.2, Bury, T.1

*université de Liege*

Introduction In running, biomechanical and physiological parameters change during the exercise (Candau et al., 1998 ; Hunter et Smith, 2007). But the relationships between these two categories of changes are not well known (Avogadro et al., 2003). Therefore, the aim of this study was to analyse relationship between changes in both energy cost (EC) and stride parameters (SP) during a long distance run. Methods 15 male athletes (age :  $34 \pm 9$  years old ;  $VO_{2max}$  :  $62 \pm 5$  mlO<sub>2</sub>/min/kg ; MAS :  $18,9 \pm 0,8$  km/h) realized a maximal effort test and, within  $7 \pm 2$  days, an exhaustive submaximal run at 80% of their maximal aerobic speed (MAS) on a treadmill. During this test, SP (contact time (CT), aerial time (AT), stride length (SL) and stride frequency (SF)), with Optojump Next system (Microgate), and physiological parameters (heart rate, lactate concentration, EC (from oxygen consumption)), were measured each five minutes from the start to the end of the exercise. Results During the run at 80% of  $VO_{2max}$  ( $15,1 \pm 0,5$  km/h ; time :  $87 \pm 25$  min ; distance :  $21 \pm 6$  km), as regards biomechanical parameters, only CT increased significantly (from  $0,208 \pm 0,02$  ms at the beginning to  $0,214 \pm 0,02$  ms at the exhaustion) during the exercise ( $p < 0,05$ ). The other SP didn't show any significant change during the submaximal test even if AT and SF tend to decrease while the SL tends to increase. As regards physiological parameters, only heart rate increases significantly (from 84% to 93% of maximum heart rate) while lactate concentration, EC, and therefore, oxygen consumption, increase but not significantly. No correlation have been found between SP and EC. Discussion The aim was to study the relationship between changes in the SP and the EC during a long distance exercise in running. We could hypothesize that fatigue generated by the intensity of the exercise could change the SP and thus, induce an CE increase. However, no correlation could be demonstrated. The disparity of results reflects the complexity of the influence of SP on RE. It would be interesting to further study by EMG analysis, especially during the phase of flight. This phase seems to have an influence on the energy cost (Santos-Concejero et al., 2014). References Avogadro P, Dolenc A, Belli A (2003). *Eur J Appl Physiol*, 90, 165-70. ### A SCOTT BENCH WITH AN ERGONOMIC PROFILE IMPROVES POSTURE DURING ARM CURL EXERCISE

Benvenuti, P.1, Biscarini, A.2, Busti, D.2, Zanuso, S.3

1: University of Verona, 2: University of Perugia (Italy), 3: University of Greenwich (UK)

Introduction: The barbell arm curl executed on Larry Scott bench (preacher arm curl) is a popular strengthening exercise for elbow flexor muscles. It is a single-joint, open kinetic-chain, auxiliary exercise, which allows a high degree of control over elbow kinematics (elbow alignment, range of movement, angular velocity and acceleration) and selective brachialis and biceps brachii strengthening, avoiding compensatory muscle activations. However, this exercise displays a drawback related to the exerciser posture. Indeed, the flat shape of Scott bench induces a considerable shoulder girdle protraction and an enhanced kyphotic curvature of the thoracic spine. The aim of this work is to assess whether an ergonomic design of the thorax pad can improve the posture maintained during the preacher arm curl exercise. Methods: We have designed and built up on a plated loaded machine (Purestrength by Technogym, Cesena-Italy) a curved ergonomic Scott bench to accommodate the thorax profile and improve the posture during the preacher arm curl exercise. Kinematic analysis and inclinometers were applied to measure shoulder protraction and thoracic kyphosis in 15 subjects performing a preacher arm curl with the machine provided by the classic flat pad. The same measures were repeated after replacing the flat pad with the new ergonomic one. Results: Compared to the standard flat pad, the new ergonomic pad decreased significantly ( $p < 10^{-3}$ ) both shoulder protraction (of about 4 cm) and thoracic kyphosis (of about 6 degrees). Discussion: The recorded postural changes induced by the ergonomic pad can, in turns, increase the sub-acromial space, improve the overall stabilization of the shoulder girdle, expand the rib cage, improve the breathing function, produce a natural decompression of inter-vertebral disks and facilitate a correct alignment of the cervical spine. Ultimately, the new ergonomic pad can significantly improve the poor posture induced by the standard flat Scott bench. References: Borstad JD. (2006). *Phys Ther*, 86, 549-557. ### THE EFFECT OF SOMATOTYPE CHARACTERISTICS OF ATHLETES ON THE BALANCE PERFORMANCE

Top, E.1, Celenk, C.2, Marangoz, I.3, Aktug, Z.B.4, Yilmaz, T.1, Akil, M.1

*Uşak University*

1: UUSBF (Usak, Turkey), 2: EUBESYO (Kayseri, Turkey), 3: KMSIUMYO (Kahramanmaraş, Turkey), 4: NUBESYO (Nigde, Turkey) Introduction Balance is fundamental in performing sport skills or even daily activities. Balance must be maintained before, during, and after performing the skill. Balance is a generic term that describes the dynamics of body posture in preventing falling (Rad et al., 2013). Our study aims to investigate the effects of somatotype characteristics of elite athletes on the balance performances. Methods The study has included 46 elite athletes totally with an average age of  $24.04 \pm 3.14$  years, average height of  $173.82 \pm 7.01$  cm, average weight of  $80.31 \pm 14.07$  kg and average body mass index of  $26.42 \pm 3.05$ . The heights, body weights, skinfold thicknesses, periphery and diameter of skinfold of the subjects included in the study have been measured and somatotype characteristics have been determined by using Heath-Carter method (Carter, 2002). The balance performances of the athletes have been evaluated by using Biodex Balance System. The balance performances have been determined as dynamic and static. Dynamic balance performances have been measured in three levels as first, second and third. It has been determined that the dynamic balance performance of the athletes has changed in accordance with the endomorph, mesomorph and ectomorph characteristics of the athletes; however, static balance performances have not changed. Results Accordingly, no difference has been observed between the oscillation indexes and static balances of the athletes ( $p > 0.05$ ), whereas

a significant difference has been found as the balance level increases in accordance with the endomorph, mesomorph and ectomorph characteristics of the athletes in terms of dynamic balances ( $p < 0.01$ ,  $p < 0.05$ ). Thus, the best balance scores belong to the athletes with endomorphic characteristics; the second best scores belong to athletes having mesomorphic characteristics and the lowest scores belong to the athletes with ectomorphic characteristics. Discussion According to the results obtained, the somatotype characteristics of the athletes affect the balance performances and the best results belong to the athletes having endomorphic characteristics followed by the athletes having mesomorphic and ectomorphic characteristics, respectively. In conclusion, it is assumed that the athletes having endomorphic characteristics may be more successful in the sports branches that put an emphasis on the balance. ## BIOMECHANICAL PREDICTORS OF WRIST SHOT SUCCESS IN FLOORBALL

Lazzeri, M.1, Kayser, B.1, Armand, S.2

(1) *Institute of Sports Sciences*, (2) *Willy Taillard Laboratory of Kinesiology*

**Introduction** Floorball is a recent sport that is becoming increasingly popular. There is lack of floorball specific biomechanical knowledge on its technical gestures to instruct coaches and to train players. The objective of this study was to identify biomechanical predictors for accuracy and speed of the wrist shot, comparing two different starting feet positions. **Methods** Ten floorball players (nine recreational and one elite) performed 2 series of 10 stationary wrist shots, in two different positions (FB: feet at a right angle to the end of the stick, oriented towards a target; LB: feet parallel to the end of the stick and to the target). A 12-camera motion capture system tracking reflective markers on key landmarks was used to record participant and stick kinematics. Accuracy of the shoot was quantified by distance of impact from target centre. Ball speed was measured at the same moment as accuracy. Player gaze was determined from head position. **Results** Regarding shot accuracy, results showed that FB position allowed a better accuracy than LB position (FB =  $0.25 \pm 0.01$  m ; LB =  $0.32 \pm 0.02$  m ;  $p = 0.007$ ). Regarding ball speed, there was no significant difference between the two positions (FB =  $22.43 \pm 0.58$  m•s<sup>-1</sup> ; LB =  $22.90 \pm 0.58$  ms<sup>-1</sup> ;  $p = 0.485$ ). More accurate players have a greater range in rotation of the head in relation to the thorax, coupled with practically non-existent absolute rotation of the head. Correlation coefficients suggested that ball speed was mainly influenced, in both positions, by the flexion of the supporting leg (ankle, knee and hip) and by the rotation of the trunk, especially for the angle formed by the pelvis and the shoulders (spine), just like in ice hockey or golf (Michaud-Paquette et al., 2011). **Discussion** The results suggest that feet position in floorball has an important influence on shot accuracy. Players' accuracy was significantly better when the feet were oriented towards the net. In a game situation, when the player is moving, this type of shot is more natural as it presents continuity with the running. The comparison between the recreational and elite players showed important differences in these technical skills. The best players settle their eyes on the target from the start to the end of the shooting movement. This strategy seems to allow better accuracy, provided that the player masters the technical skills necessary to control body and stick without visual aid. **References** Michaud-Paquette, Y., Magee, P., Pearsall, D., & Turcotte, R. ## EFFECTS OF THE LEVEL OF MUSCLE PRACTIVATION OF THE LOWER EXTREMITIES FROM DIFFERENT JUMP PATTERNS.

Shin, J.M., Lee, B.K.

*Sangmyung University*

**Introduction** Preactivation of muscle before eccentric phase might be a major factor enhancing SSC during a jump performance (Kallio, Linnamo & Komi, 2004). The different jump patterns may develop a different level of preactivation of the lower extremities muscle, and change kinetic and kinematic variables consequently. Therefore, the aim of this study is to investigate the relationship between the level of muscle preactivation and jump height as a result of jump performance. **Methods** Infrared cameras, a force platform and EMG were used to analyze the jump tasks of 10 male college students. The subjects were instructed to jump randomly on the force platform or jump box with a counter movement jump (CMJ), a drop jump from a jump height of the 40cm (DJ), and a counter movement jump including a preliminary jump (PJ). EMG activities and vertical ground reaction force (VGRF) and position data tracking the markers were measured. The integrated EMG (iEMG) of preactivation phase was calculated to show the level of the preactivation of lower extremity muscles. Repeated-measures ANOVA was used to compare three different jumps ( $p < 0.05$ ). **Results** The peak VGRF was significant increasing in DJ during the propulsive phase ( $p > 0.05$ ). There were no significant differences in jump height ( $p < 0.05$ ). The maximal angular velocity of a thigh in DJ were greater than CMJ and PJ during the propulsive phase, while the minimal angular velocity of a shank in CMJ was greater than DJ and PJ ( $p > 0.05$ ). The value of iEMG during preactivation phase showed only significant difference in Tibialis Anterior (TA) muscle ( $p > 0.05$ ). **Discussion and Conclusion** There was no improvement of the jump height, even though the peak VGRF in the DJ and the peak angular velocity of a shank and a thigh in the DJ and CMJ showed significant increasing during the propulsive phase. The change of level of preactivation was only found in the TA, contrary to expectation to be increased the activation value of Gastrocnemius muscle (Ruan & Li, 2010). The results indicated that the drop height and the preliminary jump preceding a main jump could not influence on the level of preactivation of the lower extremity muscles, improve the jump height during the jump performance in the same way. **References** Kallio, J., Linnamo, V., Komi, P. ## BIOMECHANICAL EFFECTS OF ELASTIC BANDS, CHAINS AND FREE-WEIGHT RESISTANCE ON SUBMAXIMAL BACK SQUAT EXERCISE

Mina, M.A.1, Blazeovich, A.J.2, Giakas, G.3, Draper, N.1, Kay, A.D.4

1: *UoD (Derby, UK)*, 2: *ECU (Perth, WA)*, 3: *UoT (Thessaly, Greece)*, 4: *UoN (Northampton, UK)*

**Introduction** Imposing variable resistance using elastic bands (EB) or chains (Ch) in addition to the free-weight resistance (FWR; i.e. the bar and weights) alters the loading characteristics of a squat lift. This can increase the range of motion through which substantial loading is applied, while maintaining the average load, thus reducing loading at the movement's 'sticking point'. The manipulation of the loading characteristics can enable the athlete to operate at near maximal levels for a greater proportion of the exercise, providing a greater training stimulus and thus may be a more effective training tool. The aim of the present study was to examine the biomechanical differences between EB, Ch and FWR during the submaximal squat exercise. **Methods** Fifteen strength-trained active men (age =  $26.9 \pm 7.9$  yr,

height =  $172.3 \pm 18.8$  m, mass =  $80.6 \pm 12.2$  kg) experienced in squatting (>3yr) volunteered for the study after giving written informed consent; ethical approval was granted from the University of Northampton. On three separate occasions the subjects performed FWR (control), EB or Ch (variable resistance) squat lifts for two sets of three repetitions at 85% 1-RM (35% of the load was generated from variable resistance). 3D motion analysis was used to record knee joint kinematics, and vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF) and semitendinosus (ST) electromyograms (EMG) were recorded simultaneously. To reduce EMG variability (increasing the ability to detect significant differences), VL, VM, RF EMG data were averaged to represent quadriceps femoris (QF) EMG activity. Repeated measures MANOVA's were used to examine EMG and kinematic differences between conditions; significance was accepted at  $p < 0.05$ . Results No significant differences ( $p > 0.05$ ) in peak (1.8-2.8%) or mean eccentric (2.4-6.6%) and peak (3.5-4.0%) or mean concentric (5.0-6.0%) QF EMG activity were found between conditions. Similarly, no differences ( $p > 0.05$ ) in peak (5.8-14.3%) or mean (9.2-15.8%) eccentric and peak (8.9-9.6%) or mean concentric (1.2-1.7%) knee angular velocities, or peak knee flexion angle (1-1.5%) were observed. Discussion Performing the back squat exercise with the use of elastic bands or chains to provide 35% of the resistance compared to FWR alone at 85% of 1-RM did not alter knee extensor EMG amplitude or knee kinematics during the squat lift in either eccentric or concentric phases, and did not affect squat depth. Both significant and non-significant changes in kinematics, ground reaction forces and muscle activity have been previously reported in the literature; substantial differences in methodology likely explain these equivocal findings.

### ASSESSMENT OF ELBOW TORQUE-VELOCITY CURVE FITTING WITH DIFFERENT OPTIMIZATION CRITERIA

Koroleova, G.I, Mavrevski, R.I, Kanelov, I.I, Pencheva, N.I, Milanov, P.I,2

1: SWU (Blagoevgrad, Bulgaria), 2: BAS (Sofia, Bulgaria)

**ASSESSMENT OF ELBOW TORQUE-VELOCITY CURVE FITTING WITH DIFFERENT OPTIMIZATION CRITERIA** Introduction This study concerns the elbow torque-velocity relationships of flexors and extensors. The aim was to compare four optimization criteria for assessment of the optimal fitting of these relationships with polynomials. Methods The isokinetic torque of the elbow flexors and extensors of ten females was obtained under six velocities ( $^{\circ}/s$ ): 0, 30, 75, 120, 150, 210. The least squares fitting (averages or cloud point data) of torque-velocity curves with 2nd to 4th order polynomials was assessed with Akaike information criteria (AIC), Bayesian information criteria (BIC), Minimizing the maximum residual (MMR) and Hausdorff distance criteria (HDC). The predictive relationships with the values of the optimal coefficients were also fitted. Results All criteria uniquely determined the 4th order polynomial as optimal for flexors (AIC = -89.09, BIC = -6.4, MMR, HDC = 0.36) and extensors (AIC = -76.04, BIC = 6.72, MMR, HDC = 1.3), when averages were used. The same conclusion was obtained by using point cloud data with the exception of BIC for extensors and AIC and BIC for flexors, where 2nd order was optimal. Non-physiological curvatures were obtained with polynomials of degree greater than 4. Discussion The graphics of polynomials from 2nd to 4th order were curvatures with acceptable behavior, similar to other authors (Ripamonti et al., 2008). AIC, BIC, MMR and HDC uniquely pointed out that the 4th order polynomial is an optimal model for elbow flexors and extensors, when fitting with averages, while with point cloud data AIC and BIC reveal different assessment. So, the AIC and BIC are less reliable, although commonly used, while MMR and HDC are rather novel (Mavrevski, 2014). However, in this study, the least squares fitting was used without constraints, and the graph of the 4th order polynomial is quite different from those of the classical force-velocity relationship (Hill, 1938). It remains an open question if the fitting method with constraints and polynomials will provide accurate physiological torque-velocity curves in elbow flexors and extensors, or it should be investigated with other (non polynomial) logistic equations (Looft and Law, 2013). ### Coaching

#### THE BILATERAL DEFICIT IN VERTICAL JUMPING IS AFFECTED BY BALANCE ABILITY IN YOUNG MALE ATHLETES

Veligekas, P., Bogdanis, G.C.

University of Athens, GREECE

Introduction Previous studies have shown that the height and muscle power achieved when jumping on one leg was 58.5% of that reached in two-legged jumps (van Soest et al., 1985). However, this "bilateral deficit" during vertical jumping is reduced or may even be absent in younger individuals (10-12 year old) and it was hypothesized that this may be related with the ability to balance on one leg (Veligekas and Bogdanis, 2013). Thus, the purpose of this study was to examine the relationship between balance ability and the extent of bilateral deficit. Methods Nineteen young athletes (age:  $19.4 \pm 1.5$  yrs, height:  $177 \pm 3$  cm, body mass:  $72 \pm 6$  kg) performed one- and two-legged countermovement jumps (CMJ) and the Flamingo balance test. Three trials were performed in each test with 1 min rest in between and the best result was taken for analysis. The bilateral jump deficit index was calculated as:  $1 - (\text{right} + \text{left leg jump height}) / \text{two-leg jump height} \times 100$ . Data were analyzed using Student's t-test and relationships were assessed using Pearson product-moment correlation ( $p < 0.05$ ). Results The average bilateral deficit index was  $-2.1 \pm 9.5\%$  for the whole group of athletes. However, ten participants showed a bilateral deficit, as shown by the negative bilateral deficit index ( $-9.0 \pm 6.4\%$ ), while the other nine did not exhibit bilateral deficit (bilateral deficit index  $5.5 \pm 5.6\%$ ). There was no difference between the right and left leg jump heights in all participants. The results of the Flamingo test were similar for the two legs ( $4.3 \pm 3.0$  vs.  $4.1 \pm 3.0$  falls), but falls were significantly higher in the group that showed bilateral deficit ( $2.5 \pm 2.2$  vs.  $6.1 \pm 2.6$  falls,  $p = 0.004$ ). A positive correlation was found between bilateral deficit index and the Flamingo test score ( $R^2 = 0.5449$ ). Discussion The results of the present study showed that a bilateral deficit in jumping may not be evident in some young male athletes. The finding that a large portion of the variance (54.5%) in bilateral deficit index is explained by the variance in the Flamingo Balance test score would suggest that bilateral deficit in jumping in young athletes may be masked by the ability to balance on one leg. Coaches should aim to improve leg balance in order to maximize jump training in young male athletes. References van Soest, AJ, Roebroeck, ME, Bobbert, MF, Huijing, PA, van Ingen Schenau, GJ (1985). ## SELF-DETERMINATION IN SPORT: A STUDY OF BRAZILIAN RHYTHMIC GYMNASTICS ATHLETES

Fontana, P.S., Reppold-Filho, A.R., Barbosa, M.L.L., Balbinotti, C.A.A., Balbinotti, M.A.A.

*UFRGS (Brazil), FEEVALE (Brazil), UQTR (Canada)*

**Introduction** The Self-Determination Theory (Deci, Ryan, 1985) states that self-determined athletes have higher intrinsic motivation, acting for the pleasure in the pursuit of their social, physical and psychological well-being (Ryan, Deci, 2007). This study aimed to evaluate the self-determination levels in athletes of Rhythmic Gymnastics. **Methods** The study included 47 athletes of Rhythmic Gymnastics, aged 13-16 years. For data collection, we used the 'Inventory of Self-Determination for Practitioners of Physical Activity and Sports' (IAPAFE-25) (Balbinotti and Barbosa, 2008), which assesses 5 levels of self-determination, each with 5 items, answered in a Likert scale, graduated in 5 points. Data normality was verified using the Shapiro-Wilk test. The average comparison was carried out using the paired t test. **Results** The descriptive analysis indicated that the mean ranged from 6.63 (amotivation) to 16.17 (Identified Regulation). The standard deviations associated ranged from 2.78 to 4.01 (so that they are suitable). Autonomy levels are distributed in three groups statistically different from each other ( $p < 0.001$ ): a) Intrinsic Motivation and Regulation Identified statistically undifferentiated averages ( $t = -1.63$ ;  $p > 0.05$ ); b) introjected regulation and external regulation formed a second group with statistically undifferentiated averages ( $t = -0.544$ ;  $p > 0.05$ ); c) amotivation, whose means were statistically lower than the others ( $p < 0.001$ ). **Discussion** The athletes evaluated presented, predominantly, more autonomous motivation levels, and significantly lower levels of amotivation. These levels are desirable in sports. **References** Balbinotti, M. A. A.; Barbosa, M. L. L. (2008) Inventário de Autodeterminação de Praticantes de Atividades Físicas e/ou Esportivas. ## INFLUENCE OF DIFFERENT STRENGTH TRAINING ON RATING OF PERCEIVED EFFORT OF RUNNING

Storniolo Junior, J.

*Università degli Studi di Milano*

Ratings of perceived effort (RPE) is an indirect technique utilized to monitor intensity of training. Several authors have been reported the importance of RPE for different physical activities as intermittent and continuous sports (REFERENCE). In this perspective, strength and endurance training have used RPE for obtain a similar intensity associated to the repetitions maximal (RM) and lactate concentration/heart rate, respectively. The aim of the present study was to compare RPE of recreational runners on running sessions subdivided in groups combined with different strength training programs (maximal and explosive) during 8 weeks (24 sessions). Furthermore, it were compared performance variables as maximal oxygen uptake ( $VO_{2max}$ ), running economy (RE), maximal heart rate (HRmax), deflection point of heart rate (HRDP) and velocity associated at the deflection point (vHRDP). It were selected thirty-two recreational endurance runners divided into three groups, which it were included a maximal strength training group (MAX,  $n = 11$ ), an explosive strength training group (EXP,  $n = 11$ ) and a control training group that performed only the endurance training (CON,  $n = 7$ ). An incremental test was performed to collect  $VO_{2max}$ , HRmax, HRDP and vHRDP. In a submaximal test was evaluated RE. Tests of repetition maximal (1 RM) and height of jump were evaluated to represent neuromuscular variables. These performance variables were collected pre and post-training. Training lasted 8 weeks with MAX and EXP groups performing strength and endurance training 5 times per week (3 for endurance and 2 for strength training in alternate days). Meanwhile, CON group performed only endurance training 3 times per week. During training, 30 min after each endurance training session were collected RPE based on Borg table adapted. A ANOVA one-way was applied to compare RPE in each training session between groups. Statistics data were performed on SPSS 22.0. **Results:** ANOVA results shown a significant difference in RPE 1 between MAX and EXP groups ( $p = 0.024$ ), for all others RPE sessions there were not differences ( $p > 0.05$ ). All outcome for endurance variables ( $VO_{2max}$ , RE, HRmax, HRDP and vHRDP) did not show differences between groups after 8 weeks. Meanwhile, neuromuscular variables presented diverse results, 1 RM was different for MAX group when compared before and after training ( $p < 0.01$ ). The height of counter movement jump (hCMJ) has remained similar between groups after training period ( $p > 0.05$ ). The RPE sessions presented difference in first session between MAX and EXP probably due to little adaptation to the Borg scale adapted. In accordance, RPE did not present significative differences during periodization. At the same time endurance performance variables did not show differences after 8 weeks of training between groups. Although MAX and EXP groups had a higher training volume, both did not were different with CON group. The training periodization did not influence RPE sessions, however it was not able to improve performance for the running.

## QUANTIFICATION AND ANALYSIS OF OFFENSIVE SITUATIONS IN SIDED GAMES IN SOCCER

Díaz-Cidoncha, J.1, Refoyo, I.2, Calleja-González, J.3, Dellal, A.4

*1: FIFA (Zurich, Switzerland), 2: INEF (Madrid, Spain), 3: INEF (Vitoria, Spain), 4: OGC (Nice, France).*

**INTRODUCTION** Playing soccer in reduced spaces has become particularly important, both for organised or spontaneous set-ups. This type of play offers a great deal of possibilities and combinations and gives players an increased level of interaction in the game. Nevertheless, players' need to interact with each other turns any defending or attacking situation into complex moves with a wide range of variables to be considered, in which the player is never isolated and must make the move that has the most positive impact on play. Therefore, the aim of this study was to identify the most relevant attacking moves from a technical and tactical perspective for each game format, age group and playing surface. **METHODS** 54 sided games played in three different formats (5v5, 7v7 and 9v9) and with two age groups (U9 and U14) were filmed at three soccer clubs in Spain. This study used the observational method; it is descriptive and is applied through well-prepared systematic quantitative observation in a natural environment. A key part of the method involved viewing the match recordings and logging moves that had been categorised beforehand. **RESULTS** The results show that there were significant variations depending on the game format, and the study will present a description and analysis of the aspects that had considerable influence on attacking moves in the different formats of sided games (5v5, 7v7 and 9v9). **DISCUSSION** The study has shown that there are more touches of the ball and attacking play in the smaller game formats (Sampaio and Maças, 2012); there was a higher frequency among the variables for attacking play (goals, shots on goal and balls entering the penalty area) in all age groups and playing surfaces in the smaller-sided games (5v5 and 7v7) than in the 9v9 format (Okihara et al., 2004). All of them are closely interrelated and change uniformly depending on the type of playing surface, game format and age group. Therefore, the variables cannot be seen as isolated moves but rather as part of a co-evolution. Therefore, one of the key considerations is choosing a format that gives the players a sense of freedom

which encourages their creativity and hence lets them discover the various play possibilities (Kelly and Drust, 2009), while being able to manage the spaces according to their technical, anthropometric and physiological characteristics (Rampinini et al., 2007). ### FACTORIAL STRUCTURE OF DECISION-MAKING ABILITY IN DRIBBLING PLAYS IN BASKETBALL

Yaita, A., Aoyagi, O., Kuraishi, O., Nodera, K., Kawazura, T., Ohyuama, Y., Annoura, T.

*Kyushukyoryitsu University*

Purpose: This study aimed to conduct decision-making ability tests for dribbling plays in various situations and to statistically clarify the latent structure of decision-making during such plays. Methods: Subjects were 158 university basketball players. We conducted decision-making tests by pausing videotaped basketball games during gameplay and asking subjects to choose the correct situational assessment or anticipate the next play. All videotaped game scenes were from the 63rd All-Japan College Basketball Championships. The test consisted of 75 questions including the following four decision-making processes based on 37 game scenes: 1) "Fundamental recognition of opponent's defensive style" (8 items), 2) "Selective attention to game situation" (14 items), 3) "Recognition and anticipation of game situation" (24 items), and 4) "Decision on play" (29 items). Correct responses were regarded as those chosen by at least three out of five qualified coaches. Factor analysis was applied to the 75 test items and the factorial structure was investigated. Furthermore, Quantification Theory Type One was conducted with each factor score as the dependent variable and position, athletic level and gender as independent variables; the influence of each independent variable on the decision-making ability factor was investigated. Results: Factor analysis was applied to 75 items. Four factors were extracted using a scree plot of their eigenvalues. After rotation, these factors were interpreted as follows: "F1: Decision-making ability during dribbling plays to try to break through the defense while cooperating with other teammates," "F2: Decision-making ability during dribbling plays on the left side of the court," "F3: Decision-making ability during dribbling plays on the right side of the court" and "F4: Decision-making ability during dribbling plays in open areas." For the influence of position, athletic level and gender on each factor, Quantification Theory Type One showed that for F1, the largest category weight range was found in athletic level (0.466) followed by position (0.367), and for F2, the largest range was found in gender (0.368) followed by position (0.328); no categories showed ranges of more than 0.3 in F3 and F4. When we focused on category weights of items with large ranges, in the athletic level of F1, regular (.297) was the largest category and was markedly different from bench (-.166) and other (-.169). Again, in gender for F2, male players (0.165) showed larger category weights than females (-0.203). Conclusion: Extracted decision-making ability factors were conceptually classified into two situations: "cooperating with other teammates" and "individual offensive plays." The latter was viewed from the standpoint of the sides of the court and from that of facing opponents. In addition, we found that the former was influenced by athletic level and position. A gender difference was found in F4.

### DIFFERENCES IN THE LANDING POSITIONS OF REBOUND BALLS BETWEEN ONE-HANDED AND TWO-HANDED THREE-POINT SHOTS IN BASKETBALL

Tsuyoshi, K., Osamu, A., Akihito, Y.

*1-8 jiyugaoka*

Introduction In basketball, three-point shots are taken with either one or both hands. The landing position of a rebound ball is influenced by the type of shot taken and the shooting angle. The present study investigated the influence of these two shooting techniques and shooting angle on the landing position of rebound balls. Methods Subjects were 8 male one-handed shooters and 8 female two-handed shooters from K University in Japan. The basketball court was divided into five directions ("top", "right wing", "left wing", "right corner", and "left corner"), which were divided by 36 degrees from the midpoint of the end line, and four distance areas ("near", "middle", "far", and "outside the two-point shot area"), which were divided by the distances of 2.15 m, 4.20 m, and 6.35 m. Subjects took 40 three-point shots from each of the five directions. We counted the number of unsuccessful shots that landed in each of the four areas. The differences of ratios between the landing positions of the one- and two-handed shots were examined using odds ratios (OR). The chi-square test and adjusted residuals (AR) were used to examine the relationship between the angles and distances of the landing positions based on area. Results Significant differences were found in the "near" (OR=1.276) from the corner, "near" (OR=1.276) from the top, and "near" (OR=1.903) from the wing areas, showing that the ratios of rebounds from one-handed shots were higher than those of two-handed shots in these two distance areas. A significantly higher AR than the expectation value was found for one-handed shots from the "near and top" (AR=3.670). However, two-handed shots showed a significantly higher AR (AR=3.721) for the "middle and wing on the opposite side," but not the "top." Discussion Results showed that more one- than two-handed shots landed near the basket. It is likely that two-handed shooters take shots from a tighter angle due to their inability to shoot from a distance, resulting in rebounds landing farther from the basket than those from one-handed shots. In addition, the arcs of shots thrown by two-handed shooters frequently moved from right to left. This was due to the difficulty associated with balancing the strength of both hands when shooting.

### A STUDY ON THE EFFECTIVENESS OF A NEW COACHING DEVICE FOR THE MOVEMENT COACHING

Murayama, D.

*Shigakkan Univ.*

It is important to conduct a study that examine how athletes understand movement effectively. In recent years, image devices such as VTR have been utilized in coaching. A player confirms one's movement immediately right after he performed a skill, and he can connect to movement correction. Image devices are useful and enable players to have movement images. It is critical to build the correct "movement conception" for the acquisition of technique (Grosser & Neumaier, 1982). Devices that build a movement image effectively have been already developed, and they help players to improve their performance. However, it may be said that the effectiveness of coaching devices still needs further inspection. In such a situation, we developed a new coaching device. It is a doll that can be displayed on a white board. The doll is made of magnets. The purpose of the present study was to examine the effectiveness of this specific coaching device to master the movement skills. The methods were: -to present how to make a magnet doll and introduce a way to coach using a new magnet doll, and -to inspect the effectiveness by conducting questionnaires and interviews to a player (or players) who is (or are) taught with the doll. The study found that the "movement conception" could be developed better by using this magnet doll. Therefore, it is concluded that the coaching method with our new device is effective to master the skill elements.

## ROLES OF GENETIC FACTORS IN ION OF THE VOLLEYBALL TALENT

Katalin, B.

*West Hungarian University*

**Introduction** Inspired by the desperate state of Hungarian volleyball and the lack of results in previous years, the present study aims to discuss those methods - especially the genetic factors - that give the safest indication of success and allowing of the earliest selection and nurturing of the most talented. **Methods** 141 players of 5 girls' volleyball teams and 4 boys' volleyball teams in two age groups (13-14 and 15-16 years old) participated in our study. The data were obtained between November 2012 and March 2013. To examine genetic factors we took 24 body size which were used to analyse physique, predicted adult height, difference between biological and calendar age, and a test of motor skills (18 meters sprint, stuffed ball toss forward, stuffed ball roll back, sit-up, standing broad jump, standing jump with one hand, special running with change of direction), to measure speed and explosive arm-leg-trunk strength. **Results** The correlation of the anthropometric parameters and of the motor skill tests showed that most parameters had a significant connection to stuffed ball toss forward and stuffed ball roll back. The 18m sprint and special running with change of direction correlated positively, while standing jump with one hand showed negative correlation with skinfold values. Body build analysis showed that both boys and girls were of average central body type with higher endomorph values. The difference between biological and calendar age was considerable (over 1 year) in the case of only 7 children. The predicted adult height for both sexes lags behind that recommended for volleyball players: only 4 of the girls and 8 of the boys are predicted to reach the values recommended in the professional literature (at least 180 cm for girls, and at least 190 cm for boys). **Discussion** We found 13 players (5 girls and 8 boys) who performed very well on all test of motor skills and they had higher-than-average in 17 of the 24 anthropometric parameters. But just 2 girl's and 5 boy's from these players body build type and their predicted adult height match the criteria recommended by the professional literature. The mission of the Hungarian volleyball experts have to find children, whose genetic factors probably guarantee the future success. **References** Biróné Ilics K. ## DEVELOPING A PSYCHOLOGICAL COACHING MODEL FOR UNIVERSITY BASEBALL ATHLETES —STRUCTURAL EQUATION MODEL WITH TEAM ADAPTATION AND MAL-ADAPTATION AS MEDIATOR VARIABLES—

Shimizu, Y., Miyazaki, M.

*International Christian University, J.F. Oberlin University*

**Introduction** Higher evaluated coaches lead higher athletes' performance in all sport. In sport, coaches are asked for high competitive strategies, instruction skills, team leading competency and student-athlete mental health support. Prior studies have found that positive evaluation of baseball coaching by college baseball athletes is positively associated with their collective efficacy (Shimizu & Miyazaki, 2011), and negatively associated with athletic burnout (Shimizu & Miyazaki 2014). The purpose of this study was to develop a psychological coaching model for baseball athletes with Coaching Evaluation Scale for Baseball (CESB), Team Adaptation Scale for Baseball Athletes (TASBA), Team Mal-adaptation Scale for Baseball Athletes (TMSBA) and Subjective Performance Scale for Baseball Athletes (SPSBA). **Methods** The subjects of 264 baseball athletes (mean age=19.45, SD=0.89) in four high competitive university baseball teams were asked to answer a questionnaire composed of question items on socio-demographic background as well as eight-factor with 48 question items of CESB, one-factor with 6 question items of TASBA, three-factors with 18 question items of TMSBA and one-factor with 12 question items of SPSBA. These four scales had been developed in our prior studies from 2010 to 2014. Covariance structure analysis was conducted in order to examine our hypothetical psychological coaching model. **Results** The results of covariance structure analysis showed that the hypothetical model had statistically acceptable structural validities (GFI=0.987, AGFI=0.737, CFI=0.976, RMSEA=0.185). In the model, the path coefficients from CESB to TASBA (0.37,  $p<0.001$ ) and from CESB to Escape from Practice (EP) of TMSBA (-0.25,  $p<0.001$ ) were statistically significant while the path coefficient from CESB to Absent from Club Activities (ACA) of TMSBA (-0.06, ns) and Conflict of Human Relationships (CHR) of TMSBA (0.05, ns) were not statistically significant. The path coefficients from TASBA to SPSBA (0.39,  $p<0.001$ ) and from ACA to SPSBA (0.17,  $p<0.05$ ) were statistically significant while the path coefficient from EP to SPSBA (0.11, ns) and from CHR to SPSBA (0.11, ns) were not statistically significant. **Discussion** The results of the hypothetical model above have some implications for baseball coaching interventions. High coaching evaluation from baseball athletes is positively associated with high subjective performance only via high team adaptation. This implies that coaching with focus on building mutual trust among team members, teams' confidence in their success, and promoting a sense of accomplishment and enjoyment for practice is more likely to lead to better baseball performance.

## ABILITY FOR CHANGE OF DIRECTION PERFORMANCE WITH THE REACTIVE AND DECISION-MAKING IN SOCCER PLAYERS

Hirofumi, M., Masafumi, Y., Yu, S., Kenichi, K., Gen, K., Yuki, I.

*Juntendo University*

**Introduction** Agility is an essential component in most field and team sports. More recently it has been suggested that agility contains both a change of direction movement and a perceptual and decision-making component, since changes of direction and speed are often performed in response to an opponent's actions. However, there is few studies evaluating the capabilities to integrate the change of direction performance and perceptual decision-making as the target soccer players. The purpose of this study was to consider the reactive and decision-making ability in the change of direction performance of soccer players between the disciplines and competition levels. **Methods** University soccer players (n=30) and university track-and-field athletes (n=9) took part in the study, categorized into either a higher performance group (HPG) (n=15) or lower performance group (LPG) (n=15) and university track-and-field athletes (n=9). The evaluation of the ability for change of direction performance with the reactive and decision-making was used 20m sprint and a 20m sprint cutting to 90° reactive agility test (CUT90-RAT). CUT90-RAT arranged in the point to make a decision about whether to right or left turn according to light stimulation at 2.5m, 5m and 7.5m were conducted using electric timing gates (smart-speed). To assess the change of direction performance (CODP), the difference between CUT90-RAT 5m time and CUT90-RAT 7.5m time was calculated as follows:  $CODP = (7.5m\ time - 2.5m\ time) - (5m\ time - 2.5m\ time)$  **Results** The 20m sprint time, CUT90-RAT 2.5m time, CUT90-RAT 5m time and CUT90-RAT 7.5m time of track-and-field athletes were significant faster than that of HPG and LPG ( $p<0.05$ ). There was not significant

difference between HPG and LPG. CODP is as follows: track-and-field athletes 0.194 (sec) (5.1% slower) > LPG 0.187 (sec) (4.5% slower) > HPG 0.156 (sec) (3.8% slower). Discussion This study suggested that sprint speed itself gave to ability for change of direction performance with the reactive and decision-making was small influence. Good players have a sense of stability to the reactive and decision-making during the change of direction running. In addition, they have been skilled in the ability to adjust the sprint velocity even when the ability to reactive and decision-making has been limited to their stimulus. Reference 1. ### **CORRELATION BETWEEN 400-M SPRINT PERFORMANCE AND MAXIMAL ACCUMULATED OXYGEN DEFICIT IN DIFFERENT EXERCISE MODES**

Mori, K.1, Hiruma, K.2

1: *Musashi University*, 2: *Yamagata Prefectural Yonezawa Women's Junior College*

Introduction Approximately 60% of the energy available during 400-m sprint running depends on an individual's anaerobic capacity (Duffield et al., 2005). The Wingate Anaerobic Test (WAnT) is widely used to evaluate anaerobic power and capacity (Bar-Or, 1987). And then, the output power in the WAnT is known to reflect 400-m performance. However, differences in exercise modes have not been considered. Therefore, the aim of this study was to investigate the correlation between maximal accumulated oxygen deficit (MAOD) in running and cycling exercises and the accumulated oxygen deficit during WAnT and 400-m sprint running performance. Methods Fourteen male track and field college athletes (8 sprinters [400-m sprint performance: 49.29 ± 1.27 sec.] and 6 decathletes [50.29 ± 1.27 sec.]) participated in this study. The difference in MAOD of running and cycling was determined by using a supramaximal constant load test (Medbø et al., 1988). Moreover, they performed the WAnT by using an electromagnetic brake cycle ergometer, and the peak power, mean power, and accumulated oxygen deficit were determined. The applied resistance was 7.5% of body weight, and the duration was 60 seconds. The oxygen uptake during each test was recorded by using a breath-by-breath method. The subjects' season-best records were used for their 400-m sprint performance. Results The differences in MAOD between running and cycling and the accumulated oxygen deficit on the WAnT were insignificant. However, there were significant correlations between MAOD in running and cycling ( $r=0.70$ ,  $p<0.05$ ). In all the subjects and in the sprinters, there were significant correlations between the 400-m performance and MAOD in running (respectively:  $r=-0.65$ ,  $p<0.05$ ;  $r=-0.81$ ,  $p<0.05$ ), but not between performance and MAOD in cycling. In the sprinters, there were significant correlations between the 400-m performance and the mean power on the WAnT ( $r=-0.79$ ,  $p<0.05$ ). Discussion These results suggest that the applicability of the test for evaluating the anaerobic capacity of sprinters differs between running and cycling exercises. In the measurement of physical fitness levels by using cycling exercise mode, the technical factors of sprinting and each athlete's physical status require consideration. ### **Health and Fitness**

#### **DEVELOPMENT OF HEALTH INDEX FOR SUCCESSFUL AGING IN ELDERLY PEOPLE**

Park, J., Jung, E., Kim, B., Choi, H.M., Kim, K.A., Kim, J.K., Nho, H.

*Kyunghee University Applied Physiology Lab*

The purpose of this study was to investigate the longevity age for the assessment of health and functional status in older adults based on 31 physical and physiological variables. One hundred thirty eight Korean men and women (aged 65-89 yrs) were recruited for this study. All subjects were free of any signs or symptoms of overt coronary heart disease, based on a health history questionnaire and were considered in good health. Body composition, blood pressure, blood lipid profiles were measured and physical fitness tests for the living were performed. The variables for assessing the physical fitness and cardiorespiratory fitness could be used to determine to evaluate the physical fitness for the living in older population. The blood lipid profile is useful to evaluate the metabolic syndrome and the VO<sub>2</sub>peak could be used to evaluate the respiratory fitness for the living. Ten principle factors were used to compute the longevity age in the subjects. Equation for calculation the longevity age is  $77.794 - 2.568 \times \text{sex} - 0.269 \times \text{age} + 0.093 \times \text{grip strength} + 0.122 \times \text{arm curl} - 0.170 \times \text{walking around two cons} + 0.221 \times \text{standing up and sitting down a chair} + 0.094 \times \text{functional reach} - 0.005 \times \text{total cholesterol} + 0.003 \times \text{low density lipoprotein cholesterol} + 0.292 \times \text{body mass index} + 0.075 \times \text{systolic blood pressure} - 28.907$  [ $R^2=0.694$ ]. The chronic disease and physical activity status showed excellent correlation with the longevity age in our study. In conclusion, this study may suggest that the equation derived for computing the longevity age applies to the assessment of the effectiveness in regular exercise older population as well as chronic disease patients. In addition, this equation will be a good index to improve and maintain the physical fitness for the living in older adults.

#### **INFLUENCE OF SUPERVISION RATIO IN RESISTANCE TRAINING ON CYTOKINES PARAMETERS OF THE ELDERLY WOMEN.**

Vieira, D., Tajra, V., Nascimento, D.C., Almeida, J.A., Teixeira, T.G., Farias, D.L., Tibana, R.A., Prestes, J.

*Centro Universitário UDF*

Resistance training (RT) has promote some improvements in health of older individuals and some variables may be control to improve benefices. Moreover, recently it has been show that direct supervision and supervision ratio (SR) also influence resistance-training benefices. However, there is absence about influence of SR in cytokines parameters. Thus the objective of this study was verify the effects of very high SR on cytokines parameters (Irisin, IL-1β and IL-15), Brain-derived neurotrophic factors (BDNF) and toll-like receptor 4 (TLR-4). Older individuals were divide in two exercises groups. Very high supervision (VHS) group that had one trainer to two individuals and high supervision group (HS) that had one trainer to five individuals. The training consist in whole body RT with three sets between eight to twelve maximal repetitions. BDNF, IL-1β, IL-15, irisin and TLR-4 blood markers were assess by using commercially available enzyme-linked immunosorbent assay (ELISA) kits. To Irisin a two way ANOVA was apply and to TLR-4, BDNF, IL-1β and IL-15 a Wilcoxon and Mann-Whitney analysis were apply. An alpha level less than 0.05 was considered. For both groups, no differences between baseline and post-training ( $P > 0.05$ ) were identify for Irisin (215.05 ± 70.58 to 207.29 for VHS and 219.63 ± 53.24 to 209.10 ± 58.04), TLR-4 (8.31 ± 5.76 to 7.30 ± 6.83 for VHS and 5.62 ± 2.70 to 5.24 ± 1.86 for HS), BDNF (1481.57 ± 183.57 to 1601.28 ± 116.38 for VHS and 1601.28 ± 116.38 to 1654.87 ± 75.84

for HS) and IL-15 ( $316.08 \pm 298.03$  to  $252.65 \pm 198.87$  for VHS and  $260.06 \pm 366.72$  to  $269.38 \pm 375.02$  for HS). Only for IL-1 $\beta$  the VHS group the serum levels decreased when compared with baseline ( $13.86 \pm 27.03$  to  $12.99 \pm 26.30$  for VHS;  $P = 0.002$ ). In this sense, it is possible to conclude that RT with VHS was able to improve IL-1 $\beta$ . However, in relation to other parameters RT program showed no significant difference independently of SR.

### **AFFECTIVE RESPONSE DURING A SINGLE BOUT OF HIGH-INTENSITY INTERVAL EXERCISE BETWEEN PHYSICALLY ACTIVE AND INSUFFICIENTLY ACTIVE MEN**

Costa, E.1, Frazão, D.1, Dantas, T.C.B.1, Farias Júnior, L.F.1, Krinski, K.2, Elsangedy, H.M.1, Prestes, J.3, Sarah, J.H.4

1: UFRN (Natal, Brazil), 2: UNIVASF (Petrolina, Brazil), 3: UCB (Brasília, Brazil), 4: CU (Perth, Australia).

**Introduction** Feeling of pleasure during exercise is determinant of physical activity participation and adherence. It is well established that high-intensity interval training (HIIT) results in a host of physiological adaptations including improvements in health and fitness (Gillen & Gibala, 2014). However, seems to be important to examine how individuals with different physical activity levels perceive this exercise model regarding to affective response. The aim of this study was to examine the affective response during a single bout of low-volume HIIT between sufficiently and insufficiently physically active men. **Methods** Thirty-two males (aged  $25.1 \pm 3.8$  years) participated in this study. Subjects were separated into two groups: i) insufficiently active ( $n=16$ ) and ii) physically active ( $n=16$ ). A maximal exercise test was performed to determine the peak treadmill velocity (PTV). The HIIT protocol consisted of 10 sets of 60s "work bouts" at 90% of PTV interspersed with 60s of active recovery at 30% of PTV. In the last 10s of each "work bout", the subjects reported their affective response (Feeling Scale, +5 to -5) and rating of perceived exertion (RPE, 6-20). **Results** The insufficiently active group had lower Feeling Scale (FS) values compared to the physically active group ( $p < 0.05$ ). There were no differences in RPE between the groups ( $p > 0.05$ ). Regardless of the physical activity level, there was a strong negative correlation between the RPE and FS values during the "work bouts" of the HIIT. **Discussion** Our results revealed that even with a less strenuous model of HIIT the subjects reported a decrease in FS values over time, similar to observed by Oliveira et al. (2013) and Jung et al. (2015). From a practical point of view, pleasant exercise can improve adoption and adherence to prescribed exercise programs and may enhance future exercise behavior (Garber et al., 2011). In this sense, we suggest that HIIT should not be used as a main exercise model for beginners during physical activity programs. This preliminary data support the idea that current physical activity level influences the feelings of pleasure/displeasure during a single bout of low-volume HIIT. Therefore, despite the physiological benefits of HIIT in improving health status and fitness it is important to consider that this mode of exercise is likely to be experienced as unpleasant, especially for less active individuals. **References** Gillen JB, Gibala MJ (2014). *Appl Physiol Nutr Metab*, 39, 409-12. ### **EFFECTS OF THE "NATIONAL EXERCISE REFERRAL SCHEME" IN TAIWAN TO PROMOTE PHYSICAL ACTIVITY AND PHYSICAL FITNESS IN ADULT.**

Lin, I.C., Kao Shiao, G.F., Lee, H.C., Chen, J.J.

*National Yang-Ming University*

**Introduction:** Despite the health benefits of physical activity is evident, most adults do not take the recommended amount of exercise. A novel "National Exercise Referral Scheme" (NERS), initiated by the Sports Administration, Ministry of Education, Executive Yuan, Taiwan was commenced in 2011 to encourage regular exercise participation in adults. This study aimed to investigate the effects of NERS in Taiwan to promote physical activity and physical fitness in adults with chronic conditions. **Methods:** This is a multi-center, one-group pretest-posttest study design. Subjects were recruited from the participants of NERS in Taiwan. People possessing the following chronic conditions would be qualified to enroll the NERS, including: metabolic syndrome, frail elders, and tendency toward melancholy, medically stable stroke, medically stable osteoarthritis, medically stable cardiovascular disease or anyone requiring encouragement to become physically active. The participants received a supervised class-based exercise program for, 30-45 minutes per session, at least 2 times per week. Outcome measures include 2 main categories: 1) Physical fitness (body composition, muscle strength, muscle flexibility and cardiovascular fitness); and 2) Questionnaires (self-report physical activity, quality of life, exercise motivation). Measurements were conducted at baseline and 12 weeks. **Results:** This study recruited 413 people who enrolled the NERS from 11 community exercise centers, with 70.6% female and mean age 48.9 years. After 12 weeks, positive results were found in physical activity level ( $988.3 \rightarrow 2243.3$  Kcal/week, medium effect size,  $P < .001$ ), health-related quality of life ( $0.69 \rightarrow 0.79$ , medium effect size,  $P < .001$ ), exercise motivation ( $33.3 \rightarrow 37.0$ , trivial effect size,  $P < .001$ ), exercise self-efficacy ( $7.58 \rightarrow 8.00$ , small effect size,  $P = .025$ ), as well as all physical fitness measures ( $P < .001$ ). **Discussions:** Our research found that NERS could effectively improve participants' physical fitness, quality of life, exercise motivation and physical activity level, especially for the clients with metabolic syndrome, knee osteoarthritis, osteoporosis and tendency toward melancholy. The program was considered to be worthwhile for wider implementations; nevertheless, rigorous evaluations of their effectiveness by randomized controlled clinical trial are required in the future. **References:** 1. ### **THE EFFECT OF AGE AND GENDER ON PHYSICAL FITNESS IN CHILDREN**

Zenuni, Z., Bytyqi, H., Ademaj, R., Geladas, N.

*University of Prishtina "Hasan Prishtina"*

**ABSTRACT Introduction** – The aim of this study was to identify the effect of gender and age on some anthropometric variables and two fitness tests (20m shuttle run test and countermovement jump; MSFT and CMJ) in secondary schoolchildren of Kosovo country. **Methods:** In this cross-sectional study we treated 80 schoolchildren of both genders (40 boys 40 girls), who were further divided into two age groups. The groups which were tested were: male grade 7th ( $12.8 \pm 0.4$  years old), female grade 7th ( $12.66 \pm 0.2$  years old), male grade 9th ( $14.53 \pm 0.2$  years old), and female grade 9th ( $14.66 \pm 0.3$  years old). The following parameters were tested: height, weight, Body Mass Index, waist circumference, hip circumference, two skin folds (triceps and calf), % body fat, 20m shuttle run test (MSFT) to measure cardiorespiratory fitness, and Countermovement jump (CMJ) to measure lower body power. **Results:** Based on our results there was a

significant effect between genders and between ages in height and weight; there was no significant difference among groups for BMI, whereas there was a significant effect between genders regarding the waist circumference parameter. Similarly a significant effect of gender and age was found in terms of hip circumference, CMJ and 20m shuttle run test (MSFT) Conclusion: In conclusion, the present study recorded in an ample size of sample the somatic and fitness traits of 12 and 14 years old Kosovarian girls and boys. Overall, with the exception of aerobic power the observed data are satisfactory and comparable with the data of other developed states. Reference: Robert M. ## RELATIONSHIP BETWEEN ENVIRONMENTAL FACTORS AND PHYSICAL ACTIVITY IN CHINESE OLDER ADULTS

Tu, K., Hou, M., Yang, K., Jen, I., Chen, J.

*National Yang-Ming University*

Background: Physical inactivity has strong relation with mortality and morbidity in older adults. Currently, about 50% old adults in Taiwan are physically inactive. As age increases and function decreases, old adults tend to be more hypersensitive to environmental challenges and constraints. The environmental impacts may have more influence on their physical activity (PA) and health condition when compared with other ages. However, the relations between PA and environment in older adults have not been clearly identified yet. The majority of related studies are conducted only in North American and Europe areas, and rare in Asia, where the aging population has increased rapidly. Therefore, the purpose of this study is to investigate the relationships between environmental factors and PA in older adults in Taipei and to find the key factors of them. Method: Subjects of this project were the older residents ( $\geq 65$ ,  $N=325$ ) in Taipei City. It is based on the design of International Physical Activity Environmental Network Senior (IPEN Senior). We selected the survey areas by high and low city walkability index (measured by Geographic Information System) and social economic status (SES). We used accelerometers recording (objective PA measures) and International Physical Activity Questionnaire (subjective PA measures) as the main PA outcomes, and used GIS-based walkability indices (by 500m buffer) as the environment factors. In addition we used 3 physical functioning tests as the health variables to check the influence of lower body function in this issue. The data were analyzed with Pearson product-moment correlation, and generalized linear model. Results: The study recruited 325 participants, with mean age 72.3 years and 57.85% female. The amount of objective PA was categorized into moderate/vigorous-intensity PA (MVPA), high-light PA (HLLPA), and low-light PA (LLPA). Male, less age, and better agility of lower body are significantly related with more MVPA. Less age and better walking speed are significantly related with more HLLPA. Female, less age, and better muscular endurance of lower body are significantly related with more LLPA. Subjective PA outcomes are subjective MVPA, transport walking and leisure time walking. More subjective MVPA is significantly related with less public recreation amenities. More transportation walking is significantly related with female, less public transit, and less barriers. More leisure time walking is significantly related with better agility of lower body, less public transit, and less barriers. Conclusions: This study showed that the active older adults living in high population density Asian communities are limited by personal characteristics rather than walkability factors. However, the results showed that people with more age have less PA and more health risks, so we still need to clarify the relation between PA and other supporting environment, like health promotion resources, health management services, or health care services.

## ATTENUATED GLUCOSE HOMEOSTASIS IN SIMVASTATIN TREATED PATIENTS MAY BE CAUSED BY DECREASED LIPID SYNTHESIS CAPACITY IN SKELETAL MUSCLE

Vigelsø, A., Larsen, S., Prats, C., Dela, F., Helge, J.W.

*University of Copenhagen*

Introduction A prevalent side-effect of the cholesterol-lowering drug Simvastatin is attenuated glucose homeostasis (insulin resistance). However, the underlying mechanism is unknown, but muscle lipid metabolism has previously been associated with insulin resistance (lipotoxicity). Hence, it is possible that Simvastatin-induced alterations of muscle lipid metabolism may lead to lipotoxic inhibition of insulin signaling. Therefore, our hypothesis was that patients treated with Simvastatin have lower content of the major proteins regulating uptake, synthesis, and storage of lipids and lipolysis in skeletal muscle than matched controls. Methods Ten men with hypercholesterolemia ( $45 \pm 2$  years,  $93 \pm 4$  kg, HbA1c:  $5.7 \pm 0.1\%$  and  $VO_{2max}$ :  $38 \pm 1$  O<sub>2</sub>/min/kg), treated with Simvastatin for more than 1 year (10-40 mg/day; 10 mg/day,  $n=1$ ; 20 mg/day,  $n=4$ ; 40 mg/day,  $n=5$ ), and ten healthy men as control ( $45 \pm 1$  years,  $91 \pm 4$  kg, HbA1c:  $5.2 \pm 0.1\%$  and  $VO_{2max}$ :  $40 \pm 2$  ml O<sub>2</sub>/min/kg) were included. An oral glucose tolerance test was performed and a biopsy was obtained from vastus lateralis. Western blotting was used to assess protein content in lipid uptake (CD36, LPL, DGAT 1 and 2), plasma membrane-associated fatty acid binding protein (FABPpm), and endothelial lipase (EL), lipid synthesis (diacylglycerol acyltransferase 1 and 2 (DGAT 1 and 2)), lipid storage (perilipin 2, 3 and 5) and lipolysis (adipose triglyceride lipase (ATGL) and hormone-sensitive lipase (HSL)). Results The groups did not differ in age; weight; body-mass-index; body fat (total and abdominal); maximal oxygen uptake ( $VO_{2max}$ ) or in; plasma TG, cholesterol, LDL and HDL. However, glucose homeostasis measured by the Cederholm index was lower in the Simvastatin-users compared with the control subjects. Protein content of CD36, LPL, DGAT 1 and 2 ( $P = 0.07$ ) were lower in patients treated with Simvastatin. With no differences in the other proteins related to: lipid uptake (FABP, endothelial lipase), lipid storage (perilipin 2, 3 and 5) or lipolysis (ATGL and HSL). Discussion The Simvastatin treated patients had an inferior capacity to recruit exogenous fatty acids (FA) and to synthesize FA and diacylglycerol (DAG) into triacylglycerol in skeletal muscle compared to matched controls. The decreased lipid synthesis capacity may lead to greater cytosolic levels of intermediates from lipid metabolism (FA and DAG) that causes lipotoxicity and hence attenuation of glucose homeostasis. The results add knowledge to our understanding of the molecular mechanism behind attenuated glucose homeostasis induced by chronic use of Simvastatin. Contact: avhansen@sund.ku.dk

## EFFECT OF MODERATE AND HIGH INTENSITY INTERMITTENT ENDURANCE EXERCISE ON POST EXERCISE HYPOTENSION

Gjovaag, T., Oygarden, M., Wold, I., Mirtaheer, P.

*Oslo and Akershus University College*

**Introduction** Following endurance exercise, blood pressure is reduced compared to rest and knowledge about post exercise hypotension (PEH) is important in designing first line strategies against hypertension. National guidelines for prevention and treatment of hypertension recommend 30 min. of moderate intensity exercise (MOD) at ~50-80% of HFmax (Borjesson, 2008). The hemodynamic load during high intensity intermittent exercise (HIIT) is, however, larger compared to MOD, which in turn may affect the PEH response. The present study investigates the acute effect of MOD and HIIT exercise on PEH. **Methods** Six adults performed one bout each of 28 min. MOD and HIIT bicycle exercise. MOD exercise was at 80% of HFmax, while HIIT exercise was 4x4 min at 94% of HFmax, with 4 min recovery intervals at 80% of HFmax. Mean arterial pressure (MAP), cardiac output (CO) and systemic vascular resistance (SVR) was measured at REST, at termination of exercise (TEXC), 30 and 60 min. postexercise (PEXC30, PEXC60). **Results** REST MAP, CO and SVR values were 85(8) mmHg, 5.2(0.4) L min<sup>-1</sup>, and 1235(158) dyn s cm<sup>5</sup>. TEXC values for MOD and HIIT were 122(6)\* and 130(11)\*, # mmHg, respectively (\*compared to REST; p<0.03, #MOD compared to HIIT; p<0.04), 14.7(2.8)\* and 15.9(2.6)\* L min<sup>-1</sup>, respectively (\*compared to REST; p<0.03), 476(62)\* and 438(93)\* dyn s cm<sup>5</sup>, respectively (\*compared to REST, p<0.03). PEXC30 MAP, CO and SVR values following MOD and HIIT were 84(8)&, \$ and 84(6)&, \$ mmHg, respectively (&compared to TEXC, \$compared to REST; both p<0.03), 5.5(1.4)& and 6.6(1.5)&, \$ # L min<sup>-1</sup>, respectively (&compared to TEXC, \$ compared to REST; both p<0.03, #MOD compared to HIIT; p<0.05), 1229(129)& and 1016(204)&, \$ # dyn s cm<sup>5</sup> (&compared to TEXC; p<0.03, \$compared to REST; p<0.05, #MOD compared to HIIT; p<0.05). PEXC60 MAP, CO and SVR values following MOD and HIIT were 81(6)&, \$ and 81(4)&, \$ mmHg, respectively (&compared to TEXC, \$compared to REST; both p<0.03), 5.2(1.5)& and 5.8(1.5)& L min<sup>-1</sup>, respectively (&compared to TEXC; p<0.03), 1340(78)& and 1151(226)& dyn s cm<sup>5</sup> (&compared to TEXC; p<0.03). **Discussion** Following MOD and HIIT, MAP at PEXC30 was similar to REST, but 5% lower at PEXC60 compared to REST, thus the MAP response is somewhat delayed following termination of exercise. MAP is the product of CO and SVR, and following HIIT, CO was higher, while SVR was lower compared to MOD at PEXC30, hence the initial hemodynamic recovery responses are different following HIIT and MOD. At PEXC60, there was no difference between MOD and HIIT responses, meaning that there is no added effect of HIIT on the PEH response within the short timeframe investigated in the present study. **References** Borjesson M (2008). 327-342. *Aktivitetshandboken*, Oslo.

## DIFFERENCES IN QUALITY OF LIFE BETWEEN ELDERLY RESIDENTS OF RURAL AND URBAN AREAS

Zivkovic, D., Djordjevic, M.

*University of Nis*

**Introduction** Demographic data on accelerated aging shows that age and disease that follows became not only health, but also socio-economic problem. This fact increases the need for research in this area. The aim of the study was to determine the differences in quality of life between elderly residents of rural and urban areas in terms of form of physical activity. **Methods** Our research survey was conducted on a sample of 102 elderly subjects aged from 60 to 80 years, residents of urban area, and 105 rural subjects of the same age. As a measuring instrument used is standardized survey EQ5D questionnaire on health, as well as a set of questions about the physical exercise. Chi-square test is used for statistical nonparametric analysis. **Results** There was a statistically significant difference in quality of life between elderly residents of rural and urban areas in each of the observed parameters (p<0.05). The results of our study further proof initial hypotheses about the usefulness of physical exercise in various forms of implementation for almost all the observed parameters in both urban and rural sample. **Conclusion** There is a statistically significant difference in quality of life between elderly people who lives in urban and rural areas. Physical activity is important aspect of quality of life in elderly population. **Keywords:** eq5d surveys, physical activity, elderly people, rural and urban area. **References** Spirduso WW, Cronin DL. ## EFFECTS OF 12 WEEKS EXERCISE ON PERIPHERAL BDNF, FGF AND IGF-1 IN OBESE ADOLESCENTS

Kim, S., Kim, Y.

*Kyungnam University*

Exercise has been reported to improve cognitive function in humans and rodents, possibly via BDNF (brain-derived neurotrophic factor), FGF (Fibroblast growth factor) and IGF-1 (insulin-like growth factor-1)-regulated mechanism. The purpose of this study was to investigate the effects of exercise on body composition, blood lipids, BDNF, FGF and IGF-1 in obese adolescents. The subjects of this study were 16 boys, who were divided into exercise group (EG, n=8), control group (CG, n=8). The exercise is a combined exercise that includes walking and resistance training. And the exercise program conducted 50-60 minutes per day, four times a week, for 12-week. The results of comparative analysis are as follows. The comparison of means difference before and after intervention between group, weight (p<.05), BMI (p<.05), Glucose (p<.05) of EG were more significant decreased than CG. And BDNF (p<.05) was more significant increased than CG. Fat percentage, Muscle percentage, TC, TG, HDL-C, LDL-C, FGF and IGF-1 were not different between EG and CG. But fat percentage and LDL-C of EG were more decreased than CG. FGF and IGF-1 of EG was more increased than CG. These data indicate that 12 weeks exercise decreased BMI and increased concentrations of BDNF in the serum, suggesting a possible functional role for this neurotrophic factor in exercise-induced cognitive enhancement in humans.

## APPLICABILITY OF ANTHROPOMETRIC MEASURES FOR ESTIMATING WHOLE-BODY SKELETAL MUSCLE VOLUME IN CHILDREN

Ohta, M.1, Midorikawa, T.2, Hikiyama, Y.3, Sakamoto, S.4, Kawakami, Y.4, Kanehisa, H.5, Fukunaga, T.5

1: *Chukyo Univ. (Aichi, Japan)*, 2: *J.F. Obirin Univ. (Tokyo, Japan)*, 3: *Chiba Institute of Technology (Chiba, Japan)*, 4: *Waseda Univ. (Saitama, Japan)*, 5: *National Institute of Fitness and Sports in K*

**Introduction** For children, skeletal muscle volume (SMV) reflects nutritional status and its growth-related changes associates with the development of muscular and motor fitness (Fukunaga et al, 1989). At present, magnetic resonance imaging (MRI) is regarded as the

gold standard for measuring SMV. However, this method is costly and time consuming for analysis. It is difficult to use MRI in field work aimed to investigate SMV in a large number of subjects. Thus, the purpose of the present study was to elucidate the applicability of anthropometric measures for estimating SMV in children. Methods One hundred and twenty-seven healthy Japanese children (74 boys and 53 girls, mean age 9.6yr) voluntarily participated in this study. Contiguous MRI images with a 1-cm slice thickness were obtained from the first cervical vertebra to the lateral malleoli. The whole body SMV was calculated by summing up the digitized muscle cross-sectional areas and by multiplying it by the slice thickness. Ten anthropometric measures (circumferences of upper arm, forearm, thigh, lower leg, waist, and hip, waist-to-height ratio, waist-to-hip ratio, weight-to-waist ratio, and weight-to-hip ratio) were adopted to examine their associations with the whole body SMV measured by MRI (MRI-SMV). Results & Discussion The MRI-SMV was  $8742.2 \pm 2551.2$  cm<sup>3</sup> for boys and  $8798.7 \pm 288.2$  cm<sup>3</sup> for girls. All anthropometric parameters except waist-to-height and waist-to-hip ratios were significantly correlated to MRI-SMV ( $r = 0.62 - 0.91$ ,  $p < 0.005$ ). Among these parameters, weight-to-waist ratio was the best predictor of MRI-SMV ( $R^2 = 0.825$  and  $SEE = 856.2$  cm<sup>3</sup> [9.8%]). The SMV values estimated from the regression equation with the weight-to-waist ratio as an independent variable ( $y = 24536.3x - 4911.0$ ) did not significantly differ from MRI-SMV. Bland-Altman plot showed that the residual had no systematic error which depends on the magnitude of SMV. Weight-to-waist ratio can be considered as an index of the whole body density, because waist is a convenient measure estimating fat mass (Mehdad et al. 2012; Daniels et al. 2000). This may be a reason for the strong association between weight-to-waist ratio and MRI-SMV. Conclusion Anthropometric measures, especially weight-to-waist ratio, are useful for estimating the whole-body SMV in Japanese children. References Fukunaga et al. ### FITNESS TESTS TO PREDICT FUNCTIONALITY IN OLDER ADULTS WITH AMNESTIC MILD COGNITIVE IMPAIRMENT

Tortosa-Martínez, J., Caus, N., Manchado-López, C., Cortell-Tormo, J.M., Carreres-Ponsoda, F.

*Universidad de Alicante*

Introduction Amnesic Mild Cognitive Impairment (a-MCI) is usually considered a previous stage for Alzheimer's disease (Petersen, 2004). Functionality is a key component of quality of life and risk of frailty in older adults. The aim of this study was to explore the baseline correlations and power of prediction of different fitness tests with functionality measurements in this population. Methods Forty-one people diagnosed by trained neurologists with Amnesic Mild Cognitive Impairment, according to Petersen (2004) criteria, were recruited from the Neurology Unit of the Hospital de San Vicente del Raspeig (Spain). Fitness tests included the 6 minute walk test (6MWT), the 8-meter walk test (speed of gait), the timed get up and go test (TGUG), and the Chair-Stand test (CST). The Disability Assessment for Dementia (DAD) and the Functionality Assessment Questionnaire (FAQ), were used to measure functionality. Partial correlations and a stepwise linear regression model were used in order to explore baseline associations between fitness tests and functionality measurements. Results Partial correlations controlling for age, gender and education, showed that a better performance in the TGUG strongly correlated with better functionality as measured in both the the DAD ( $p < 0.001$ ), and the FAQ ( $p < 0.001$ ). The 6MWT showed a positive tendency with functionality. Speed of gait and the Chair Stand Test did not correlate with either the DAD or the FAQ. When the regression model was applied, the TGUG remained as a predictive variable for the DAD ( $p < 0.001$ ) and the FAQ ( $p < 0.001$ ). Discussion People with Mild Cognitive Impairment start to experience a decrease in functionality that causes difficulties in activities of daily living (Brown et al. 2011). In our study, the fitness test that best correlated with functionality was the TGUG test. A better performance on this test has been also associated with a reduced risk of falling (Shumway-Cook et al., 2000) and with improved executive function and memory (Donoghue et al., 2012) in older adults. Considering the reduced time and cost of using this test, it should be considered by clinicians as a tool for assessing functionality in older adults with Mild Cognitive Impairment. ### RELATIONSHIPS BETWEEN PARENTAL AWARENESS OF PHYSICAL ACTIVITY DURING THEIR CHILD'S EARLY CHILDHOOD AND MOTOR SKILLS IN LATER CHILDHOOD

Hirano, T., Kozakaj, R.

*Nagoya college, Hokusho Univ.*

AIM: This study examined relationships between parental awareness of physical activity during early childhood, motor skills and activities of daily living in later childhood. METHOD: Participants were 108 children (55 boys, 53 girls; age from 6y to 11y). we collected the results of elementary-school children motor skills tests and ran a questionnaire for boys, girls, and their parents. RESULTS: The sons of parents who answered that 'they tried to get their children to engage in physical activity in early childhood' had higher motor skills throughout the six-years of elementary school. In addition, the sons of parents who answered they tried to get their children to engage in physical activity in early childhood liked physical exercise and were more likely to play outside after returning home from school. This results showed that parental awareness during their child's early childhood possibly has an effect on the child's motor skills, level of physical activity and enjoyment of exercise in later childhood. However, no significant relationship between parental awareness and child motor skills was observed in girls. The reason was that girls overall are less motivated to exercise and are more likely to play indoors after returning home from school. Furthermore, no relationship between the later-childhood motor skills and number of years using a stroller during infancy and means of going to kindergarten was observed.

### WOMEN HEALTH-RELATED FITNESS PARTICIPANTS' PERCEIVED AUTONOMY SUPPORT AND BASIC PSYCHOLOGICAL NEEDS IN TERMS OF EXERCISE STAGES OF CHANGE

Mehrtash, S., Ince, M.L.

*Middle East Technical University*

Introduction Nowadays physical activity paradigm has been focused on health-related concept for promoting the healthy lifestyle. It is claimed that motivational climate might be influential on sport participants' engagement and satisfaction of their basic psychological needs like autonomy, competence and relatedness (Duda, 2001). Using self-determination theory (Deci, & Ryan, 2008) as an effective concept in human behavior, the aim of this study was to examine the women health-related physical activity participants' perceived autonomy support and basic psychological needs in exercise setting in terms of their exercise stages of change (five stages including pre-contemplation, contemplation, preparation, action and maintenance) at a university setting. Methods The sample consisted of 175

women (M age= 25.1, SD= 7.2) participating in health-related physical activity program in a university setting. Participants completed the Perceived Autonomy Support (Hagger et al., 2007), Basic Psychological Needs in Exercise Setting (Vlachopoulos, & Michailidou, 2006) and Exercise Stages of Change (Prochaska & DiClemente 1983) questionnaires. Data analyzed by using one-way ANOVA and one-way MANOVA ( $p < .05$ ). Results Findings indicated that perceived autonomy support was significantly different by exercise stages of change ( $p < .05$ ). Further analysis indicated that only the participants in the action stage had higher perceived autonomy support from the participants in the contemplation stage. Findings on basic psychological needs in exercise revealed that there was no significant difference between basic psychological needs in exercise and exercise stages of change ( $p > .05$ ). Discussion To meet the needs of women health-related physical activity participants, health-related physical activity program instructors should pay more attention to provide an autonomy supportive climate by the needs of each participants' exercise stages of change. ## PREDISPOSITION TO PHYSICAL ACTIVITY IN FIREFIGHTERS OF LOMBARDY

Cereda, F.I, Forte, E.I, Gatti, M.I

*I:University Cattolica del Sacro Cuore of Milan (Italy)*

**Introduction** The purpose of this preliminary survey was to explore the predispositions to physical activity (PA) in firefighters (F) from Lombardy (a region in the north of Italy), through the observation and analysis of their motor habits, both in service and out, linked with their socio-anagraphic characteristics and their BMI (Body Mass Index). Depending on the results obtained from the survey is proposed a plan of general actions to prevent injuries and protect F's health. **Methods** The survey was conducted on a sample of 1328 F from 11 Commands of Lombardy through a descriptive questionnaire on PA (Vivian, A., 2013). F were classified according to BMI into four categories: underweight (BMI<18.5), normal weight (18.5≤BMI≤24.9), overweight (25≤BMI≤29.9), and obese (BMI≥30), and compared in relation to PA and socio-demographic variables considered. Statistical differences between groups were identified through SPSS statistical programme. Results F were almost all male (99,8%), aged 39,2±8,7; 54.6% results being normal-weight, 38.9% overweight; 6.5% obese. No underweight was found. A chi square statistic is used to investigate the answer of different categories. The number of normal-weight subjects decreases significantly with age ( $p < 0.05$ ). PA on duty is practiced regularly by only 14.6% of normal weight, by 8.7% of overweight and 4.7% obese ( $p < 0.05$ ). PA outside the workplace is regularly done only by 62.5% normal weight subjects; 50.5% of overweight and 50% of obese subjects does just occasionally exercise. F who always practise PA (n=155) has an high educational level. F who don't have children appear to be less overweight ( $p < 0.05$ ). **Discussion** F of Lombardy don't take part regularly in PA, both off and especially in duty. This gives them a harder time in particularly demanding interventions. A gradual lack of interest towards PA seems to be related to the increasing of age. Other factors which influence PA are the level of education, the presence of children, the family status, personal issues, such as the very little interest in exercise and barriers as the availability of spaces and equipment. All these aspects could be overcome through a movement education addressed to everyone, to the personnel with its family and to those holding a major role. In support of importance of PA in duty, the collected data show that, who follows that habits, has a more balanced BMI and perceive less fatigue during critical interventions. ## SLEEP TIME MEASURED BY ACTIGRAPHY IN OLDER ADULTS: A BRIEF REVIEW

Sanchis-Soler, G., Valencia-Peris, A., Sanchis-Sanchis, R., Blasco-Lafarga, C.

*University of Valencia, Spain*

**INTRODUCTION** Older adults' (OA) current lifestyles produce imbalances in their circadian cycles, which are influenced by aging and particular factors that impede getting out of home (1). Inappropriate and irregular sleep time (ST) cause serious diseases, especially in this population (2). Actigraphy has become an essential tool in sleep research (3) but there is still a gap related to its reliability and efficacy among the elderly, mainly in the last stage of life, when individuals are mostly sedentary. This brief review aims to deep in the use of accelerometers in the assessment of ST in OA, remarking some particularities. **METHODS** Electronic searches for ST studies in OA were performed in SCOPUS, PUBMED, MEDLINE, EBSCO, WEB OF SCIENCE and GOOGLE SCHOLAR until January 2015. Inclusion criteria were: 55+ years of age, published from 2013 and measured with actigraphy. Relevant studies were graded according to the Oxford Levels of Evidence. **RESULTS** We screened 3990 search results. After careful reviewing, only 10 studies have met the inclusion criteria for this review. They focus on sleep activity patterns, ST quality, insomnia, total ST, sleep efficiency, wake after sleep onset, sleep-wake cycles, sleep initiation, periodic leg and body movements and evening light. Authors point out the relationship between actigraphy and quality of life, depression, dementia, obesity, EPOC, diabetes and cardiovascular diseases, among others (4). 50% of the studies used wrist actigraphy, 20% waist, 10% PAM-LR devices, 10% were review manuscripts, and the remaining 10.3% did not specify the device employed. **DISCUSSION** Evidence from studies reviewed suggests the adequacy of actigraphy to measure ST patterns in OA as well as the effectivity in documenting the effects of various behavioural and medical factors related with sleep-wake cycles in this population. Likewise, accelerometers are devices of small size, relatively cheap and easy to use. However, several problems have been detected in their implementation with OA: small samples, necessity of increasing the validation of these particular devices, more feasible algorithms and low usefulness in patients with cognitive disorders, insomnia or respiratory illness. Further studies are required in order to improve and verify the suitability of actigraphy on measuring ST in OA; mainly among chronically ill and sedentary OA subpopulations. **REFERENCES** 1. ## EVALUATION OF RISK FACTORS ASSOCIATED WITH EXERCISE-INDUCED BRONCHOSPASM IN ADOLESCENTS

Leite, N.1, Consentino, C.L.M.1, Silva, L.R.1, Lopes, W.A.2,3, Alle, L.F.4, Milano, G.E.1,4, Lazarotto, L.1, Cavaglieri, C.R.3

*Federal University of Paraná*

1: NQV- Federal University of Parana (Curitiba, Paraná, Brazil), 2: State University of Maringa (Maringa, Paraná, Brazil), 3: University of Campinas (Campinas, São Paulo, Brazil), 4: Department of Genetics of Federal University of Paraná (Curitiba, Paraná, Brasil) Introduction Exercise-induced bronchospasm (EIB) is considered a limiting factor for exercise and has been associated with several factors such as asthma history, poor physical fitness and obesity. Also, the presence of the adrenergic receptor polymorphism (ADRB2) has been related to the presence of asthma and obesity. However, the association between ADRB2 polymorphism and EIB has not been investigated. Therefore, the aim of this study was to analyze the influence of asthma history, obesity, physical fitness and ADRB2 polymorphism on the presence of EIB. Methods The study was composed of 160 adolescents, of both genders, divided into two groups according to EIB presence. Anthropometrics, asthma history and physical fitness were evaluated. Genotyping of ADRB2 polymorphisms was achieved by using a TaqMan. The Chi-square test and Spearman's correlation were used for statistical analyzes, considering  $p < .05$  for significant difference. Results The positive EIB group had a higher incidence of asthma history (Chi=20.96;  $p \leq .0001$ ) and lower frequency of inadequate physical fitness (Chi=4.44,  $p = .03$ ) than the negative EIB group. No differences were found in overweight frequency (Chi=1.95;  $p = .16$ ), elevated waist circumference (Chi=.62;  $p = .43$ ) and allele polymorphism Gln27Glu (Chi=.001;  $p = .97$ ), while for Arg16Gly, trend was found between the groups (Chi=2.87;  $p = .08$ ). The EIB was directly correlated with the presence of asthma ( $r = .47$ ,  $p < .05$ ). There was no difference in the presence of ADRB2 polymorphisms. Discussion In this study, the positive EIB was not associated with anthropometric variables, corroborating Cichalewski et al (2015), who did not identify association between BMI and EIB. However, it was found that the presence of asthma history is the most important factor for the occurrence of EIB in this population. This result was similar to Lopes et al. (2009). The presence of ADRB2 polymorphisms is associated with asthma severity (Paiva et al., 2014). However, it does not influence the presence of EIB. References Welsh L, Kemp JG, Roberts RG. (2005). *Sports Med.* 35(2):127-34. De Paiva, A. C. Z., Marson, F. A. de L., Ribeiro, J. D., & Bertuzzo, C. S. (2014). *Allergy Asthma Clin Immunol*, 10(1), 8. ## PHYSICAL ACTIVITY BEFORE AND DURING PREGNANCY IN HUNGARY

Barka, N.1, Rénes, L.2, Orvos, H.2, Paulik, E.1

*University of Szeged*

Introduction The advantages of regular physical activity during pregnancy are improved emotional well-being, reduced risk of gestational diabetes mellitus (Dempsey et al., 2004), and excess maternal weight gain (Clapp & Little, 1995). Currently, little is known about the physical activity patterns of pregnant women in Hungary. The aim of this study was to analyse the lifestyle of pregnant women with a special attention on their physical activity before and during pregnancy. Methods The self-administered questionnaire-based study was conducted among women who had given birth to their babies at the Department of Obstetrics and Gynecology, University of Szeged. The mothers were interviewed one or two days after the delivery. It is an ongoing study, data collected in the first six months of 2014 were involved into the preliminary evaluation ( $n = 660$ ). The study protocol was approved by the Research Ethics Committee of the University of Szeged. Results The mean age of the participants was 31.76 years. Prior to their pregnancy, 50.7% of women were engaged in some kind of physical activity (swimming, running, and cycling). The frequency of exercise was quite variable: 3.4% of women exercised at least once a week, whereas 44.6% of them exercised once a day. The duration of the physical activity per occasion was also different: 33.9% of women preferred a 60 minutes-long workout session. 15.1% of women did competitive sport, but most of them discontinued the competitive exercise after the detection of pregnancy, so during pregnancy only 6.5% of women did some kind of sport, although more than 50% of women were physically active, and walking was the most preferred form of exercise during pregnancy. Only 8.8% of all women attended pregnancy gymnastic classes. Discussion Our results are in accordance with the literature (Domingues & Barros, 2007), such as the prevalence of physical activity is low among Hungarian pregnant women, and walking is the most frequent activity. The improvement of the healthy way of life at population level, and especially during pregnancy plays significant role in the prevention of later chronic diseases, so young women have to be educated about the importance of active lifestyle in women of childbearing age. ## CHANGES AFTER AN 8-MONTHS SCHOOL-BASED PHYSICAL ACTIVITY INTERVENTION PROGRAM FOR OBESE CHILDREN AND ADOLESCENTS

Martins, C.1, Aires, L.2, Silva, G.2, Lemos, L.3, Silveira, D.1, Mota, J.4

1: PAPGEF/ UFPB (Brazil), 2: CIAFEL, ISMAI (Portugal), 3: UFPB (Brazil), 4. CIAFEL (Portugal)

Introduction: Programs to prevent and control weight-related problems are needed and should be implemented in early ages. The aim of the present study was to evaluate the changes in several health indicators after an 8-months school-based physical activity (PA) intervention program. Methods: 56 overweight and obese children and adolescents (25 control e 31 intervention) from 7 to 16 year-olds (31 girls) of 6 public schools in Porto participated in an 8-months school-based physical activity intervention program, consisted of 3 hours of Physical Education and 2 hours of after-school exercise sessions (five hours per week). Physical exercise sessions were designed to develop aerobic endurance, strength, flexibility, coordination and balance, through games with balls, bows, strings, callisthenic exercises and strength training. The exercise program was also designed to develop the enjoyment and body awareness looking to long-term changes in behavioural patterns. Anthropometry, blood pressure, blood samples (lipid profile, apolipoproteins, vitamin D, insulin, glucose, liver enzymes), PA and sedentary behaviour (accelerometry), cardiorespiratory fitness (ergospirometry), and body composition (DXA), were taken before and after the intervention. Changes between baseline and post-intervention data were calculated by paired samples t-test in SPSS (version 20.0), and level of significance was set up at 95%. Results: When comparing intervention and control groups, significant positive changes were observed for bone density, lean mass, cardiorespiratory fitness, moderate-to-vigorous PA, light PA, and sedentary behaviours. For the intervention group, baseline and post intervention results showed significant positive changes for bone density, moderate-to-vigorous PA, sedentary behaviours, apolipoproteins, liver enzymes, lipid profile and glucose. Conclusion:

An 8-months school-based physical activity intervention program promoted significant positive changes in several health indicators. Contact: clarice.br@fade.up.pt

### AGE AND GENDER-RELATED DIFFERENCES IN FUNCTIONAL FITNESS AMONG COMMUNITY-DWELLING OLDER ADULTS IN TAIWAN

Lee, H.

*National Yang-Ming University*

**Introduction:** Population is growing old rapidly in Taiwan, the proportion of people older than 65 is projected to be 14% in 2017, and up to 20% in 2025. The combined effects of aging process, disease, and sedentary life style tend to reduce functional fitness and result in difficulties in daily life activities and normal functioning of the elderly. This cross-sectional study aimed to explore the age and gender-related differences in functional fitness among a group of community-dwelling older adults in Taiwan, and further to compare their fitness level with that of published criterion fitness standards in other countries. **Methods:** Older adults aged 65+ from six community senior-care stations of Hsinchu city, Taiwan were recruited to participate in a 12-week community-based physical activity (PA) intervention program. Functional fitness was assessed using the Senior Fitness Test to evaluate the effects of the intervention program. The measurement items included: body height, body weight, body mass index (BMI), waist circumference, 30-sec arm curl, 30-sec chair stand, back scratch, chair sit & reach, 8-ft up & go, and 2-min step. The subjects' functional fitness performance at baseline was presented here to explore the age and gender-associated patterns. Data analyses were conducted by using SPSS version 19.0 for Windows. Significance was set at 0.05. **Results:** A total of 138 senior adults were recruited with predominantly female (89%). Their mean age was 77.2±6.3 years, mean body height 152.4±6.7cm, and mean body weight 57.4±9.1Kg; mean BMI 24.7±3.5 with 45% were overweight or obese and 62% with central obesity. Significant age-related declines were found for 30-sec arm curl, 30-sec chair stand, chair sit & reach, 8-ft up & go, and 2-min step across 6 age subgroups (65-69, 70-74, 75-79, 80-84, 85-89, and 90+) with sharp decline around 80 years. Female showed better flexibility than male subjects. When comparing their fitness level with that of published criterion fitness standards, the overall functional fitness performance of our study subjects were graded approximately at "poor" level. **Discussions:** The functional fitness of community-dwelling senior adults decreased significantly with age with sharp decline around 80 years. Regular PA was shown to slow the rate of decline in both aerobic and musculoskeletal systems and hence improve functional capacity. It is expected to see whether participation in a group-based or pedometer-assisted PA intervention program may positively affect community-dwelling older adults' PA level, functional fitness, and health-related quality of life while reversing frailty status. **References:** 1.Adamo DE, Talley SA, Goldberg A. Age and task differences in functional fitness in older women: comparisons with Senior Fitness Test normative and criterion-referenced data. *J Aging Phys Act.* 2015;23(1):47-54. 2.Milanovic Z, Pantelic S, Trajkovic N, Sporis G, Kostic R, James N. Age-related decrease in physical activity and functional fitness among elderly men and women. *Clin Interv Aging.* 2013;8:549-56.

### EFFECTS OF INTERVAL TRAINING VERSUS CONTINUOUS TRAINING IN MODERATELY OBESE WOMEN: A PILOT STUDY

Garnier, S., Idiart, A., Laffargue, P., Liu, L., Candebat, R., Joanisse, D.R., Joffroy, J., Mauriège, P.

*Université Paul Sabatier*

**Introduction** Epidemiological evidence supports the notion that both sedentarity and obesity are associated with numerous risk factors for all causes of mortality and premature death, and more particularly, coronary heart disease in women (Mora et al., 2006, Mosca et al., 2007). Although high-intensity intermittent exercise was suggested to reduce body weight and fat mass in overweight individuals, more studies are clearly needed (Boutcher, 2011). The main objective of this study is to compare the effects of interval training, IT vs continuous training, CT on weight loss, cardiorespiratory fitness (CRF), perceived health, quality of life (QoL) and eating behaviors. **Methods** 49 voluntary, healthy, sedentary and moderately obese (mean body mass index, BMI = 32 ± 4 kg/m<sup>2</sup>) women (37.5 ± 9.5 years old), were randomized to IT (24) or CT (25) group. The two groups performed exercise 3 times a week, during 12 weeks. Each session of interval training gradually increased from 6 to 10 X 1-min cycling at 75 to 85 % of heart rate reserve (HRR), and continuous training gradually increased from 20 to 35 min cycling at 50 to 60% HRR. Following measurements were obtained from 10 and 13 women respectively subjected to IT and CT, before and after 12 weeks: CRF assessed by the 2-km walking test and estimated VO<sub>2</sub>max calculated (Laukkanen et al., 1993), height, weight (BMI calculated) and waist circumference measured using standardized procedures, fat mass and fat-free mass determined by bioelectrical impedance, perceived health estimated by the short perceived health questionnaire (SPHQ; Garnier et al. 2013), QoL estimated by SF-36 (Ware and Gandek, 1998), eating behaviors estimated by the three-factor eating questionnaire (TFEQ) (Stunkard et al., 1985). **Results** Estimated VO<sub>2</sub>max remained unchanged while BMI, waist girth and fat mass decreased in the two groups (p<.01). The physical component of QoL (SF-36) (p<.01), cognitive restraint and hunger (TFEQ) as well as the six items of perceived health (SPHQ) increased in the two groups (p<.05). **Discussion** Results of this randomized pilot study performed in healthy, sedentary and moderately obese women showed that the 12-weeks interval training or continuous training program led to similar improvements in CRF and perceived health, and body weight and fat mass losses. **References** Boutcher SH. ### AEROBIC CAPACITY AND TEST OF VARIABLES OF ATTENTION PERFORMANCE IN ELEMENTARY SCHOOL-AGE CHILDREN

Wen, H.1, Chen, C.2, Shen, T.1, Ang, B.3, Chang, Y.1

1: *Tzu-Chi University, (Hualien, Taiwan)*, 2: *Tzu-Chi General Hospital (Hualien, Taiwan)*, 3: *Universiti Sains Malaysia (Kubang Kerian, Malaysia)*

**Introduction** The impact of aerobic fitness on childhood cognitive and brain health has only recently gained attention. Aerobic fitness has been shown positive association multiple aspects of cognitive control (Scudder, Lambourne, Drollette, Herrmann, Washburn, Donnelly, Hillman, 2014). The Test of Variables of Attention (TOVA) is a continuous performance test (CPT) that assesses attention, impulsivity, and processing speed. CPTs are used in the assessment of attention-deficit/hyperactivity disorder (ADHD) in children and adults (Greenberg, Kindschi, Dupuy, & Corman, 1996). The TOVA norms are based on a standardization sample that was tested early in the day, and any TOVA administered after 1:00 p.m. will be flagged as potentially invalid (Hunt, Momjian, Wong, 2011). The purpose of current study was to examine the relationship between children's performance on the Progressive Aerobic Cardiovascular Endurance Run (PACER) subtest of

the FitnessGram® and aspects of continuous performance test that are believed to support academic success. Methods Twenty-three healthy female of second-grade (age  $7.87 \pm 0.08$  years, weight= $25.14 \pm 0.72$  kg; height= $127.38 \pm 1.05$  cm, BMI= $15.47 \pm 0.37$  kg/m<sup>2</sup>) from community attended the PACER tests and TOVA on weekend morning. Pearson correlation was conducted on the distance of PACER tests and indices of TOVA. Results Greater aerobic fitness was significantly related to fewer omission (inattention) errors ( $r = -.437$ ,  $p = .037$ ) and shorter reaction time ( $r = -.433$ ,  $p = .039$ ), but relationship to commission (impulsivity) errors was not found. Discussion The human brain is not fully developed until the third decade of life; Maintaining aerobic fitness in childhood may be a critical guideline to follow for physical as well as cognitive and brain health (Khan & Hillman, 2014). Children with a history of grade retention had significantly lower scores on the same measure of sustained attention (Gordon, Mettelman, Irwin, 1994). Cardiorespiratory fitness was related to academic achievement (Sardinha, Marques, Martins, Palmeira, Minderico, 2014). The findings suggesting better sustained attention in higher-fit children that are believed to support academic success. ### ASSOCIATIONS BETWEEN PERMANENCE TIME IN A PHYSICAL ACTIVITY PROGRAM CARRIED OUT IN PRIMARY HEALTH CARE AND FUNCTIONAL FITNESS IN BRAZILIAN ADULTS

Campos, L., Papini, C.B., Teixeira, I.P., Campos, B.A., Nakamura, P.M., Kokubun, E.

UNESP

Introduction World Health Organization, the Centers for Disease Control and Prevention, and the ACSM have been working together with Universities worldwide to determine which physical activity intervention can be more effective and efficient to promote healthy lifestyles (Pratt et al, 2010). According to Gomes et al (2014), 39.5% of the Primary Health Care Unit (PHCU) in Brazil offer physical activity program. However, these programs did not show the influence of the permanence time in the program with functional fitness. Thus, the aim of this study was verify the association between permanence time in a program carried out in the PHCU and functional variables in Brazilians adults. Methods This study evaluated 45 ( $53.5 \pm 11.4$  years of age) participants of the "Programa de exercício físico em unidades de saúde" in Rio Claro-SP, Brazil. The program offers sessions of moderate general exercise. The permanence time was calculated using percentual of class ministred with class frequency during six-months. The functional fitness was evaluated thought AAHPERD test. The simple linear regression test was used to verify associations between functional fitness and permanence time using STATA 12.0. Results The range of frequency was 22.2% and 96.4% respectively. The coordination variable showed positive association with the frequency in program (coef=0.7;  $p < 0.05$ ). The strength, agility, flexibility and aerobic capacity variable were not significantly associated with permanence time ( $p > 0.05$ ). Discussion According Nakamura et al. (2007) program with more session frequency is better to improve functional fitness. This result showed that more physical exercise people, more they improve the coordination. In PHCU this kind of exercise program is an important strategy to improve functional fitness. However, others studies are necessary to understand the role among frequency in the class with improve in variable relation with functional fitness. ### HIGH CARDIORESPIRATORY FITNESS ATTENUATES CAROTID ARTERIAL STIFFENING IN MEN WITH THE METABOLIC SYNDROME

Park, S.

Korea Institue Sports of science

Introduction Carotid arterial stiffness is associated with an increased risk of stroke and cardiovascular disease. Even, metabolic syndrome (MetS) is associated with increased carotid artery stiffness (Czernichow et al., 2005). On the other hand, high cardiorespiratory fitness (CRF) is associated with slower progression of early atherosclerosis in men. However, the associated between CRF and carotid arterial stiffness in men with MetS is under established. Thus, the purpose of this study was to test hypothesis that high cardiorespiratory fitness attenuates carotid arterial stiffening in men with the Mets. Methods The study participants were 536 Korean men (19 - 64 yrs) from the first year of the Korea National Fitness Award Project. The CRF was quantified from the duration of a maximal treadmill exercise test. Based on cut-off point associated with MetS for Korean men (Park, 2014, in submission), participants were divided by high and low fit. Carotid artery intima-media thickness (IMT) and stiffness parameters were measured on ultrasound image using e-tracking. And, brachial ankle pulse wave velocity (baPWV) was measured. Results In logistic regression analysis, a dose-response relationship was observed between increased levels of CRF and decreased prevalence of MetS in Korean men (high fitness: OR=0.342, 95%CI 0.182-0.644). The risk was 39% lower for the increase by 1 METs (OR=0.614, 95% CI 0.486-0.775) in multivariate adjusted model. There was no difference in carotid arterial stiffness indices between fit men with and without the MetS. However, high-fit men with the MetS had significantly lower cIMT (MetS/low-fit  $0.59 \pm 0.14$  mm vs. MetS/fit  $0.54 \pm 0.09$  mm vs. Healthy/low-fit  $0.59 \pm 0.13$  mm vs. Healthy/fit  $0.51 \pm 0.1$  mm,  $p = 0.002$ ),  $\beta$  (MetS/low-fit  $8.53 \pm 3.52$  (arbitrary units) vs. MetS/fit  $5.83 \pm 1.53$  vs. Healthy/low-fit  $7.53 \pm 2.98$  vs. Healthy/fit  $6.38 \pm 2.48$ ,  $p = 0.016$ ) and baPWV (MetS/low-fit  $1434 \pm 237$  cm/s vs. MetS/fit  $1279 \pm 118$  cm/s vs. Healthy/low-fit  $1327 \pm 191$  cm/s vs. Healthy/fit  $1251 \pm 170$  cm/s,  $p < 0.001$ ) than both low-fit men with the MetS and even without the MetS. Discussion The major finding of this study was that high CRF attenuated carotid arterial stiffness in men with and without the MetS. Furthermore, high CRF men with the MetS showed the attenuation of carotid arterial stiffness compared to low CRF men with and without the MetS. There are limitations that need to be highlighted. First, given the cross-sectional nature of this study, we were not able to determine causality. Second, these results may not be generalized to women. The study results suggest that high CRF may be a strong protective effect of cerebro-cardiovascular disease in men with the MetS. Reference Park S. et al., 2014 in submission. ## BODY COMPOSITION, PHYSICAL ACTIVITY AND DIETARY INTAKE OF JAPANESE CHILDREN

Sasahara, C., Muraoka, Y.

*Meisei University*

**Introduction** Increased number of obesity has recently observed in Japanese children and it has become public health concern. Keep adequate body composition, particularly body fat percentage from childhood is important to prevent lifestyle-related diseases. The purpose of this study was to investigate the differences in physical activity and dietary intake between higher body fat (H-fat) and lower body fat (L-fat) groups in Japanese elementary school children. **Methods** This was a cross-sectional study with sixty-four children, 30 boys and 34 girls aged 10-11 years old, measured height, weight and body fat percentage. Subjects were divided by body fat percentage into two groups, H-fat and L-fat, according to gender. The subjects' physical activity and dietary intake were assessed by wearing accelerometer in a week and using self-reported three-day food records, respectively. **Results** Among boys, average body fat percentage of H-fat was  $22.9 \pm 5.3\%$ , of L-fat was  $9.8 \pm 2.4\%$  and among girls,  $25.1 \pm 5.6\%$  and  $16.4 \pm 3.0\%$  (mean $\pm$ SD) respectively. H-fat in boys had a higher week averaged total energy expenditure ( $p < 0.05$ ) but a lower week maximum counts of steps (steps/day) ( $p < 0.05$ ) and a lower week maximum activity time ( $p < 0.05$ ) than L-fat in boys. H-fat in girls had a higher week averaged total energy expenditure ( $p < 0.05$ ) than L-fat in girls. H-fat in boys consumed a smaller amounts of milk and milk products ( $p < 0.05$ ), and also had a higher energy intake percentage in breakfast ( $p < 0.05$ ) and a lower energy intake percentage in dinner ( $p < 0.05$ ) than L-fat in boys. While, there were no significant differences in dietary intake between H-fat and L-fat among girls. **Discussion/Conclusion** Different body fat percentage groups in Japanese elementary school children had some important trends in physical activity and dietary intake especially in boys. Further studies are needed to develop successful strategies that address physical activity and dietary intake to prevent obesity among Japanese children.

## RESEARCHING THE HEALTH STATUS OF HEALTHCARE PROFESSIONALS WORKING IN AN INSTITUTE FOR CHRONICALLY ILL PSYCHIATRIC PATIENTS

Nagyvárad, K., Mátrai, Zs.

*West Hungarian University*

**Introduction** Several research works in the related international literature on sociology and health sciences deal with the state of health in one selected population. These studies predominantly examine the self-rated subjective health status using questionnaires. In light of that our research is limited to the employees of a certain institute, it can be considered a case study within the scope of qualitative measurement methods. Moreover, our approach was to assess the objective state of health alongside the subjective factors, as our hypothesis was that the majority of the indicators presumably coincided. **Methods** In order to assess the subjective state of health, the individuals had to fill out three functionally different questionnaires. The first one examined the mental well-being based on the answers given to the five questions of the WHO WBI-5 international test and the WHOQOL-BREF26 concerned the interviewees' satisfactions with their quality of life, the third questionnaire containing 56 questions along the background part – that explored the following dimensions: place of employment, working conditions. Regarding the indicators of objective health status, we measured the ratio of height and body components (water, protein, mineral matter and fat), also the fat–muscle ratio, waist–hip ratio, the extent of abdominal obesity and the BMI (Body Mass Index). **Results** The subjective and objective data do not overlap in most cases. The objective results of only 31 people in the 'Fine and satisfied' group were in harmony with the subjective self-rating of health. In the 'Unwell and unsatisfied' cluster only 9 out of 43 people's objective data did not challenge the subjective results. In the 'Fine but unsatisfied' cluster, the objective indicators prevailed to such an extent that there was only one person whose objective and subjective indicators showed the same outcome (Nagyvárad, 2014). **Discussion** As already emphasized in the beginning of our research paper, our hypothesis claims that if we take into account the subjective health indicators along with the objective ones, they would presumably coincide to a big extent. However, based on the findings it is apparent that our hypothesis was not verified. **References** 1. Mavaddat N., Parker R.A. et al. (2014). ## THE EFFECT OF BIKE LANES DISTANCE ON BICYCLE COMMUTING ADOPTION – A LONGITUDINAL STUDY

Teixeira, I.P.1, Nakamura, P.M.1,2, Campos, L.1, Smirmaul, B.P.C.1, Kokubun, E.1

*1. São Paulo State University, UNESP (Rio Claro, Brazil); 2. Federal Institute of Education, Science and Technology, Muzambinho, MG, Brazil*

**Introduction** Although new bike paths/lanes are often built to promote bicycle use, there are few studies using objective measures to investigate the influence of these structures. In addition, studies which showed association between cycling and bike paths/lanes have typically been conducted in high-income countries and employed cross-sectional designs (Fraser and Lock, 2010). Therefore, the aim of this study was to investigate the effect of bike lanes distance on bicycle commuting adoption in adults. **Methods** Longitudinal study, with a sample of 381 adults non-bikers, living in Rio Claro city - SP – Brazil. The baseline was conducted in 2008 and the follow-up in 2014, after the implementation of 22 bike lanes segments, totalling 18.8 km. The shortest distance between the participant's house and the bike lanes were determined through the Geographic Information System. To evaluate bicycle commuting, a question regarding the frequency and time of use from the International Physical Activity Questionnaire was utilized. Poisson regression was performed, adjusting for age, gender and socioeconomic status. **Results** Among the 381 participants followed, 4.2% started cycling after the bike lanes implementation. Participants living farther than 800 meters from the bike lanes showed lower chances of bicycle commuting adoption (Relative Risk= 0.30; Confidence Interval-95%=0.09-0.95) when compared to those living within 200 meters from the bike lanes. **Discussion** These results reinforce the positive effect of bike lanes implementation on bicycle commuting adoption. In addition, bike lanes implementation should consider the distance between the target population and the bike lane. **References** Fraser SDS, Lock k (2010). Cycling for transport and public health: a systematic review of the effect of the environment on cycling. *European Journal of Public Health*. 21(6), 738-743. ### PHYSICAL ACTIVITIES AND PHYSICAL EXERCISE THERAPY FORM REDUCING BLOOD PRESSURE AND HEART RATE FOR BETTER QUALITY OF LIFE.

Bankoff, A.D.P., Zamai, C.A., Bispo, I.P., Rodrigues, M.

*Universidade Federal de Mato Grosso do Sul e Universidade Estadual de Campinas*

**Introduction** The beneficial effects of physical exercise must be recovered in the initial treatment of hypertensive individuals. In sedentary and hypertensive individuals, clinically significant reductions in blood pressure can be achieved with relatively modest increase in physical activity, above the sedentary levels, in addition to the amount of exercise required to lower blood pressure may be relatively small, possible be achieved even by sedentary individuals (Bankoff and Zamai, 2012). **Methods** We evaluated 114 male subjects aged 35-55 years, mean age 46 years using a questionnaire containing the name, weight, height, blood pressure measurements, heart rate, power, sedentary lifestyle, chronic diseases and other issues. We separated the 37 questionnaires which caught our attention for the results. It was proposed to them a program of moderate physical activity 03 times a week last in gone hour each class totaling three hours per week. It was also suggested that they look for other activities outside the program. The prescription of physical activity was: Monday walking, stretching exercises and a series of breathing exercises; Wednesday free dance movements individual and double and Thursday physical activities and guided free exercises for a period of six months. After six months they were reevaluated considering the same variables. **Results** There was a reduction of blood pressure and resting heart rate, reduction in anthropometric measurements and body mass index of the subjects studied; there was a change in eating habits and reducing deleterious habits for health promoting better quality of life. **Surveys data** -1st prior to physical activity program and 2nd before the physical activity program after six months of constant physical activity related to systolic blood pressure, diastolic blood pressure, heart rate, Average age, weight, height and BMI were treated statistically through the ANOVA test: two criteria, were significant at  $p < 0,01$ . **Discussion** Carvalho (2013) describes that ballroom dancing has been used as a means of fitness, with the adoption of varied rhythms in cardiac rehabilitation. Regular exercise can also improve myocardial blood flow and slow the progression of heart disease, or at least maintain an adequate blood supply to the heart muscle to compensate the coronary arteries narrowed by fatty deposits within its walls (Bankoff and ZAMAI 2012; Bankoff et al 2013) **References** Bankoff, ADP ; Zamai, C A ; Rocha, J ; Guimarães, P R Mendes. ### CONSCRIPTS PHYSICAL PERFORMANCE COMPARISON BEFORE AND AFTER BASIC TRAINING COURSE IN 2012 AND 2013

Stamm, M., Antson, H.

*Tallinn University/Estonian Defense Forces*

**Introduction** The purpose of this study was to compare the physical ability level before and after Basic Training Course (BTC) of the conscripts. Service in defense forces requires high moral volition level and good physical ability. Quick adaptation with the new conditions are also important because of the short duration of military service (in Estonia 8-11 months). With good physical preparation conscripts can adapt quickly with service and with new living conditions. **Methods** The sample of this study consists of conscripts who began service in 2012 (n=3235 conscripts) and in 2013 (n=3255 conscripts). To assess soldiers physical condition and their progress of training suitability we use in Estonian Defense Forces (EDF) the United States Army Physical Fitness Test (PFT) which is modified for the EDF demands. PFT is designed to test the muscular strength, endurance, and cardiovascular respiratory fitness of soldiers (Army Physical Readiness Training 2012). The test consists three different exercise: (1) push-ups in two minutes; (2) sit-ups in two minutes and (3) 3.2 kilometers run. Scoring of the PFT is based on gender, age category and number of repetitions performed, where each event ranges from 0 to 100 points. The sum of the three exercises must be more than 190 points to pass the PFT. All soldiers in EDF must do the PFT; first test at the start of the BTC, second at the end of the BTC and third at the end of the service time. In this study we focus on first two tests. **Results** The PFT analysis revealed that in 2012 passed the first test successfully 38.6% of conscripts. After 10 week BTC, where conscripts have been getting regular physical exercise training lessons, 87.4% of conscripts passed the second physical performance test. In 2013 the first test passed successfully 42.3% and after BTC the number of successfully passed conscripts is raised up to 92.7%. Both results are higher in 2013 than in 2012, although the results were not statistically significant. **Discussion** In conclusion we can say that the physical preparation of the conscripts are very different before military service. By USA Fitnessgram standard (Meredith, Welk 2007) for 17-18 year-old boys are minimum requirements in push-up test 35 and in sit-up test 43 repetitions. To pass the PFT (190points), the requirements are almost the same: 40 push-ups, 46 sit-ups and run 3.2 km in 15.54 minutes. While conscripts physical condition at the beginning of BTC are lower than the minimum requirements are, is necessary to raise their physical ability level before military service, to make BTC more effective for conscripts. **References** Meredith M, Welk G. Fitnessgram/Activitygram. Test administration manual. The Cooper Institute, Dallas, Human Kinetics, 2007. Army Physical Readiness Training. (2012) FM 7-22, HQ, Department of the Army, Washington, DC, USA.

### PHYSICAL ACTIVITY AND CARDIORESPIRATORY FITNESS AS PROTECTIVE FACTORS TO HEALTH INDICATORS IN STUDENTS IN FULL TIME SCHOOL IN THE COUNTRYSIDE

Brito, L.M.S., Leite, N., Boguszewski, M.C.S.

*Federal University of Parana and CAPES*

**Introduction** Physical activity (PA) in schools has been discussed, whether in regular (or extracurricular classes or back turn. Students on Full Time schools have up to 7-9 hours of PA. **Methods** 117 students in Full Time school (60 girls), mean age of  $11.9 \pm 0.9$  years, answered the PA - 3DPAR questionnaire. PA was categorized as  $< 300$  or  $> 300$  minutes/week (min/w). Weight, height and waist circumference (WC) were evaluated and body mass index (BMI) Z scores were calculated. Individuals were classified as normal weight and overweight. Cardiorespiratory fitness (CR) was determined by the maximum  $VO_2$  during the Come and Go 20 meters Test proposed by Léger. Students were grouped according to PA and CR in - CF weak/very weak and PA  $< 300$  min/w, CF weak/very weak and PA  $> 300$  min/w, CF satisfactory and PA  $< 300$  min/w, and finally CF satisfactory and PA  $> 300$  min/w. The program STATISTIC and the square x2 test for linear trends were used. **Results** 21 students (18.8%) were overweight, 25% in the group CF weak/very weak and PA  $< 300$  min/w, whereas 75% were considered CF satisfactory and PA  $< 300$  min/w ( $p = 0.02$ ). 12 students (10.3%) had increased WC, 6 with CF weak/very weak and PA  $< 300$  min/w and 6 with CF satisfactory and PA  $< 300$  min/w ( $p = 0.0003$ ). Only 4 students (3.6%) had increased BP, all with CF satisfac-

tory and PA < 300 min/w. Among the remaining students with normal weight, normal BP and normal WC, the majority had CF satisfactory and PA < 300min/w. Approximately 30% of them were considered CF satisfactory and PA >300 min/w. Discussion The majority of the students had PA < 300 min/w, despite the spent time at school. CF weak/very weak were seen only among those with overweight and increased WC. Students with appropriate WC and BMI presented with CF satisfactory. The best CF has already been reported between countryside individuals<sup>1</sup>. The large number of students of rural school that self-assessed with PA <300 min/w may be due to the fact that the student be adapted to the daily routine like to travel to school on foot or by bike, not considering these activities as severe / very severe, demonstrating the positive influence of the activities, habits and customs of the country side CF these individuals. Conclusion Programs aimed to increase PA along with improved levels CR should be encouraged. References GLANER, M. F. Physical activity level and health-related physical fitness in rural and urban boys. *Rev. paul. Educ. Fis., São Paulo*, 16(1): 76-85, jan./jun. 2002. Contact lilian-messias@yahoo.com.br

## MUSCULOSKELETAL PATHOLOGY EPIDEMIOLOGY FOR MILITARY PERSONNEL AND CIVIL GROUPS

Plavina, L.1, Karklina, H.2, Viksne, I.3

<sup>1</sup>National Defence Academy of Latvia, <sup>2</sup>Riga Stradins University, <sup>3</sup>General practice Doctorate of Riga region

Introduction Musculoskeletal pathology forms a high rate of morbidity in groups of civil population and military personnel. Musculoskeletal disorders manifest with pain symptoms and functional disorders that have an influence upon daily activity and working capacity. Three most important pain areas are those of lumbar / sacral part, shoulders and lower extremities. It is important to recognize risk factors and their impact upon individual in order to provide preventive measures and reduce the rate of musculoskeletal disorders linked to specific job and treatment at an early stage. The nature of musculoskeletal problems suggest that a combination of ergonomic and individual/organizational intrinsic and extrinsic factors associated to military environment, as well as psychosocial factors may play a role in development, exacerbation and maintenance of work disability in groups of military and civil population. Material and method We provide with assessment of Anthropometric characteristics in two groups. Anthropometric characteristics of military personnel (men; n=60) that leave active service and civil population in the same age range (men; n=100) were collected during a two-year period (2011/2012). Evaluated anthropometric characteristics were height, body mass and anthropometric indices. Body fat ranges for standard adults were calculated according to NIH/WHO body mass index (BMI) guidelines. Data collected by anonymous survey also showed the number of smokers and revealed information on medical history of parents. Results BMI with Musculoskeletal pathology above standard level was identified in 55% of military personnel group cases and in 71.3 % of civil population group cases. Analysis of anthropometric characteristic revealed that above standard level BMI was identified in 61.3 % of soldiers and 73.7 % of officers with musculoskeletal pathology (deforming dorsopathies as the most frequent one). In 14% of cases regarding the civil population group the diagnosis – deforming cervical or lumbar Spondilosis – was confirmed. It was defined that complaints about back pain, which could possibly lead to deforming spondilosis, appear earlier in case of smokers comparing to non-smokers, however the index is statistically insignificant ( $p \geq 0.05$ ). Conclusions Musculoskeletal pain frequently affects daily activities of patients. One of the reasons the musculoskeletal pathology is the overweight it may be important to provide preventive measures to reduce the risk of musculoskeletal disorders linked to specific job and treatment at early stage. Assessment of risk factors (smoking, genetic, inflammation, inappropriate physical exercise) in an early stage of musculoskeletal disorders allowed starting prophylactic and therapeutic measures for maintaining work capacity and health standards.

## SHORT- AND LONG-TERM EFFECTS OF 10-WEEK CYCLE ERGOMETER INTERVENTIONS FOR OLDER ADULTS IN ASSISTED LIVING FACILITIES

Van Roie, E., Martien, S., Seghers, J., Boen, F., Delecluse, C.

*KU Leuven*

Introduction Regular participation in physical activity (PA) has been shown to reduce the impact of aging. However, many older adults, especially those with functional limitations, are not regularly involved in PA. Therefore, the promotion of PA should be considered as a public health priority in this population. The aim of the current study was to evaluate the short- and long-term effectiveness of 10-week cycle ergometer interventions on PA, functionality and muscle strength in older adults in assisted living facilities. Methods Eight assisted living facilities (n=95; 82.1±5.9 years) were randomly assigned to (1) structured coaching (STRUC), consisting of three weekly supervised sessions on a cycle ergometer, (2) need-supportive coaching based on the Self-Determination Theory (NEED), consisting of an individualized cycle ergometer program with minimal coaching contact, or (3) a control group (CON). Initial training volume was based on a 6-minute cycle test and was gradually increased over the 10-week period. Outcome measurements were training adherence rate (number of training sessions performed as a percentage of the recommended number of training sessions), self-reported PA (using the Physical Activity Scale for Elderly), objectively measured PA (using Sensewear armbands), 6-minute walk distance, modified Physical Performance test (mPPT) and static knee extension strength. Measurements were performed at baseline, post-intervention (10 weeks after pre) and at follow-up (24 weeks after post). Results Adherence to the 10-week program was higher in STRUC (89±13%) compared to NEED (68±31%,  $p=0.001$ ). However, adherence rates were similar in the long-term, although training volume was higher in STRUC. Self-reported moderate intensity PA increased more from pre to post in STRUC and NEED compared to CON ( $p=0.034$ ). However, only NEED showed short-term gains in daily energy expenditure. Adherers (at least 80% of training sessions from pre to post) showed better short-term results on mPPT and knee extension strength. Conclusions Minimal contact with a coach is sufficient to promote cycle ergometer use among older adults in assisted living facilities. Although more structure and assistance of a coach during the initial period resulted in higher training volumes, a limited number of contact moments is favored as it is more feasible in real-life settings. The effects on functionality and muscle strength of our short-term ergometer interventions were limited, but there is potential for improvement. Further research is required to assess the effects of PA programs of longer duration and at higher intensities in assisted living facilities. Contact Eeven.vanroie@faber.kuleuven.be

## APPLICATION OF SOMATIC MOVEMENT EDUCATION FOR TEACHING PILATES TO MIDDLE-AGED WOMEN

Lee, L.

*University of Taipei*

Introduction Pilates is a physical training system created by Joseph Pilates in 1990. In the general public's understanding, it focuses on the training of our core muscles. This physical training system emphasizes breathing, concentration, control, movement flow, core muscles,

and precision. Other than strengthening our muscles, the main goal is to establish a mind and muscle connection through these fitness exercises. Based on the Theory of Somatics, the somatic movement approach enhances one's self-awareness to the structure and capabilities of their own body through a series of physical exercises. The concept is similar with the main principle of Pilates exercise. For the reason that, the purpose of this study was to examine the effect of the curriculum underlying somatic movement education on perceived benefits of Pilates among middle-aged adults. Method Three participants, who were accepted an 8-month Pilates program, 60 minutes per week, were recruited from a private fitness club. Semi-structured interviews were conducted at the end of the program to collect data regarding suggestion for course contents and perceived benefits in mental and physical aspects. The trustworthiness of the data was identified by the principles of triangulation. Result The result revealed a positive feedback about the application of somatic movement education to the Pilates course. The participants reported that the program could enhance their self-awareness to the structure and capabilities of their own body, and maintain healthy and energetic. Moreover, they did self-practice after the class at home, expected the curriculum, and exhibited a positive attitude toward the whole program. Conclusion The results indicated that the Pilates curriculum incorporating somatic movement approach was highly appraised by the participants. The application of somatic movement approach to Pilates class is beneficial to enhance learners' self-awareness of body, relaxation, and physical fitness. This study suggests that the Pilates instructors can design a systematic curriculum underlying somatic movement education, which will be helpful for participants to gain more mental and physical benefits. ### BONE CHARACTERISTICS AND ANTHROPOMETRY IN HUNGARIAN MALE ELITE ATHLETES

Szmodis, M., Bosnyák, E., Trájer, E., Protzner, A., Szóts, G., Farkas, A., Tóth, M.

*University of Physical Education*

**Abstract Introduction** The beneficial effects of regular physical activity on bone status seems evident. Anthropometric parameters of athletes differ by sports. The main goal was to find and analyse the relationships between bone and anthropometric variables in elite athletes. **Materials and Methods** Participants were (N=184) Hungarian male elite athletes [kayak-canoe (KC=43); triathlon (T=16); track and field (TF=46); water polo (WP=19) and age-matched non-athletic control males (C=60)]. Anthropometric measurements were taken according to the suggestion of International Biological Program. Physique was characterised by Heath-Carter somatotype. Calcaneal Quantitative Ultrasound (QUS) parameters were registered with Sonost 3000 densitometer. The analysis included speed of sound (SOS, m/s), broadband ultrasound attenuation (BUA, dB/MHz), bone quantity index (BQI= $\alpha$ SOS+ $\beta$ BUA,  $\alpha$ ,  $\beta$ : temperature corrections). Differences of the subgroups and correlation patterns were analysed ( $p < 0.05$ ). **Results and Discussion** There were significant differences of QUS parameters between subgroups. Decreasing order of the bone characteristics' quality was as follows: TF; KC; T; WP and C groups. SOS in TF: 1519.30±16.00; KC: 1512.91±20.80; T: 1505.61±12.41; WP: 1500.24±16.95; C: 1495.15±10.85. BUA was the smallest at WP. TF: 106.51±14.82; T: 98.92±11.49; KC: 98.73±16.48; C: 92.20±8.83; WP: 79.42±20.55. BQI in TF: 91.97±16.67; KC: 84.76±19.63; T: 79.23±13.08; WP: 73.71±18.58; C: 69.31±10.05. Relative muscle mass related positively, absolute bone measurements related inversely to bone parameters. Moderate correlations were found between bone parameters and somatotype, especially with endomorphy component. Higher QUS values associated with lower endo- and mesomorphy while more linear physique was related to better bone variables. **Conclusions** Type of exercise and physique appear to affect bone status. Both weight-bearing and non-weight bearing exercise improve bone characteristics in different degrees.

### POSTPRANDIAL ARTERIAL STIFFNESS IN EXERCISE-TRAINED VERSUS UNTRAINED MEN

Kobayashi, R., Yoshida, S., Okamoto, T.

*Nippon Sport Science University*

**Introduction** Postprandial hyperglycemia increases arterial stiffness (Baynard et al. 2009). Arterial stiffness (Vaitkevicius et al. 1993) and insulin resistance (Weiss et al. 2014) were lower in exercise-trained humans than in untrained humans. However, the effect of exercise on arterial stiffness after glucose ingestion in young adults remains unknown. The present study investigates the effect of aerobic exercise on arterial stiffness after glucose ingestion in young men. **Methods** Ten exercise-trained males (ETR; age, 21.0 ± 0.2 y) and 9 healthy untrained males (UTR; age: 22.0 ± 0.7 y) participated in this study. Carotid-femoral pulse wave velocity (PWV) reflecting central (aortic) arterial stiffness and femoral-ankle PWV reflecting peripheral (leg) arterial stiffness were measured using an automated oscillometric device. Brachial and ankle blood pressure (BP) and heart rates were simultaneously measured using an automatic oscillometric device and electrocardiography during waveform recording. Blood glucose was measured using the glucose oxidase method. All parameters were measured before (baseline) and at 30, 60 and 120 min after the 75 g oral glucose tolerance test (OGTT). **Results** Aortic PWV did not change from baseline at 30, 60 and 120 min after glucose ingestion in both groups. Leg PWV increased from baseline at 30 ( $P < 0.01$ ) and 60 ( $P < 0.05$ ) min after glucose ingestion in the UTR, but not in the ETR group. Leg PWV was significantly higher at 30 min after glucose ingestion in the UTR, than in the ETR group ( $P < 0.05$ ). Brachial systolic BP did not change from baseline at 30, 60 and 120 min after glucose ingestion in both groups. Ankle systolic BP increased from baseline at 30 ( $P < 0.01$ ) and 60 ( $P < 0.05$ ) min after glucose ingestion in the UTR, but not in the ETR group. Ankle systolic BP 30 min after glucose ingestion was significantly higher in the UTR, than in the ETR group ( $P < 0.05$ ). Blood glucose increased from baseline at 30 ( $P < 0.01$ ) and 60 ( $P < 0.05$ ) min after glucose ingestion in both groups. **Discussion** It is well known that leg PWV and systolic BP are decreased after one bout of aerobic cycling (Kingwell et al. 1997). Moreover, Beck et al. (2013) reported that 8 weeks of aerobic exercise reduced leg PWV and SBP in young adults. Thus, regular aerobic exercise might attenuate the increase in leg PWV and ankle SBP after glucose ingestion. The present findings indicate that regular aerobic exercise suppresses increases in postprandial arterial stiffness. **References** Baynard T, Carhart RL Jr, Weinstock RS, Ploutz-Snyder LL, Kanaley JA. ## AGE-RELATED CHANGES IN GROUND REACTION FORCE PARAMETERS DURING SIT-TO-STAND MOVEMENT IN MEN AGED 18–92 YEARS

Nakatani, T., Terada, K., Nadamoto, M., Shiraishi, A., Murakami, K., Kawata, Y., Miura, S.

*Human Performance Laboratory*

**Introduction** Muscle power tends to decline more rapidly than muscle strength with age. The ability of the leg extensor muscles to rapidly develop force is important for performance and has shown to contribute to several activities of daily living, such as sit to stand and stair climbing. The aim of this study was to investigate age-related changes in ground reaction force (GRF) parameters during a sit-to-stand (STS) movement in Japanese men aged 18–92 years. **Methods** Participants comprised 484 healthy adult men, aged 18–92 years. All participants were free of cardiovascular, respiratory and neuromuscular diseases. Subjects sat on a chair of standard height (40 cm) with their feet on a force plate and stood as quickly as possible. The body weight overshoot (SUI), rate of rise in GRF (RFD) and reaction time (RT) data were collected on the computer during STS movement (Freming et al., 1991; Chang et al., 1998). **Results** There were significant inverse relationships between SUI ( $r = -0.63$ ,  $P < 0.001$ ), RFD ( $r = -0.68$ ,  $P < 0.001$ ), RFD/kg ( $r = -0.55$ ,  $P < 0.001$ ) and RT ( $r = -0.21$ ,  $P < 0.001$ ) with age. Across the adult lifespan all GRF parameters (SUI, RFD, RFD/kg and RT) during STS movement decreased by the third decade. The oldest group (80–92 years) had lower RFD (43.7%) and RFD/kg (29.9%) values when compared with the youngest group. Percent changes for RFD and RFD/kg were 9.1% and 5.8% per decade, respectively. **Discussion** The major finding of this study is that the decline in the developing forces production during a STS movement seems to accelerate with advancing age in adult men. Previous studies (Izuquiedo et al., 1999; Kostka et al., 2009) have estimated the relative rate of decline in the explosive force production or anaerobic power to be 10–12% per decade on an average in adult men. In the present study, the percent changes of the decline of RFD and RFD/kg per decade during STS were smaller than that of those results. Further studies are required on how explosive training in addition to strength training can minimize age-related decline in functional capacity. **References** Freming BE, Wilson DR, Pendergast DR (1991) Arch Phys Med Rehabil, 72, 886-889. ## RELATIONSHIP BETWEEN CURRENT AND PAST PHYSICAL ACTIVITY PARTICIPATION AND BONE HEALTH STATUS IN MIDDLE-AGED AND OLDER WOMEN

Kimura, Y.

*Institute for Fitness and Health Sciences*

Prevention of osteoporosis has been linked to chronically higher levels of physical activity (PA). Current research indicates that higher amount of weight bearing PA over an individual's lifetime have been associated with greater bone mineral density and slower rates of bone loss in the post-menopausal time period. However, the relationship between current PA and risk for osteoporosis has not been described. **PURPOSE:** The purpose of this study is to evaluate the relationships between past PA history, current PA participation and relevant osteoporosis risk factors with current bone health status in a middle-age and older women. **METHODS:** Forty-three women (age:  $46.9 \pm 6.5$  yrs., BMI:  $24.4 \pm 5.2$  kg/m<sup>2</sup>) in both pre- (n=29) and post-menopausal (n=14) stages volunteers to participate in this study. Subjects completed an osteoporosis risk factors, lifestyle history, and PA history questionnaires. Quantitative Ultrasound method (AOS-1000NW, ALOKA, JAPAN) performed to determine the bone health status (bone mass-OSI) and PA was assessed using a triaxial accelerometer (Active style Pro HJA-350IT, Omron, JAPAN). **RESULTS:** Ten subjects had low bone mass. Age ( $p=0.046$ ) and post-menopausal status ( $p=0.011$ ) were significant predictors of low bone mass. Daily inactive time ( $p=0.159$ ) and small amount of Moderate-to-Vigorous PA (MVPA) ( $p=0.081$ ) were related to low bone mass. PA including weight and non-weight bearing PA were found to not significant predictors of low bone mass. Relationships between MVPA and higher bone mass, and inactivity and low bone mass trend toward statistical significant. **CONCLUSIONS:** This study confirmed both age and post-menopausal status are significant predictors of current low bone mass in this mixed menopausal-stage population. ## TO THE QUESTION OF SPORT BALLROOM DANCING INFLUENCE ON THE PSYCHO-EMOTIONAL STATUS OF 35-45 YEARS OLD WOMEN.

Kovalenko, T.1, Shklyarenko, A.2, Bushtets, L.2, Ulyanov, D.1

1: *Volgograd State University (Volgograd, Russia); 2: Kuban State University branch in Slavyansk-on-Kuban (Slavyansk-on-Kuban, Russia)*

**Introduction** In recent years, ballroom dancing has become increasingly popular and has been widely spread in many countries of the world. **Methods** The methods of psychological testing were used. The indices of reactive anxiety (RA), 'health', 'activity', 'mood' (H.A.M), concentration of attention (AC), emotional (ES) and depression states (DS) of 35-40- years old women in the experimental (n = 18) and control groups (n = 16) were tested. **Results** The advanced information about the motives and needs of women aged 35-45 years have led to the development of a pilot program aimed at the physical and psychological rehabilitation of people going for sport ballroom dancing. The results of mental state of testees show that more noticeable and significant changes ( $R < 0,05$ ) both the experimental and control group were registered in terms of RA, H.A.M and AC. The positive changes in these terms of experimental group are observed in the range of 8,3% to 30,7%, control group – in the range of 4,15 to 22%. It is less in ES of testees. The stabilization is observed in DS with some improvement of terms (3,2% and 1,2% at  $R < 0,05$ ). Probably it can be explained by individual characteristics of people and biological resistance of human emotional and depressive states to the training influences. The largest differences among terms to the side of experimental group there were in CA (over 11,5%), in the terms of «activity» (over 11,2%), RA (over 8,7%) and «health» (over 8,4%), which is obviously related with that the author's technique of training was aimed especially at the «internal» work during the coordination exercises and it was aimed at strengthening of personal feelings. The least differences among groups there were in terms of «mood», ES and DS (resp. over 4,1%, 3,7% and 2,0%). **Discussion** A sufficiently high level of motivation to prolong the active longevity, to save health, to increase life and business activity as well as conscious desire to have a healthy lifestyle and self-improvement have formed the appropriate psychological settings of the engaged people both groups, but more consciously they appeared in the experimental group. These settings and expectations were sustained by the health and mental improvement of involved people, also by the increase in social activity and therefore they have increased the motivation to go in for sport ballroom dancing. **References** Bebik, M. ## THE EFFECT OF LOW AND MODERATE INTENSITY PHYSICAL EXERCISE ON POSTURAL CONTROL AMONG 65 YEARS OLD AND OLDER MEN

Stemplewski, R., Osiński, W.

*University School of Physical Education*

Despite many long-term health benefits associated with systematic physical activity, a single bout of physical exercise can be associated with changes causing a reduction in the quality of performed motor tasks, including the maintenance of a stable body posture. The aim of the study was to analyze the degree of disruptions in postural control resulting from global exercise of low to moderate intensity in older men. The analysis included the results of 25 men (aged between 65 and 81 years,  $x = 71.6 \pm 5.1$  years). This group was selected based on medical qualification, taking into account the lack of contraindications to moderate physical exercise. The experiment comprised of five sessions (one session for control measurement and four experimental sessions). During the experimental sessions I to IV, the participants were subjected to a 10-minute exercise on a cycloergometer with the intensity set at 15%, 30%, 45%, and 60%  $VO_{2max}$ , respectively. A single session included 2 tests of postural control (P1 – pre-exercise, P2 – post-exercise). The postural control was examined with AccuGait™ posturographic force plate (PJB-101, AMTI). Subjects were given the task of standing barefooted as still as possible on the force plate with eyes open for 30 seconds. The difference between the centre of pressure (COP) displacements and the centre of gravity (COG) displacements was considered as a parameter of postural control. Both the overall difference (SD) and its components in frontal (SDML) and sagittal (SDAP) plane were taken into account, as well as the elliptic area of the 95th percentile of COP displacements (A95%). The data on COG displacements was obtained as a result of the low-pass filtering of COP signaling. Statistically significant differences (higher post-exercise values) of analyzed parameters were documented during session II, III, and IV for SD ( $p < 0.05$ ,  $p < 0.01$ ,  $p < 0.001$ , respectively) and SDAP ( $p < 0.05$ ,  $p < 0.01$ ,  $p < 0.001$ , respectively). During session IV, also a post-exercise increase in SDML ( $p < 0.001$ ) was documented. No significant changes in the area of COP displacement were noted. The analysis revealed markedly more pronounced (step-wise) deterioration of postural control in older individuals performing exercise with an intensity of 60%  $VO_{2max}$ . Perhaps, due to safety concerns (increased risk of falling), older individuals should undertake exercises of lower intensity (45%  $VO_{2max}$  or lower) during activities of daily living and recreation if not otherwise contraindicated. On the other hand, undertaking exercise of intensity of 60%  $VO_{2max}$  under supervision (rehabilitation, intervention programs) can promote adaptation and gradual reduction of post-exercise disruptions of postural control.

## EFFECTS OF DIFFERENT SCHOOL-BASED PHYSICAL ACTIVITY INTERVENTIONS ON CHILDREN'S MOTOR PROFICIENCY

Gallotta, M.C.1, Iazzoni, S.1, Emerenziani, G.P.2, Meucci, M.3, Guidetti, L.1, Baldari, C.1

*1: Foro Italico University (Rome, Italy), 2: La Sapienza University (Rome, Italy), 3: Appalachian State University (Boone, USA)*

**Introduction** To evaluate the effectiveness of two 5-months school-based physical activity (PA) interventions on primary school children's health-related outcomes. **Methods** 230 children were assigned to one of three intervention groups: Traditional PA, Experimental PA, or Control group (no PA intervention). Pre- and post- intervention tests assessed pupils' fitness (The Cooper Institute, 2006) and gross motor coordination abilities (Kiphard & Schilling, 2007). Traditional PA intervention was structured without any specific coordinative request (D.M. n. 254, 16 November 2012) while experimental PA intervention was structured in four different didactic modules focused on specific coordinative abilities proper to sport-games, rhythmic, gymnastics and fitness activities. Results Both Traditional and Experimental PA Groups significantly increased some fitness and coordinative tests (Sit and Reach Test, Curl-Up Test, Push-Up Test, Shifting Platforms Test, Balance Test, Jumping Laterally Test, Motor Quotient) after the intervention period. Control Group decreased significantly on the Push-Up and Balance Tests. Gender significantly affected Sit and Reach, Balance, Jumping on one leg tests and the Motor Quotient score. Specifically, in Sit and Reach Test, both girls and boys of Traditional PA Group improved their performances ( $18 \pm 5$  vs  $20 \pm 5$  cm,  $15 \pm 6$  vs  $17 \pm 5$  cm;  $P < 0.05$ , respectively). Girls' performances of the Control group increased after the intervention ( $17 \pm 5$  vs  $19 \pm 6$  cm;  $P < 0.05$ ), while boys' performance decreased after the intervention period ( $15 \pm 6$  vs  $14 \pm 6$  cm;  $P < 0.05$ ). Only girls improved Balance Test ( $82 \pm 16$  vs  $87 \pm 18$  num;  $P < 0.05$ ) and Hopping on one leg over an obstacle Test after the intervention period ( $54 \pm 11$  vs  $59 \pm 13$  num;  $P < 0.05$ ). Girls showed a more pronounced improvement of Motor Quotient after the intervention period than boys ( $61 \pm 15$  score vs  $69 \pm 14$  score,  $p < 0.05$ ;  $67 \pm 11$  score vs  $72 \pm 13$  score;  $P < 0.05$ , respectively).  $VO_{2max}$  significantly decreased after the intervention period ( $43.51 \pm 2.85$  vs  $42.44 \pm 2.80$  ml · kg<sup>-1</sup> · min<sup>-1</sup>;  $P < 0.05$ ). **Discussion** Results demonstrated the effectiveness of a qualitative school-based PA approach to improve children's motor performance. **References** The Cooper Institute (2006). ## HYDROGYMNASTICS TRAINING PROGRAM ON PHYSICAL FITNESS IN ELDERLY WOMEN

Hall Lopez, J.

*Autonomous University of Baja California*

The aim of this study was to evaluate the effect of a hydrogymnastics training program on physical fitness in 26 elderly women (experimental group  $n=16$ , control group  $n=10$ ). The physical fitness was determined by the senior fitness test protocol, the hydrogymnastics consisted in aerobic exercise at 50%-60% of maximum heart rate, 5 times a week in a period of 12 weeks. ANOVA 2x2 as statistical test was used, indicating statistically significant interaction ( $p=0.052$ ) between groups and measurements on test strength endurance in the legs by squatting on chair in 30 s, agility test 2.4 meters was significant interaction ( $p \leq 0.01$ ) between groups and measures, testing aerobic capacity test step 2 minutes ( $p=0.02$ ) and six minutes walk indicated significant interaction between groups and measurements ( $p=0.50$ ), the results shown that hydrogymnastics in the elderly women participants was effective improving endurance, strength and agility mainly in legs.

## COMBINED SCHOOL-BASED PHYSICAL ACTIVITY AND NUTRITIONAL INTERVENTION TO IMPROVE LIFESTYLE IN CHILDREN

Iazzoni, S.1, Gallotta, M.C.1, Emerenziani, G.P.2, Meucci, M.3, Migliaccio, S.1, Guidetti, L.1, Baldari, C.1

1: *Foro Italico University (Rome, Italy)*, 2: *La Sapienza University (Roma, Italy)*, 3: *Appalachian State University (Boone, USA)*

COMBINED SCHOOL-BASED PHYSICAL ACTIVITY AND NUTRITIONAL INTERVENTION TO IMPROVE LIFESTYLE IN CHILDREN Iazzoni, S.1, Gallotta, M.C.1, Emerenziani, G.P.2, Meucci, M.3, Migliaccio, S.1, Guidetti, L.1, Baldari, C.1: *Foro Italico University (Rome, Italy)*, 2: *La Sapienza University (Roma, Italy)*, 3: *Appalachian State University (Boone, USA)* Introduction To evaluate the efficacy of two different combined school-based physical activity (PA) and nutritional interventions on children's lifestyle. Methods 230 students were classified according to their adiposity status (McCarthy, 2006) and they were randomly assigned to a Traditional PA Group (TPA), to an Experimental PA Group (EPA) combined with a nutritional intervention or to a Control group (nutritional intervention). Their weight, height, BMI z-score, fat mass percentage (% FM), lean body mass (LM), total weekly leisure-time PA, sitting time (Godin & Shepard, 1985) and eating habits (Vereecken, 2008) were assessed before and after intervention period. Traditional PA intervention was structured according to the Ministerial Programs of Physical Education (D.M. n. 254, 16 November, 2012). Experimental PA intervention was structured in four didactic modules focused on sport-games, rhythmic, gymnastics and fitness activities. Results %FM increased after intervention (18.9±8.6% vs 19.4±8.5%) in all groups. Total weekly leisure-time PA significantly increased after intervention (72.2±28.2 vs 84.8± 23.7 MET/week). Sitting time significantly decreased after the intervention period (565.7±252.9 vs 492.1±230.9 min/week). Obese children's BMI z-score significantly decreased after intervention (2.0±0.3 vs 1.9±0.3). Children significantly changed the consumption of some specific foods after the intervention period. Consumption of vegetables (3.9±1.6 time/week vs 4.2±1.5 time/week) and fruits (4.3±1.6 time/week vs 4.8±1.7 time/week) increased after intervention period while consumption of sweets decreased in TPA Group (4.5±1.7 time/week vs 5.2±1.7 time/week) and in EPA Group (4.5±1.7 time/week vs 5.2±1.7 time/week). Consumption of sweets decreased in TPA Group (4.5±1.7 time/week vs 5.2±1.7 time/week) and in EPA Group (4.5±1.7 time/week vs 5.2±1.7 time/week). Consumption of drinks decreased in TPA Group (4.1±1.6 time/week vs 2.7±1.5 time/week) and in EPA Group (3.2±1.4 time/week vs 1.4 ±1.3 time/week). Consumption of snacks decreased in TPA Group (3.4±1.8 time/week vs 1.9±0.9 time/week) and in EPA Group (3.0±1.7 time/week vs 2.1±1.3 time/week) while consumption of fruit increased in both group with a combined intervention, respectively, (4.12±1.69 time/week vs 5.21±1.67 time/week; 4.57±1.71 time/week vs 5.25 ±1.77 time/week). Discussion This pilot study revealed the effectiveness of a 5-month combined school-based PA and nutritional intervention to improve children's lifestyle. However, it need of a congruous involvement to maintain patterns of healthful dietary practices and to encourage an active lifestyle.

## PRELIMINARY STUDY ON THE SYNERGISTIC EFFECT OF ACUPUNCTURE USING PRESS TACK NEEDLE AND RESISTANCE TRAINING IN YOUNG ADULTS

Terada, K.1, Moriwaki, K.1, Yamazaki, S.1, Kobayashi, Y.1, Kawata, Y.2, Murakami, K.2, Shiraishi, A.1, Nadamoto, M.3, Nakatani, T.1

1: *Tenri University (Tenri, Japan)*, 2: *Kokugakuin University (Yokohama, Japan)*, 3: *Poole Gakuin University (Sakai, Japan)*

Introduction Press tack needles are small needles (approximately 0.5–1.5 mm long) that are fixed with adhesive plaster, and have the advantage of easy insertion into the epidermis, allowing them to be used during exercise. These needles reportedly reduce pain and fatigue after insertion. Miyazaki et al. performed a double-blind, randomized controlled trial to investigate the effect of press tack needles on lower back pain. The group treated with press tack needles demonstrated significantly lower subjective pain on the visual analogue scale (VAS) than the local anesthesia group (Miyazaki et al., 2009). We conducted a preliminary study to investigate the synergistic effect of acupuncture using press tack needles and resistance-training programs in young adults via a randomized controlled trial. Method Eighteen healthy young male adults aged between 20 and 22 years (mean age, 21.4 ± 0.6 years) were randomly and equally assigned to two groups: the exercise and acupuncture using press tack needle intervention (Pn, n = 9) and resistance training intervention groups (Ex, n = 9). Pn group participants underwent structured acupuncture using press tack needles, and their exercise regimen consisted of home-based resistance training of the lower limbs (squat) using one's own bodyweight. They measured exercise intensity with the newly developed perceived exertion Japanese scale (S-scale, a 4-point scale), and performed repetitions until they reached a perceived exertion intensity of 3 out of 4 for 4 weeks. Ex group participants underwent the same resistance-training program for 4 weeks. The outcome measures were body composition, vastus lateralis muscle thickness, 30-s chair-stand test, vertical jump, rebound jump index, and number of squats during exercise. Evaluation parameters such as subjective leg pain caused by delayed onset muscle soreness were measured on the 100-mm horizontal VAS. Results After 4 weeks of intervention, we identified a statistically significant two-factor interaction between the Pn and Ex groups in terms of the number of squats ( $F = 4.2$ ,  $p < 0.05$ ). However, no statistically significant synergistic effect of acupuncture using press tack needles and resistance training was observed in the other measures. Conclusion These results suggest that the effect of exercise may be slightly enhanced by intervention with concurrent acupuncture using press tack needles. Reference Miyazaki S et al. (2009). Applicability of press needles to a double-blind trial: a randomized, double-blind, placebo-controlled trial. *Clin J Pain*, 25(5), 438-44. Contact terada@sta.tenri-u.ac.jp

## EFFECT OF 12 WEEK NON SUPERVISED WORK PLACE INTERVENTION ON DEPRESSION AND WORK ABILITY OF EMPLOYEES OF UNIVERSITY IN SAUDI ARABIA

Tomar, R., Allen, J.

*King Fahd University of Petroleum and Minerals*

Introduction Workplace gives an ideal opportunity to reach large numbers of people for purpose of promoting good health and preventing disease (Atlantis Et al 2006). Therefore, aim of study was to examine the effect of 12 week non-supervised physical activity intervention on depression and work ability on employees of King Fahd University of Petroleum and Minerals (KFUPM) Saudi Arabia. Methods Participants were 25 employees of KFUPM. Participants were randomly assigned to intervention (n=12) and control group (n=13). Exercise guidelines were issued in form of Leaflets and posters. A formatted diary was given to each participant in intervention group to record his activities. Duration of intervention was 12 weeks (two sessions per week), 30 minutes for each session. Intervention consisted of aerobic and resistance training. Depression symptoms were assessed by PHQ-9 depression scale (Spitzer et al 1999). WAI was used to assess work ability (Tuomi et al 1991). Mann Whitney Test was used to compare differences between intervention and control group. Results There was significant difference between exercise and control group's median depression score (mean ranks of exercise group and control group was 8.64 and 14.36 respectively;  $U = 29$ ,  $P = 0.035$ ). There was no difference between the median WAI scores of the exercise and

control group (the mean ranks of exercise group and control group were 13.55 and 9.45 respectively;  $U = 38$ ,  $p = 0.138$ ). Discussion Depression symptoms in exercise group were reduced significantly after the 12 weeks of non-supervised exercise programme when compared to the control group. Recently a study done by (Zarshenas et al 2013) also confirmed the significant decrease in depression symptoms in experimental group compared to control group ( $p < 0.5$ ). Zeeuw et al, 2010 also confirmed that exercise can reduce the risk of depression in employees with sedentary jobs, an inactive lifestyle, and a high-risk of depression. Although Work ability in the exercise group did not improve significantly but there were sign of improvement. References Atlantis E, Chow CM, Kirby A, Fiatarone MA. *Health Promot Int*, 21, 191–200. ### **EFFECTS OF FOUR MONTHS OF PERIODIZED AQUATIC EXERCISE PROGRAM ON FUNCTIONAL AUTONOMY IN POST-MENOPAUSAL WOMEN WITH PARKINSON'S DISEASE**

Ochoa Martinez, P.

*Autonomous University of Baja California (UABC)*

Aim: To determine the effect of a periodized aquatic exercise program on functional autonomy in post-menopausal women with Parkinson's disease. Methods: Nine post-menopausal women diagnosed with idiopathic Parkinson's disease, with stage I-III according to Hoehn and Yahr scale, (age  $60.4 \pm 3.87$  years) participated in the 16-week of periodized aquatic exercise program five times a week, 30 minutes of aquatic exercise with work heart rate reserve of 40-50% (1-8th week) increasing the load to 50-60% (9-16th week). The protocol of the Group of Latin-American Development for Maturity (GDLAM) was used to evaluate functional autonomy; As statistical analyses student T test for paired samples was used, also percent changes ( $\Delta$  %) were calculated, the results showed significant improvement ( $p < 0.05$ ) comparing before and after the aquatic exercise program in 10 meters walk test (C 10m) ( $p = 0.001$ ) and general GDLAM index (IAF) ( $p = 0.003$ ), percent changes ( $\Delta$  %) showed positive improvements in the five components of GDLAM. Conclusion: Periodized aquatic exercise program was able to enhance (C 10m) and (IAF) however, will be appropriated in the future more studies to better clarify the possibilities of improvements between aquatic exercise program and functional autonomy in post-menopausal women with Parkinson's disease.

### **PROMOTING OFFICE STANDING VIA POINT OF CHOICE PROMPTS: EFFECTS ON SITTING TIME, CONCENTRATION AND NEUROMUSCULAR PERFORMANCE IN OFFICE WORKERS**

Zahner, L., Faude, O., Roth, R., Donath, L.

*University of Basel*

Introduction Physical inactivity is considered a major public health concern (Blair 2009). Sedentary behavior has been additionally shown to be an independent risk factor for the development of various disease conditions (Li & Siegrist 2012). As prolonged office sitting adversely affect neuromuscular and cardiovascular health parameters, the present study investigated the effects of prompts on occupational sitting and standing time, neuromuscular performance and concentration. Methods A single blinded randomized controlled trial with parallel group design was conducted. Thirty-eight office workers (age: 41 (SD: 11) years, body mass index: 24 (4) kg/m<sup>2</sup>, weekly working hours: 38 (8) hours) with experience in using sit-stand desks were randomly assigned (Strata: PA, BMI, gender, workload) to a prompt (INT) and non-prompt (CON) group. INT received screen-based prompts three times a workday within 12 weeks. CON was only one time instructed about the benefits of using height-adjustable working desks (HAWD) prior to the start of the study. Sitting and standing time were assessed for one entire working week employing the ActiGraph wGT3X-BT and the occupational sitting and physical activity questionnaire (OSPAQ) at baseline, after 6 and 12 weeks. Concentration (d2), postural sway (under single, dual and triple task) and lower limb strength endurance (heel-rise) were collected as secondary outcomes. Results With moderate between group effects at each time point, INT reduced occupational sitting time by -7.3% (CON: -1.7%,  $d = 0.61$ ) after 6 weeks. This is a daily reduction of approximately 30 minutes. Although no further reductions were observed between week 6 and 12 for either group, standing time was still elevated compared to baseline level. Concentration and neuromuscular performance did not differ between both groups after the intervention period (0.23

### **ORTHOOREXIC EATING BEHAVIOR IN RELATION TO HEALTH STATUS AND PHYSICAL ACTIVITY: A COMPARISON BETWEEN STUDENTS IN TWO UNIVERSITY PROGRAMS**

Malmberg, J.1, Bergman, S.2,3, Bremander, A.1,3

*1,2,3.Halmstad University, 2,3.Spenshult Research and Development Center*

Background Orthorexia nervosa (ON) is a condition described as 'unhealthy' behaviors regarding diet and physical activity. There is an ongoing discussion if ON is more common among adolescents studying in the area of health care and exercise. The research on ON is scarce and few studies assess ON and its association to health related quality of life (HRQoL). Aim The aim was to study orthorexic eating behavior, levels of physical activity and HRQoL in students enrolled at university programs focusing on health and exercise compared to those enrolled in business programs. Method 128 subjects, 32 men and 38 women from Biomedicine – Athletic Training (Biomedicine) and 22 men and 36 women from Construction and Real Estate Business (Business) participated in this cross-sectional study. The subjects completed the Short Form-36 Health Survey (SF-36) to measure HRQoL, the International Physical Activity Questionnaire (IPAQ) to measure levels of physical activity and ORTO-15 which examines eating behavior. A score less than 40 on ORTO-15 (score ranging from 0-60, worst to best) indicated an unhealthy relation to diet and was considered as ON in this study (Donini et al., 2005). Differences between groups were analyzed with t-tests and chi-square test. Results A total of 105 out of 128 (82%) subjects had a score indicating ON. Students from Biomedicine had a higher frequency of ON in comparison to Business ( $p < 0.000$ ) and in the SF-36 subscale bodily pain, Biomedicine students reported a higher frequency of pain ( $p = 0.006$ ). Results from measurements of physical activity did not differ significantly between Biomedicine and Business students, but there was a trend for high-intensity physical activity to occur more frequently in men than in women in general ( $p = 0.014$ ). Conclusion ON is a common condition in university students and even more frequent in students enrolled in a program directed towards health and nutrition. The high frequency of ON seen in Biomedicine students could be a problem that needs to be addressed since the students, after graduation, are expected to coach other people to a healthy living. Further studies are needed to explore associations with ON to health and physical activity. There is also a need to develop valid and reliable instruments

for assessing the condition. References Donini, L. M., Marsili, D., Graziani, M. P., Imbriale, M. & Cannella, C. 2005. Orthorexia nervosa: validation of a diagnosis questionnaire. *Eat Weight Disord*, 10, e28-32. e-mail: julia.malmborg@hh.se

### EFFECTS OF 12-WEEK CIRCUIT WEIGHT TRAINING AND AEROBIC EXERCISE ON BODY COMPOSITION, PHYSICAL FITNESS, AND PULSE WAVE VELOCITY IN OBESE COLLEGIATE WOMEN

Kang, H.1, Kim, Y.2, Lee, B.3, Kang, D.4

1: Soonchunhyung Univ. (Asan, South of Korea), 2: Seoul National Univ. (Seoul, South of Korea), 3: Sangmyung Univ. (Cheonan, South of Korea), 4: Soonchunhyang Univ. (Asan, South of Korea)

**Introduction** The obesity caused by an imbalanced intake of calories and decreased exercise has led to related health problems including diabetes, hypertension, and arteriosclerosis, and has worsened the quality of life of young Koreans. The purpose of this study was to study the effects of 12 weeks of circuit weight training and aerobic exercise on body composition, physical fitness, and pulse wave velocity in obese collegiate women. **Methods** Twelve obese collegiate women were randomly assigned either to an exercise training group (TG) or control group (CG). 12-week exercise program was composed of an approximately 40–65 min session of circuit weight training (resistance training and aerobic exercise) as well as jogging at an intensity of 50–70% of the age-predicted heart rate reserve. The circuit weight training program was made by Korean Institute of Sport Science and was modified as needed for obese collegiate women. **Results** The results indicated that after the 12-week intervention, there was a significant interaction of time by group with respect to body weight ( $p < 0.05$ ), % body fat ( $p < 0.01$ ), and WC ( $p < 0.01$ ) and there was a significant change in back strength between the TG before beginning the program and the TG after having completed the program ( $p < 0.01$ ). There was also a significant interaction of time by group with respect to back strength ( $p < 0.01$ ), grip strength ( $p < 0.05$ ), sit and reach ( $p < 0.01$ ), sargent-jump ( $p < 0.01$ ), and the one leg balance with eyes closed ( $p < 0.01$ ). Further, there was a significant interaction of time by group with respect to the 1,200 m run for cardiopulmonary endurance ( $p < 0.01$ ); however, this difference was not statistically significant between the TG pre and TG post. In addition, there was a significant in sit-ups ( $p < 0.01$ ) and the 1,200 m run ( $p < 0.01$ ) between the TG and CG. **Discussion** Our study found that body composition and physical fitness were improved after the combination of circuit weight training and aerobic exercise program in obese collegiate women. Physical activity has positive effects on the occurrence of obesity and changes of physical fitness and therefore, college students need regular exercise (Yoo, 2005; Bensimhon et al., 2006). Further studies are needed that will consider the effects of pulse wave velocity of a combined exercise program, and also to help to identify the intensity, duration and frequency of exercise to attain optimal benefits. ### PHYSICAL ACTIVITY DURING PE LESSON AND AFTER-SCHOOL HOURS: ARE THEY ASSOCIATED WITH CHILDREN DAILY PHYSICAL ACTIVITY?

Cheung, P.

*The Hong Kong Institute of Education*

**Introduction** School-based physical activity (PA), including PE and after-school sport class are possible occasions to increase children daily PA. Recent studies, however, questioned if increasing activity during the school hours may in return compensate children to be less active outside of school. The purpose of this study was to examine the association of school-based PA (i.e., PE class and after-school sport class) in different intensity (i.e., MPVA and sedentary) within various periods (i.e., in school hours and whole day). **Methods** Participants were 212 children with mean age of 8.9 from four local primary schools in Hong Kong. Children's PA level was measured by accelerometer (ActiGraph GT3X) for four consecutive days. Participants reported if they had scheduled PE lesson or participated in after-school sport class on the measurement period. The accelerometer counts derived into the time (min) of MVPA and sedentary behavior using age-specified criteria. Participants were grouped into 1) with PE lesson (PE group); 2) with after-school sport class (AFS group); or 3) no PE or after-school sport class (N-Act group). ANOVA was conducted to examine if children's MVPA and sedentary behavior is a function of the participation of PE lesson or after-school sport class. **Results** Excluding the non-school days data, 514 measurements were entered for analysis. Overall, children school-based MVPA during after-school hours (12.0 min) were higher than in PE lesson (8.6 min). Children daily MVPA was statistically significantly different between groups with various school-based PA participation [ $F(2,125) = 14.6, p < .000$ ] and increased from N-Act group (37.9 min) to PE group (46.1 min) and AFS group (59.5 min). For the sedentary behavior, significant difference was found between groups with various school-based PA participation [ $F(2,511) = 3.4, p = .03$ ] and decreased from N-Act activity (1190 min) to PE group (1173 min) and the AFS group (1151 min). **Discussion** The present study added information on the understanding of children school-based PA participation. First, children's participation in school-based PA was associated with their daily MVPA level, in which children with after-school participation were engaged in higher daily MVPA than their counterparts. The importance of after-school hours and PE class to increase children's PA participation is further confirmed. Second, children daily sedentary behavior was significantly decrease in the group with PE and after-school sport class participation. The involvement in PA during school hours, therefore, may not result in lower daily PA. On the contrary, is possible to enhance the lifestyle PA of children. ### THE RELATIONSHIP BETWEEN AEROBIC FITNESS AND COGNITIVE PERFORMANCE: ROLE OF BRAIN POTENTIALS

Sun, J., Wang, C., Shih, C., Tsai, C., Liu, D.

*Institute of Physical Education, Health & Leisure Studies, National Cheng Kung University*

The aim of the present study was to investigate the role of brain potentials in the relationship between aerobic fitness and cognition. Forty-six male subjects participated in this study. The electroencephalographic (EEG) and behavioral data were simultaneously collected when subjects performed an endogenous visuospatial attention task. The results revealed that  $VO_{2max}$  value was associated with faster reaction times (RTs) along with greater P3 amplitude and shorter P3 latency in the valid condition, after accounting for age and body mass index. Moreover, we observed that RTs were related to P3 amplitude, while such effect was not seen for P3 latency. Importantly, the Bootstrapping model result showed that P3 amplitude fully mediated the relationship between  $VO_{2max}$  and RTs. The present study demonstrated that higher levels of aerobic fitness are associated with greater amounts of attentional resource allocation, which may translate into faster processing speed performance.

### THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND VISUO-SPATIAL COGNITIVE FUNCTION IN ELDERLY ADULTS: AN EVENT-RELATED POTENTIAL STUDY

Wang, C., Tsai, C., Sun, J., Liu, D.

*Institute of Physical Education, Health & Leisure Studies, National Cheng Kung University*

Physical activity has been shown to be positively related to higher-level cognitive function in late life. However, such effect on visuo-spatial cognition, which was suggested to be sensitive to aging, has been rarely investigated. Here we compared event-related potential (ERP) from physically active elderly adults (aged  $66.63 \pm 1.31$  years; female =10) and age- and gender-matched sedentary counterparts (aged  $67.31 \pm 1.25$  years) when they performed a visuo-spatial cognitive task involving different levels of cognitive load (e.g., attention and working memory conditions). The findings showed that physically active elderly adults had better accuracy on the visuo-spatial cognitive task regardless of levels of cognitive load. In terms of ERP data, the results revealed that elderly adults with higher levels of physical activity displayed greater P3 amplitude at Fz and Pz electrodes across conditions. Moreover, the correlation results showed that physical activity was positively related to accuracy performance in both attention and working memory conditions, and is also positively associated with P3 amplitude during the encoding and retrieval stage in the working memory condition. The results suggest that physical activity may be beneficial for the aging cognition, especially for that having higher vulnerability (e.g., visuo-spatial cognition) to aging.

#### INFLUENCE OF PHYSICAL EXERCISE AND/OR ENALAPRIL IN THE ASSOCIATION BETWEEN HYPERTENSION AND SLEEP-RELATED MOVEMENT DISORDERS

Frank, M.K., de Mello, M.T., Lee, K.S., Daubian, P., Tufik, S., Esteves, A.M.

*Universidade Estadual de Campinas*

The relationship between hypertension and sleep-related movement disorders has been hypothesized for humans, but the causes and mechanisms have not been elucidated. We investigated whether the alteration of blood pressure (BP) induced by physical exercise and/or an angiotensin-converting enzyme inhibitor (enalapril) can affect the locomotor activity of spontaneously hypertensive rats (SHR) by acting on the dopaminergic system. We used SHR and normotensive Wistar rats distributed into 4 groups for each strain: Control, Physical Exercise, Enalapril and Enalapril+Physical-Exercise. Physical exercise was performed on a treadmill and enalapril was administered by gavage, both for 8 weeks. During this period, locomotor activity was evaluated in an open field test and BP was evaluated by tail plethysmography. Dopaminergic receptors, dopamine transporter and tyrosine hydroxylase in the striatum were evaluated by western blot. The control SHR group showed higher BP, more activity in the open field test and lower levels of D2 receptor and tyrosine hydroxylase compared with all other groups throughout the experimental period. In general, physical exercise and enalapril attenuated these alterations. This study suggests the existence of comorbidity between hypertension and sleep-related movement disorders in SHR, which is mediated by dopaminergic changes. Physical exercise and enalapril conferred protection from both hypertension and the observed behavioral changes.

#### SERUM FAS-LIGAND AND MIR-21 LEVELS AND THEIR ASSOCIATIONS WITH PHYSICAL PERFORMANCE OF MASTER MALE SPRINTERS – A 10 YEAR FOLLOW UP STUDY

Kangas, R., Pöllänen, E., Törmäkangas, T., Kovanen, V., Korhonen, M.T.

*University of Jyväskylä*

**Introduction** Physical exercise is known to affect the gene regulation and subsequently cause changes in the phenotype. MicroRNAs (miRs) are small molecules which form a crucial part of the regulatory system by blocking the protein translation of several genes. In untrained people, aging has found to be associated with changes in the levels of certain miRs and other circulating molecules such as an apoptotic marker FasL. **Methods** In the current study we investigated the interplay between serum miRs, FasL and physical performance of master sprinters (n=50) aged 40 to 85 years at the baseline in a 10 year follow up study design. Paired sample test was used for comparison analysis and Generalized Estimating Equations (GEE) models were constructed to model longitudinally the effects of miR and FasL on performance measures. **Results** Our results showed that serum FasL concentrations decreased ( $p=0.016$ ) and serum miR-21 levels increased ( $p=0.034$ ) among all the sprinters during 10 years. When grouping the athletes into 3 different age groups the changes were most significant for FasL among the youngest sprinters aged 40 to 55 at baseline ( $p=0.009$ ) and for miR-21 among the oldest, aged 70 to 85 ( $p=0.004$ ). In GEE models with age as a time scale, FasL had a significant main effect on knee extension strength ( $p=0.016$ ), bench press ( $p<0.001$ ), countermovement jump (CMJ) ( $p=0.032$ ) and 60m sprint performance ( $p=0.025$ ). Quadratic interaction effect with age modified the FasL effect on knee extension strength (age $\times$ FasL,  $p=0.026$ ; age $^2$  $\times$ FasL,  $p=0.040$ ), bench press (age $\times$ FasL,  $p<0.001$ ; age $^2$  $\times$ FasL,  $p<0.001$ ) and CMJ (age $\times$ FasL,  $p=0.030$ ; age $^2$  $\times$ FasL,  $p=0.025$ ), while the effect on sprint performance was modified by cubic effects (age $\times$ FasL,  $p=0.018$ ; age $^2$  $\times$ FasL,  $p=0.013$ ; age $^3$  $\times$ FasL,  $p=0.010$ ). MiR-21 had significant main effects on bench press ( $p=0.034$ ) and CMJ ( $p=0.035$ ). **Discussion** Master sprinters with long-term training and competition background are a unique model to study aging itself, since the accumulations of conditions and diseases caused by sedentary lifestyle, are ruled out. Aging effect in the FasL and miR-21 levels was detected among the study participants. Potentially, circulating markers including FasL and miR-21 could be used as tools in determining the state of a physical performance of an athlete. **References** Kavathia N, Jain A, Walston J, Beamer BA, Fedarko NS. #### WHETHER REGULAR EXERCISE IN THE JUVENILE PERIOD PREVENTS DEPRESSION-LIKE BEHAVIOUR IN THE MATURATION PERIOD

Nakajima, S.

*KYORITSU WOMEN'S J U N I O R COLLEGE*

The purpose of this study was to investigate whether regular exercise during childhood can prevent depression-like behaviour induced by psychological stress during maturation. Male 5-week-old C57BL/6 mice were randomly divided into three groups: (I) Control (C) mice

were involved in the behavioural test at the same time as other groups, i.e. after 18 weeks of feeding period, (2) Stressed (S) mice did not exercise during the juvenile stage; they were fed for 16 weeks, and then they underwent the behavioural test after being stressed and (3) Exercise and stress (ES) mice were fed for 12 weeks after finishing exercise during the juvenile stage and underwent the behavioural test after being stressed. The treadmill exercise was conducted for 4 weeks on a thrice-weekly basis at a pace of 15 m/min for 60 min. We tested the behaviour of mice in all groups using the forced swimming and sucrose haemolysis tests to investigate depression-like behaviour. To evaluate neurogenesis, bromodeoxyuridine (BrdU) was intraperitoneally administered to mice before stress. All mice were sacrificed after behavioural tests, and brain slices prepared from harvested brains were immunostained with BrdU to check neurogenesis in the hippocampus. Because brain-derived neurotrophic factor (BDNF) is reported to promote neurogenesis and its expression is increased after exercise, we measured the mRNA expression level of BDNF. C and ES mice underwent stress using the method called social defeat stress for 14 days, which was designed to imitate stress that humans experience. The hippocampal neurogenesis did not significantly differ among the groups; however, BDNF mRNA expression levels significantly increased in the C and ES mice. S mice demonstrated depression-like behaviours, such as long-term akinesia in the forced swimming test, and the BDNF mRNA expression level of this group was significantly higher compared with that in the resting group. The sucrose haemolysis test did not reveal any significant difference among the groups in the first 3 days. However, on the fourth day, sucrose consumption was significantly lower in the S mice compared with that in the C mice, demonstrating depression-like behaviour, such as insensitivity, in the S mice, but sucrose consumption in the ES mice did not show any significant difference. These findings suggest that regular exercise during childhood may reduce depression-like behaviour induced by psychological stress in the maturation period.

### OSTEOCALCIN GENE POLYMORPHISM AND BONE DENSITY IN HUNGARIAN ATHLETES

Bosnyák, E., Trájer, E., Protzner, A., Komka, Zs., Györe, I., Szmodis, M., Tóth, M.

*University of Physical Education*

**Introduction** Osteoporosis is a public health problem, mainly determined on the basis of bone mineral density. The rs1800247 polymorphism of the osteocalcin gene is associated with bone mineral density. The aim of the study was to examine the possible connection between the polymorphism and the bone ultrasound parameters in Hungarian population, including elite athletes. **Methods** A total of 302 subjects participated in the study. Genotype analysis was carried out via a DNA chip, anthropometric measurements were taken according to the International Biological Program. 63 of the participants were also measured by calcaneal ultrasound bone densitometer. **Results** The genotype frequencies of osteocalcin polymorphism in the total sample were: 59.9 % hh, 36.1 % Hh and 3.97 % HH. We separated the 63 subjects by the presence or absence of H allele and there were no significant differences between the two groups neither in the anthropometric, nor in the ultrasound parameters. Grouping the sample by genotypes, no difference was detectable in any of the bone characteristics. Athletes compared to the controls had significantly higher results in all of bone ultrasound values. **Conclusion** The polymorphism of the osteocalcin gene showed no effect on bone quantity in the examined Hungarian population. All of the ultrasound characteristics were greater in the athletes compared to the control group. **References** Lorentzon M, Lorentzon R, Nordstrom P. Vitamin D receptor gene polymorphism is related to bone density, circulating osteocalcin and parathyroid hormone in healthy adolescent girls. *J Bone Miner Res.* 2001; 19:302–307. ### THE EFFECT OF ESTROGEN ON THE RECOVERY PROCESS OF DAMAGED SKELETAL MUSCLES –USING HSP70 AS A MARKER–

Sakurai, T.

*Toin University of Yokohama*

**Introduction** This study investigates gender differences in the damaged muscle recovery process by observing the relationship between the female hormone estrogen and HSP70 in damaged skeletal muscles. **Methods** Damaged muscles were created by administering 0.5% bupivacaine hydrochloride (BPVC) to the tibialis anterior muscle. Fourteen-week-old male Wistar rats were divided into four groups, i.e., a control group (Group C) (n=6), an estrogen-administered group (Group E; 40mg/kg) (n=6), a BPVC-administered group (Group B; 5ml) (n=6), and a group that received both estrogen and BPVC (Group EB; 40mg/kg, 5ml) (n=6). The tibialis anterior muscles of rats in Group B and Group EB were isolated 3, 5 and 7 days after BPVC administration. The tibialis anterior muscles in Group C and Group E were harvested on the day corresponding to post-BPVC day 3 in other two groups. HSP70 expression was measured by Western blot analysis of homogenized tibialis anterior muscles. **Results** At 5 days after BPVC administration, the HSP70 expression level in the tibialis anterior muscle was markedly higher in Group EB than that in Group B. The HSP70 expression levels at 3, 5 and 7 days after BPVC administration were increased in the estrogen-treated rats compared with those in non-treated group. There was no difference in HSP70 expression between Group C and Group E. **Discussion** These results demonstrated that HSP70 expression was promoted early in the damaged muscle recovery process in male rats that received estrogen, suggesting a possible difference between males and females in the recovery process of damaged muscles.

### FIBRINOLYTIC ACTIVITY IS INHIBITED AFTER ACUTE STRENUOUS EXERCISE IN YOUNG OVERWEIGHT MEN

Fukada, K., Kushi, H., Takashina, T., Yoshida, A., Amano, K.

*Nihon University*

**[Introduction]** Some studies reported an increase in fibrinolytic activity after acute strenuous exercise. Conversely, some studies reported a state of low-grade inflammation and inhibited fibrinolytic activity in overweight subjects. The present study aimed to evaluate whether being overweight affects fibrinolytic activity after acute strenuous exercise. Overweight was defined using body mass index (BMI) as a measure of the degree of obesity. **[Subjects and Methods]** Twelve healthy young men 19 to 23 years old who engaged in daily exercise participated in this study. Based on the definition of overweight as a BMI  $\geq 25$  kg/m<sup>2</sup>, seven and five participants were categorized in the BMI <25,  $\geq 25$  group, respectively. Venous blood samples were collected from the subjects before and after performing the Cooper test which involved running as far as possible within a 12-minute period. IL-6 (inflammatory cytokine) and E-selectin (adhesion molecule expressed on endothelial cells) levels were measured using the blood samples collected before the Cooper test.  $\alpha 2$ -plasmin inhibitor / plasmin complex (PIC, as a marker of fibrinolytic activity) levels were measured using the blood samples collected before and after the

Cooper test. [Results] Values are shown as mean  $\pm$  standard error (SE). Characteristics of the BMI <25 group were age,  $20.8 \pm 0.5$  years; height,  $175.2 \pm 1.4$  cm; weight,  $63.8 \pm 0.7$  kg; and BMI,  $20.8 \pm 0.4$  kg/m<sup>2</sup> and those of the BMI  $\geq 25$  group were age,  $20.0 \pm 0.4$  years; height,  $167.4 \pm 3.3$  cm; weight,  $92.6 \pm 5.9$  kg; and BMI,  $33.1 \pm 2.0$  kg/m<sup>2</sup>. The IL-6 levels were significantly higher in the BMI  $\geq 25$  group than in the BMI <25 group ( $1.1 \pm 0.2$  and  $0.5 \pm 0.05$  pg/mL, respectively;  $p < 0.05$ ). The E-selectin levels were significantly higher in the BMI  $\geq 25$  group than in the BMI <25 group ( $48.7 \pm 3.3$  and  $35.0 \pm 4.4$  ng/mL, respectively;  $p < 0.05$ ). The PIC levels increased significantly in the BMI <25 group (before and after the Cooper test,  $0.5 \pm 0.02$  and  $1.8 \pm 0.3$   $\mu$ g/mL, respectively;  $p < 0.01$ ), but these were not significantly increased in the BMI  $\geq 25$  group ( $0.5 \pm 0.08$  and  $0.9 \pm 0.1$   $\mu$ g/mL, respectively;  $p > 0.05$ ). [Conclusions] We speculated that the BMI  $\geq 25$  group was in the state of low-grade inflammation compared with the BMI <25 group. This study showed that being overweight induced a low-grade inflammatory state, and fibrinolytic activity is inhibited after acute strenuous exercise.

### INACTIVATION OF SOCS3 IN LEPTIN RECEPTOR EXPRESSING CELLS PROTECTS MICE FROM HYPERPHAGIA AND WEIGHT REGAIN AFTER A CALORIE-RESTRICTED PERIOD

João, P., Isadora, F., Thais, Z., Angela, R., José, D.

*University of São Paulo, São Paulo*

Calorie-restricted diets can be an efficient nutritional intervention to promote weight loss in obese subjects. However, the long-term success in maintaining the weight lost is usually poor because individuals tend to eat more after dieting. So, putative interventions that could attenuate the hyperphagia after a period of caloric restriction could have a substantial impact on obesity treatment success rate. Leptin is a key hormone for the long-term regulation of body weight. Leptin resistance is a hallmark of obesity and some proteins such as the suppressor of cytokine signaling 3 (SOCS3) plays an important role in inhibiting leptin signaling. Because fasting-induced hyperphagia takes a relatively long time to cease (several days in mice), we hypothesized that SOCS3 may play a role in inducing the hyperphagia and weight regain generally observed after a period of caloric restriction. Thus, we generated cell-specific SOCS3 knockout (SOCS3 KO) mice using the Cre-loxP system by deleting *Socs3* gene only in leptin receptor-expressing cells. SOCS3 KO mice and control (CON) littermates were fasted for 48h and then refed ad libitum for 7 days. SOCS3 KO mice showed an attenuated food intake and weight regain during the refeeding days. We euthanized SOCS3 KO and CON mice in ad libitum state and after 48h fasting, 1, 3, 5 and 7 days of refeeding. Both groups exhibited a decreased circulating leptin levels during fasting. However, while leptin levels in CON group increased above basal levels during the refeeding period suggesting a leptin resistance state, leptin levels remained at the basal levels in the SOCS3 KO group. We performed gene expression analyses in the hypothalamus and only the CON group exhibited an increased SOCS3 mRNA expression after 48h fasting. In addition, 48h fasting caused a peak in the expression of the orexigenic neuropeptides AgRP and **POMC**. This peak was attenuated in SOCS3 KO mice. Furthermore, the expressions of protein tyrosine-phosphatases, which are associated with leptin resistance, were greater in CON group compared to SOCS3 KO group after 1 day (PTPR $\bullet$ , PTPN2) and 5 days (PTP1B, PTPN11, PTPR $\bullet$ , PTPN2) of refeeding. In conclusion, these results indicate that the inhibitory role of SOCS3 in leptin signaling amplifies fasting-induced hyperphagia and weight regain. Therefore, our findings demonstrate that the suppression of SOCS3 is a potential therapeutical approach to prevent weight regain after calorie-restricted diets.

### RESPONSE OF THE CARDIAC PHOSPHOPROTEOME TO A GRADED EXERCISE TEST TO MEASURE PEAK OXYGEN UPTAKE .

Burniston, J.G., Guo, H., Isserlin, R., Emili, A.

*Liverpool John Moores University*

Introduction. Endurance exercise improves cardiac performance and affords protection against cardiovascular diseases but the signalling events that mediate these benefits are largely unknown. Phosphorylation is an important and widely studied post-translational modification involved in intracellular signalling pathways. To discover novel signalling events associated with acute exercise we have profiled changes in the cardiac phosphoproteome in response to a graded exercise test of peak oxygen uptake (VO<sub>2</sub>peak). Methods. Male Wistar rats ( $346 \pm 18$  g) were assigned to 3 independent groups (n= 6, in each): control, 0 h and 3 h. All rats were familiarised with the motorised treadmill and metabolic chamber then animals assigned to the 0 h and 3 h groups performed a graded exercise test (Burniston 2009) to measure their VO<sub>2</sub>peak. Groups of animals were killed either immediately (0 h) after or 3 h after completing the exercise test. Control rats were killed at the same time of day as the exercised animals, to minimise the influence of circadian differences. Cardiac homogenates were digested with trypsin and phosphopeptides were enriched by selective binding to titanium dioxide (TiO<sub>2</sub>). Phosphopeptides were analysed by liquid chromatography and high-resolution tandem mass spectrometry. Phosphopeptides were quantified by spectral counting and identified against the UniProt knowledgebase using MaxQuant (v1.3.0.5). Results. The average VO<sub>2</sub>peak of rats in the 0 h and 3 h groups was  $66 \pm 5$  ml•kg<sup>-1</sup>•min<sup>-1</sup> and  $69.8 \pm 5$  ml•kg<sup>-1</sup>•min<sup>-1</sup>, respectively. Proteome profiling detected 1169 phosphopeptides and one-way ANOVA found 149 peptide differences at  $P < 0.05$  with a false discovery rate of 10 %. The significantly regulated phosphopeptides mapped to 105 cardiac proteins and 38 of these have perviously been reported as phosphopeptides, for example S232 & S239 of pyruvate dehydrogenase E1 component subunit alpha, S23 of cardiac troponin I, S16 of phospholamban, S15 heat shock protein beta-1, S59 alpha B-crystallin, Y182 of p38 MAPK and S83 of the cAMP-dependent protein kinase 1-alpha regulatory subunit. Discussion. Some of the phosphoproteins identified have known roles in myocardial contractility and protection against cardiac disease. The majority of phosphoproteins that were differentially regulated in the hours after a standardised bout of endurance exercise were novel discoveries. Therefore, this work provides a rich source of new information to understand the cardiac benefits of exercise. Burniston JG (2009) Adaptation of the rat cardiac proteome in response to intensity-controlled endurance exercise, *Proteomics*, 9: 106-15.

### THE EFFECT OF AEROBIC, ANAEROBIC AND COMBINED TRAINING ON BLOOD IRON, TIBC AND TS OF ELITE WRESTLERS

Gahreman, D.E., Mahmoodi, S.A., Mahdian, H., Javadi Ashrafi, F.

*Charles Darwin University*

THE EFFECT OF AEROBIC, ANAEROBIC AND COMBINED TRAINING ON BLOOD IRON, TIBC AND TS OF ELITE WRESTLERS Gahreman, D.E.1, Mahmoodi, S.A.2, Mahdian, H.3, Javadi Ashrafi, F.2 1: CDU (Darwin, Australia), 2: MAZUMS (Sari, Iran), 3: IAU (Sari, Iran) Introduction Reduced level of iron may comprise athletes' performance by reducing total oxygen carrying capacity of blood. In wrestling, like many other sports, both anaerobic and aerobic energy pathways are employed (Callan et al.,2000) and therefore wrestlers are required to train both energy systems during conditioning phase. Therefore, the aim of this study was to investigate the acute effect of aerobic, anaerobic

and combined aerobic and anaerobic training session on Iron, Total Iron Binding Capacity (TIBC) and Transferrin Saturation (TS) of elite freestyle wrestlers. Methods Twenty four elite male wrestlers were randomly divided into aerobic, anaerobic and combined aerobic and aerobic groups. Aerobic training was consisted of 35 minutes running with 60% of HRmax while anaerobic training consisted of 20 stations where each athlete completed 15 seconds of intense exercise at minimum 80% of HRmax followed by 15 seconds active recovery between stations. The combined group completed both aerobic and anaerobic training in one session. Blood samples were collected before, immediately after training, 3 hours and 24 hours after training session. Blood iron and TIBC level were measured using enzyme-linked immunosorbent assay (ELISA). A mixed model ANOVA was used to investigate the effect of different training protocols on iron, TIBC and TS. Results A significant main effect for time was observed  $F(3, 63)=8.175, p=.000$ , partial eta squared = .280 with blood iron level 24 hours after training ( $M=108.75, SD=29.95$ ) being lower than before training ( $M=117.62, SD=32.91$ ) and immediately after training ( $M=117.66, SD=34.81$ ). There was also a significant main effect for time  $F(3, 63)=6.730, p=.001$ , partial eta squared = .243 with blood transferrin saturation 24 hours after training ( $M=31.73, SD=9.20$ ) being lower than before training ( $M=34.55, SD=10.30$ ) and immediately after training ( $M=34.98, SD=11.09$ ). There was no significant main effect for time, training type or interaction of time and training type on TIBC. Discussion Mechanical stress and profuse sweating during physical activity may result in significant reduction of iron level amongst elite wrestlers up to 24 hours after each training session. Compromised iron level may affect athletic performance as well as general health including immune function, cognitive development and ability to thermoregulate (Weaver and Rajaram,1992). It is advisable to meet RDI for iron and allow adequate recovery between training sessions. References Callan S D, Brunner D M, Devolve K L, Mulligan S E, Hesson J, Wilber R L, Kearney J T. ### EFFECTS OF HABITUAL JOGGING EXERCISE ON GENE EXPRESSIONS IN MIDDLE-AGED HUMAN SKELETAL MUSCLE

Tetsuo, Y.

*University of Tokushima*

Introduction The molecular mechanisms leading to prevention of metabolic diseases during habitual jogging are unknown. We examined effects of habitual jogging on gene expressions using DNA microarray analysis. Methods The study consisted of ten Japanese females (age range 55-60 years old). Six females had jogging habit (2-3 hours/week for three years) and four females had no habitual jogging or other exercise. We performed biopsies from vastus lateralis muscle after 24 hour resting condition. We extracted total RNA from frozen muscle and examined gene expressions using microarray. Results A total of 85 differentially expressed genes were identified (fold change  $> \pm 3, P < 0.05$ ) between jogging and non-jogging group. Upregulated genes in jogging groups were BDNF, VEGF, FGF11, and LIF, and downregulated genes were myostatin and BMP3. Genespring pathway analysis revealed that pathways of 1) adipogenesis, 2) BDNF signaling, 3) focal adhesion, and 4) striated muscle contraction were listed in the upregulated transcripts, and pathways of 1) Wnt signaling and 2) neural crest differentiation were listed in the downregulated transcripts. Discussion The present study suggests that multiple pathways related to genes expressions of myokines at resting condition. Additional studies are needed to clarify the relationship between myokine expression and terms of exercise.

### Motor Learning

#### THE QUIET EYE TRAINING IN THE AIMING MOTOR SKILL: INFLUENCE ON MOVEMENT PREPARATION

Mizusaki, Y.1, Nakamoto, H.2, Ishii, Y.3, Ikudome, S.2, Unekaka, S.2, Funo, T.2, Takeuchi, T.2, Ogasa, K.2, Mori, S.2

1: Faculty of sports and health science, Fukuoka University (Fukuoka, Japan) 2: National Institute of Fitness and Sports in Kanoya (Kagoshima, Japan) 3: Japan Institute of Sports Sciences (Tokyo)

The Quiet Eye training in the aiming motor skill: influence on movement preparation Introduction The aiming motor skill is the most fundamental skill while playing sport. Vickers (1996) reported that the accuracy would be improved by acquiring the Quiet Eye (QE). However the relationship between the improvement of the accuracy and the acquisition of the QE is still unknown even though several hypotheses have been proposed. Therefore the purpose of the present study was to investigate how the QE works for improving the accuracy of the aiming motor skill by measuring Movement-related cortical potentials (MRCP) whose participants acquired a distinctive feature of QE through the QE training. Methods Nine male college students ( $23.7 \pm 0.67$  years; mean  $\pm$ SD) who are all right handed participated voluntarily in this study. They had no visual limitation with either little or no experience of playing darts. All participants threw 100 darts before and after the QE training as pre- and post-tests. The QE training was composed of 900 darts throws within 3 weeks but limited 100 darts throws per day. Results All participants improved the skill of throwing dart and increased the QE duration after the completion of QE training. Moreover, it showed that the amplitude of MRCP components for the long QE duration tended to be smaller than the one for the short QE duration. Discussion The results of the study that were the improvement of throwing skill as well as the increase of QE duration were similar to the previous studies (Moore et al., 2012). Regarding MRCP, the amplitude of MRCP components for the long QE duration was smaller than the one for the short QE duration. The activity of brain decreased while the elite of shooting sports was aiming a shot by comparing with the novice (Haufler et al., 2000). Therefore it is conceivable that the amplitude of MRCP components become smaller due to the acquisition of QE in the study. Through the study, it was shown that the QE might contribute to the efficient activity of brain cortex that works for the construction of motor programming. References Haufler, A. J., Spalding, T. #### EEG BRAIN ACTIVITY IN DIFFERENTIAL, CONTEXTUAL INTERFERENCE, AND CLASSICAL REPETITION ORIENTED BADMINTON SERVE TRAINING

Henz, D., Kenville, R., Simon, M., Leinberger, O., Schöllhorn, W.I.

*University of Mainz*

Introduction Several studies demonstrate higher learning rates in differential compared to classical repetition oriented training (e.g. Schöllhorn, Hegen, & Davids, 2012), and contextual interference training (Hegen, Kuby, Horst, & Schöllhorn, 2014). To our knowledge, little

is known on the underlying neuronal processes comparing differential and contextual interference training. In the present study, we compared effects of differential, contextual interference, and classical repetition oriented badminton serve training on EEG brain activation patterns. Methods Eight semi-professional badminton players performed differential, contextual interference, and traditional badminton serve training in a within-subjects design. Electroencephalographic activity was recorded from nineteen electrodes according to the 10-20 system before, and immediately after each 20-minute exercise. Analyses of variance were performed for the EEG data of power density for the theta (4-7.5 Hz), alpha (8-13 Hz), beta (13-30 Hz), and gamma (30-70 Hz) band. Results Increased theta and alpha activity was obtained in contralateral parietal and occipital regions in the differential compared to the classical training condition. After contextual interference training, increased theta activity was found in the contralateral somatosensory area P3. Beta activity was increased in the classical training condition in prefrontal areas. Discussion Results indicate different underlying neuronal processes in differential, contextual interference, and classical repetition oriented training with a higher involvement of parietooccipital areas in differential training, contralateral parietal areas in contextual interference training, and frontal areas in repetition oriented training. Our results suggest that differential training stimulates the visual and somatosensory system, and therefore engages due to its specific characteristics more regions of the cortex, whereas contextual interference training activates specifically the contralateral somatosensory brain area. Repetition oriented training seems to rely on a rather executive controlled processing. References Hegen, P., Kuby, M., Horst, F., & Schöllhorn, W.I. (2014). ### PERCEPTUAL TRAINING EFFECTS ON ANTICIPATION OF DIRECT AND DECEPTIVE 7-METER THROWS IN HANDBALL

Alsharji, K.

*College of Basic Education*

This research investigated the effects of video-based perceptual training on the performance of handball goalkeepers when anticipating the directions of both direct and deceptive 7-meter throws (i.e., penalty throws). Forty two Kuwaiti handball goalkeepers voluntarily participated in this study and were randomly assigned to 3 matched-ability groups based on their pre-test performance: participants in the perceptual training group received video-based perceptual training over 7 consecutive days; participants in the placebo training group received video-based regular training; and participants in the control group received no training. The primary findings demonstrated that video-based perceptual training significantly improved anticipatory performances from pre- to post-test under both throwing conditions (i.e., direct and deceptive). Although perceptual training significantly improved anticipation of direct and deceptive throws, anticipation of deceptive throws showed less improvement. The current findings support the first research hypothesis that perceptual training group would improve their anticipation under both throwing conditions more than placebo training and control groups. The findings also support the second research hypothesis that anticipation of deceptive 7-m throws would show less improvement compared to anticipation of direct throws. In conclusion, this study confirms the importance of perceptual training for anticipation skills in sport and adds to the literature that perceptual training can also improve anticipation of deceptive actions. In addition, this study confirms that deception in handball is a challenging task that goalkeepers can minimize, but cannot eliminate, its effect by enhancing their perceptual skills.

### SPORT AND IMAGINATION IN YOUNG SCHOOL ATHLETES WHO COMPETED IN KÜTAHYA

Eynur, B.R., Eynur, A., Çetinkaya, E.

*DUMLUPINAR UNIVERSITY*

Introduction The most academic study about preparation for compete, emphasizes that mental preparation is important such as physically preparation. (Gallego, DenotLedunois, Vardon, & Perruchet, 1996; Heath & Gonzalez, 1995; Kuhling, 1989). When thought this situation, In this study, purposed that young school athletes of imagination in sport levels. Methods This study is a descriptive study. In this study, as measuring tool, The Sport Imaginary Questionnaire was used which translated and converted by Kafkas (KAFKAS, 2011). Sampling was created by primary and secondary 420 students who participated in Kütahya inter school races. Independent simple t-test and One-Way ANOVA tests was used as statistical methos. Significantly level was accepted as  $p < 0,05$ . Results At the end of this study, According to gender, The items of "I would imagine that others tell me I did a good job." ( $t_{.05} = 2,077$ ;  $p < 0,05$ ), "I imagine that I kept my cool competitions." ( $t_{.05} = 2,252$ ;  $p < 0,05$ ), "I imagine wanting amazing attention as a lost case control." ( $t_{.05} = 2,261$ ;  $p < 0,05$ ), "I imagine myself to be reached with the successful outcome of a difficult situation." ( $t_{.05} = 2,316$ ;  $p < 0,05$ ), was seen significantly different. According to species of sport (team or individual), The items of "I would imagine that others tell me I did a good job." ( $t_{.05} = -2,021$ ;  $p < 0,05$ ), "I would imagine that the audience cheering for me." ( $t_{.05} = -2,507$ ;  $p < 0,05$ ), "I imagine myself as a champion." ( $t_{.05} = -2,179$ ;  $p < 0,05$ ), "Before the competition in my mind I imagine how cool I am." ( $t_{.05} = -2,211$ ;  $p < 0,05$ ), "I can imagine how it would be exciting to be in a competition." ( $t_{.05} = -1,985$ ;  $p < 0,05$ ), "I imagine myself as collected in a difficult situation to my attention." ( $t_{.05} = -2,104$ ;  $p < 0,05$ ), "I imagine wanting amazing attention as a lost case control." ( $t_{.05} = -2,881$ ;  $p < 0,05$ ), "I imagine myself to be reached with the successful outcome of a difficult situation." ( $t_{.05} = -2,577$ ;  $p < 0,05$ ) was seen significantly different. Discussion When seen in this findings. Gender differencies can be looked as important factor for imagination in sport. However coaches must be think attentionally about technics and compete for gender. Other important factor for imagination in gender; was seen sport species. Imagination is very important but coaches must be wide awake about instruction. Wrong thought can be resulted unwanted situation. ## Neuromuscular Physiology

### ECCENTRIC, BUT NOT CONCENTRIC PEAK TORQUE IS RELATED WITH COUNTERMOVEMENT JUMP PERFORMANCE IN HIGH LEVEL POWER ATHLETES

Bogdanis, G., Skordis, D.

*University of Athens*

**Introduction** Both eccentric and concentric muscle force are considered important for maximizing countermovement jump height (Lafayette et al., 2014). A recent study showed that peak isokinetic knee extension torque was the single significant predictor of CMJ, while the relationship was increased with increasing angular velocity (Yapici et al., 2014). However, in the same paper, a significant indicator of CMJ was found to be the eccentric quadriceps peak torque. The purpose of the present study was to examine the relative importance of isokinetic . **Methods** Nine high level athletes (age: 27.6±4.6 yrs, height: 184±6 cm, body mass: 82±8 kg, body fat: 8.5±3.2%) took part in the study. Isokinetic dynamometry (Kin Com) was used to measure peak torque during maximal concentric knee extension/flexion at angular velocities of 60 and 180 degrees per second. Eccentric peak torque of the knee extensors was also measured at an angular velocity of 60 degrees per second. Countermovement jump was measured using a contact mat. Torque data were compared using two-way ANOVA with repeated measurements (leg x angular velocity). Relationships between variables were assessed using Pearson product-moment correlation ( $p < 0.05$ ). **Results** There was no significant difference between the two legs in all peak torque values. Peak concentric knee extension torque at 60 and 180°/s were 245±31 and 171±22 Nm, while the corresponding flexion peak torques were 151±30 and 118±25 Nm. Peak eccentric knee extension torque was 357±39 Nm or 4.36±0.46 Nm/kg body mass (146±13% of concentric extension peak torque at 60°/s). CMJ height was 44.0±3.4 cm. Low and non-significant correlations were found between absolute knee extension and flexion peak torques and CMJ ( $r < 0.40$ , ns). When peak torque values were expressed per kg body mass, the correlations between CMJ height and concentric extension and flexion peak torque increased, but did not reach significance ( $r = 0.40$  to 0.51, ns). However, the correlation between CMJ height and eccentric knee extension peak torque was high ( $r = 0.80$ ,  $p < 0.01$ ). **Discussion** The results of the present study showed that eccentric knee extensor peak torque is related with CMJ height and thus confirm the notion that eccentric strength is more important than concentric in terms of jumping performance. Coaches are advised to increase eccentric strength when the aim is to improve CMJ. **References** Laffaye G1, Wagner PP, Tombleson TI (2014). *J Strength Cond Res.* 28(4), 1096-1105 Yapici A, Findikoglu G, Dundar U (2014). *J Sports Med Phys Fitness.* PMID: 25410575 Contact gbogdanis@phed.uoa.gr

### DOMINANT VS NON-DOMINANT ARM EMG ACTIVITY DURING MENTALLY SIMULATED ISOMETRIC HAND CONTRACTIONS IN RIGHT HANDERS

Paizis, C.1,2,3, Gandrey, P.1,2, Martin, A.1,2, Lebon, F.1, Papaxanthis, C.1

1 : UFR STAPS University of Burgundy (Dijon, France), 2 : INSERM 1093 (Dijon, France), 3 : CEP G. Cometti, (Dijon, France)

**Introduction** Laterality is an important feature of motor behavior. Several studies have shown that lateralization in right-handed young adults (i.e., right versus left arm superiority) emerges also during imagined actions, that is when an action is internally simulated without any motor output (Paizis et al. 2014). In the present study, we investigated whether right-handers can generate EMG activity during motor imagery with their right or left arm. With this aim, subjects carried out imagined isometric hand muscle contractions (Lebon et al. 2008) for different level of intensity. **Methods** Twelve right-handed males (mean age: 23.7 • 4.4 years) held the grip strength of a dynamometer, either with their dominant right hand or with their non-dominant left hand, and carried out 3 tasks. In the actual grip task, they were requested to develop, grip forces at 4 intensities: 25%, 50%, 75%, or 100%. Maximum grip strength was previously calculated on the basis of 3 trials. In the imagined grip task, participants imagined performing the 4 specific intensities. In the rest task, participants kept their arms relaxed on the table for 5s. We evaluated the level of muscle activation during actual and mental contractions by recording EMG signals from the Flexor Carpi Radialis (FCR) and Extensor Carpi Radialis, (ECR) muscles. **Results** We found that MI was accompanied by a subliminal specific EMG activity of agonist muscles, but also that of antagonist, fixator muscles. Further, the results revealed a greater EMG activity during MI than during the rest condition, whatever the muscle of right or left arm. The ECR muscle for Dominant and Non Dominant arm shows similar patterns EMG activity. On the other side, we found a different effect of intensity contraction during MI for the FCR for the Dominant than the Non Dominant arm. We observed similar levels of EMG subliminal activities for different levels of intensity contraction for the Non-Dominant arm that for the Dominant arm (only à 100%). **Discussion** These findings suggest difference in motor output between the dominant and the non-dominant arm during imagined actions concerning grip strength task and flexor muscles in the right handers. **References** Paizis C, Skoura X, Personnier P, Papaxanthis C. ### ACTIVATION PATTERNS AND CO-ACTIVATION OF SHANK MUSCLES IN YOUNG CHILDREN AND ACTIVE SENIORS BEFORE AND AFTER A SLACKLINE BALANCE TRAINING INTERVENTION

Kurz, E., Faude, O., Roth, R., Zahner, L., Donath, L.

*University of Basel*

**Introduction** Children' and seniors' show comparable fall incidence rates. However, studies examining the relative muscle activation and co-activation of shank muscles are rare. The aim of this study was therefore to examine the contribution of selected ankle muscles to single leg standing (SLS) and co-activation during maximum voluntary contraction (MVC) before and after a supervised slackline balance training intervention in different age-groups. **Methods** Twenty-six active and healthy seniors (age: 62.9 (SD 6.3)) and 17 young children (age: 9.7 (0.5)) were assigned to either an intervention (INT) or control (CON) group. INT performed supervised and gradually increased slackline balance training for six weeks on Gibbon Slackracks (ID Sports, Stuttgart). Before (Pre) and after (Post) the intervention, all participants performed SLS while standing on stable ground for 30 seconds and MVC on their dominant leg (i.e. limb preferred to kick a ball). Surface EMG (Imago, Freiburg) data of selected ankle muscles (tibialis anterior, TA; medial head of gastrocnemius, MG; soleus, SO) was used to characterize relative muscle activity contributions (percent of cumulative muscle activity) of every measured muscle during SLS. The amount of co-activity of the antagonist muscle (TA, SO) was determined using the value reached by the antagonist during the agonist MVC activation over the MVC value during its own agonist task (Maganaris et al. 1998). Differences were verified with repeated measures

analyses of variance. Additionally, effect sizes (partial eta squared,  $\eta^2$ ) were calculated. Pairwise comparisons were performed using Student's t test. Results Baseline comparisons showed significant main effects for age-group for muscle activity contributions of TA and SO ( $P < 0.01$ ; children: TA 18% (9), mean (SD); SO 39% (10), seniors: TA 30% (14), SO 24% (9)) during SLS and co-activity ( $P < 0.05$ ) during MVC. No time interaction effects were found for co-activity and relative contributions ( $P > 0.05$ ). Age-group independent analyses, however, revealed a significant intervention effect for co-activity of SO ( $P = 0.012$ ,  $\eta^2 = 0.24$ ) in seniors only. The post hoc analysis showed a significant reduction of SO co-activity in INT ( $P < 0.01$ ; Pre 49% (28), Post 33% (17)) but not in CON. Discussion Compared to young children, healthy seniors showed inversed ankle coordination patterns during SLS. This finding may point towards different postural strategies in both age-groups, which remain unaltered even after demanding balance interventions. Additionally performed calf muscle strength training might support balance training adaptations in seniors. References Maganaris et al. (1998). *Exp Physiol*, 83, 843-855. ### EFFECTS OF DEPTH IN COLD WATER IMMERSION ON RECOVERY FROM PLYOMETRIC EXERCISE-INDUCED MUSCLE DAMAGE

Tseng, W.C.1, Huang, C.H.1, Nosaka, K.2, Huang, G.L.3, Lin, M.J.3, Chen, C.L.3

1: National Taiwan Sports University (Taiwan), 2: Edith Cowan University (Australia), 3: National Chiayi University (Taiwan)

**Introduction** Cold water immersion (CWI) is one of the popular interventions to facilitate recovery from fatigue and/or exercise-induced muscle damage (EIMD). It has been reported that water immersion depth, hence the area of hydrostatic pressure to the body, is a factor affecting the effect of CWI on recovery from EIMD [1]. Although a recent study compared two different positions (i.e. seated and standing) of CWI to the waist level on recovery from EIMD [2], no previous study has compared the effect of CWI to the waist and chest at the same position such as sitting. The present study compared two different cold water immersion depths for their effect on recovery from plyometric exercise-induced muscle damage to the lower limbs. **Methods** Twenty four untrained men (age:  $23.6 \pm 1.2$  y, high:  $172.2 \pm 4.7$  cm, weight:  $68 \pm 7.3$  kg) performed 5 sets of 20 drop jumps from a high of 0.6 m box with 2 min rest between sets. The exercise was followed by either passive recovery (CON, n=8), CWI to the waist (CWI-W, n=8), or CWI to the chest (CWI-C, n=8) for 15 min at  $14^\circ\text{C}$  immediately and every 24 hours for 3 days after exercise. Maximal voluntary isometric contraction (MVC) torque, upper thigh circumference (CIR), muscle soreness (SOR) and counter movement jump (CMJ) height were measured before, immediately and 1-4 days after exercise from non-dominant leg. Changes in these variables after exercise were compared between the groups by two-way repeated measures ANOVA. **Results** Significant changes in MVC torque (CON: 19-36%, CWI-W: 22-38%, CWI-C: 21-37% decrease from immediately to 3 days post-exercise), CIR (CON: 3-18 mm, CWI-W: 3-11 mm, CWI-C: 4-14 mm increase), SOR (CON: 10-41 mm, CWI-W: 6-48 mm, CWI-C: 3-41 mm increase in a 100-m visual analog scale) and CMJ height (CON: 11-20%, CWI-W: 6-20%, CWI-C: 10-19% decrease) were evident ( $P < 0.05$ ) after exercise. At 3 days post-exercise, MVC, SOR and CMJ were still significantly different from the baseline values. There were no significant differences between CON, CWI-W and CWI-C groups for the changes in any of the variables during the 4-day recovery period. **Discussion** These results show that changes in indirect muscle damage markers after plyometric exercise were not modified by CWI regardless of the water depth, although some of the muscle damage markers did not return to the baseline values at 3 days post-exercise. It is concluded that the CWI protocols used in the present study did not affect the time course of recovery from EIMD, and the depth of CWI had little effect on the recovery. **References** 1) Vaile et al. ### REPEATED PAIRING OF STRETCH REFLEX AND TRANSCRANIAL MAGNETIC STIMULATION TO INDUCE MOTOR CORTEX PLASTICITY

Kumpulainen, S.1,2, Mrachacz-Kersting, N.2, Peltonen, J.1, Karczewska, M.3, Fatela, P.4, Mil-Homens, P.4, Avela, J.1

*University of Jyväskylä*

**INTRODUCTION** Paired associative stimulation (PAS) is a non-invasive stimulation method developed to induce long-term potentiation (LTP)- and long-term depression (LTD)-like plasticity at the target synapse. PAS combines electrical stimulation of a peripheral nerve with transcranial magnetic stimulation (TMS) over motor cortex. The change in the excitability has also been related with behavioral changes. However, considerable inter-individual variability of PAS-induced effects has been reported. This wide variability has been associated e.g. with differences in functional brain areas (Ridding and Ziemann 2010). Thus, the purpose of this study was to modify the traditional PAS in order to reduce this inconsistency. In the modified PAS (PASreflex), the synchronous electrical stimulation of Ia afferents was replaced by a more asynchronous burst like activity induced by natural fast muscle stretch. **METHODS** Subjects sat on an ankle dynamometer with their right foot resting on a pedal. Motor cortex excitability was assessed by TMS to measure input-output curve (IO-curve) of resting soleus motor-evoked potentials (MEPs) before, immediately after and 30 min after the interventions. PASreflex (14 subjects) consisted of soleus stretch reflex elicited with a perturbation induced by the ankle dynamometer and a single TMS pulse, which were paired 200 times to induce LTP-like plasticity. The intervention of the control group (PAScont; 9 subjects) included only the stretch reflex. **RESULTS** In the PASreflex group the slope of the IO-curve decreased non-significantly at post0 and increased significantly at post30. There was a significant difference between the post0 and post30 measurements. Mean MEP amplitudes increased significantly by  $36 \pm 86\%$  at post30. There were 9 responders out of 14 subjects at post30. There were no changes in slopes or mean MEPs in the PAScont group. **DISCUSSION** It was interesting that PASreflex modulated cortical excitability differently immediately after and 30 min after the intervention. It is most likely, that due to the nature of the stretch reflex, a number of different intracortical tracts can be operative. Thus, stretch reflex might have activated several sets of interneurons in the motor cortex, which then could have interfered with each other by homosynaptic and heterosynaptic modifications leading to both LTP- and LTD-like after-effects. Unfortunately, the variability did not decrease after PASreflex since there were 9 responders out of 14 subjects at post30, which is about the same as has been reported for traditional PAS. **REFERENCES** Ridding MC, Ziemann U. ### EFFECTS OF COLD-WATER IMMERSION CRYOTHERAPY $<15^\circ\text{C}>$ ON VERTICAL JUMP PERFORMANCE AFTER EXERCISE-INDUCED MUSCLE DAMAGE

Bezerra, M.S.1, Gomes, L.C.1, Vieira, A.1, Ferreira-Junior, J.B.1, Siqueira, A.F.1, Soares, S.1, Bottaro, M.1, Martorelli, A.S.1, Martorelli, S.S.1, Cleto, V.A.1

1: University of Brasilia (Brasilia, DF, Brazil)

**INTRODUCTION:** Athletes and physically active people can decline strength and height of vertical jump when associated to unaccustomed strenuous exercise (Leeder et al., 2012) (eccentric actions such as vertical jump), causing exercise-induced muscle damage. The cold-

water immersion (CWI) has been widely recommended to fasten the recovery period from muscle damage by exercise scientists and athletic trainers. However, ideal temperature and time of stay in water for optimal muscle damage recovery is conflicted (Bleakley et al., 2010). It is important to evaluate the vertical jump as functional movement possible to identify changes in vertical jump height caused by training, injuries resulting from this or not (Nuzzo et al., 2011). Therefore, the aim of this study was to evaluate the effects of one only session of CWI at 15°C in 20 min. on vertical jump performance recovery after the exercise-induced muscle damage. **METHODS:** 23 physically active men (20±2,16years; 70±8,21kg; 175±6,96cm; 12±6,47%BF) completed five sets of 20 drop jumps with 2 min of rest interval between sets. The exercise drop jump consisted of landing on the floor from a 60 cm box and jump immediately upward maximally. After exercise, participants were randomly assigned to two groups: 1) CWI during 20 min at 15°C (n=12) and 2) Control (n=11). Vertical jump performance, in height (cm) was measured in force plate (BP400600, AMTI, Watertown, MA, USA) at baseline and 24, 48, 72, 96 and 168 hours after exercise. **RESULTS:** There was no significant difference between intervention and time on vertical jump height for both groups ( $F = 1.370$ ,  $p = 0.71$ ). The greater vertical jump height decrement ( $44±4.93$ cm to  $38±6.44$ ) was observed 24 hours and returned to baseline value at 168 hours ( $p>0,05$ ) after exercise for both groups. **DISCUSSION:** The results from the present study demonstrated that CWI at 15°C do not provide any additional muscle recovery of vertical jump performance on compared with passive control. Further studies should investigate underlying mechanisms of major variables of the vertical jump and other movements of reactive strength. **REFERENCES:** Bleakley, C.M. and G.W. ### THE INFLUENCE OF FILTER TECHNIQUE ON QUADRICEPS ELECTROMYOGRAPHY DATA RECORDED DURING WHOLE BODY VIBRATION

Sanderson, M., Sproule, J., Turner, A.

*Institute for Clinical Exercise & Health Science*

**Introduction** The use of surface electromyography (sEMG) measurements during whole body vibration (WBV) allows potential individualised responses to WBV frequency to be recorded but is problematic due to electromagnetic noise recorded by sEMG. As yet the effect of different filtering techniques on sEMG data collected during WBV is relatively unknown and whether portions of muscle sEMG data are removed post filter application. Therefore, the objective of this study was to investigate the effect of filter techniques on quadriceps EMG data collected during WBV in trained participants. **Methods** Three filtering techniques (Unfiltered; Filter 1; Filter 2) were individually applied to identical sEMG quadriceps data sets, collected during WBV of varying frequencies (30; 35; 40; and 50Hz). The filter techniques consisted of: Unfiltered, no digital filter; Filter 1, a 14th Order Butterworth band pass filter (20 – 300Hz, passband 3dB, attenuation 40dB); Filter 2, the same band pass filter with a series of 14th Order Butterworth notch filters (band stop  $\pm 1.5$  Hz centred at WBV fundamental frequency and relevant sub-harmonics). The sEMG data was then root mean squared (sEMGrms). Filter 2 was then applied to 'clean' sEMGrms data recorded during 0Hz. Statistical analysis included a 2-way repeated measures ANOVA (filter [unfiltered, filter 1, filter 2] x frequency [30, 35, 40, 50 Hz]). Finally, Pearson's correlation coefficients ( $r^2$ ) were calculated following the three filters for all WBV frequencies. Results Presence of motion artifacts at fundamental and subsequent sub harmonics frequencies were confirmed via power spectral density. Significant main effects for filter were found with significant differences between all filter techniques. No main effects were found for filter 2 when applied to 'clean' sEMGrms data. **Discussion** Significant portions of sEMGrms data signal were removed depending on the type of filter technique (Filter 2 > Filter 1 > Unfiltered). Applying notch type filters may not remove significant portions of muscle activity signal. These results indicated that even though notch filtering may remove significant portions of sEMGrms signal, it appears that it is not muscle signal. This supports previous research Fratini et al. (2009) in that inclusion of motion artifacts within EMG data recorded during WBV may lead to over estimation of muscle activity. However, the data conflicts with Ritzmann et al. (2010) who reported minimal influence of motion artifacts. This highlights the discrepancies within WBV research due to differences in WBV platforms and parameters. Further research investigating the effect of filter techniques across WBV characteristics is required. **References** Fratini, A., Cesarelli, M., Bifulco, P. & Romano, M. ### REPRODUCIBILITY OF CORTICAL VOLUNTARY ACTIVATION LEVEL ON TIBIALIS ANTERIOR MUSCLE

Souron, R., Farabet, A., Millet, G., Lapole, T.

*Université Jean Monnet (Saint-Etienne)*

**Reproducibility of cortical voluntary activation level on tibialis anterior muscle** 1 Souron, R., 1 Farabet, A., 2 Millet, G., 1 Lapole, T. 1 Laboratoire de Physiologie de l'Exercice, Université de Lyon, Saint-Etienne, France 2 Human Performance Laboratory, University of Calgary, Calgary, Canada **Introduction** It is clearly established that training induces several nervous adaptations leading, in fine, to an augmentation of the maximal voluntary contraction (MVC). One potential mechanism is the enhancement of the descending motor command at a cortical level (Goodall and al., 2014). The assessment of the cortical voluntary activation level (VA) is now possible with the transcranial magnetic stimulation (TMS) technique. If these measurements were already reported to be reliable on the elbow flexor muscles (Todd and al., 2003) and the quadriceps muscle (Goodall and al., 2009), the reproducibility of VA on the tibialis anterior muscle remains to be determined. The present study aim to assess the inter-session reproducibility of the cortical voluntary activation. **Methods** The motor cortex of the right leg area was stimulated with a double 110mm cone coil. The optimal was determined and marked before each visit. The optimal intensity of magnetic stimulation was determined using a recruitment curve, at a 20%MVC level of contraction. This intensity corresponded to the intensity eliciting a maximal motor evoked potential on the tibialis anterior muscle and a maximal amplitude of the superimposed twitch (SIT) (i.e. the increased in muscle force). Voluntary activation was then assessed during MVC using this formula:  $VA = (1 - |SIT/ERT|) \times 100$  with ERT, the estimated resting twitch determined by linear regression of the relation between SIT amplitude and voluntary force at 100, 75 and 50% MVC. VA was measured on two separate days on 13 subjects in order to assess intra-session reproducibility, characterized by the intra-class correlation coefficient (ICC), standard error in measurement (SEM) and coefficient of variation (CV). Results VA presented an excellent reproducibility with 0.99 ICC, 0.8% CV and 0.5% SEM. **Discussion** VA of the tibialis anterior is highly reproducible as previously reported for other muscles groups (Todd and al., 2003; Goodall and al., 2009). Thus, it can be reliably used to investigate the training-induced nervous adaptations at the cortical level. **References** Todd, G., et al. (2003). ### **HIP AND TRUNK MUSCLE ELECTROMYOGRAPHY DIFFERENCES BETWEEN BILATERAL AND UNILATERAL BODYWEIGHT RESISTANCE EXERCISES**

Frandsen, B., Olsson, C.

*Halmstad University*

**Introduction** In sports, force production and movement are predominantly generated in a unilateral weight-bearing stance. Therefore, unilateral resistance training may possibly elicit more sport-specific strength gains compared to traditional bilateral strength training. Hip- and trunk- muscles stabilize the pelvis and trunk to maintain proper technique and posture in resistance training and are thought to play a central role in sports performance as well as injury prevention. Hip- and trunk- muscle activity increases as the body weight balance change from a bilateral to a unilateral stance. Little research has examined the magnitude of change in muscle activation differences between bilateral and unilateral stance in lower body exercises. **Aim** The aim of this study was to examine the electromyographic (EMG) activity in hip and trunk muscles in three bodyweight exercises performed in a bilateral and a unilateral stance. **Methods** 14 healthy, young adults participated in a single session, single-group, observational study. Manual muscle testing was used to attain a maximal voluntary isometric contraction (MVC) value for gluteus medius, gluteus maximus, rectus abdominis, and erector spinae. EMG measurements (4 channel ME6000, MegaWin Software, Kuopio, Finland) were taken during performance of squat, bridge, and plank exercises in both a bilateral and a unilateral stance. **Results** In all three exercises, EMG activity (presented as magnitude of change) was greater in the unilateral stance compared to the bilateral stance ( $p < 0.05$ ), for the muscles gluteus medius (squat 478%, bridge 204%, plank 285%) and gluteus maximus (squat 371%, bridge 172%, plank 233%). In addition, in plank, EMG activity was greater in unilateral stance compared to the bilateral stance ( $p < 0.05$ ) in rectus abdominis (120%) and erector spinae (127%). In the squat and bridge, no differences were identified in EMG activity for rectus abdominis and erector spinae between the bilateral and the unilateral stance. **Discussion** Nearly all unilateral exercises activated the hip muscles (gluteus medius, gluteus maximus) more than double compared to the same exercises performed bilaterally. In particular, gluteal muscle activity during the unilateral squat was more than 3.5 fold greater as compared to the bilateral stance. This greater magnitude of change in the unilateral squat might be explained by the single contact point with the ground in the squat, whereas the bridge and plank exercises include more ground contact points even in their unilateral stance. A unilateral training program including squat exercises might be beneficial for developing hip strength which is of great importance in sports performance. Contact bjorn.frandsen@hh.se

### **COMPARISON OF THREE PROTOCOLS FOR MEASURING EXERCISE INDUCED MUSCLE SORENESS**

Mavropalias, G., Fatouros, I.G., Chatzinikolaou, A., Draganidis, D., Jamurtas, A.Z., Michailidis, Y., Douroudos, I., Leontsini, D., Avloniti, A.

*School Of Physical Education & Sports Science, Komotini, Greece*

**Introduction** Delayed-onset muscle soreness (DOMS) has been defined as a form of muscular hyperalgesia and manifests as pain and stiffness in the muscles several hours after strenuous or unaccustomed exercise (Clarkson et al., 1992). Multiple methods exist to assess the perceived soreness, however there are some limitations such as the standardization of the force applied during palpation and the difference of soreness perceived along the length of the muscle (Newham et al., 1983). The aim of this study was to compare different DOMS assessment protocols in their sensitivity to DOMS and other indicators. **Methods** Three different protocols of evaluating DOMS were compared in response to: a) a football match, b) a basketball match, c) a handball match, d) acute eccentric exercise, e) acute plyometric exercise, f) a weight training bout, g) acute intense running. DOMS and performance (vertical jumping, speed, maximal strength) were measured at baseline, 12 hours post-exercise as well as 1, 2, 3 and 4 days of recovery. The protocols of DOMS evaluated perceived soreness in quadriceps femoris by palpation a) in the standing position (STAN), b) in the sitting (SIT) position and c) in the standing position following three repetitions of a squat movement (SQUAT). Participants in these studies were a) both males and females, b) pre-adolescents, adolescents, adults and elderly and c) trained and sedentary. **Results** Data analysis revealed that SQUAT produced higher values than the other two DOMS protocols at 24 (for all exercise modes) and 48 hours (for eccentric exercise and plyometric training) of recovery. This difference was more pronounced in sedentary (vs. trained) and older participants (vs. younger adults and pre-adolescents/adolescents). No differences were noted between males and females. A significantly ( $p < 0.05$ ) higher correlation was observed between changes in SQUAT and performance at 24h and 48h than between changes in STAN and SIT. SQUAT produced higher DOMS values following team sports and running as compared to other exercise modes. **Discussion** The results of this study indicate that DOMS measurement following three squat repetitions may provide a more sensitive measure of muscle damage development following various exercise modes. **References** Clarkson, P.M., Nosaka, K. & Braun, B. ### **LINEAR AND NONLINEAR ASSESSMENTS OF POSTURAL CONTROL**

Liang, Y., Xi, Y.B.

*Anhui Normal University*

Nonlinear analysis (wavelet) has been suggested to better describe motor control mechanism underlying postural sway. **Purpose:** The purpose of this study was to examine relationships between traditional linear measures of postural sway and nonlinear measures of postural sway (wavelet), in order to provide references for optimal description of research in motor control area. **Method:** Six collegiate baseball players and six college students who had never had sport training experience were asked to maintain standing balance with barefoot on forceplate for 10 seconds under the conditions of eyes-open and eyes-closed. **Results:** Linear and nonlinear center of pressure (CoP) calculations reveal that when vision was removed, both groups demonstrated larger postural sway; wavelet observed that the baseball players utilized great sensory information from spinal reflective loop, muscle activity and cerebellar with respect to ordinary in the anterior-posterior direction and from cerebellar and vestibular system in the media-lateral direction. However, linear measures of postural performance reveal that there were no significant relationships between neuromuscular response and subjects who whether have sport training experience. Independent variables from wavelet have more comprehensive explanation to dependent variables.

Conclusion: Detailed description in wavelet may suggest that effectively physiological parameters and more neuromuscular information could be achieved through nonlinear analysis.

### MOVEMENT LATERALIZATION AND BIMANUAL COORDINATION IN TENNIS PLAYERS

Faelli, E., Carrara, G., Avanzino, L., Pelosin, E., Perasso, L., Limardo, F., Ruggeri, P.

*University of Genoa*

**Introduction.** Tennis is a sport that requires asymmetric movements and mainly involves proximal upper limb muscles. Skilled tennis players learn by training to improve dominant hand performance in terms of precision and strength. However, motor transfer between proximal and distal upper limb muscles has not been studied in tennis players (TP) so far. The aim of our study is to investigate movement lateralization and bimanual coordination of finger opposition movements in TP. **Methods.** 14 TP and 14 healthy controls (HC), matched for age and gender, were recruited for the study. All subjects were right handed. Using a sensor-engineered glove, they were executed the following motor sequence: opposition of thumb to index, medium, ring and little finger. They practiced the task with the right hand and subsequently with both hands. Subjects were asked to tap in synchrony with a metronome cue at 0.5 /2 Hz for 45 s. We evaluated: touch duration (TD; contact time between the thumb and another finger), inter-tapping interval (ITI); time between the end of one tapping and the beginning of the subsequent one), and the percentage of correct movements (SEQC). Kinematic data were analyzed to explore: movement lateralization, comparison of right hand performance on single-hand (RH-S) and bimanual tasks (RH-B), and bimanual coordination, comparison of right- and left-hand performance during the bimanual task. **Results.** On Movement Lateralization, TP showed longer TD, shorter ITI and a larger number of SEQC with respect to HC ( $p < 0.05$ ). No main effects of condition (RH-S vs RH-B) or rate or interactions were found. On bimanual coordination, statistical analysis showed a significant effect of GROUP for TD, ITI and SEQC ( $p < 0.05$ ). TP exhibited longer TD, shorter ITI, and a larger number of SEQC with respect to HC. A significant effect ( $p < 0.05$ ) of HAND for TD, ITI and SEQC was also found. Indeed, in both groups performance of right hand was characterized by shorter TD, longer ITI and a larger number of SEQC with respect to the left hand. **Discussion.** Our results suggest that when TP have to perform finger movements following an external cue, they showed a longer TD, a shorter ITI and a higher number of correct movements with respect to HC. Thus, TP were more accurate, likely thanks to the change of motor strategy adopted (longer TD and shorter ITI). Whereas ITI is likely to represent a pure motor phase, TD may be regarded as the combination of a sensory phase and a motor preparation phase. We can speculate that TP make a more accurate use of sensory information in order to make faster and more accurate the movement time because of training. These findings suggest that a transfer of learning between proximal and distal upper limb muscles has been occurred. Contact: emanuela.faelli@unige.it

### AGE-RELATED MORPHOLOGICAL DEGENERATION OF THE MYELIN SHEATHS AND CAPILLARIES IN THE DISTAL TIBIAL NERVES WITH AGING OF RATS

Sakita, M.1, Murakami, S.2, Saito, T.3, Fujino, H.4

*1) Kyoto Tachibana University, 2) Himeji-Dokkyo University, 3) Aso Rehabilitation College, 4) Kobe University*

**[Purpose]** The atrophy and dysfunction of myelinated fibers with ageing mainly appears with failure of interactions with capillary metabolism. However, it is not morphologically clear whether both the distal sites of peripheral neurons and capillaries degrade with aging. The aim of this study is to investigate morphological changes in the myelinated fibers and capillary architecture of the distal tibial nerve on aging in rats. **[Materials and Methods]** The male Wistar rats aged 20 weeks (young group,  $n = 3$ ) and 90 weeks (elderly group,  $n = 3$ ) were used in this study. The bilateral hindlimbs were perfused by contrast medium solution through the abdominal aorta. From the frozen tibial nerves of several millimeters, serial transverse sections of  $5\mu\text{m}$  thick were sliced with a cryostat microtome (CM3050; Leica Microsystems, Germany) and myelin sheaths were stained with 1 % toluidine blue. Then, transverse sections were visualized with a light microscope. The 3-D capillary architecture in the sample block of tibial nerve was imaged by confocal laser scanning microscopy (TCS-SP; Leica Instruments, Germany) with an argon laser. The myelinated fibers were divided into three fiber types (large, middle and small fibers) according to histogram of the fiber diameter. A two-way ANOVA was performed under three fiber types to compare the myelin sheath thickness, axon diameter and G-ratio (axon diameter/fiber diameter) between the young and elderly groups. An unpaired t-test was used to compare the capillary diameter and the number of microvascular ramifications between the young and elderly groups. **[Results]** Two-way ANOVA revealed there were the main effects in the fiber types ( $p < 0.0001$ ) and groups ( $p < 0.0001$ ), except for G-ratio. The myelin sheath thickness and axon diameter of all fiber types in the elderly group were significantly lower ( $p < 0.01$ ) than that observed in the young group. The capillary diameter and number of microvascular ramifications in the elderly group indicated significant decrease ( $p < 0.01$ ) than the young group. **[Conclusions]** Both the myelinated fibers and capillaries in the distal tibial nerves degrade with aging. The finding of recent studies is that apoptosis and degeneration of old cell were associated with elevated intraneuronal levels of reactive oxygen species. In brief, the increase in oxidative stress may indirectly be responsible for regressions of myelin sheath and capillary. Furthermore, expression levels of vascular endothelial growth factor and brain derived neurotrophic factor that respectively promotes angiogenesis and Schwann cell survival may decrease with aging.

### IS THERE A PREFERENTIAL HYPERTROPHY WITHIN A MUSCLE DUE TO RESISTANCE TRAINING?- A STUDY IN RECTUS FEMORIS AND VASTUS LATERALIS MUSCLES -

Araki, K., Ikezoe, T., Kobayashi, T., Nakamura, M., Ichihashi, N.

*Kyoto University*

**Introduction:** It has still not been established whether individual muscle hypertrophies to a greater degree at a particular location (proximal, middle, or distal level) due to resistance training (RT). The purposes of this study were to investigate the time course of change in muscle thickness (MT) in different locations of the rectus femoris (RF) and vastus lateralis (VL) during 8 weeks of RT, and to clarify the intramuscular difference in muscle hypertrophy. **Methods:** Eight healthy males ( $23.7 \pm 3.0$  years) performed a RT program on the knee extensors with intensities of 80% 1RM. The subjects completed a program of three days per week for 8 weeks, which consisted of three sets with eight repetitions. MT was assessed as an index of hypertrophy at three anatomical sites (proximal, medial and distal regions) of RF and VL, respectively, using ultrasonography. MT was measured before (pre), and at 4 weeks, 6 weeks and 8 weeks during the RT. Two-way ANOVA with repeated measures (time  $\times$  region) was used to analyze the effects of hypertrophy and intramuscular difference in MT. When significant interactions were observed, rates of change in MT after RT were compared between regions using the one-way ANOVA with repeated measures and post hoc testing. **Results:** The two-way ANOVA showed that there was the main effect for time, but not for

the regions both in RF and VL. Significant interaction was shown only in VL. As for the rates of change in MT of VL, significantly greater rate was seen in the distal region than in the proximal region at 6 weeks, while there was no difference between regions at 4 and 8 weeks after RT. Discussion: Intramuscular difference in muscle hypertrophy after RT was observed only at 6 weeks in VL. This result suggests that the significant hypertrophy in the distal region may occur from 4 to 6 weeks, whereas the significant hypertrophy in the proximal region may occur from 6 to 8 weeks. That is, this result suggests that time course of change in MT after RT differs by region in VL. Previous study reported that oxygenation saturation after RT at the distal region of VL muscle was significantly greater than that at the middle region (Miyamoto et al., 2013). Our results which show that hypertrophy of distal region of VL occurred at early phase after RT may result from the difference in metabolic factor during RT between regions. ### EFFECTS OF TENDINOUS TISSUE ON THE TORQUE-ANGLE RELATIONSHIP OF THE KNEE JOINT

Wataru, T.

*Kogakkan University*

**Introduction** The joint torque generated by muscle contraction depends on the joint angle. Behavior of the tendinous tissues to which muscle fibers are attached is also likely to influence the torque-angle relationship. In general, the more the joint is passively extended, the greater the slack in tendinous tissues of extensor muscles. If the tendinous tissue does influence the torque-angle relationship, the discrepancy between length of muscle shortening and joint torque will increase as the joint is extended. This study was designed to clarify the relationship between joint torque and fascicle behavior in vivo and to examine the indirect contributions of tendinous tissues to joint torque. **Methods** Fifteen male subjects performed isometric knee extensions voluntarily (VOL) and electrically (ELE) at knee joint angles of 30°, 60° and 90° (0° = full extension). In the VOL condition, they increased knee joint torque (KJT) at the same rate every 3 s and let it reach the maximum in 27 s. The maximum torque was measured beforehand at 30° (59.7±21.1 Nm), 60° (121.4±34.2 Nm) and 90° (138.7±49.4 Nm), and divided into 9 intensity levels. In the ELE condition, electrical stimulation (ES) at 20 Hz was applied to the vastus lateralis muscle (VL) in the same way as VOL while the subjects were fully relaxed. The maximum ES was defined as the highest tolerable intensity (38.1±14.9 mA). VL activity was measured by electromyography (EMG) and movement by ultrasonography (USG). Changes in the point (P) where a fascicle arises from the deep aponeurosis and the pennation angle were calculated from USG. Results In VOL, strong positive relationships were observed between EMG and KJT at all knee joint angles. In ELE, KJT was almost constant at 30° regardless of ES intensity. As the knee joint angle became larger, positive relationships between ES intensity and KJT became gradually stronger. On the other hand, the smaller the knee joint angle, the larger P moved in the proximal direction, completely opposite to the result in VOL, where movement of P increased with knee joint angle. **Discussion** Maximum KJT evoked by ES (5.9±7.5 Nm) was much smaller than that exerted by voluntary contraction. An interaction between the small KJT and muscle slack may explain the relationships among KJT, ES intensity, and P movement in ELE. It is likely that tendinous tissue slack at more extended positions allowed for greater muscle length contraction but that the small force evoked by ES could not be transmitted to the joint. This is consistent with the increase in KJT with ES intensity at more flexed knee angles. In conclusion, joint torque was influenced not only by sarcomere length and moment arm but also by behavior of tendinous tissue. **References** Lieber RL, Boakes JL. ### INFLUENCE OF DIFFERENT GROUNDS DURING WALKING ON CORTICAL ACTIVITY

Maus, J., Henz, D., Eekhoff, A., Schöllhorn, W.I.

*University of Mainz (Germany)*

**Introduction** Several studies on cortical brain activity substantiate a shift of electroencephalographic (EEG) activity during and after walking (e.g. Wagner et al., 2012). In the present study, we investigated the effects of walking on even and uneven grounds on EEG activity. We hypothesize an increase in beta activity due to walking on uneven ground as an indicator of maintaining a sensorimotor state under novel conditions of motion (see Engel & Fries, 2010). **Methods** 16 healthy subjects (22-29 years) performed a 20-minute walk at 0.8-0.9 m/s on two different grounds (even, uneven). Spontaneous resting EEG was recorded from 19 electrodes according to the international 10-20 system before, during, and after walking. Analysis of variance were performed for the data of power density for the theta (4.0-7.5 Hz), alpha (8.0-13.0 Hz), beta (13.0-30.0 Hz) and gamma (30.0-70.0 Hz) band. **Results** Results during eyes-open baseline show increased temporal ( $p < .05$ ), parietal ( $p < .01$ ) and occipital ( $p < .05$ ) alpha activity after walking on uneven ground compared to control condition. After walking on uneven ground, increased frontal ( $p < .05$ ), central ( $p < .01$ ), temporal ( $p < .05$ ) and parietal ( $p < .05$ ) theta activity as well as increased frontal ( $p < .05$ ), central ( $p < .05$ ) and temporal ( $p < .05$ ) alpha activity was measured at eyes-closed baseline. Increased central beta activity ( $p < .01$ ) occurs after walking on uneven ground during eyes-closed baseline. In comparison to control condition a higher temporal ( $p < .05$ ) and parietal ( $p < .05$ ) gamma activity was measured after walking on uneven ground in eyes-closed condition. **Discussion** Our results demonstrate that walking on uneven ground causes alterations of brain activity. While previous studies indicate decreased alpha and beta activity after walking on even ground (see Wagner et al., 2012), we found increased alpha and beta activity after walking on uneven ground. These findings indicate divergent cortical processing for walking on uneven ground. We assume that the alterations of brain activity result from higher affordances on somatosensory information processing for novel movements. Divergent activation patterns of theta activity may reflect increased attentional focusing during walking on uneven grounds. **References** Engel, A. K. & Fries, P. (2010). ### MONOSYNAPTIC REFLEX IN ATHLETES: COMPUTATIONAL MODELLING APPLIED TO ELECTROENCEPHALOGRAPHIC SIGNALS IN RANDOMIZED CONTROLLED TRIAL

Cugliari, G.1, Boccia, G.2, Pretari, F.3, Ivaldi, M.3

1: Unit of Medical and Genomic Statistics, University of Pavia, Italy 2: CeRiSM Research Center, Rovereto, Italy 3: Service Center S.U.I.S.M., University of Turin, Italy

**Introduction** Monosynaptic reflex is triggered by a muscle stretch and consists into a rapid contraction of the muscle itself. The following study describes electro-cortical activity generated by a monosynaptic reflex on quadriceps femoris elicited by Babinski hammer jab; thus highlighting differences in the cortical activity between before and after stimulus and the changes due to a variation of the body position of the volunteer during the test. **Methods** Twenty healthy volunteers (10 females and 10 males, aged 24-28 years) were chosen from

athletes who practiced at least 6 hours of activity per week. Each volunteer, deprived of sight, received 20 stimulations of sub-patellar tendon, 10 in seated and 10 in supine decubitus position, performed with a Babinski hammer; the lengths of rest between stimuli were randomized (ranging from 5 to 10 s) to prevent that volunteers could expect the stimulus. To highlight the differences between the two times (pre and post stimulus) and the two positions (seated, decubitus) was used a 2-way ANOVA evaluating the contributions of each independent component (IC). After Kolmogorov-Smirnov test, clustering functions with K-means algorithm were used to assess the consistency of ICA decompositions across subjects and conditions. The level of significance was set at  $p < 0.05$  under False Discovery Rate. Results During pre-stimulus time were not statistically significant differences in electrocortical activity among the two positions; during post-stimulus time statistically significant differences among the two positions were found: seated position showed greater cortical activation than supine decubitus position at alpha, beta and gamma frequencies. Time-frequency analysis highlighted an activation (respect to the baseline) at about 160 ms after the stimulus at all frequencies; it's possible also to highlight a similar activation at about 250 ms after the stimulus at higher frequencies. Discussions Power spectrum analysis indicates differences due to a variation of the body position after monosynaptic reflex elicited, no one else studies investigated this topic. Time-frequency analysis indicates two periods when the electro-cortical field activity is significantly different respect to baseline; these results show the time for the transmission of informations in the spino-cortical (ascending) pathways, as shown by Spieser et al., in 2010. ## RELATIONSHIP BETWEEN INTRACORTICAL INHIBITION DURING PRESET AND PERFORMANCE DURING JUMP

Yoshida, T.1, Hayashi, R.2, Kariyama, Y.1, Takahashi, K.1, Zushi, A.1, Maruyama, A.2, Zushi, K.1

1.Uniiversity of Tsukuba, 2.Niigata University of Health and Welfare

Introduction Drop jump (DJ) can be useful in improving the performance in many sports events. Previous studies reported that DJ performance is acted upon by variables such as pre-activation, stretch reflex and stiffness (Taube et al., 2012). Another study reported that short interval intracortical inhibition (SICI) before movement is supposed to play an important role in motor control (Reynolds & Ashby, 1999). Thus, we assumed that the preset state immediately prior to the jump off from drop heights also influences the DJ performance. The purpose of this study was to clarify the effect of SICI at preset state on DJ performance. Methods Male athletes participating in athletics were classified into two groups: jump athletes (jump group) and other athletes (other group). DJs were performed for three drop heights (30 cm, 45 cm and 60 cm). This DJ performance was evaluated by measuring the DJ-index (jump height/contact time) for each drop height. Motor evoked potentials were measured from the medial gastrocnemius muscle (MG) during preset in both groups (MG-SICI), and these potentials were measured from the tibialis anterior muscle (TA) only in the jump group (TA-SICI). SICI was evaluated using a paired-pulse transcranial magnetic stimulation (TMS) paradigm to the motor cortex. The measurements obtained from these muscles underwent different trials (MG-SICI and TA-SICI). The protocol was performed on the basis of two conditions: 1) DJs performed from each drop height with TMS during preset (pre30, pre45, pre60) and 2) TMS performed in the standing position (control). Results & Discussion DJ-index and jump height were significantly higher in the jump group as compared to the other group for all the drop heights. Contact time was significantly shorter in the jump group as compared to the other group for all the drop heights. MG-SICI was significantly decreased in the jump group as compared to the other group at pre60 in DJ trials. The jump group SICI was significantly decreased in pre60 trial as compared to the control trial and pre30. TA-SICI was only measured in the jump group and no differences were observed for any of the drop height. In the jump group we found that MG-SICI during preset decreased with an increased drop height. This was assumed to occur because the jump group regularly practiced movements that were similar to DJ that involved increased drop heights. Therefore, disinhibition of the agonist muscle during preset is thought to be important for DJ performance. ## Nutrition

### DIETARY NITRATE SUPPLEMENTATION: RELATIONSHIPS BETWEEN MUSCLE NITRATE CONCENTRATION, SUBMAXIMAL EXERCISE ECONOMY AND EXERCISE TOLERANCE

Kelly, J., Vanhatalo, A., Mohr, M., Krstrup, P., Wylie, L.J., Blackwell, J.R., Jackman, S., Black, M.I., Winyard, P.G., Bangsbo, J., Jones, A.M.

University of Exeter, UK; University of Gothenburg, Sweden; University of Copenhagen, Denmark.

Introduction It has consistently been reported that NO<sub>3</sub><sup>-</sup> supplementation significantly increases circulating plasma [NO<sub>3</sub><sup>-</sup>] and [NO<sub>2</sub><sup>-</sup>]. However, it is currently unknown whether dietary NO<sub>3</sub><sup>-</sup> supplementation can increase [NO<sub>3</sub><sup>-</sup>] within skeletal muscle tissue, and whether this is important in eliciting the physiological and performance effects previously reported. Therefore the aim of this study was to assess the relationship between skeletal muscle [NO<sub>3</sub><sup>-</sup>], pulmonary VO<sub>2</sub> responses and exercise tolerance to constant-work-rate exercise following NO<sub>3</sub><sup>-</sup> supplementation. These data may enable better understanding of the mechanisms by which dietary NO<sub>3</sub><sup>-</sup> supplementation can affect exercise economy and exercise tolerance. Methods Following ethical approval, eight healthy males supplemented their diet with 140 ml-d<sup>-1</sup> of NO<sub>3</sub><sup>-</sup>-rich beetroot juice (8.4 mmol NO<sub>3</sub><sup>-</sup>; BR) and 140 ml-d<sup>-1</sup> of nitrate-depleted beetroot juice (PL) for 3-days prior to moderate and severe-intensity cycle exercise trials in a double-blind, randomised, crossover design. Plasma [NO<sub>2</sub><sup>-</sup>], [NO<sub>3</sub><sup>-</sup>] and pulmonary VO<sub>2</sub> was measured at rest and during exercise, and muscle [NO<sub>3</sub><sup>-</sup>] was determined from muscle biopsies before and immediately after the exercise bouts. Results Overall muscle [NO<sub>3</sub><sup>-</sup>] was 72% higher following BR compared to PL (BR: 27.8 ± 11.7 vs. PL: 16.2 ± 8.9 nmol/mg DW,  $P < 0.05$ ). Plasma [NO<sub>2</sub><sup>-</sup>] (BR: 493 ± 287 nM, vs. PL: 43 ± 34 nM,  $P < 0.05$ ) and [NO<sub>3</sub><sup>-</sup>] (BR: 238 ± 79 vs. PL: 11 ± 4 μM,  $P < 0.05$ ) were higher following BR compared to PL. The change in muscle [NO<sub>3</sub><sup>-</sup>] following BR compared to PL was positively correlated with the change in severe-intensity exercise tolerance ( $r = 0.67$ ;  $P < 0.05$ ). The change in steady-state VO<sub>2</sub> during moderate-intensity exercise following BR compared to PL was negatively correlated with the change in severe-intensity exercise tolerance ( $r = -0.66$ ;  $P < 0.05$ ). Conclusion Short-term dietary supplementation with BR increases muscle [NO<sub>3</sub><sup>-</sup>] as well as plasma [NO<sub>2</sub><sup>-</sup>] and [NO<sub>3</sub><sup>-</sup>]. Relationships between muscle [NO<sub>3</sub><sup>-</sup>], steady-state VO<sub>2</sub> and severe-intensity exercise tolerance suggest that improved skeletal muscle efficiency consequent to greater NO bioavailability (as inferred from greater muscle [NO<sub>3</sub><sup>-</sup>]) following BR may promote improved exercise performance. Additional work is required to clarify the inter-relationships between skeletal muscle NO bioavailability (and its malleability via dietary supplementation), metabolic and mechanical efficiency, and fatigue resistance and performance. ## NO EFFECT OF ORAL TYROSINE ADMINISTRATION ON MOOD AND MOTIVATION OR HEART RATE VARIABILITY DURING ENDURANCE PERFORMANCE IN THE HEAT.

Tumilty, L.I., Davison, G.2, Beckmann, M.I., Thatcher, R.1

1: AU (Aberystwyth, UK), 2: UoK, (Chatham, UK).

**Introduction** Acute oral administration of the catecholamine precursor tyrosine has been associated with increased exercise tolerance in the heat, perhaps due to maintenance of central and/or peripheral catecholamine function. Therefore, we examined whether acute tyrosine administration affects subjective mood and motivation and heart rate variability during prolonged exercise performance in the heat. **Methods** Seven male, endurance cyclists (median age 20 (range, 26) years, median stature 1.83 (0.13) m, mean body mass 77.9 ( $\pm$  11.7, SD) kg, peak oxygen uptake 4.6 ( $\pm$  0.6) l $\cdot$ min<sup>-1</sup>), unacclimated to exercise in the heat, performed two trials separated by 7 d. Subjects drank 500 ml of sugar-free flavoured tap water containing 150 mg $\cdot$ kg body mass<sup>-1</sup> tyrosine (TYR) or an isocaloric quantity of hydrolysed whey powder (PLA), in a randomised, double-blind fashion. After an hour they performed 60 min of constant-load exercise at 57 ( $\pm$  4) % peak oxygen uptake followed by a simulated cycling time trial lasting approximately 35 min. Mood and motivation were assessed using validated questionnaires (UWIST mood checklist and Dundee Stress State Questionnaire, respectively), at pre-exercise before drinks administration and after 53 min of constant-load exercise. Heart rate variability during the time trial was assessed using a Polar heart rate monitor continuously logging the oscillatory interval between heart beats and analysed in the time and frequency domains using automated analysis software (Kubios HRV version 2.0). Results Mood questionnaire subscale scores ( $P > 0.05$ ) and success ( $P = 0.499$ ), intrinsic ( $P = 0.718$ ) and overall motivation ( $P = 0.986$ ) were similar between trials. Tense arousal increased from pre-exercise in both trials ( $P = 0.172$ ). Mean heart rate variability during 20 min of the time trial (last common time-point at which all subjects were still exercising,  $P = 0.444$ ) and during consecutive 5 min periods did not differ between trials ( $P = 0.447$ ). Standard deviation of all normal to normal heart beats declined after 5 min of time trial ( $P = 0.018$ ) to a similar extent in both trials ( $P > 0.05$ ). Square root of the mean squared differences of adjacent normal to normal intervals did not differ between trials ( $P > 0.05$ ). Low frequency ( $P = 0.655$ ), high frequency ( $P = 0.499$ ) and low frequency: high frequency ( $P = 0.546$ ) power spectra, total power ( $P = 0.587$ ) over 20 min of the time trial, and consecutive 5 min periods ( $P > 0.05$ ) were similar between trials. **Discussion** Acute administration of a catecholamine precursor, in a dose previously reported to increase exercise capacity in the heat, did not influence subjective mood and motivation nor heart rate variability in hyperthermic participants. Contact llf07@aber.ac.uk

## NUTRITIONAL PRACTICES IN TRAINED CYCLISTS PRIOR TO AND DURING AN ULTRA-ENDURANCE CYCLOSPOITIVE

Sparks, S.A., Bridge, C.A., Bell, M.T., Lindsay, C.

Edge Hill University

**Introduction** Cyclosporitive events often take riders > 5 hours to complete. These events therefore require considerable training and appropriate nutritional strategies prior to and during the event if optimal performance is to be achieved. Recently, the recommendations for carbohydrate (CHO) ingestion during exercise bouts > 4 hours have been increased to 90 g/hr, but little is known about the habitual ingestion strategies of these athletes in preparation for and during cyclosporitive events. The aim of the study was to determine the caloric intake of trained cyclists prior to and during an ultra-endurance cycling event. **Methods** Eight trained male cyclists (age 40.3 $\pm$ 6.6 yr, weight, 79.6 $\pm$ 7.2 kg) completed a 241 km undulating route with 3225 m of vertical ascent at a mean ambient temperature of 17.5 (range 12.2 – 22.2) C. During the event, food stations at 103, and 196 km provided participants with opportunities to ingest additional food and fluid. Records of ingestion during each section of the event and at each station. Prior to the event participants also completed a 3-day diet diary. Dietary analysis was used to calculate total caloric intake and rate of CHO ingestion during the event. Perceptions of fullness, thirst, muscle aches and effort were also measured prior to the start, at each station and at the end of the event. One sample t-tests were used to compare CHO ingestion rates to recommended amounts and repeated measures ANOVA was employed to determine changes in perceptual responses during the event. Results Mean caloric content of the pre-event diets for the 3-days was 3032.6  $\pm$  537.4 kcal with 3907.0  $\pm$  910.9 kcal ingested on the day prior to the event. Participants achieved just 5.8 g/kg CHO, which is significantly lower than the recommended intake (mean diff = 4.2 g/kg,  $t = 8.47$ ,  $p < 0.001$ , ES = 0.95). The pre-event meals contained 638.1  $\pm$  222.9 kcal and during the event riders consumed 2356.7  $\pm$  654.0 kcal. Rates of CHO ingestion during the event of 40.9  $\pm$  12.2 g/hr were significantly lower than recommended (mean diff = 49.1 g/hr,  $t = 11.36$ ,  $p < 0.001$ , ES = 0.97). Stomach fullness was unchanged ( $f = 2.08$ ,  $p = 0.133$ , ES = 0.23), but thirst ( $f = 14.71$ ,  $p < 0.001$ , ES = 0.68), muscle aches ( $f = 50.54$ ,  $p < 0.001$ , ES = 0.88), and effort ( $f = 67.10$ ,  $p < 0.001$ , ES = 0.91) increased significantly during the course of the event. **Conclusion** The cyclists ingested insufficient CHO in the days leading up to and during the ultra-endurance event. This prevented them from achieving an optimal nutritional strategy, with likely negative performance implications. Contact Andy.Sparks@edgehill.ac.uk

## SODIUM CITRATE SUPPLEMENTATION ENHANCES TENNIS SKILL PERFORMANCE

Cunha, V.C.R.1, Gomes, R.V.2, Zourdos, M.C.3, Moreira, A.2, Aoki, M.S.2, Capitani, C.D.1

1: University of Campinas (Limeira, Brazil), 2: University of São Paulo (São Paulo, Brazil), 3: Florida Atlantic University (Boca Raton, USA)

**Introduction** The primary aim of this study was to investigate the effect of sodium citrate (SC) supplementation on skilled tennis performance. **Methods** Ten Brazilian nationally ranked young male tennis players (age: 17.0  $\pm$  1.2 years; height: 176.7  $\pm$  5.2cm; weight: 68.4  $\pm$  7.9kg; body fat: 11.7  $\pm$  1.4%) participated in this crossover, placebo-controlled, double-blind study. The experimental study design comprised three days: day-1 was used as a familiarization session for selected tests (the skill tennis performance test [STPT] and the repeated-sprint ability shuttle test [RSA]), day-2 (3 days after day-1) and day-3 (10 days after day-2) were experimental testing sessions. Upon arrival (baseline-BL) in the experimental sessions, a baseline (BL) blood sample was collected for metabolic analysis of metabolic parameters (i.e. base excess-BE, pH, bicarbonate-HCO<sub>3</sub>, and blood lactate-[La]). Following blood collection subjects ingested either SC (0.5g.kg-1BW in capsules of 500mg) or a placebo (PLA-NaCl 0.1g.kg-1BW + Pounder 0.4g.kg-1BW in capsules of 500mg). Two hours later, a pre-match blood sample was collected then STPT and RSA tests were performed followed by a 1-hour simulated match. Immediately following the simulated match, a post-match blood sample was collected, and STPT, and RSA tests were again administered. Finally, 30-minutes later subjects recorded a session-RPE and completed a gastrointestinal (GI) questionnaire. Results There was no difference ( $p > 0.05$ ) between conditions for metabolic parameters at BL. A significant increase in all metabolic parameters (BE, pH, HCO<sub>3</sub>, [La];  $p < 0.05$ ) was detected from BL to pre-match and was sustained at post-match in SC. Additionally, each metabolic parameter was greater (BE, pH, HCO<sub>3</sub>, [La];  $p < 0.05$ ) in SC trial compared to PLA trial at pre- and post-match time points. A greater shot consistency ( $p < 0.05$ ) at post-match in the STPT was observed in SC compared to PLA. Furthermore, a greater amount of games won was noticed in the SC condi-

tion (vs. PLA;  $p < 0.05$ ) during the simulated match. There was no difference ( $p > 0.05$ ) between conditions for RSA performance or session-RPE score. Importantly, no subjects reported any severe GI distress symptoms during either condition. Discussion CS supplementation significantly increased all metabolic parameters (i.e. BE, pH, HCO<sub>3</sub>, [La]) and enhanced skilled tennis performance (i.e. percent shot consistency and games won during simulated match play) compared to a PLA condition. Moreover, no players reported any significant GI discomfort following SC supplementation. Therefore, from a practical perspective, it appears that SC supplementation can be safely and effectively utilized in tennis players to enhance specific skill performance. email: caroline.capitani@fca.unicamp.br

### **EFFECT OF NITRATE-RICH BEVERAGES ON AVERAGE POWER, PEAK POWER, HR, AND RPE IN MODERATELY ACTIVE YOUNG ADULTS**

Gabel, K., Kessler, K.

*Montana State University Billings*

**INTRODUCTION** Known to athletes as an ergogenic aid, nitric oxide enhances blood flow. In a systematic review, Hoon, et.al. (2013) suggests that increased dietary nitrate can increase athletes' endurance during exercise and lower rate of perceived exertion (RPE). Whole beetroot and beetroot juice have frequently been tested in athletes; however, nitrate-rich spinach and non-trained athletes have not been thoroughly tested. The aim of this research was to evaluate effects of nitrate-rich beverages on anaerobic power, endurance, heart rate (HR) and RPE in moderately active male and females. **METHODS** Within a randomized cross-over design, participants were placed into three groups with groups receiving a different beverage over three test weeks. After initial analysis, participants were classified as a trained athlete or recreational athlete for secondary analysis. Before each trial, participants consumed a control beverage or 1500 mg of nitrate from nitrate-rich beverages (freshly prepared spinach or commercially prepared Biotta beetroot juice) in a random order. For testing, participants were fitted with a Polar heartrate monitor and tested on a Monark 884 E Sprint bike using a 7 sec Wingate protocol. SPSS and Vassarstats were used for descriptive statistics and repeated measures ANOVA. **RESULTS** Participants (n=17, 11 male, 6 female) consisted of healthy college students of ages  $22.7 \pm .9$  years, mass of  $80.6 \pm 4.0$  kg, and stature of  $176.2 \pm 1.7$  cm. Endurance was defined as number of stages completed during a Wingate trial. Average stages (M $\pm$ SD) completed after consumption of control ( $24 \pm 5$ ), spinach ( $28 \pm 7$ ), and beetroot ( $24 \pm 5$ ) beverages were not significantly different ( $p \leq 0.05$ ). No significant differences were found in average or peak power, RPE and HR. However, secondary analysis of a subset of trained athletes (n=9) tended to show a greater variation in endurance (control:  $31 \pm 9$ , spinach:  $41 \pm 2$ , and beet root juice ( $35 \pm 9$ ) and RPE (control:  $17 \pm 1$ , spinach:  $16 \pm 1$ , beet root:  $15 \pm 1$ ). Although not significantly different, a larger sample size of trained athletes may have supported differences in effects associated with the nitrate-rich beverages. **DISCUSSION** Past research primarily focused on well-trained athletes (Cermak et al., 2012). In the current study, trained athletes tended to have a greater willingness to push through physical discomfort than recreationally active participants during the Wingate test. Data tended to show differences of nitrate-rich beverages on trained participants, supporting future research focused on athletes and different tests for endurance. **REFERENCES** Hoon, M., Johnson, N. ### **PLASMA CREATINE KINETICS AFTER INGESTION OF NOVEL MICROENCAPSULATION DELIVERY FOR CREATINE MONOHYDRATE WITH ENHANCED STABILITY IN AQUEOUS SOLUTIONS**

Hone, M.1, Scotto Di Palumbo, A.1, Kent, R.3, Bleiel, S.3, De Vito, G.1,2, Egan, B.1,2

*University College Dublin (1,2), Anabio Technologies Limited, Dublin (3).*

**Introduction** Creatine supplementation is a well-established ergogenic aid for enhancing sport and exercise performance. While creatine represents one of the largest sports supplement markets, the degradation of creatine to creatinine presents a major concern for the sports supplement industry, since this is a clear indication of creatine instability, and therefore reduces the effectiveness of oral supplementation when delivered in ready-to-drink format (Jager et al., 2011). Microencapsulation is an emerging technology capable of enhancing stability and bioavailability of bioactives in aqueous solutions. The aim of the present study was to investigate the plasma kinetics of creatine after ingestion of creatine monohydrate delivered using a novel microencapsulation method (Anabio Technologies). **Methods** In a double blind design, physically-active male participants were randomly assigned to ingest a 70 mL shot either containing 3 g of microencapsulated creatine monohydrate (CM) (n=5), or a placebo (PLA) (n=5) containing 3 g of maltodextrin. Plasma creatine concentrations were assessed at baseline before ingestion and every 30 min for 3 h after ingestion. **Results** Plasma creatine concentrations were unchanged in the PLA group, and averaged  $\sim 45 \mu\text{M}$ . In the CM group, plasma creatine concentration peaked after 30 min at  $101.6 \pm 14.9 \mu\text{M}$  ( $p < 0.05$ ), representing a 2.3-fold increase over resting concentrations. Thereafter, plasma creatine concentration gradually declined downwards towards baseline levels, but remained significantly elevated ( $\sim 50\%$  above baseline levels) at 3 h after ingestion. **Discussion** These results confirm that microencapsulated creatine monohydrate is stabilized and remains bioavailable when delivered in an aqueous solution, suggesting potential use of microencapsulation for ready-to-drink formulations for creatine supplementation. Future work will focus on the ability of a supplementation protocol with this delivery method to increase muscle creatine concentrations and enhance exercise performance. **Reference** Jager R, Purpura M, Shao A, Inoue T, Kreider RB (2011) Analysis of the efficacy, safety and regulatory status of novel forms of creatine. *Amino Acids* 40, 1369-1383.

### **EFFECT OF A MEDITERRANEAN DIET ON INFLAMMATORY AND CARTILAGE DEGRADATION MARKERS IN OSTEOARTHRITIS**

Davison, G., Dyer, J.R., Marcora, S.M., Mauger, A.R.

*University of Kent*

**Introduction** Osteoarthritis (OA) is a group of chronic, painful, disabling conditions. Traditionally thought of as a disease of degradation only, inflammation is now also recognised in OA. Whilst current management strategies include exercise, weight loss and pharmacological therapies, there is evidence to suggest that particular food sources consistent with a Mediterranean type diet (e.g. rich in omega-3 fatty acids) may slow the pathogenesis of degenerative joint diseases and moderate inflammation. The aim of the present study was to assess whether following a Mediterranean type diet would moderate selected biomarkers of relevance to OA. **Methods** Following full institutional ethical approval, 61 participants with OA were randomly allocated to an experimental (DIET) or control (CON) group (54 completed: DIET = 29, CON = 25). Participants completed a 7d food frequency questionnaire (FFQ) pre-intervention and at months 2 and 4 (post-intervention). Venous blood samples were taken pre- and post-intervention to obtain serum for analysis of serum cartilage oligomeric matrix protein (COMP) (a marker of cartilage degradation) and other inflammatory and/or OA-related biomarkers (including a

panel of pro- and anti-inflammatory cytokines, in addition to MCP-1 and MMP-9). The CON group were asked to maintain their usual activity and dietary practices, whereas the DIET group were asked to follow dietary guidelines consistent with a Mediterranean type diet. Compliance was assessed by the 2 and 4 month FFQs. Results and Discussion Adherence to the guidelines increased in the DIET group (group  $\times$  time interaction  $P = 0.047$ ): no change in CON group ( $P = 0.493$ ), significant improvement in DIET group ( $P = 0.046$ ). Furthermore, 23 out of 29 participants improved compliance from low ( $< 65\%$ ) to high ( $> 65\%$ ) in DIET compared to 4 of 25 in CON (Chi square test  $P < 0.001$ ). There were no differences between groups in the response of any biomarker, except the pro-inflammatory cytokine IL-1 $\alpha$  (interaction  $P = 0.019$ ), which decreased pre-to post-intervention in the DIET group ( $0.43 \pm 0.38$  to  $0.23 \pm 0.29$  pg/ml,  $P = 0.01$ ) compared to no change in CON ( $0.21 \pm 0.21$  to  $0.23 \pm 0.22$  pg/ml), although interpretation of this is complicated by the pre-intervention difference between groups. A similar, albeit non-significant (interaction  $P = 0.057$ ) pattern was evident for COMP (DIET  $13.1 \pm 4.7$  to  $12.1 \pm 4.5$  U/L; CON  $10.9 \pm 2.4$  to  $11.0 \pm 2.2$  U/L, noting that  $\leq 12$  U/L is considered 'normal'). The dietary intervention had little impact on the biomarkers investigated. However, the DIET group did lose  $\sim 1.6$  kg ( $-2.1\%$ ) body mass. Changes in body mass have been demonstrated to benefit OA, therefore future studies should examine longer periods and include exercise interventions that may cause greater weight loss.

### PROBIOTICS SUPPLEMENTATION IMPROVE MOOD STATE AFTER MARATHON

Silva, E.T., Santos, S.A., Lemos, V.A., Caris, A.V., Antunes, H.K.M., Santos, R.V.T.

UNIFESP - Universidade Federal de Sao Paulo

Introduction Supplementation of microorganisms and their effects on the central nervous system (CNS) are matters of recent interests of researchers. Some studies suggest that the microbiome created by probiotics can modify brain functions and they are utmost importance for normal CNS health. A two-way communication system between gastro-intestinal system and CNS could be mediate by the effects of probiotics supplementation on mood state before and after a marathon race. The purpose of this study was to determine whether probiotic supplementation alters mood status before and after a marathon – race 42,195 km. Methods Twelve marathoners aged 30-45 years were supplemented with probiotics or placebo in capsules 2,0g, one capsule per day for 30 consecutive days of Lactobacillus Acidophilus, Lactobacillus Casei, Lactobacillus Lactis, Bifidobacterium Lactis and Bifidobacterium Bifidum 109 UFC or cornstarch as placebo. After this month all individuals underwent a marathon, implying that they realized that distance in shortest time possible. The volunteers were randomly separated, five in the placebo group (PCG) and seven in the probiotics group (PBG). Before and after the race, the volunteers answered the Brunel Mood Scale questionnaire (Terry et al., 2003) to measure mood profile. The protocol was approved by Unifesp Ethics Committed (#691.519). Results Tension was significantly lower in probiotic's group (PCG  $1.40 \pm 0.34$ ; PBG  $0.57 \pm 0.38$   $p < 0.05$ ); Stamina was significantly higher on probiotic's group (PCG  $6.00 \pm 3.60$ ; PBG  $13.71 \pm 2.75$ ,  $p < 0.05$ ). Depression, Anger, Fatigue there was no significant differences and Mental Confusion was significantly higher in both groups compared pre and post-race (PCB Pre  $0.80 \pm 3.10$ , Post  $5.83 \pm 3.56$ ) and (PBG Pre  $1.14 \pm 1.01$ , Post  $5.28 \pm 1.22$ )  $p < 0.05$ . The data were described as mean  $\pm$  standard deviation. Comparison between the pre and post condition was assessed using repeated measures ANOVA and significance  $p < 0.05$ . Discussion Probiotic supplementation was able to modulate mood, decreasing significantly tension and increasing significantly the stamina, but it was not sufficient to recovery mental confusion after marathon suggesting strong influence of microbiome on the CNS as describe by Tillisch K, 2014. ### CAN RESISTANCE TRAINING AND SUPPLEMENTATION WITH LEUCINE ATTENUATE THE LOSS OF STRENGTH IN DIABETIC RATS?

Tirapegui, J., Ribeiro, H.Q.T., Martins, C.E.C., Lima, V.B.

University of São Paulo

INTRODUCTION Diabetes is associated with important health complications, including a decline in muscular strength, which may impair functional capacity and quality of life of diabetics. Resistance training is described as having a role in enhancement of strength and supplementation with leucine may potentialize these effects. Hence, the aim of this study was to determine the effects of resistance training and supplementation with leucine on gain of strength in diabetic rats. METHODS Three groups were analyzed in this study: healthy but sedentary (to compare the level of strength between this group and diabetics with interventions), diabetic submitted to resistance training and supplemented with leucine (DTL) or non-essential amino acids (DTA, control of leucine). 5-day old male Wistar rats were inoculated with streptozotocin (120 mg/kg in 10 mmol/L of sodium citrate buffer, pH 4.5; diabetics) or sodium citrate buffer (healthy). After 21 days-old, diabetic rats were fed with isonitrogenous diet containing 5% leucine or 5% non-essential amino acids, and submitted to resistance training, consisted of 4-9 climbs in ladder. The rats were adapted during 1 week (4th week), and trained once every 3 days for 8 weeks with progressive loads. On the first day of 5th and 12th week of the experiment, maximum repetition tests were performed. Results were obtained based on the ratio between maximum weight lifted in one repetition and total body weight of rats. Differences between the groups were determined by one-way ANOVA followed by Tukey's post-hoc test. The significance level adopted was  $p = 0.05$ . RESULTS On the first test (before resistance training), healthy rats expressed more pronounced strength than DTA group (19%;  $p < 0.05$ ). However, on the second test (after 8 weeks of resistance training), strength was improved in DTL and DTA groups compared to healthy group (56% and 55% respectively;  $p < 0.001$ ). CONCLUSION Despite the fact that diabetes induces a markedly loss of strength, the results showed that strength was higher in trained diabetic rats than in healthy but sedentary rats, suggesting that resistance training was capable to attenuate the decline in muscular strength. The results also showed similar values to both diabetic groups, suggesting that both leucine and non-essential amino acids, in this concentration, promoted similar effects on muscular strength. ### IS A HIGH CARBOHYDRATE INTAKE SUSTAINABLE DURING ULTRA-ENDURANCE RUNNING EVENTS?

Mahon, E.A., Stott, T.A., George, K.P., Davies, I.G.

Liverpool John Moores University

Introduction The International Olympic Committee advises athletes to consume up to 90 g carbohydrate (CHO) per hour during ultra-endurance events by using products providing multiple transportable CHOs (IOC, 2011). Whilst high intakes ( $> 60$  g/h) have been reported in cycling events (Havemann & Goedecke, 2008), intakes in running events tend to be lower. The purpose of this study was to observe the dietary intakes of mountain marathoners who had been given CHO intake guidelines, to identify source of CHO ingested, associations

with performance, and possible barriers to meeting recommendations. Methods Sixteen male participants [mean age: 42 (SD: 15) y, body mass index: 24.0 (SD: 2.5) kg/m<sup>2</sup>] entered in the Longmynd Hike [50 mile mountain race] received written guidelines for CHO intake. Participants completed a weighed food inventory of all items consumed during the race. Data are expressed as means (SD), statistical significance  $p < 0.05$ . Qualitative data regarding adherence to the recommendations was collected via a post-race questionnaire. Results Hourly CHO consumption was lower than recommended [36 (13) g/h, range: 16-57 g/h], yet positively correlated with performance ( $r = 0.622$ ,  $p = 0.017$ ). Percentage of energy and CHO from sports products also showed strong correlation with performance ( $r = 0.556$ ,  $p = 0.039$ ;  $r = 0.650$ ,  $p = 0.012$ , respectively). Seventy-five percent of participants used sport supplements, yet they accounted for only 24% of total CHO intake. Comparison of nutrient intakes from competitors using sports products [energy: 11.9 (2.8) kJ/kg/h, CHO: 41 (9) g/h, 71 (10) % energy, fat: 22 (8) % energy, protein: 7 (2) % energy,  $n = 12$ ] versus those not [energy: 7.3 (0.9) kJ/kg/h, CHO: 19 (3) g/h, 53 (5) % energy, fat: 39 (4) % energy, protein: 8 (0.9) % energy,  $n = 4$ ], showed a more favourable nutrient profile for the former. The most common barrier to consuming higher intakes of CHO was that the quantity of food was too great. Discussion It has been proposed that sub-optimal intakes of CHO in such events may be due to the practical difficulties of ingesting foods whilst running (Kimber et al., 2002). However, the relatively high proportion of energy derived from fat and protein in this sample, coupled with the qualitative data, suggest it may also be due to over-consumption of whole foods. Athletes may be choosing a selection of whole sources in order to avoid sensory-specific satiety that might occur with high-CHO sports products. More research and guidance is needed to help athletes sustain higher CHO intakes over longer races, whilst limiting overall food intake and possible flavour fatigue. ## INTEREST OF CREATINE SUPPLEMENTATION IN SOCCER

Miny, K.1,2, Burrowes, J.2, Jidovtseff, B.1

1: *ULg (Liège, Belgium)*, 2: *LIU Post (New York, USA)*

Introduction Studies have consistently indicated that creatine supplementation increases muscle creatine and phosphocreatine concentrations by approximately 15 to 40%, enhances anaerobic exercise capacity, and increases training volume leading to greater gains in strength and power (Cooper et al., 2012). Soccer can be described as an intermittent prolonged-duration high-intensity exercise. In terms of physiology, phosphocreatine and muscular glycogen are the two primary energy sources used by soccer players (Bangsbo et al., 2006). Therefore, this article aimed to summarize the current state of understanding on creatine supplementation for soccer players. Methods Searches were performed using PubMed and SPORTDiscus. Key terms used were ("creatine" OR "creatine supplementation") AND ("soccer" OR "football"). In order to meet the inclusion criteria, an article had to involve soccer players and investigate the potential ergogenic effect of creatine supplementation on soccer-specific skills and performance. Eight articles in total were retrieved from the computerized searches (Claudino et al., 2014; Williams et al., 2014; Mohebbi et al., 2012; Manchado et al., 2008; Ostojic, 2004; Cox et al., 2002; Larson-Meyer et al., 2000; Mujika et al., 2000). Results Creatine supplementation can have positive effects on dribble, sprint and vertical jump performances in soccer players. This supplementation may also enhance soccer players' muscle strength and adaptation to a high-intensity training regimen. In addition, creatine may be able to enhance muscle glycogen storage, reduce oxidative stress, and improve muscular repair and hypertrophy. It may have a protective effect against proteolysis during the first weeks of pre-season training and/or after intensive practices preceded by a long rest period. Creatine supplementation does not seem to affect aerobic performance. Discussion Soccer players could take creatine during pre-season training (3 to 5 g/day) in order to help them endure a high-intensity training regimen and/or enhance their muscular strength and adaptation. The same dosage might also be sufficient and beneficial during the season in case of fatigue, in order to sustain adequate levels of creatine, phosphocreatine and glycogen in the muscles, or to also give a physical (and mental) boost before games and extenuating practices. Further research is needed regarding the aerobic part of soccer. References Bangsbo, J., Mohr, M., & Krstrup, P. (2006). Physical and metabolic demands of training and match-play in the elite football player. *Journal of sports sciences*, 24(07), 665-674. Cooper, R., Naclerio, F., Allgrove, J., & Jimenez, A. (2012). ## THE EFFECTS OF CAFFEINE INGESTION TIMING ON ACUTE TESTOSTERONE AND CORTISOL RESPONSES TO RESISTANCE EXERCISE

Bo-Han, W., Chih-Min, W.

*National Pingtung University of Science and Technology ; Cheng Shiu University*

Caffeine ingestion has been shown to affect hormonal responses to resistance exercise. However, few studies examined effects of caffeine ingestion timing on acute responses of anabolic and catabolic hormones to a single bout of resistance exercise. PURPOSE: The purpose of this study was to examine the effects of different caffeine ingestion timing on acute hormonal responses to a single bout of resistance exercise (RE). METHODS: Twelve university male students (age, 21.4±1.9 yr; mass, 70.1±4.8 kg) who regularly performed RE participate in this study. All subjects performed 1RM test, then assigned to four treatments: caffeine ingestion 60 min prior to RE (PRE60, 6 mg/kg), caffeine ingestion prior to RE immediately (PRE-EXE, 6 mg/kg), caffeine ingestion during RE (EXE, 6 mg/kg) and control (CON) in counter balance order and within subject crossover design. All subjects ingested caffeine according to each treatment, then, the subjects performed RE (two exercises, 5 sets of 10 repetitions at 75% of 1RM). Blood samples were collected prior to caffeine ingestion (baseline, BL) and 0, 15, 30 min post to RE (P0, P15, P30) for analysis of testosterone, cortisol, insulin, blood lactic acid, glucose and free fatty acid. Each experiment separated by 7 days. In this study, statistical analysis of a two-way analysis of variance (treatment by time) with repeated measures was applied. Statistical significance set at  $\alpha = 0.05$ . RESULTS: After ingesting caffeine, the concentration of free fatty acid (P0) in PRE60 was significantly higher than CON (0.57±0.09 vs. 0.41±0.10 mmol/L) ( $p < 0.05$ ). The responses of testosterone (P0, P15, P30) (PRE60: 676.75±145.82, 643.38±149.25 and 575.50±192.44; PRE-EXE: 654.25±121.23, 619.50±121.63 and 571.25±123.97 vs. CON: 584.75±136.19, 531.25 ±146.57 and 496.38±137.42 ng/dl,  $p < 0.05$ ) and cortisol (P0, P15, P30) (PRE60: 23.31±3.00, 22.02±2.16 and 20.13±2.78; PRE-EXE: 22.29±2.84, 21.86±2.23 and 20.3±4.40 vs. CON: 18.40±2.30, 17.92 ±2.41 and 16.21±2.10 µg/dl,  $p < 0.05$ ) were significantly higher than CON in PRE60 and PRE-EXE. However, no significant difference was seen in resting and after RE concentrations between treatments for insulin ( $p > 0.05$ ). CONCLUSION: The results of this study indicated that caffeine ingestion prior to RE (PRE60 and PRE-EXE) will significantly affect the acute hormonal responses. However, caffeine ingestion during RE might not significantly change acute responses of anabolic and catabolic hormones.

### **PASSIVE SMOKING REDUCES AND VITAMIN C INCREASES EXERCISE-INDUCED OXIDATIVE STRESS: DOES THIS MAKE PASSIVE SMOKING AN ANTI-OXIDANT AND VITAMIN C A PRO-OXIDANT STIMULUS?**

Theodorou, A.A., Paschalis, V., Kyparos, A., Panayiotou, G., Nikolaidis, M.G.

*European University Cyprus*

**INTRODUCTION** The current interpretative framework states that, for a certain experimental treatment (usually a chemical substance) to be classified as 'anti-oxidant', it must possess the property of reducing (or even nullifying) exercise-induced oxidative stress. The aim of the study was to compare in the same experimental setup, redox biomarker responses to an identical acute eccentric exercise session, before and after chronic passive smoking (considered a pro-oxidant stimulus) or vitamin C supplementation (considered an anti-oxidant stimulus). **METHODS** Twenty men were randomly assigned into either passive smoking or vitamin C group. All participants performed two acute eccentric exercise sessions, one before and one after either exposure to passive smoking or vitamin C supplementation for 12 days. Vitamin C, oxidant biomarkers (F2-isoprostanes and protein carbonyls) and the non-enzymatic antioxidant (glutathione) were measured, before and after passive smoking, vitamin C supplementation or exercise. **RESULTS** It was found that chronic exposure to passive smoking increased the level of F2-isoprostanes and decreased the level of glutathione at rest, resulting in minimal increase or absence of oxidative stress after exercise, contrary to the current scientific consensus. Conversely, chronic supplementation with vitamin C decreased the level of F2-isoprostanes and increased the level of glutathione at rest, resulting in marked exercise-induced oxidative stress. If these findings are explained within the current framework, a rather confusing conclusion is reached that passive smoking acted as an anti-oxidant stimulus and vitamin C as a pro-oxidant stimulus. **DISCUSSION** Although it is straightforward to define oxidants and reductants chemically, characterising the effects of an "oxidant" or an "anti-oxidant" in a biological environment has proven to be a very difficult task. We provide for the first time empirical evidence that the current interpretative framework of exercise-induced oxidative stress can be misleading and we propose a novel one. Contrary to the current scientific consensus, our results show that, when a pro-oxidant stimulus is chronically delivered, it is more likely that oxidative stress induced by subsequent exercise is decreased and not increased. Reversely, it is more likely to find greater exercise-induced oxidative stress after previous exposure to an anti-oxidant stimulus. We believe that the proposed framework will be a useful tool to reach more pragmatic explanations of redox biology phenomena. **CONTACT** nikolaidis@auth.gr

### **CARBOHYDRATE SUPPLEMENTATION INCREASES HSP-70 CONCENTRATION AFTER STRENUOUS EXERCISE IN HYPOXIA**

Caris, A., Lira, F.S., Oyama, L.M., Santos, R.V.T.

*Unifesp*

**CARBOHYDRATE SUPPLEMENTATION INCREASES HSP-70 CONCENTRATION AFTER STRENUOUS EXERCISE IN HYPOXIA** **Introduction** There is controversy regarding the effect of exercise on HSP-70 concentration at sea level. On the other hand, exercise in hypoxic conditions represents an additional stress to the organism compared with exercise in normoxia (Mazzeo, 2008). In extreme environmental conditions, especially in hypoxia, the organism suffers several changes including a physiological and biochemistry changes. The aim of this study was to evaluate the effects of carbohydrate supplementation on the serum concentration of HSP-70 after strenuous exercise in hypoxic conditions simulating altitude at 4,500 m. **Methods** Nine healthy and physically active men were submitted to two sessions of exercise at an intensity of 70% VO<sub>2</sub>peak until exhaustion in a normobaric chamber (Colorado Altitude Training\_ (CAT)/CAT-12 Air Unit) simulating altitudes of up to 4500 m. These sessions were as follows: 1) hypoxia with placebo (Crystal Light® - Kraft Foods, Inc. strawberry), 2) hypoxia with supplemented 8% maltodextrin (200 mL/20 min, during and 2 h after exercise). All the procedures were double-blind and random. The haemoglobin O<sub>2</sub> saturation (SaO<sub>2</sub>%) was evaluated at the baseline and after 2h of exposure, whilst the serum concentration of HSP-70 was evaluated before entry into the chamber (baseline), after 2h of rest (pre-exercise), after exercise (post-exercise) and after 2h of recovery. Data normality was verified and descriptive analysis was performed by calculating the mean ± SE. Analysis of variance for repeated measures was carried out, followed by a Tukey post hoc test, and P-value = 0.05 was considered significant. The software Statistics 7.0 (StatSoft, Inc.) was used for the statistical analyses. In the exercise in hypoxia group, the SaO<sub>2</sub> decreased (p<0,05) relative to the corresponding values in normoxia. **Results** In the hypoxia and hypoxia+carbohydrate conditions, SaO<sub>2</sub>% decreased by approximately 10% after 2 h of exposure to hypoxia in relation to the baseline (before exercise.) The quantity of HSP-70 showed an increase from the baseline versus post-exercise (P = 0.0008), pre-exercise versus post-exercise (P = 0.0008), and pre-exercise versus after 2 h (P = 0.01) in the hypoxia+carbohydrate condition. **Discussion** The carbohydrate supplementation increased the concentration of HSP-70 after exercise and after 2h of recovery, suggesting that supplementation may stimulate the protective effects of cells mediated by HSP-70 in hypoxia. **Reference** Mazzeo RS. (2008). *Sports Med*, 38, 1-8. **Contact** alinecaris@hotmail.com **Financial support:** Fapesp: 2014/03237-4

### **METABOLIC FATE OF A FRUCTOSE LOAD INGESTED BEFORE OR AFTER EXERCISE**

Cros, J., Egli, L., Lecoultre, V., Rosset, R., Tappy, L.

*University of Lausanne*

**Introduction** Overconsumption of fructose may promote hypertriglyceridemia in healthy sedentary subjects, possibly by targeting fructose carbons into de novo lipogenesis. This effect is largely prevented by exercise. To assess how exercise impacts fructose metabolism, we compared the metabolic fates of oral <sup>13</sup>C-labelled fructose loads (OFL) consumed a) in resting, non-exercising condition, b) before and c) after an acute aerobic exercise. We hypothesized that fructose ingested before an exercise session would be immediately oxidized, whereas fructose ingested after exercise would be mainly used to replenish glycogen stores. **Methods** 8 sedentary young males were studied on 3 occasions after 4 days on a weight-maintenance, high-fructose diet (30% daily energy needs as fructose). On the 5th day, they ingested an OFL (ie. 0.75g <sup>13</sup>C-labelled fructose/kg) either a) in resting condition (C), b) with a low to moderate aerobic exercise (FruEx; 60 min cycling at 100 W) starting 90 min after fructose ingestion, or c) with the same exercise starting 75 min before ingestion (ExFru). On each occasion, fructose oxidation (<sup>13</sup>CO<sub>2</sub>), non-oxidative fructose disposal (NOFD, defined as fructose ingestion – <sup>13</sup>C fructose oxidation, corresponding to net glycogen storage), conversion of fructose into plasma glucose (plasma <sup>13</sup>C-glucose kinetics), and plasma lactate and triglyceride (TG) concentrations were measured over 7 hours after fructose loading. **Results** Fructose oxidation was significantly higher in FruEx than in C (80 ± 3% OFL vs 49 ± 1% OFL; p<0.001), but was unaltered in ExFru (46 ± 1% OFL; p=0.14 vs C). Consequently, NOFD was significantly lower in FruEx than in C (20 ± 3% OFL vs 51±1% OFL; p<0.001) and in ExFru (54 ± 1% OFL, p<0.001 vs FruEx). The integrated incremental area under the curve of plasma TG were not significantly different (5.44 ± 20.58, 1.56 ± 24.98, and 1.09 ± 13.09

mmol/L\*420 min in C, FruEx and ExFru, respectively). Similarly, fructose conversion into glucose as well as plasma lactate concentrations remained unchanged in both FruEx and ExFru, as compared to C. Discussion Exercise performed after fructose ingestion stimulates fructose oxidation at the expense of glycogen storage. Preferential oxidation of fructose-derived glucose and lactate by working muscle is likely to be responsible for this effect. In contrast, exercise performed before ingestion does not significantly alter the metabolic fate of a subsequent fructose load. These results suggest that exercise, when performed immediately after fructose ingestion, may be essentially efficient at preventing adverse metabolic effects of fructose by targeting fructose carbons directly into oxidative pathways. This work was supported by the Swiss National Science Foundation. Contact: Jeremy.cros@unil.ch

## EFFECT OF LINCZI AND ELIXIR FENIX FOOD SUPPLEMENTS ON SPORTSMEN'S PHYSICAL AND FUNCTIONAL CAPACITY

Dadeliene, R., Milasius, K.

*Lithuanian Educational Science University*

Aim was to determine the effect of food supplement LINCZI and elixir FENIX on physical and functional capacity of athletes to work in various energy production zones. Methods. Twenty-eight men were divided into two groups. I group subjects took the supplement LINCZI (0,5 g./day) and FENIX (30 ml/day) for 20 days. II group - consumed lactose as a placebo. The 1st testing was one day before the intake of food supplements and 2nd testing - three days after the intake of food supplements. We tested psychomotor reaction time, single muscle capacity and anaerobic lactic muscle power, anaerobic lactic-glycolytic muscle power and aerobic capacity; heart rate at rest, after standard physical load and after 60s recovery. Haemoglobin concentration and Haematocrit were determined. Results. Supplementation of LINCZI in combination with elixir FENIX for a period of twenty days effectively influenced anaerobic lactic-glycolytic muscle capacity, cardiovascular system capacity and aerobic capacity. VO<sub>2</sub>max increase from 42,64±3,69 till 49,68±4,94 ml/min/kg. Supplementation has not significant influences on athletes' single muscle capacity power, anaerobic lactic muscle power, CNS function, Haemoglobin and Haematocrit concentration. Discussion. We have found that food supplement LINCZI and FENIX has more influence on increasing anaerobic lactic-glycolytic muscle capacity and aerobic capacity. Kumar et al., (2011) reported, that Cordyceps Sinensis supplementation improves exercise endurance capacity of rats. The study Parcello et al., (2004) didn't show significant influence of supplements Cordyceps sinensis to VO<sub>2</sub>max elite women cyclist. While, Walker (2006) found, that of supplementation of Cordyceps sinensis effected results in running middle and long distance. Our study did not show significant increases in athletes' single muscle capacity and anaerobic lactic muscle power. Chen et al. (2012) examined lentinus edodes and found it's antioxidant capacities. ## PHARMACOKINETICS OF ACUTE TYROSINE INGESTION AT REST

Taylor, L., Christmas, B., Watson, P., Horsfall, R., Coull, N.

*The University of Bedfordshire*

Introduction Acute ingestion of tyrosine (TYR), a catecholamine precursor, has been shown to improve aspects of cognitive function and mood during exposure to stressful environments, in military and sport specific settings. Currently, there is limited research exploring the optimal dose of TYR relative to blood values, to prescribe pre-exercise or before exposure to a stressor. Therefore, the aim of this study was to investigate the effects of different TYR dosing strategies on serum TYR concentrations at rest. Methods Twenty-one healthy males were randomly allocated to one of three groups (n = 7 per group); HIGH (300mg/kg TYR in total), LOW (150mg/kg TYR in total) and CON (sugar free squash placebo). Ingestion of TYR/CON was double blinded and was administered in a drink form (dissolved in 250mL sugar free squash) in two separate doses at both 0900 and 1300. Participants consumed a standardized breakfast (0800) and lunch (1200) prior to consumption of TYR and remained in the laboratory from 0900-1700 having blood drawn every hour from a cannula. Blood samples were analysed via HPLC to assess TYR concentrations across all time points. Measures of blood pressure, gastric discomfort and perceived readiness to invest physical and mental effort (RTIPE/RTIME) were also recorded. Results Significant differences in serum TYR concentrations were observed between groups (P < 0.001), with the HIGH dose (399 ± 69 µmol/L) resulting in the largest elevation compared to the LOW dose (279 ± 76 µmol/L) and CON (64 ± 11 µmol/L). Ingesting TYR as a double-dose did not significantly increase the peak in serum TYR compared to the first dose in both groups; low (221 vs 273 µmol/L) and high dose (331 vs 368 µmol/L) (P > 0.05). No significant differences were observed in blood pressure, gastric discomfort, RTIPE or RTIME over time or between groups (P > 0.05). Discussion This study demonstrates that ingestion of a single dose of 150 mg/kg body mass-1 TYR may be sufficient to elevate serum TYR concentrations (350 µmol/L) and that the peak in TYR concentration typically occurs 2 h post ingestion (without the need for a second identical dose 4 h later). Furthermore, ingestion of this dose does not seem to influence perceived RTIPE/RTIME, blood pressure or induce gastric discomfort and therefore may be safely administered prior to a stressful encounter.

## THE EFFECT OF ENDURANCE EXERCISE AND RESISTANCE EXERCISE ON POSTPRANDIAL LIPEMIA

Wu, C.1, Chiu, C.2, Chen, P.1, Cheng, C.2

*1:National Chung Hsing University, 2:National Taiwan University of Sport*

Introduction Most studies were set to investigate the effect of acute endurance exercise on postprandial lipemia. There were limited studies investigating the effect of resistance exercise and endurance exercise on postprandial lipemia. Previous studies concluded that postprandial lipemia could be reduced after a acute endurance exercise. However, there is no consensus when it comes to resistance exercise. Methods Six recreationally trained men (aged 21.7±1.4 yrs) completed 3 experimental trials. Each trial lasted for 2 days and was separated a week apart. In order to rule out the effect of muscle damage, all the participants took two week recess after resistance exercise trial. On day 1 afternoon (4-5pm), the subject either took endurance exercise (50% VO<sub>2</sub>max walk), resistance exercise (ten kinds of resistance exercise, 12 RM, 2 sets) or rest (control). On day 2, after overnight fast, subjects were asked to consume the oral fat tolerance meals and were asked to rest for 6 hours. Venous blood samples were taken during fasting and 6 hours postprandial period. Result Endurance exercise significantly reduced the concentration of plasma triglyceride incremental area under the curve (IAUC) compared to control group (P=0.038). There were no significant differences on plasma insulin, glucose, Non-esterified fatty acid, glycerol, D-3-Hydroxybutyrate, high-density lipoprotein cholesterol, cholesterol, CK and LDH concentrations. Conclusions The current study suggested the endurance exercise significantly reduced postprandial lipemia when compared to control group. There was no significant effect of

resistance exercise on postprandial lipemia. References Burns, S. F., Broom, D. R., Miyashita, M., Ueda, C., & Stensel, D. J. (2006). MSSE, 38(3), 527-533. Burns, S. F., Corrie, H., Holder, E., Nightingale, T., & Stensel, D. J. (2005). J.Sports Sci., 23(3), 251-260.

### **ZEOLITE SUPPLEMENTATION AFFECTS INTESTINAL BARRIER INTEGRITY OF ENDURANCE TRAINED SUBJECTS, ACCOMPANIED BY ANTIINFLAMMATORY EFFECTS**

Oberwinkler, T.1, Lamprecht, M.2,3, Bogner, S.2,3, Greilberger, J.F.3,4, Schuetz, B.5, Petek, T.6, Bachl, N.8, Schippinger, G.7  
 (1)Panaceo GmbH, A (2)Green Beat, A (3)Medical University, A (4)Dr Greilberger GmbH, A (5)Biovis Diagnostic, D (6)Lorenz & Petek Ltd, A (7)SportchirurgiePlus, A (8)University of Vienna, A

**Introduction** Zeolites are microporous, crystalline aluminosilicate minerals featuring three-dimensional channels and cavities. Their structure is formed by tetrahedra of AlO<sub>4</sub> and SiO<sub>4</sub> which are the basic building blocks for building these channels. Zeolites exhibit a negatively charged framework, which is counter-balanced by positive cations resulting in a strong electrostatic field on the internal surface. Natural zeolites are therefore able to bind toxins (adsorption) present in the body and release essential minerals (ion-exchange) into the body at the same time. In this study it was investigated whether supplementation with a natural zeolite could influence biomarkers of gut wall integrity in endurance trained individuals. **Methods** In a randomized, double-blinded, placebo controlled trial, 52 endurance trained men and women, similar in body fat content, non-smokers, 20–50 years, received 2g of zeolite per day for 12 wk. Stool and blood samples for determination of tight junction modulators Zonulin as well as antiinflammatory IL-10 were drawn at the beginning and the end of the study. Nutrition and physical exercise training were standardized before sample collections. For statistical analyses a 2-factor ANOVA was used. **Results** At baseline both groups showed increased stool zonulin and plasma IL-10 concentrations. After 12 wk zeolite supplementation stool zonulin was significantly ( $p < 0.05$ ) decreased in the supplemented group. IL-10 was increased with a trend ( $p < 0.1$ ) in the zeolite group. Zeolite supplementation exerted beneficial effects on gut wall integrity via modulation of tight junctions. This was accompanied by antiinflammatory effects in subjects undergoing chronic exercise training. We could also show that this natural zeolite did not affect serum Al concentrations when ingested over 3 months. **Discussion** It is suggested that zeolite modulated the zonulin system by interacting with intestinal bacteria. Further research is needed to explore mechanistic explanations for the observations in this study. Our observations could be of practical relevance for athletes under the perspective that an improved intestinal barrier reduces athlete's susceptibility to endotoxemia.

### **EFFECT OF 5-AMINOLEVULINIC ACID AND EXERCISE TRAINING ON HEMOGLOBIN MYOGLOBIN AND CYTOCHROME C OXIDASE LEVELS**

Suda, K., Kashiwase, T., Ogura, S., Usui, S., Fumoto, M., Ishiwata, T.

*Tokyo Institute of Technology*

**Introduction** Aerobic exercise is considered to prevent some diseases by using excess energy stored in the body. To make exercise more effective, quantity of oxygen transporting substances may be important. 5-Aminolevulinic acid (ALA) is a precursor of heme, and heme consists oxygen transporting substances such as hemoglobin, myoglobin and cytochrome c oxidase (COX). ALA is widely distributed both in plants and animal cells. Lately, ALA can be made relatively low cost. If ALA administration increases these oxygen transporting substances, exercise would be more effective to prevent the diseases. Therefore, in this study, we compared levels of hemoglobin, myoglobin and COX activity between the rats with and without ALA administration. **Methods** Three weeks old male Wistar rats were divided into 4 groups, sedentary (control), sedentary+ALA (Sed+ALA), exercise (Ex), exercise+ALA (Ex+ALA). Each group was consisted of 10 rats. ALA was dissolved in water and administered about 10mg/kg/day. Exercise rats swam 5 days a week. Swimming duration was 15 min at 3 weeks old, gradually increased to two hours. Blood hemoglobin concentration and soleus myoglobin concentration and COX activity were measured. Two-way ANOVA was used for statistical analysis. **Results** Body weight of both exercise groups were significantly less than the two sedentary groups. ALA administration decreased blood hemoglobin concentration when Ex and Ex+ALA compared. Myoglobin concentration in the soleus was not different among the four groups. Main effect of ALA was found. ALA administration increased COX activities. **Discussion** Body weight decrement in the Ex and the Ex+ALA groups proved that these rats trained well. Hemoglobin plays an important role in transporting oxygen from the lung to peripheral tissues and ALA is precursor of hemoglobin. So we had thought this value would increase but the result was opposite. This change does not necessarily reduce exercise ability because hematocrit also decreased in the Ex+ALA group. So blood flow was more smooth in the Ex+ALA group. Anyway, combination of exercise and ALA did not increase blood hemoglobin concentration. Exercise and ALA administration did not affect myoglobin concentrations in soleus. On the other hand ALA administration significantly increased COX activities in mitochondria. These results suggest that ALA administration affects some oxygen transporting substances. In conclusion, it is possible that ALA administration increases effectiveness of exercise for decreasing body weight. Further studies are necessary to understand effect of ALA administration in detail. **References** Ogura S, et al.(2011) "The effect of 5-aminolevulinic acid on cytochrome c oxidase activity in mouse liver", BMC Research Notes 4:66, Ishizuka M. et al. ## **Philosophy and Ethics**

### **RESEARCH ON THE SPORTS ORDER IN THE PERSPECTIVES OF PHILOSOPHY**

Long, Q.

*Guangdong Institute of Education*

Base on the philosophy of Marxism, Rationalism, libertarianism and anthroposophy to analyze sports order and its processes of spontaneity, autonomously and self-discipline. Make clear the concept of order, self-discipline, spontaneity and autonomously, develop the principle and requirement of order, self-discipline, spontaneity and autonomously. This article argues that the sustainable development of sport must follow the principle that individual benefit and group interests should be united and coordinated. People needs to develop individual spontaneity, realize that the sports activities belong to oneself and people should take the responsibility by own self for the health and live self-discipline. People can participate the sports in order to keep fit and entertain them self autonomously. The government meets the needs of individual to enact the policy and use the power of administration reasonably so that the unity of individual and group interests can be making.

## Physical Education and Pedagogics

### VALIDATION OF THE ATTITUDE/MOTIVATION TEST BATTERY IN MEXICAN UNIVERSITY STUDENTS FROM FACULTY OF SPORT

Cocca, M., López-Walle, J., Cocca, A., Kendzora, T.

*Autonomous University of Nuevo León*

Introduction Learning English for professional purposes (EPP) is fundamental for students engaged in sports-related faculties. In fact, it positively affects their overall knowledge and cultural background, as well as it increases their professional opportunities as coaches, teachers, or future researchers (Cianflone and Coppolino, 2009). However, the association "English First" underlined that engagement in ESP classes and motivation towards learning it are low among Mexican university students. The aim of this study is to validate the Attitude/Motivation Test Battery (AMTB) assessing motivation towards learning English (Gardner and MacIntyre, 1993) in the Mexican context. Methods We selected 242 students attending the first semester at the Faculty of Sports Organization of Monterrey (Mexico), who filled in a previously created Mexican version of AMTB (Sandoval Pineda, 2011) during the first week of classes. Results Initial reliability analysis showed low scores (Cronbach's Alfa = .432). After removing contradictory items, the questionnaire showed good reliability (Cronbach's Alfa = .948). Structural modelling demonstrated the goodness of the structure of the instrument (NNFI = .988; CFI = .989; RMSEA = .054; GFI = .634), which was confirmed by Confirmatory Factorial Analysis as well. Discussion Mexican version of AMTB is a valid instrument and can be used to assess motivation towards learning ESP in Mexican students from the faculty of Sports Organization. In the future, this tool can help us better understand students' attitude towards English, consequently promote this important issue in a more efficient and individuality-attentive way. ### HEALTH AND PHYSICAL ACTIVITY OF TEENAGERS: SOCIAL AND PEDAGOGICAL ASPECTS

Fyodorov, A., Sivokhin, I., Baimyrzayev, K.

*South Ural State University*

Introduction The importance of a problem of research self-keeping behaviour of schoolboys is caused: first, special importance of the teenage period for all subsequent human life; second, presence of negative tendencies in a state of health of modern Russian schoolboys; the third, what teenagers represent potential productive work and populated resources of our country [1]. The purpose of research – revealing of the social and pedagogical factors promoting formation at teenagers self-keeping behaviour and healthy style of a life. Methods Research was carried out within the framework of realization of the international scientific program «Health Behaviour in School-aged Children» in Ural region during the period with 2010 for 2014 years at participation of schoolboys 11, 13 and 15 years (n=2000). During research it was used sociological, pedagogical, psychological methods, and also methods of the logic and mathematical analysis. Results During research it is established, that the level of physical activity of teenagers as a whole can be estimated as insufficient. On a regular basis are engaged in physical exercises during after-hour time of 4-6 times in a week and more than 39,8% of respondents, and 60,2% of respondents are not engaged in physical exercises. 41,7% of respondents are members sports секций, on a regular basis and is organized go in for sports, and 58,3% of respondents are not involved in the organized employment by sports. Teenagers use opportunities of productive leisure on fresh air insufficiently. The level of physical activity of girls is essentially lower in comparison with young men of one age. On a regular basis are engaged in physical exercises outside of school lessons of 48,0% of young men and 30,1% of girls, and in physical exercises with achievement of training effect of 26,9% of young men and only 9,8% of girls. Discussion / Conclusion The analysis of results of research testify to the following. First, health of teenagers has essential specificity of studying which essence consists that a self-estimation of health and its real condition is connected not so much to actual diseases, how many with biological, social and cultural circumstances. Second, it is necessary to recognize officially teenagers as group of risk and accordingly to them to concern. Measures on preservation and strengthening of health of teenagers should take into account social, pedagogical and psychological features of a life and activity of teenagers. Thirdly, the modern system of physical education of children and teenagers not to the full meets to showed requirements and requires innovative transformation. References 1. Zhuravlyova, I.V. ### INVESTIGATION ON THE KNOWLEDGE AND THE NOTION OF JUNIOR HIGH SCHOOL BOYS ABOUT GIRL'S MENSTRUATION

Yuko, F., Fujitsuka, C., Yonetani, S.

*Kawasaki university medical and welfare*

Introduction: It is important for boys and girls to understand each other during puberty. Many girl students were missing the opportunities of appropriate exercise which were needed for their body developments since some studies showed that more than 80% girls had tendencies to be absent from swimming lessons during their menstruation. Some studies showed boys' knowledge and consciousness about menstruation. However there are few studies that clarify what boys think about girl's menstruation and their menstrual life. The purpose of this study was to clarify the knowledge and the notion of junior high school boys about menstruation. Methods: We created original questionnaires survey to 54 boys from a junior high school. The teacher of health and physical education explained about our investigation to the boys. And we asked the boys who agreed with the purpose of our investigation to answer our questionnaire. The questionnaire had the following questions: Q1: Do you know what menstruation is? –Yes, No and not sure. Q2: How long menstruation lasts? Q3: What is your image of menstruation? Q4: What do you think of girls who join in the swimming lessons during their menstruation? Q5: Five true-false questions about menstruation and exercise. Results Q1: was 'Yes' (50.0%), 'No' (13.0%), 'not sure' (35.2%) and 'unanswered' (1.9%). Q2: was 'one day' (50.0%), 'two days' (3.7%), 'three days' (20.4%), 'four days' (3.7%), 'five days' (11.1%), 'six days' (3.7%), 'a week' (25.9%), 'more than a week' (14.8%). Q3: (multiple answers) was 'not sure' (40.7%), 'It's normal condition for women' (38.9%), 'It must be burden' (27.8%), 'It must be complicated' (20.4%), 'It's important' (14.8%), 'It's mysterious' (9.3%) et al. Q4: (Multiple answers) was 'It's up to them' (55.6%), 'No problem. They can swim' (27.8%), 'It's not good for their health. they should observe' (25.9%), 'It's not good for them

because the pool water is not clean enough for them' (13.0%), The menstrual bleeding will contaminate the pool so they should not swim' (5.6%), 'I don't want to swim with them for some reason' (5.6%) and 'others' (1.9%). Q5; the correct answered rates of three questions were clearly different by a school year. Discussion: In this study, we clarified boys' knowledge and notice about menstruation. It was obviously for boys to have not negative notice of menstruation and exercise. However they had little knowledge about menstruation in itself though they had had sexual education at class. Therefore it is necessary for them to provide more correct and useful information not only menstrual mechanism but also menstrual period and continuation days, the symptom with menstruation in their future.

### **AFTER-SCHOOL SPORTS IN NOTTINGHAM . A CASE STUDY.**

Franco Sola, M., Mills, N.

*Universitat Ramon Llull*

This is a case study focused at three schools in Nottingham (UK): Southwark, Hyden (primary schools) and Djanogly City Academy (secondary school). We validated by experts a questionnaire and we conducted 178 with boys and girls, 9-16 years of ages. The questionnaire included questions about the after-school sports practice. SPSS (v.15.0.1) was use calculating frequencies. Results showed that 73% of students practice Sports after school. The most practiced sports are football, basketball, cricket, swimming, tennis and athletics. The main reason for the sports practice (40%) is to practice their Sports with their friends (social motivation). These data had shown similar un previous Studies conducted in the case study in a School from Barcelona (Spain) conducted by Franco-Sola (2011). Students also rate highly (38%) new learning about techniques and tactics sports (quality in the activity). The place where these sports are practiced in the school's facilities (85%). In relation to the families of the students surveyed, 42% of them plays sports compared to 58% who do not. The findings show that children and young people tend to play sports even if their parents do not. Colleges offering, organizing and facilitating spaces for sports. The main motivation of students for sport is social, therefore, want to feel part of the group of friends. As future research, we will collect qualitative data by focus groups.

### **PHYSICAL EDUCATION BASED ON EVIDENCE VERSUS PRACTICES BASED ON EVIDENCE**

Cazzoli, S.

*University of Torino, Italy*

Aim: The Physical Education was defined the science of teaching and coaching in the cross-disciplinary sport science directory (ICSSPE, 2008, 2013; Declaration of Berlin 2013) It was preliminary study and want to analyze and to develop the Education Based on Evidence (EBE) and Practice Based on Evidence (PBE) paradigm. Methods The history research methods was used was by systematic examination and explanation of change PE teaching in the 3rd millennium . The historical evidences are based on the primary sources (originally documents, laws and international declaration, international position statement by archives, library or web based archives in first-hand accounts) and external criticism (to establish the authenticity of the sources); internal criticism (to establish credibility, consistency and accuracy- of sources Results The evidence-based practice or evidence was oriented at effectiveness (EBP). They was developed in the clinical practice from 1992 in according at Cochrane A.L. (epidemiology studies, 1972). The EBE and EBP were developed by the new neurological research , new technologies of investigation and the new sharing knowledge by internet data bank connection. The evidence-based practice (EBP) 'implies making decisions for the promotion of education by integrating the best available evidence with professional experience, features, status, needs, values and preferences of students that are compatible with the environmental and organizational context. The professional decisions was taken by theoretical studies, qualitative studies and quantitative studies selected on the basis of the effectiveness of sources.. (Hjørland, Birger, 2011) The research were empirical, controlled and randomized and analyzed by meta-analysis and review (Chambless, DL. 1998) The most effective practices were become interaction between: 1) instructional design (history of theoretical models and their progressive and systematic comparison); 2) education based on evidence (scientific collecting and documenting of experimental evidence) 3) educational evidence -based practices The Physical education based on evidence was become priority of teaching orientation as declared in the international PE ant Teacher research (Eurydice, 2013) and the perspective for the PE Teacher training (pre-service, in-service and long life learning) (Cazzoli, 2014) Reference Borms J. (2008). Directory of Sport Science – 5th Edition Featuring: a journey through time – The changing Face of ICSSPE. Berlin: ICSSPE, ISSN.: 1729-3227 UNESCO (2013). Declaration of Berlin – The Minister meeting at 5th International Conference of Ministers and Senior Officials Responsible for Physical Education and Sport (MINEPS V). Berlin 28-30 May 2013. Cazzoli S. Quality of physical education as sport science based on evidence, (Chapter, pp 174-182) in Scheuer C., Antala B., Holzweg (Editors) Physical education: quality in management and teaching Logos Verlag Berlin GmbH 2014 (Reviewed), ISBN 978-3-8325-3802-6, ISSN 1866-1653 p. 174-181

### **DEVELOPMENT OF EVALUATION SYSTEM AS A FEEDBACK TOOL FOR PEDAGOGICAL PROGRESS OF PHYSICAL EDUCATION TEACHERS**

Sharma, P.C., Ahmed, S., Ajit, K.

*KMC, University of Delhi*

Using data from an Indian University we developed physical education trainee teacher's evaluations of teaching quality as a feedback tool for improvement of pedagogical techniques among trainee teachers. The objective focus on improvement in teaching practices among trainee teachers instead of being used for mere evaluation technique. The developed feedback tool through evaluation process of physical education trainee teachers comprise of five primary parameters (competencies): knowledge, class management, communication, appearance and effort along with identification of their secondary subsets through content analysis. The content of the tool have been tested, evaluated, revised and validated by scientific process. The correlation coefficient among the testers were calculated for stability reliability and rater reliability along with Cronbach alpha scores for internal consistency reliability, indicating positive results and suggesting that the prepared evaluation system can be highly beneficial in evaluating and improving the overall competency of physical education trainee teachers.

## THE INTERVENTION OF PHYSICAL EDUCATION TEACHERS TOWARDS STUDENTS WITH ADHD IN PRIMARY SCHOOL: A CASES STUDY

Labrador Roca, V., Hernández Vázquez, F.J.

*INEFC Barcelona*

Introduction The Attention deficit hyperactivity disorder (ADHD) is, together with the oppositional defiant disorder, the most frequently diagnosed disorder in school-aged children (August, G.J., Realmuto, G.M., McDonald, A.W., Hugeret, S.M. and Crosby, 1996). In this presentation we will show you the project design of our research and how will it works. The objectives are: to identify the behaviours patterns of students diagnosed with ADHD in Physical Education classes; to analyse the intervention from PE teachers to students with ADHD during Physical Education classes; and to describe the effects on behaviour because teacher intervention. Methods In this research we are using two different but compatible analytical instruments: 1. Direct non-participative observation instrument (field notes) will be used. 40-60 entire Physical Education sessions (1 hour each) will be observed (8-10 sessions / school). 2. Teachers' interview (8 PE teachers). The sample consisted of 8 PE teachers with an ADHD students in their class (diagnosis based on DSM -IV- TR), from primary schools from Barcelona (upper primary school, 9-10 years old). First results (observation) After analysing the literature and collected related information, has thought it necessary to observe a set of sessions to learn what kind of "behaviour" of students with ADHD are given in physical education classes observed. A total of 711 behaviours have been observed in 42 PE sessions, with an average of 16.9 behaviours per session. A part of that, in each behaviour observed, we register the PE teacher's intervention. The interventions were classified based on behaviour modification techniques (Labrador, Cruzado, & Muñoz, 1993). Discussion Personality of those diagnosed with ADHD is conditioned by this disorder. Symptoms of inattention, hyperactivity and impulsivity involve attitudes and behaviors which often turn into conflicts: disturbing classmates, inattentiveness, striking, insulting... The PE class is usually carried out in a particular context, in which each individual is expressed as he/she is: that is why students with ADHD are shown as they are. Currently, we are working with the results of the PhD. And we would like to show the rest of the research early. References August, G.J., Realmuto, G.M., McDonald, A.W., Hugeret, S.M. and Crosby, R. ## THE EXAMINE OF SELF-LIKING AND SELF-COMPETENCE LEVELS OF STUDENTS' WHO DO/DON'T SPORT AND EDUCATED IN POLICE ACADEMY BITLIS VOCATIONAL HIGH SCHOOL

Eynur, A., Kahraman, M.Z., Eynur, B.R.

*DUMLUPINAR UNIVERSITY*

Introduction In order to professional succeed; self-competence is very important. The competence is socio-psychological behaviour emphasizes on beliefs about decides and motivation (ÇEVİK, 2010; Jeffreys, 2010). When we seek at this point, it can be important point for police-officers. At this study, we examined to find emphasize of sport on self-liking and self-competence. Because decide and motivation can be effected by sports (ÇETİNKAYA, 2013). Methods This study is a descriptive study. Descriptive models are past or present existing research approach aiming to describe the situation as it is there. Events of the research, individual or object, as defined in its own conditions and tried to be. Them to change in any way, affect the effort is not displayed. Known to have the desired thing and there. Importantly, it in an appropriate manner 'observing' was to determine (KARASAR, 2005). Sampling was created by university student who who Do/Don't Sport and Educated in Police Academy Bitlis Vocational High School. For study, Two-Dimensional Self-Esteem:Self-Liking/Self-Competence Scale was used. Significantly level was accepted as  $p < 0.05$ . To evaluation, independent sample t-test and one-way anova statistical tests were used. Results At the end of this study, According to tests scores, was found significant levels differential between do/don't sport students self-liking ( $t_{.05}=4,321$ ;  $p < 0,05$ ), self-competence ( $t_{.05}=5,518$ ;  $p < 0,05$ ) and was not found significant level differential between age groups self-liking ( $F=1,407$ ;  $p > 0,05$ ), self-competence ( $F=0,884$ ;  $p > 0,05$ ). Discussion In this study according to tests scores, Sport is very important for self-liking and self-competence on students. Another consequence, age does not lead to differences in self-liking and self-competence level. Even in the age of self-liking and self-competence levels of individuals, can not affect much the sport. References ÇETİNKAYA, E. (2013). ## THE CURRENT STATE OF PHYSICAL EDUCATION IN THE ISOLATED ISLAND AREA

Iida, T., Honda, S., Matsumoto, N.

*Shujitsu University*

Introduction We showed result that is no difference between inland and isolated island area of physical fitness, until the junior high school from the higher grades at elementary school, although the physical fitness level of the children in the lower grades at school of an isolated island area is high. As this reason, we thought that a combined class of an isolated island affects physical fitness level of children. Therefore, the purpose of this study was to show clearly the current state of physical education in the isolated island area. Methods Investigation 1(questionnaire survey) We got cooperation from 9 schools (Elementary schools are 6, Junior high schools are 3.) in isolated island area and 79 schools (Elementary schools are 57, Junior high schools are 22.) in interior of Okayama and Okinawa Prefecture in Japan. We distributed the questionnaires to these schools. The questionnaire contents were 2 points, about the state of the physical education and the students taking the lesson. Investigation 2(interview survey) 7 schools (Elementary schools are 4, Junior high schools are 3.) in isolated island area of Okayama and Okinawa Prefecture in Japan volunteered for this study. We had the interview to the teachers. The interview contents were 3 points, about the state of the physical education, about difference between the physical education of isolated island area and inland, and about the careful idea at the physical education. Results and Discussion As a result of questionnaire survey, it was clarified that the physical education of targeted schools at island is carried out by a combined class, the competitive sense of students at island is low, and a teacher of island feels difficulty about the class contents and school facilities. And, we ob-

tained the following views from interview survey. Because there are few students, their motor skill is easy to improve, but the events and contents of the class are limited. Furthermore, the students in combined class has gap at the physique and the fitness level, so it isn't so easy to teach physical education. In conclusion, the school in island has few sport facilities. And there are combined classes that have different developmental stage. Therefore, the result of this study suggests that the physical education in isolated island area have to consider these factors. ### **STUDY ON THE EVOLUTION OF SOMATIC PARAMETERS IN FEMALE STUDENTS FROM THE UNIVERSITY OF BUCHAREST PARTICIPATING IN THE "SPORT FOR HEALTH AND RECREATION" PROGRAM**

Ganciu, O., Ganciu, M.

*University of Bucharest*

Introduction Hippocrates and Galen claimed over 2000 years ago the existence of a close relationship between our locomotor skills and our physical and mental health. Even so, the conducted research shows that more than 50% of the students are sedentary and have an above-average weight. The purpose of this research is to underline the evolution of important somatic parameters as an effect of practicing systematic motoric activities during free time. Methods A number of 250 Students from the University of Bucharest took part in an ameliorative experiment during which they participated in one main Physical Education course and 3-4 courses for the "Sport for health and recreation" program in their free time every week. The latter program included aerobics, social dance, swimming and jogging. In order to correctly evaluate the efficiency of these activities on the experimental group, a control group that only preferred the activity from the main course was used. The evaluated somatic indicators were the height, the weight and the abdominal, hips and thighs areas. With the help of the obtained values it was possible to determine the Body Mass Index and the Body Adiposity Index, which were then statistically interpreted and represented graphically. Results The female students from both the experimental and control groups were able to improve their somatic indicators, amelioration which can be observed in the results from the final test. The experimental group had a considerable increase in score between the initial and final examination in all the tested indicators ( $p < 0,05$ ), in contrast with the witnessing group where the score increase between the initial and final examination was insignificant ( $p > 0,05$ ). Discussion Through these tests it can be estimated how much the independent variable has influenced the data obtained, thus generating the differences between the two final sport tests. I believe that this program which underwent experimentation through specific exercises aiming to improve the body shape was efficient. Making the students aware of their own morphofunctional state of the body can be one very important way of boosting their motivation of actively participating in the Physical Education courses. Moreover, this self-awareness can also enable them to practice different forms of physical activities independently. Youth mobilization should become a purpose in itself for teachers in order to make the new generations more physically active. References Bota, A. (2006), *Exerciții fizice pentru viața activă*, Ed. ### **ENGAGING AND EMPOWERING PRE-SERVICE TEACHERS IN PETE PROGRAM THROUGH PROBLEM BASED LEARNING AND EXPERIENTIAL LEARNING**

Wen Yi Wang<sup>1</sup>, Chih Min Wu<sup>2</sup>, & You Yi Chen<sup>1</sup>

*1. Graduate Institute of Sport Pedagogy, University of Taipei, Taiwan ; 2. Department of Leisure and Sports Management, Cheng Shiu University*

Introduction The "pre-service teachers" professional development has been unprecedented attention in high education (Senne & Strand, 2009). The aim of this study will be employed Problem-based learning (PBL) and experiential learning theory (ELT) methodology as a means of engaging pre-service teachers on a physical education teacher education (PETE). Methods First, we will focus on their acquisition of skills and content relevant to their professions learning experience of "Knowledge", "Theory-Practice Relationships", "Professional Collaboration", "Critical Thinking" and "Self-Directed Learning". Second, understand their learning experience of teaching reflection behavior in PBL and ELT. All the participants are focus on 12 pre-service teachers in their teaching practical course in elementary school. This study ran over an academic year (18 teaching weeks) and will be designed around two teaching sessions per week: a classroom-based seminar (1.5 hours) involving the use of PBL scenarios and a practical-based session (2.5 hours) on a specific issue in PE. Results All the data will be collected from their discussion sheets, reflection journals, and learning depth interviews. And the manuscript analysis will be used NVivo10 qualitative data analysis software. The study found that the PBL and ELT can effectively develop pre-service teachers professional development in five themes of "Knowledge", "Theory-Practice Relationships", "Professional Collaboration", "Critical Thinking" and "Self-Directed Learning". And most of them can facilitate learn, improve learner develop deeper discussion of learning contents in PCK. Discussion This study also tries to focus on the functions and limitations of PBL and the application of PBL in pre-service teacher education (Hmelo-Silver, 2004; Askell-Williams, Murray-Harvey, & Lawson, 2007). In conclusion, through the exploration of documents and foreign experiences, I recommend the application of PBL in pre-service PE teacher education in the future. ### **PROJECT-BASED LEARNING IN PE. BENEFITS AND PROBLEMS**

Heszteráné Ekler, J.

*University of West Hungary*

Introduction The project – as a more and more widespread study method – provides several advantages. Optimally, it makes students strive for acquiring knowledge as they are activated and motivated by their personal interests (Larmer and Mergendoller, 2010). In our methodological research we aimed at applying project-based learning in PE. Realizing the set educational target relied heavily upon students' ideas, independent activities and creativity. This process represented a new, unusual task not only for the students but maybe even more so for the professors conducting the experiment. Methods During the period between 2010 and 2014, 106 professors with the help of 106 classes each processed a certain subject matter in project system. The duration of the projects were 4-6 weeks with the

following stages: 1. Introductory stage: brainstorming, timelines, action plan, checkpoints; 2. Project stage: realizing project programs; 3. Final stage: project product, checking. The efficiency of the project work was assessed by measuring the advancement (motor and/or skill tests), and by interviewing the project managing professors about the potentials of the project as a way of organizing learning. Results The efficiency of curriculum processing were verified by adequate tests. Regarding the measured, established or observed parameters, the students achieved better results at the end of the project than at the beginning. The professors considered the project work interesting (98%) and useful (77%), and altogether 81 % of them would apply it in the future. According to them, the biggest strengths of the project were its activating effect on the students and its potentials for differentiating. On the school level, its benefit was subject-marketing. Weaknesses included organizational and project-technical matters: how to handle passive stages, how to select the adequate tests, the evaluation, and the problems of the co-thinking professor's role. Discussion The PE. project is definitely a suitable instrument for curriculum processing. The students increasingly engaged in motion games and other kinds of activities in the course of the project. As activities relating to other subjects and areas were introduced during the PE. lessons, unexpectedly, more students became interested. Differentiating became apparent as the tasks were shared and the various activities of the project ensured that many students could enjoy a sense of achievement. The whole process was characterized by the development of student independence, cooperative solutions and outside contacts (with non-school personnel). The students quickly identified themselves with the opportunities provided by the project as opposed to our colleagues who had a hard time. References Larmer J., Mergendoller J. R. (2010) Meaningful Work. V. 68 | Nr 1. 34-37. Contact hekler@mnsk.nyme.hu

## ALTERATION OF SPORT FACULTY STUDENTS' PERFORMANCE LEVELS IN TERMS OF SKILLS IN ATHLETIC THROWING EVENTS

Miklós, K.

*West Hungarian University*

Introduction We study the alteration of the performance levels of college and university students considering the last 25 years. The reason of our survey was the significant negative change in athletic skills and subject requirements. Methods In the period of our survey we processed the performance of the entire substance which meant more thousands of sport faculty students. Considering the throwing events, we took the results measured and registered by the colleagues, who teach the subject, as a basis. We processed the data by applying the SPSS statistical program package. Beside the normal statistic index we made correlation calculation for examining the relation between athletic performance levels and motoric skills. We determined the significance in  $p < 0.05$ . Results Our study proved a significant drop in performance levels as well as in motoric skills. The setback of performance in athletic throwing events is the direct consequence of the drop in motoric skills. Discussion In our opinion students arriving from high school into university have very low bases in technical knowledge as well as in motoric skills. The setback of performance is the direct consequence of the changes in education structure and the reduced lessons of the subject. In 2012 daily sport lessons were introduced in elementary and high schools. It should effect better performance in motoric skills and athletic requirements. University students can compensate the reduced athletic lessons by the syllabus with more practice and individual processing of the subject. References 1. Harris, J. & Cale, L. ## PHYSICAL EDUCATION SCHOOL IN BRAZIL - A CASE IN SANTA CATARINA

Manfro, M.N., Marinho, A.

*State University of Santa Catarina (UDESC)*

**Introduction** Due to the territorial extension, the natural and cultural diversity, among other factors, Physical Education school in Brazil has different nuances and characteristics when compared to other countries. In this context, this study was conducted in a public school located in Costa da Lagoa, in Florianópolis, belonging to the state of Santa Catarina in southern Brazil. In this region children can only reach such a school by trail or by boat, with no roads. In addition, the physical conditions of its school and its surroundings are peculiar: it has no sports field; there is a grass field next door; there is a pond of great extension in front; and is surrounded by a nature reserve. Based on these considerations, the aim of this study, part of a broader research was to investigate how the physical education classes at the School of Costa da Lagoa occur. **Methods** This is a qualitative research, carried out by means of ethnography (Geertz, 1989). Therefore, the researcher lived for three months in the community of Costa da Lagoa, and followed the physical education classes during this period. The instruments used were: field notes, informal conversations and participant observation. The data were analyzed by means of triangulation of data. This study was approved by the Ethics Committee, UDESC, N. 701,067 / 2014. Results Even in circumstances as diverse, there are many possibilities of being worked the contents of Physical Education. Classes were observed with "slack line" between the trees, hiking on search of birds, stand up in the pond, football in a backyard with grass without pre-established demarcations, dance packed by nursery rhymes, among other possibilities. A coherent educational proposal to the context, with their children, time and space was found, which goes through the close relationship with the natural environment and its surroundings, and can bring positive resonances in the triad leisure, sport and sustainability. **Discussion** The possibility of following the routine of physical education in that particular context shows that there are several possibilities of working body culture with different activities and nature-related (Cornell, 1996). In addition, the exchange of teachers working in different contexts in the area of physical education can help strengthen the range of opportunities offered children in class, in the pursuit of building more humane and sensitive educational plan. **References** Cornell, J (1996) Play and learn from nature. ## INFLUENCE OF INSTRUCTION WITH OR WITHOUT NUMERICAL VALUE ON THE GRIP FORCE GRADING.

Hayami, T.1, Hayashi, Y.2, Hirono, J.1, Kizuka, T.3

*1: Shinshu University (Nagano, Japan), 2: Hosei University (Tokyo, Japan), University of Tsukuba (Ibaraki, Japan)*

**Introduction** Several reports have investigated the ability of force grading under the condition that aimed force intensities were instructed with numerical number such as "30%", "50%". In the fields of physical education, however, teachers or coaches often use abstracted intensities without numerical value such as "strongly than half", "less than maximum". The purpose of this study was to clarify the influence of two conditions that instructed with numerical value and without numerical value on the force grading. **Methods** Thirty-nine subjects were participated in the experiment. Experiment was conducted in accordance with the Declaration of Helsinki. Subjects were instructed to exert their grip force under the two conditions, i.e. with numerical value condition (WN) and without numerical value condition (WoN). First of all, maximum voluntary contraction (max) of grip force was evaluated in each subject. In the WN condition, the instructed force were set to nine grades from 10%max to 90%max. In the WoN condition, the instructed force were setting six grades, i.e. slightly less than maximum, less than maximum, stronger than half, slightly stronger than half, slightly less than half, and less than half. Two trials were conducted in each intensity, and all trials were randomized. The Constant Error (CE) was calculated as indices the errors between the target force and the actual force in the WN condition. In the WoN condition, relative values against subject's MVC (%max) were calculated. For the statistical analysis, One-way ANOVA by means of intensity factor was conducted in each condition. Results In the WN condition, the significant difference was not observed in the instructed intensity next to each other from 20%max to 60%max ( $p > 0.05$ ). CE showed overshoot from 10%max to 50%max, and undershoot from 60%max to 90%max. In the WoN condition, the significant difference was not observed between "slightly less than half" and "less than half" ( $p > 0.05$ ). Other intensities showed significant differences against all intensities ( $p < 0.05$ ). **Discussion** The overshoot of CE at lower intensities in WN condition supported previous study. From the results of both conditions, it was suggested that the grip force grading was roughly at the intensities become less than 50%max. We had a hearing to subjects how intensities were they image. Average of their imaged intensities were about 40% at "slight less than half", and about 30% at "less than half". Thus, it was considered that subject could image their force intensities but couldn't achieve generating it. Teacher or coaches should pay attention to that phenomenon when they instructed force or exercise intensities without numerical value. Contact: hayamit@shinshu-u.ac.jp

## SPORT FOR ALL IN ANÁPOLIS: A PROGRAM TO BE FOLLOWED

Oliveira-Silva, I., Vidal, S.E., Venâncio, P.E.M., Tolentino, G.P.

*Unievangelica*

**Introduction** Physical inactivity is a public health problem that hovers over the country (Hobbs et al., 2014), concerning researchers to propose alternatives and public politics that promote physical activity. For this reason, encourage regular physical activity is a strategy to change this situation. Today, the literature emphasized that an individual who is physically active has the ability to do daily activities with vigor and alertness, without fatigue and still has enough energy to pursue leisure-time activities and prepare for emergencies that succeed, while minimizing the risk of acquiring opportunistic diseases (Hanifah et al, 2014). In addition to the physiological matter, the psyche is also very affected and relates personal identity with sports practice, and gender issues. The purpose of this study was to display in the recipients view the effects of a sport program called Sport for All in Anápolis-Go. **Methods** It was a cross-sectional study that included 3115 subjects aged between 11 and 70 years, who were participants in one of the 53 public spaces and/or partner spaces that developed activities of the Sport for All program in Anápolis (PST-Aps). The program coordination assembled an evaluation instrument consisting of three opened questions, and instructed the collaborative team, composed of three officials who regularly visited the program area, to apply this instrument to the program recipients during technical visits in the period of August to October 2014. The recipients were approached by the evaluator and those who agreed to answer the questions did it immediately. The data were registered by approximation of response and the pooled results were analyzed qualitatively. Results The program supplied a gap that existed in the past by creating opportunities of sports activities (soccer, futsal, handball, volleyball, basketball, athletics, judo, karate, capoeira, skate, wheelchair basketball and sitting volleyball) and physical activities (water exercise, gym work, dance, guided walk and road race) in regions where people live, avoiding large displacements which generate costs and avoid the participation. It was evident that young people occupy a good part of the free time from school involved in sports activities, reducing downtime which could be exploited by criminals

forming followers. It was noticed in the expression of many young assessed (27%) that the sport has raised them a personal identity, factor identified in the literature as salutary (GASTALDO et al 2011). Among adults and elderly, the satisfaction was great with the activities. Many of them highlighted the decreased on the use of medications, the improve on physical and psychological well-being, willingness to daily and working activities, and the creation of new social groups. Discussion It was evidenced in the recipient view that the Sport for All program in Anápolis was an action that effectively brought positive effects to the local community in physiological, psychological and social aspects, strengthening the evidence presented in the literature.

### EFFECTS OF AN OUT OF SCHOOL SPORT PROGRAM BASED ON THE PERSONAL AND SOCIAL RESPONSIBILITY MODEL TO ENHANCE POSITIVE YOUTH DEVELOPMENT

Carreres-Ponsoda, F.1, García-Montes, M.E.2, Escarfi, A.3, Cortell-Tormo, J.M.1, Machado-López, C.1, Tortosa-Martínez, J.1

1:UA (Alicante,Spain) 2:UM (Murcia,Spain) 3:UV (Valencia,Spain)

Introduction Hellison's Teaching Personal and Social Responsibility Model (TPSR) (2003) emphasizes the need to teach, through sports and physical activity, values and behavior to increase the competencies that adolescents need to adapt successfully to the different challenges of life. This study examined the influences of participation in a 6 months extracurricular sport program (from January to June 2014) based on Hellison's Teaching Personal and Social Responsibility Model (TPSR) in adolescents' self-efficacy, pro-social behaviour and personal and social responsibility. Method Participants were 34 male adolescents between the ages of 14 and 16 years ( $M = 15,18$ ;  $SD = 0,728$ ) divided in two groups of 17 who played football as extracurricular activity in Alicante (Spain). Measures include Spanish versions of The Multidimensional Scales of Perceived Self-Efficacy (Bandura, 2001), Personal and Social Responsibility Questionnaire (Escarfi, Gutiérrez, Pascual & Llopis, 2010) and Prosocial Behaviour Questionnaire (Caprara & Pastorelli, 1993) were administered individually to each of the participants. Descriptive statistics are presented as means $\pm$ SDs. A one-way analysis of variance (ANOVA) with repeated measures was used to assess differences between the psychological variables. Results Adolescents participating in the intervention group of the TPSR Model showed higher levels in self-efficacy ( $F(2,824) = 0.444$ ,  $p = 0.000$ ), prosocial behaviour ( $F(2,118) = 0.687$ ,  $p = 0.016$ ) and personal and social responsibility ( $F(3,765) = 0.708$ ,  $p = 0.000$ ) than the comparison group. Discussion TPSR is an effective model for improving psychological and social skills in adolescents in out of school settings. Our current findings are consistent with those studies that implemented TPSR Model for improving fundamental areas of psychological and social development (Escarfi et al., 2010). Further research are needed with larger number of adolescents and explore, through longitudinal studies the long-term effects of the TPSR Model. References Bandura A. ### A BOWLER'S NARRATIVE INQUIRY OF FATHER'S SUPPORT

Juang, Y.T., Cheng, H.C., Kuo, L.C.

*Graduate Institute of Sport Pedagogy*

Introduction Support from parents is considered as the most important resource that facilitates the development of elite athletes. The purpose of this study was to explore a bowler's training and competition process in addition to his father's life story of being multiple roles as a father, coach and sponsor more than 10 years. In 1999 after the innovate lane machine was sanctioned by the World Tenpin Bowling Association, the Taipei spinner bowling style was no longer glorious at international tournaments. This big change in bowling environment makes lots of teenagers switch from spinners to hook ball bowlers. The targeted bowler have been playing hook ball over 16 years and was interviewed to express his experience in how his father supported him to be an elite bowler. Methods The approach of narrative inquiry was used in this study. The participant was a bowler (aged 35) who had been a member of national bowling team over 16 years. Semi-structured in-depth interviews were implemented as the main source of data collection supplemented by the collection of relevant document such as photos, game results, trophies, awards of tournaments and dairy, etc. The combination of these data sources led the analysis of the story. Results The study showed the fact that during the process of being an elite bowler, his father played as multiple roles which provided him technical, mental, and financial supports. The story was narrated in three parts of his father's role: a father, a coach, and a bowling lover. Due to long term involvement in bowling sport, his father was viewed either as a spectator or a coach that both offered significant supports to the bowler. Discussion Psychological and financial supports from parents are highly related the development of young athletes' talent. To encourage adolescents to participate in competitive sport, parents' assistance is needed to let younger players get more resources and a better training environment. References Vella, S. (2000), *Journal of Science and Medicine in Sport*, 3(2), 176–185. Eccles, J. S. & Harold, R. D. (1991), *Journal of Applied Sport Psychology*, 3(1), 7–35.

### EFFECTS OF A DANCING PROGRAM ON THE SPATIAL CONCEPT OF KINDERGARTEN CHILDREN

Kuan, W.W., Tzu, W.L., Chien, C.C.

*Graduate Institute of Sport Pedagogy*

Introduction The development of children's spatial concept is created by personal self-orientation combining the impact of outer environment. The purpose of this study was to investigate the effects of a dance program on the spatial concept of kindergarten children. Method Eight children with the average age of 5 years old were recruited from a kindergarten as the participants of this study. The participants accepted a dancing program, featuring the coordination of body and eyes, for 3 weeks, 2 hours a week. A dance teacher graded the spatial movement performance before and after the dance program. At the spatial test, the children were required to recognize the directions and sides (right, left, up, down). Results The result indicated that the spatial movement performance was enhanced after the dancing program. However, two children were only observed a limited improvement in recognizing the directions because they strongly relied on their own reference system. Conclusion In the early stage of cognition development, dancing incorporating spatial components would be helpful for children to enhance their spatial concept. For dance instructors, the combination of body movement, voice guidance, and eye coordination within a dancing program is beneficial for children's development of spatial concept. However, a limited amount of children may not be easy to improve their spatial concept only through dancing. For these cases, it is important to help them develop a

more accurate reference system of directions by using another curriculum. References Poole, C., Miller, S.A., & Church, E.B. (2006). *Early Childhood Today* 20(6), 25-30. ## Physiology

### **A WETSUIT PREVENTS BODY CORE COOLING IN COOL <22°C> WATER, WITHOUT CAUSING EITHER MARKED OR INSIDIOUS HEAT STRAIN IN COLD-TOLERANT SWIMMERS**

Cotter, J.D., Bradford, C.D., Hill, T.J.G., Francois, M.E., Lucas, S.J.E., Gerrard, D.F.

*University Of Otago*

**Introduction** Two threats facing endurance swimmers in open-water competition are hypothermia and autonomic conflict (Tipton & Bradford, 2014); each has several contributing factors that make it problematic to determine a safe minimal water temperature for these events. A minimum temperature of 16 °C is applied by FINA (wetsuits are prohibited), whereas the ITU prohibits wetsuit use only above 20 and 22 °C for elite and age group athletes, respectively, in short events (<=1500 m). Wetsuits provide buoyancy but can also be heat stressful. There are few studies to help inform these guidelines hence the purpose of this study was to test thermal responses in experienced open-water swimmers with and without a wetsuit in water of 22 °C. **Methods** Eight surf swimmers and triathletes (body fat 14 ±5%; range: 6 – 22%) consented to participate in this ethically-approved study. In a randomised crossover design, they completed two 1500-m flume swims (Streamlinz, New Zealand), with and without a 3-mm full wetsuit, on different days, after a 5-min warm up. Water and air temperatures were 22 °C and 21.4 °C, respectively. Core temperature (Tc) was measured in the oesophagus, to approximate right atrial temperature. **Results** Without a wetsuit, Tc fell in two swimmers, by 0.6 and 0.9 °C - reaching 35.3 °C in one - without notable cold discomfort (3 and 2, on scale 1 - 10). Tc rose in both when swimming in a wetsuit. For the group, Tc rose 0.6 ±0.6 °C more when wearing the wetsuit than not (0.8 vs 0.2 °C; P=0.03; ES=0.94); more so in those who were coolest without it (r=0.77). In two swimmers the Tc rose >1.0 °C without a wetsuit, but wearing a wetsuit had negligible additional effect on Tc (<0.3 °C) in these swimmers. In four swimmers the Tc rose >1.0 °C in a wetsuit, but they reported marked heat discomfort (rating 5+). Adiposity accounted for one third of the Tc response when not wearing a wetsuit, and almost none (1%) when wearing a wetsuit. **Discussion** Substantive core cooling can occur in lean swimmers over 1500 m in borderline (22 °C) water temperature when a wetsuit is not worn, though the typical response is a slight rise, as observed previously (Lowden et al., 1992; Trappe et al., 1995). A wetsuit prevented core cooling in this cohort, without causing an excessive rise. Most importantly, swimmers in this study demonstrated strong behavioural thermoregulatory cues against hyperthermia (when wearing wetsuits) that were not evident against hypothermia. **References** Tipton M, Bradford C. ### **A STUDY ON SPINAL CORD MOTOR NEURONS AND NEUROMUSCULAR JUNCTION MORPHOLOGY IN OLD RATS**

Nishizawa, T., Kasuga, N.

*sigakkan junior university, Aichi University of Education*

In the past, skeletal muscles were said to be innervated by motor neurons. However, the current authors found that changes in the morphology of the neuromuscular junction (NMJ) occurred in conjunction with increases and decreases in muscle activity, and these findings suggested that changes in the NMJ are regulated myogenically. **Objective** : Numerous studies have reported that morphological changes in the cell bodies of motor neurons in the spinal cord (MNsoma) and morphological changes in the muscle fibers they innervate are a factor for a loss of muscle strength in old age. The current study sought to ascertain the effect that morphological changes in muscle fibers and MNsoma had on the morphology of the NMJ in old age. In addition, this study examined the factors leading to changes with age. **Methods** : The laboratory animals used were 344 female Fisher rats (body weight: 280–330 g) that were 16 weeks old (the C group) and 2 years old (the 2Y group). MNsoma were labeled by injecting 10% horseradish peroxidase into the extensor digitorum longus (EDL) 12–24 hrs prior to removal of the spinal cord. The spinal cord was frozen and 40-µm serial transverse sections of the anterior horn of the spinal cord were prepared. Afterwards, the sections were stained with 3,3',5,5'-tetramethylbenzidine (TMB) and Nile red (NR). The muscle studied was the EDL. The EDL was frozen and then 50-µm serial transverse sections were prepared. Sections were stained with cholinesterase (ChE) and impregnated with silver and then the NMJ was identified. The MNsoma and NMJ were observed under a light microscope and measured with the software cellSens (Olympus). **Results and Discussion**: Differences in the surface area of MNsoma in the C group and the 2Y group were not noted. A previous study reported finding degeneration of the MNsoma in animals 2 and a half years old, though changes were not noted at 2 years of age. The 2Y group had significantly less skeletal muscle mass in comparison to the C group, and both groups had similar results in terms of the diameter of muscle fibers (fiber diameter or FD). Thus, muscular atrophy was found to have occurred in old age. The surface area of the motor endplate (endplate area or EpA) was significantly smaller, and the value of EpA/FD was smaller. A decrease in EpA greater than muscular atrophy (in percent) was noted. Microscopic images of the NMJ revealed evidence of abnormalities such as the loss of axon branches and axon terminals and the elongation of axon collaterals in atrophied muscle fibers. Results suggested that the loss of muscle strength in old age involves atrophy of muscle fibers, degeneration of the motor endplate, and degeneration of the NMJ. That atrophy and degeneration is then presumably followed by changes in the MNsoma.

### **EFFECT OF DIFFERENT WEIGHT LOSS PERIOD ON THE DEHYDRATION STATE IN WRESTLERS**

Mio, N., Hiroki, T., Hyeon Ki, K., Karina, A., Mi, X., Masayuki, K., Shizuo, S.

*Waseda University*

**Effect of different weight loss period on the dehydration state in wrestlers** Mio Nishimaki<sup>1</sup>, Hiroki Tabata<sup>1</sup>, Hyeon-Ki Kim<sup>1</sup>, Karina Ando<sup>1</sup>, Mi Xiang<sup>1</sup>, Masayuki Konishi<sup>2</sup>, Shizuo Sakamoto<sup>2</sup> <sup>1</sup> Graduate School of Sport Sciences, Waseda University (Tokorozawa, Japan) <sup>2</sup> Faculty of Sport Sciences, Waseda University (Tokorozawa, Japan) **Introduction** Many wrestlers undergo extreme dieting with-rapid weight loss and fluid restriction, so that their weight is below the rule weight, as measured before a match (Artioli et al.,2010). Rapid weight loss with intense training and food / fluid intake restrictions could be extreme stressor to our ability to adapt to stress. This stress is thought to be induced body dysfunction such as exsiccation, hypoglycemia, regulation of body temperature functional decline, and reduced immune

function (Celeste et al., 1998). Rapid weight loss of short-term in wrestler is especially accompanied by dehydration due to sweating. In this case, it has been reported that such changes hematocrit increases (Triplette et al., 2010). About 70% of the wrestler had performed weight loss within 7 days (Aizawa et al., 2007). There is a need to compare the weight loss period. The aim of this study was to investigate the effect of different weight loss periods on the dehydration of wrestlers. Methods Six university student wrestlers (weight: 65.7±7.4kg) were participated in this study, and they have experienced rapid weight loss many times. All subjects completed three trials with different periods of rapid weight loss (seven days, three days, and one day) separated by more than 4 weeks. Each wrestler's body composition, hematocrit as an index of dehydration, visual analog scale responses (subjective fatigue, thirst, and hunger), and maximal oxygen consumption (Takagi et al., 2013) were measured at three time points: before weight- loss, at weigh- in, 12 hours after weigh- in. These measurements were compared across weight loss periods. Results No significant differences were found in hematocrit and visual analog scale maximal oxygen consumption in relation to different weight loss periods. Discussion&Conclusion The present results indicated that dehydration and maximal oxygen consumption were not affected by different weight loss periods. ### TIME COURSE OF HEAT ACCLIMATION, DECAY AND RE-ACCLIMATION IN ELITE LASER SAILORS PREPARING FOR A WORLD CHAMPIONSHIP EVENT IN HOT CONDITIONS: CASE STUDY USING A REAL WORLD MODEL

Casadio, J.R.

*High Performance Sport New Zealand*

Aim: To determine the time course of decay and re-induction of heat acclimation and its effects on aerobic fitness parameters in elite sailors preparing for the World Championships in Muscat, Oman. Methods: Two elite laser class sailors ( $VO_{2max} = 5.05 \pm 0.35$  L/min) completed 5 consecutive days of heat acclimation (HA) ( $T_a = 35^{\circ}C$ , 60% RH). A heat response test (HRT) was performed at baseline and 5 of HA, then on the 7th (Decay 1) and 14th (Decay 2) day following HA. Participants were then re-acclimated (RA) for 2 days, followed by a final HRT ~72 h post-RA. Rectal temperature, skin temperature, heart rate, sweat rate, as well as thermal comfort and sensation were measured during each HRT. Changes in plasma volume and the power-to-heart rate ratio (P:HR) during sub-maximal cycling in the heat were monitored weekly for the duration of the study; the P:HR in thermoneutral conditions (~19°C, 50%RH) was measured during decay and RA. Results: Physiological and performance responses were similar for both sailors. Mean rectal temperature during the HRT was lowered from baseline ( $37.60 \pm 0.26^{\circ}C$ ) to day 5 of HA ( $37.14 \pm 0.29^{\circ}C$ ), and remained lowered through decay and RA (Decay 1 =  $37.26 \pm 0.27^{\circ}C$ ; Decay 2 =  $37.31 \pm 0.27^{\circ}C$ ; RA =  $37.29 \pm 0.26^{\circ}C$ ). Plasma volume showed minimal increases at day 5 HA ( $1.3 \pm 1.8\%$ ), but increased incrementally each week following (Decay 1 =  $3.4 \pm 1.1\%$ ; Decay 2 =  $8.1 \pm 1.3\%$ ; RA =  $15.5 \pm 1.1\%$ ). The P:HR, improved (11.0%) in the heat from day 1 to 5 of HA, then remained at a similarly elevated level at Decay 1 (7.4%) and Decay 2 (11.6%), then increased (19.9%) further after RA, compared with baseline values. Similarly, the P:HR in thermoneutral conditions improved (7.7%) from Decay 1 to RA. Conclusion: HA increased heat tolerance and the decay of these adaptations were minimal. Plasma volume and the P:HR progressively improved throughout the 4 weeks and were likely related to the combined heat and endurance training regime.

### THE EFFECT OF SHORT-TERM STRETCHING EXERCISE ON THE PROPERTY OF MUSCLE-TENDON UNIT

Muraoka, Y., Yasuda, T.

*Meisei University*

Introduction Static stretching is often used in sports and rehabilitation field to improve flexibility. Many studies reported the effect of stretching training on muscle property, however, few studies have examined the acute effect of stretching. The purpose of this study was to investigate the acute effect of short-term stretching exercise on the property of human gastrocnemius muscle-tendon unit. Methods Healthy male subjects carried out static dorsiflexion stretching exercise for successive 3 days. They were standing on the stretch board in 1 min x 5 sets x 3 times/day x 3 days. Between the 1min stretching, they had 1 min intervals with standing on the floor. The ankle angle of stretching exercise was determined as a comfortable joint angle that could be maintained for at least 1 min. Before and after the 3 days of stretching exercise, the maximal passive range of motion, passive plantarflexion torque, maximal voluntary contraction (plantar flexion torque), muscle fascicle length and displacement of myotendinous junction were measured. The subject kept supine position with their right leg extended and right foot secured by the straps to a footplate. Muscle fascicle length was measured by using B-mode ultrasound from medial gastrocnemius muscle at rest and during passive stretching condition. Results and Discussion After 3 days of stretching exercise, the passive range of motion of dorsiflexion increased significantly ( $p < 0.05$ ). The passive plantarflexion torque at the certain ankle joint angle (pre maximal range of motion) and the maximal plantar flexion torque showed decreasing trend after stretching exercise, but they were not significant. The fascicle length in both rest and stretching conditions did not change significantly after stretching exercise. The stretching reduced the passive torque in acute effect (McNair et al, 2001). In this study, 3 days stretching exercise could change the joint range of motion. However, it could not change the passive torque in identical ankle joint angle. In conclusion, the results indicate that the short-term successive stretching exercise increases the joint flexibility without changing the maximal voluntary contraction torque and fascicle length. ### ELEVATED TEMPERATURE ACCELERATES RECOVERY OF MOUSE AND HUMAN SKELETAL MUSCLE FOLLOWING FATIGUE

Faiss, R.1,2, Cheng, A.J.3, Willis, S.J.1, Zinner, C.1, Ivarsson, N.3, Chaillou, T.3, Holmberg, H.C.1, Westerblad, H.3

*1Swedish Winter Sports Research Centre, Mid Sweden University, Östersund, Sweden; 2Swiss Federal Institute of Sports, Magglingen, Switzerland; 3Karolinska Institute, Stockholm*

Introduction This study was designed to determine whether elevated muscle temperature allows muscles to recover their force or power more rapidly following fatigue. Methods Intact single fibers from mouse flexor digitorum brevis muscle were fatigued at 31°C (70-Hz 350-ms tetani once every 10 s until initial force decreased to 30%). During a subsequent 2-hr recovery period, the fibers were perfused in Tyrode solution at either 31°C (physiological temperature) or 36°C and isometric force and cytoplasmic free  $[Ca^{2+}]_i$  ( $[Ca^{2+}]_i$ ) were measured during 30-Hz tetani evoked periodically. In addition, seven human subjects performed fatiguing arm exercise consisting of 3 x 5min maximal effort arm cycling at 100 rpm followed by 4 x 15 min at an intensity of 50% of  $VO_{2peak}$ . Then followed 2 hr of recovery during which both arms were either heated or not heated at 5°C above physiological temperatures using arm cuffs continuously perfused with

temperature-regulated water; the order of heating vs. not heating was randomized between two visits. Intramuscular temperature was recorded with probes inserted 1.5 cm into the lateral head of the triceps brachii muscle. During the recovery period, subjects consumed 1.0 g/hr/kg body weight carbohydrates to support glycogen repletion. After recovery, the subjects repeated the 3 x 5 min time trials to evaluate the effect of the recovery intervention. Results Recovery from fatigue in mouse single fibers was dependent on muscle glycogen restoration since fibers perfused with glucose-free Tyrode did not recover contractile force ( $P < 0.05$ ). After 30 min of recovery, the tetanic  $[Ca^{2+}]_i$  was  $107 \pm 10\%$  and  $92 \pm 8\%$  and the corresponding forces were  $69 \pm 15\%$  vs.  $49 \pm 14\%$  of the initial values for the heated and non-heated muscles, respectively. In seven human subjects, 2 hr of muscle heating also appeared to improve muscle recovery, leading to higher mean power output in the post-recovery arm cycling time trial than without muscle heating. Discussion Elevating muscle temperature by  $5^\circ C$  above physiological temperature accelerates recovery in mouse muscle in-vitro and in human skeletal muscle in-vivo and this appears to depend on faster muscle glycogen resynthesis following fatigue.

### ENDOTHELIAL FUNCTION IN HIGH SCHOOL FEMALE RHYTHMIC GYMNASTS: IMPACT OF PSYCHOSOMATIC STRESS AND MENSTRUAL STATUS

Hayashi, K., Nakamura, F., Watanabe, R., Takamatsu, A., Omori, T.

*Kokugakuin University*

Introduction: Endothelial function is associated with progression of atherosclerosis and endothelial dysfunction predicts development of coronary heart diseases. Increased psychosomatic stress and estrogen deficiency associated with menstrual disorder impair the endothelial function. The endothelial function is suppressed in young female endurance athletes with menstrual disorder 1). However, no studies have examined the endothelial function in high school female rhythmic gymnasts, high risk group for the menstrual disorder. Purpose: The aim of present study was to determine the effects of psychosomatic stress and menstrual status on endothelial function in female high-school rhythmic gymnasts. Methods: Twenty-five high school female rhythmic gymnasts (age;  $16.4 \pm 0.9$  yrs, mean  $\pm$  SD) participated in a cross-sectional study. They were separated into two groups based on their competitive ability: Athlete (ATH) group ( $n=13$ ); rhythmic gymnasts who participate in national tournament for high school students in Japan, Recreation (REC) group ( $n=12$ ); rhythmic gymnasts who enjoy rhythmic gymnastics recreationally. Endothelial function was determined as flow-mediated vasodilation (FMD) measured by high frequency ultrasound in the brachial artery. Profile of Mood States (POMS) and saliva cortisol levels were used to measure psychological and physiological stresses, respectively. A formal interviews regarding menstrual status was conducted, and menstrual disorder was defined as the status including oligomenorrhea, secondary amenorrhea and delayed puberty. Results: The normalized %FMD (relative peak diameter increase normalized to the area under the curve of shear rate with hyperemia) was significantly lower in the ATH group ( $0.112 \pm 0.057$  A.U.) than in the REC group ( $0.189 \pm 0.098$  A.U.). Scores of "Anger-Hostility (A-H)" and "Fatigue (F)" of POMS were significantly higher in the ATH group (A-H;  $48.4 \pm 7.9$ , F;  $48.5 \pm 9.0$  points) than in the REC group (A-H;  $41.4 \pm 3.5$ , F;  $42.1 \pm 5.9$  points), and the scores of A-H was negatively correlated to normalized %FMD ( $N=25$ ,  $r=-0.416$ ,  $p < 0.05$ ). Saliva cortisol levels tended to be higher in the ATH group than in the REC group ( $p=0.050$ ). Menstrual disorders were seen with a higher frequency in the ATH group (84.6%) than in the REC group (25.0%). However, there were no difference in normalized %FMD, scores of POMS and saliva cortisol levels between subjects with normal or disordered menstrual status. Conclusion: These results revealed that the higher psychosomatic stress but not presence of menstrual disorder may be involved in impaired endothelial function in high school female rhythmic gymnasts. ### CELL-FREE DNA DURING INTERMITTENT VS. CONTINUOUS STEP-WISE PROGRESSIVE RUNNING INTERVALS

Sterzing, B., Breitbart, S., Magallanes, C., Simon, P.

*Johannes Gutenberg-University Mainz*

Introduction: Different types of running exercises have been shown to increase the concentrations of circulating cell-free DNA (cfDNA) (1,2). Little is known about the influence of type and intensity of exercise on cfDNA levels. Here we examined the influence of intermittent versus continuous step-wise progressive treadmill running on cfDNA concentrations. Methods: Thirteen male handball players and 13 hobby-triathletes performed two different step-wise progressive treadmill running tests applying spirometry and lactate measurements. First, we employed a classical protocol starting at 6 km/h increasing 2 km/h every 3 min determining an individual anaerobic threshold (IAT) (1) and an intermittent protocol consisting out of intervals with a slow 15 sec. component remaining constant at 6 km/h, and a fast 15 sec. component starting at 8 km/h and increased by 2 km/h every 3 min. Capillary and venous samples were collected before and directly after exercise. cfDNA was measured by direct quantification from unpurified plasma using a real-time qPCR assay. Results: Type of sports was neither associated with significant differences in  $VO_{2max}$  or IAT and did not have an influence on any of the following reported associations. Average speed at exhaustion was 16.0 km/h for continuous tests and 13.6 km/h for intermittent tests with a respective approximated fast interval component of 21.2 km/h. Lactate at exhaustion and  $VO_{2peak}$  were not different in intermittent versus continuous exercise testing, while venous cfDNA concentrations were significantly 1.48-fold higher (CI: 1.14-1.93,  $p < 0.01$ ) and capillary values 1.58-fold higher (CI: 1.19-2.09,  $p < 0.01$ ) following the intermittent protocol. Total energy expenditure was 1.22-fold higher (CI: 1.13-1.31,  $p < 0.001$ ) for intermittent testing. Discussion: The intermittent protocol was associated with significantly higher cfDNA increases, while  $VO_{2peak}$  and lactate did not differ between exercise protocols. Potential reasons for the higher cfDNA levels could be the higher duration and higher energy expenditure during the intermittent protocol. Energy expenditure has recently been shown to be a factor associated with cfDNA increases (1). The precise factors associated with cfDNA increases remain to be elucidated in order to evaluate its full potential as an exercise marker. ### THE ACUTE AND PROLONGED CHANGES IN VASCULAR FUNCTION IN RESPONSE TO ENDURANCE AND RESISTANCE EXERCISE TRAINING

Dawson, E.A., Cable, N.T., Green, D.J., Thijssen, D.H.J.

*Liverpool John Moores University*

Introduction: The impact of exercise training on vascular function has been well studied. However, little is known about how acute exercise-induced changes in vascular function relate to exercise training, and whether this depends on the type of exercise. Therefore the aims of this study were to 1) examine the acute (single bout) and chronic (4 weeks) changes in vascular function to endurance (ET) versus

resistance training (RT), and 2) examine the relationship between acute changes in vascular function in response to a single bout of exercise and chronic changes following 4-weeks of exercise training. **Methods:** Using a randomised cross-over design, seven male subjects (age:  $21 \pm 3$  yr, weight:  $73 \pm 9$  kg, height  $177 \pm 4$  cm) were assigned to 4-week ET and RT (randomly ordered) exercise training program (3 sessions per week), with a washout of 6 weeks. Vascular function was assessed using flow-mediated dilation (FMD), both before and immediately after the first exercise bout and after 4-weeks training. **Results:** Following an acute bout of exercise, we found a significant increase in FMD (main effect 'time':  $P=0.041$ ), which was not significantly different between both types of exercise (interaction-effect:  $P=0.11$ ). Brachial artery FMD following an acute bout of resistance exercise increased from  $7.4 \pm 2.2\%$  to  $10.6 \pm 3.6\%$ , whilst endurance exercise caused an immediate increase in  $6.7 \pm 1.8\%$  to  $7.1 \pm 2.0\%$ . We found no significant changes in FMD following the 4-week exercise training in either group (main effect 'time':  $P=0.12$ ,  $7.4 \pm 2.2\%$  to  $8.36$  for resistance training and  $6.7 \pm 1.8\%$  to  $8.7 \pm 3.1$  for endurance training). There was no significant correlation between acute changes in FMD after a single bout of exercise and exercise training-induced changes in FMD ( $r=0.09$ ,  $P=0.75$ ). **Conclusion:** Our data suggest an acute improvement in vascular function following an acute bout of 30-minute exercise, independent on the type of exercise. Despite these immediate changes in vascular function, we found that 4-weeks endurance or resistance exercise training did not alter vascular function. Moreover, the acute changes in vascular function did not relate to the change in vascular function after 4 weeks. These data suggest that adaptation to 4 week exercise training, both after endurance and resistance exercise, cannot be simply explained through examining acute changes in vascular function to a single bout of exercise.

## THERMOREGULATION IN ENDURANCE TRAINED ADULTS

Galán, J., Suárez, A., Guerra-Balic, M.

*Faculty of Psychology, Science Education and Sport of Blanquerna*

**THERMOREGULATION IN ENDURANCE TRAINED ADULTS** Galán-Carracedo, J. 1,2, Suárez, A.2, Guerra-Balic, M. 1 1: FPCEE-Blanquerna, Ramon Llull University, Barcelona (Spain) 2: Corporació Mèdica Catalana, Cornellà (Spain) **Introduction** Thermoregulation is the ability of an organism to keep its body temperature (BT) within certain values, even when the environmental temperature is very different. The BT is related to metabolic activity and external environment conditions. The internal thermoregulation process is one aspect of homeostasis, which involves seeking homeothermic control. Many studies show how muscle activity increases our temperature due to metabolic heat production, and the importance of preventing hyperthermia. Any tendency to hypothermia ( $BT < 35^\circ C$ ) can also cause cardiovascular disorders and exhaustion, becoming one of the main metabolic factors leading to fatigue in trained subjects. The aim of this study was to determine the evolution and the effect of BT in trained adults of endurance sports during a progressive increasing treadmill running test. Our intention was to observe if there is a characteristic pattern of temperature behavior among individuals with better functional capacity. **Methods** Ten trained adults of endurance sports (age=  $38,55$ ,  $SD= 7,08$  years), previously familiarized with the experimental procedures, performed a progressive increasing treadmill test with a constant environment temperature of  $24^\circ C$ . During the test, BT was obtained with axillar digital thermometer High-Speed (Microlife), while fatigue level was also obtained through Borg's RPE scale. A 6 minute warm up period at  $6-8$  km/h was performed. The test began at  $8$  km/h with increments of  $1$  km every 2 minutes, until exhaustion, and  $10'$  of recovery. The treadmill slope was constant at  $1,5\%$ . BT of each participant was obtained at basal time, at the end of the warm up, at the end of the testing and during the  $5'$  and  $10'$  of the recovery period. Descriptive for all variables were calculated, and non-parametric Wilcoxon matched pairs test was applied to compare the differences of the BT between phases. **Results** Mean temperatures at basal phase, end of warming up, end of testing and recovery  $5'$  and recovery  $10'$  were  $35,9^\circ C$ ,  $35,8^\circ C$ ,  $35,5^\circ C$ ,  $36^\circ C$  and  $36,1^\circ C$ , respectively. The mean BT present significant differences decreased at the end of the warm up and at the end of the test comparing basal data ( $p < 0.01$ ;  $p < 0.02$  and  $p < 0.005$ ), just when exhaustion appeared. **Discussion** Results showed a decrease of BT when exhaustion appeared in trained adults of endurance sports, associated to fatigue. Endurance high intensity training could improve the metabolic response and thermoregulation of individuals. More research is needed.

## THE EFFECT OF INSULIN ON HEART RATE VARIABILITY AT REST AND DURING SUBMAXIMAL EXERCISE

Volianitis, S., Ahlers, F.H., Schunck, L.N., Hansen, T.S., Hansen, R.

*Aalborg University*

**Introduction** The purpose of the study was to investigate the effect of insulin on heart rate variability (HRV) at rest and during submaximal exercise **Methods** Ten healthy male subjects ( $23 \pm 1$  yr) performed in different days 20 min of cycling at  $35\%$  HRR, with and without ingestion of  $200$  g of glucose (maltodextrin). Capillary blood glucose concentration was measured by fingerstick at rest, 20 min following glucose ingestion and every 5 min during exercise. Plasma insulin was calculated from the blood glucose measurements using the Glucosafe model (Pielmeier et al. 2012). Heart rate (HR) was measured noninvasively (Finometer) during all trials and RR intervals were processed by fast Fourier transform (FFT) for determination of low-frequency (LF,  $0.045-0.15$  Hz) and high-frequency (HF,  $0.15-1.0$  Hz) components. **Results** Plasma insulin was higher at 0 min ( $P < 0.001$ ) and 5 min ( $P < 0.001$ ) during exercise with glucose supplementation compared to baseline. Furthermore, there was higher plasma insulin between the first three measurements; 0 min, 5 min and 10 min ( $P < 0.05$ ) during exercise with- compared to exercise without glucose supplementation. The LF and HF components expressed as absolute power ( $ms^2$ ) decreased significantly at the onset of exercise ( $P < 0.05$ ) but there was no difference between the two conditions at any time interval during exercise. The LF/HF ratio was not different with and without glucose supplementation, or during exercise and rest. **Discussion** There was no effect of plasma insulin on HRV at rest and during submaximal exercise. **References** Pielmeier et al. (2012). *J Clin Monit Comput* 26:319-28 Contact Svolian@hst.aau.dk

## PERIPHERAL AND CENTRAL EFFECTS OF SMOKELESS TOBACCO ON EXERCISE ENDURANCE IN MEN

Zandonai, T.1, Bruseghini, P.2, Tam, E.2, Capelli, C.2, Chiamulera, C.1

*1. Neuropsychopharmacology Lab., Dept. Public Health and Community Medicine, University of Verona, Italy 2. Dept. of Neurological and Movement Sciences, University of Verona, Italy*

**Introduction** A proliferation of nicotine use in the sport environment has been observed in recent years mainly as smokeless tobacco (Zandonai et al., 2013). Nicotine has been listed in World Anti-doping Agency's Monitoring Program from 2012 to 2015 in order to detect potential patterns of abuse. The aim of this study was to investigate the effects of Snus (SS), an oral smokeless tobacco, on the perception of fatigue during aerobic exercise to TTE. **Methods** The study was a double-blind placebo controlled (SP) crossover design. Fourteen healthy male non-smokers were recruited. Subjects were studied during three sessions on cycle-ergometer: experimental session 1 (Exp1) consisted in an incremental exercise test to determine maximal aerobic power (Wmax); Exp2 and Exp3 consisted in exercise at  $65\%$

Wmax until exhaustion in SS or SP conditions. During the Exp2 and Exp3, muscle and cerebral oxygenation by means of NIRS (near-infrared spectroscopy) and global rating of perceived exertion (RPE) were recorded. Before and after all experiments, the Profile of Mood of State questionnaire (POMS) was administered to subjects. Subjects were then tested by means of Transcranial Magnetic Stimulation (TMS) to assess changes in cortico-motor excitability due to the prolonged exercise. Results Time to exhaustion (TTE) was not significant difference ( $64.4 \pm 41.5$  min SS;  $51.6 \pm 17.2$  min SP) (19.2%) in paired Student's t-test. RPE in the first 30 minutes during both of the sessions showed a significant difference after 10 minutes from start exercise. POMS questionnaire values did not show any significant differences under both conditions (SS, SP). We found significant differences in the cerebral and muscular tissues oxygenation levels in the first 30 minutes of the exercise during SS and SP tests. In particular, at cerebral level, tissue oxygenation index was significantly larger in SS than in SP from the 10th to 30th min of exercise. Conclusion The study showed that the SS effect, compared to placebo condition, could not be an improvement of fatigue during an endurance exercise until exhaustion despite of an increase in tissue muscular and cerebral oxygenation. These data supported the hypothesis of a major activity induced by nicotine as a central stimulator (Mundel and Jones, 2006). References Mundel T, Jones DA. (2006). ### CHANGES IN SKIN-GAS ACETONE CONCENTRATIONS FOLLOWING A LOW INTENSITY CONSTANT-LOAD EXERCISE

Itoh, H.1, Matsuura, K.1, Yoshii, Y.1, Komura, T.1, Nagase, S.1, Takekawa, S.1, Ohkuwa, T.1, Tsuda, T.1

1: Nagoya Institute of Technology (Nagoya, Japan)

Introduction Ketone bodies (3-hydroxybutyrate, acetoacetate and acetone) are generated in the liver, mainly from the oxidation of fatty acids, and are exported to peripheral tissues, such as the brain, heart, kidney and skeletal muscle for use as energy fuels (Mitchell et al. 1995). Acetone is mainly generated from decarboxylation of acetoacetate. Therefore, during exercise increased acetone levels related to exercise intensity have previously reported in plasma (Balasse et al. 1989), expired air, and skin-gas (Yamai et al. 2009). On the other hand, Romijn et al. (1993) have reported that peripheral lipolysis was stimulated maximally at 25 % VO<sub>2</sub>max during constant-load exercise. The purpose of the present study was to confirm changes in skin-gas acetone concentrations following a low intensity constant-load exercise. Methods Nine healthy male students performed constant-load (20% HRmax) cycle exercise for 30 min. The skin-gas samples were obtained by the covering left hand for 30 sec with a polyfluorovinyl bag (Tedlar bag; GLScience, Tokyo, Japan) in which pure nitrogen gas was introduced, and collected in a sampling bag at rest, 3, 6, 9, 12, 15, 20, 30 min after, and 5, 10, 20 min recovery of the exercise. Acetone concentration was analyzed by gas chromatography Results The skin-gas acetone concentration significantly increased 9-30 min after the exercise compared to the resting values ( $p < 0.05$ ), then immediately returned to resting values 5 min recovery of the exercise. Thus the peak skin-gas acetone concentration in the subjects was significantly ( $p < 0.05$ ) higher than the resting values ( $0.07 \pm 0.02$  vs  $0.17 \pm 0.07$  ppm; mean  $\pm$  SD). Discussion Increasing skin-gas acetone concentrations after the exercise in this study indicated that low intensity constant-load cycle exercise induced the production of ketone bodies in the liver, mainly from the oxidation of fatty acids (Mitchell et al. 1995), and some of increased ketone bodies eliminated as skin-gas acetone (Yamai et al. 2009). Furthermore, the levels of skin-gas acetone concentration seemed steady state 9-30 min after the exercise. These results indicated following possibilities. First, the production of ketone bodies in the liver might be reached maximal (Romijn et al. 1993) during this constant-load study. Second, the production of ketone bodies in the liver and consumption of ketone bodies in peripheral tissues such as skeletal muscles 9-30 min after the exercise might be same. ### THE DEVELOPMENT OF FATIGUE MODEL IN A TISSUE-ENGINEERED MUSCLE

Nakamura, T.1, Takagi, S.1, Akimoto, T.2, Kamon, T.1, Fujisato, T.1

1: Osaka Institute of Technology (Osaka, Japan), 2: University of Tokyo (Tokyo, Japan)

Introduction Muscle fatigue is one of the typical physiological phenomena in physical exercise. Muscle fatigue can be classified as central fatigue or peripheral fatigue. Although peripheral fatigue is thought to be important contributor to muscle fatigue, the research have been limited because there are few useful model. Three-dimensional tissue-engineered muscle (3D TEM) is a powerful tool in studying muscle biology and physiology. However, it is not clear if 3D TEM can be a useful model in studying peripheral fatigue. Therefore, the aim of this study was to develop and evaluate fatigue model in 3D TEM. Methods 3D TEM having two artificial tendons were constructed from C2C12 myoblasts embedded in type-I collagen gel. 3D TEM in 3 weeks culture was used for fatigue experiment. The contraction of 3D TEM was induced by electrical stimulation. Isometric twitch force of 3D TEM was induced and measured in every 10 min by electrical stimulation. The isometric twitch contractility was evaluated after electrical stimulation. The LDH cytotoxicity assay was done to investigate muscle cell damage by electrical stimulation. Twitch force was re-measured at 24h after fatigue-induction to assess force recovery. Results The twitch tension of 3D TEM rapidly declined to nearly 10% to maximal twitch tension by 60 min with electrical stimulation. Relaxation time of 3D TEM did not significantly alter by the tension decline. There was no significant differences in LDH release between 3D TEMs stimulated and non-stimulated by electrical pulse. Twitch tension of 3D TEM could not recover from tension decline for 24h. Discussion One definition of fatigue is any decline in muscle performance associated with muscle activity (Allen et al., 2008). In this study, twitch tension in 3D TEM rapidly declined for 60 min with electrical stimulation. The decline of muscle strength with fatigue in vivo gradually recover to normal level. however, the tension decline did not recover for 24h in 3D TEM. According to the LDH cytotoxicity assay, the decline did not accompany cell damage. In case of muscle fatigue in vivo, the muscle relaxation time becomes longer but no significant alternation was observed after tension decline in 3D TEM. Taken together, 3D TEM can be highly applicable to the study of defining physiological mechanisms in peripheral muscle fatigue but the mechanisms may reflect a part of complicated pathways in peripheral muscle fatigue in vivo. ## INFLUENCE OF VO<sub>2</sub> FLUCTUATIONS ON AMPK, p38-MAPK AND CAMKII SIGNALLING IN HUMAN SKELETAL MUSCLE

Combes, A.1, Dekerle, J.2, Webborn, N.2, Watt, P.2, Bougault, V.1, Daussin, F.N.1

1: UL (Lille, France), 2: UB (Brighton, United Kingdom)

**INFLUENCE OF VO<sub>2</sub> FLUCTUATIONS ON AMPK, p38-MAPK AND CaMKII SIGNALLING IN HUMAN SKELETAL MUSCLE** Introduction Skeletal muscle contraction increases intracellular ATP turnover, calcium flux and mechanical stress initiating signal transduction pathways that modulate transcriptional programs. The purpose of this study was to determine if the metabolic disturbances per se regulate signalling cascades known to regulate peroxisome proliferator-activated receptor  $\gamma$  coactivator-1 $\alpha$  (PGC-1 $\alpha$ ). Methods Nine males performed a continuous (30min) and an intermittent (30 times: 1min of exercise-1min of rest) exercises at 70% of VO<sub>2</sub>peak on two separate occasions. Skeletal muscle biopsies from the vastus lateralis were taken at rest and at +0h and +3h after exercise. Results VO<sub>2</sub> response analysis reveals a 3.3-fold higher metabolic fluctuations after intermittent exercise despite an identical energy expenditure (317  $\pm$  41 vs. 312  $\pm$  56 kJ after intermittent and continuous exercise, respectively). AMP-activated protein kinase (AMPK) (~2.9-fold,  $P < 0.01$ ), calcium/calmodulin-dependent protein kinase II (CaMKII) (~2.7,  $P < 0.01$ ) and p38 mitogen-activated protein kinase (MAPK) (~4.2,  $P < 0.01$ ) phosphorylation increased immediately after intermittent exercise to a greater extent compared to continuous exercise (condition-by-time interaction,  $P < 0.05$ ). Discussion The metabolic disturbances induced by intermittent exercise regulate the activation of multiple signaling pathways in response to a single bout of exercise. Further work is required to determine if the marked difference in signaling pathways activation during the present protocol would be manifest as divergent increases in mitochondrial content after a period of exercise training with the respective modalities. ## THE RELATIONSHIP BETWEEN SELECTED ANTHROPOMETRIC MEASURES AND COMPETITIVE RANK IN PROFESSIONAL FEMALE SURFERS.

Barlow, M., Willmott, B.

Leeds Beckett University

Surfing is an intermittent exercise which in recent years has experienced a rapid increase in participation rates and growing professionalism amongst competitive athletes. Previous studies have investigated the relationship between anthropometric profiles and competitive ranking in various sports and within surfing in males. However no study has investigated these relationships in female surfers and no normative data exists for the anthropometric profile of professional female surfers competing under the current judging criteria. The aim of this study was to investigate the relationship between anthropometric measures and competitive ranking in female professional surfers. Following institutional ethical approval and the completion of informed consent professional female surfers (N = 27, age = mean 23.09, s = 4.58 years) participated in anthropometric measures of stature, body mass, skinfolds (Triceps, subscapular, biceps, iliac crest, supraspinal, abdominal, front thigh and medial calf), girths (arm flexed and tensed, waist, gluteal and calf) and breadths (humerus and femur). All measures were taken in accordance with the guidelines of the International Society for the Advancement of Kinanthropometry (ISAK). These were used to calculate body mass index, waist to hip ratio and body fat percentage. A Spearman's correlation analysis was performed using IBM SPSS Statistics 21 between the measured anthropometric variables and the numerical national ranking of the subjects. Significant ( $P < 0.05$ ) correlations with ranking were found for Sum of eight Skinfolds  $r = 0.42$  ( $R^2 = 0.26$ ) and Biceps skinfold  $r = 0.46$  ( $R^2 = 0.19$ ). Thus the coefficient's of determination for these suggest that 26% to 19% of the variance in ranking is explained by these measures within the sample used. No other significant correlations were found. These data provide some normative body composition data for this population of athletes and also suggest that higher levels of adiposity as measured through the sum of eight skinfolds and the biceps skinfold are associated with poorer rankings.

## ROLE OF ZINC IN THE EFFECT OF EXERCISE ON INTERMITTENT HYPOXIA-INDUCED LEFT VENTRICULAR DYSFUNCTION

Chen, Y.C.1,2, Yang, K.T.1, Yang, C.F.1,2, Tu, W.C.1, Yu, T.Y.1, Chen, T.I.1

1 Tzu Chi University, Hualien, Taiwan, 2 Buddhist Tzu Chi General Hospital, Hualien, Taiwan

**Background:** Obstructive sleep apnea (OSA) is the recurrent obstruction of the upper airway leading to intermittent hypoxia (IH) during sleep. Although exercise can provide beneficial effects against myocardial injury induced by IH, its mechanism remains unclear. **Purpose:** To investigate the role of zinc in the effect of exercise on the left ventricular dysfunction in patients with OSA using an animal model mimicking IH of OSA. **Methods:** Nine-week-old male Sprague-Dawley rats were randomly assigned to four groups: control (CON, N = 15), intermittent hypoxia (IH, N = 15), exercise (EXE, N = 15) and IH combined with EXE (IH/EXE, N = 15). Each group was randomly assigned to receive intraperitoneal injections of the vehicle (n = 5), 10-mg/kg zinc chloride (ZnCl<sub>2</sub>, n = 5) or 5-mg/kg N,N,N',N'-tetrakis(2-pyridylmethyl)ethylenediamine (TPEN, n = 5). All injections were administered 30 min before IH exposure for 14 days. IH rats were raised without any intervention for first 8 weeks. At week 9 and 10, IH rats were exposed to 14 days of IH (2%-6% O<sub>2</sub>, 2-5 sec/75 sec) for 8 h/day. EXE rats were subjected to an animal treadmill for 10 weeks (5 day/week, 60 min/day, 24-30 m/min, 2%-10% grade) without IH exposure. IH/EXE rats were subjected to exercise training combined with IH exposure at week 9 and 10. At the end of 10 weeks, echocardiographic data were collected before rats were sacrificed. Then, their hearts were removed to determine the myocardial levels of inflammatory factors (tumour necrosis factor- $\alpha$ , interleukin-6 proteins and monocyte chemoattractant protein-1 and vascular cell adhesion molecule-1 mRNA), oxidative stress (2-thiobarbituric acid reactive substances and protein carbonyl), antioxidant capacity (catalase, superoxide dismutase, glutathione peroxidase and reduced glutathione activity), metallothionein and zinc. **Results:** Compared with those in CON rats, IH rats had a lower LV fractional shortening (LVFS %) and ejection fraction (LVEF %;  $p < 0.05$ ), which were reversed by ZnCl<sub>2</sub>. Furthermore, IH induced higher myocardial levels of inflammatory factors, oxidative stress and lower levels of antioxidant capacity ( $p < 0.05$ ), which were also reversed by ZnCl<sub>2</sub>. These changes were not observed in EXE and IH/EXE rats ( $p > 0.05$ ). Compared with the IH rats, IH/EXE rats had higher levels of cardiac function and antioxidant capacity as well as lower levels of inflammatory factors and oxidative stress ( $p < 0.05$ ); however, these results were reversed by TPEN intervention ( $p < 0.05$ ). **Conclusion:** Zinc exerts dual antioxidant and anti-inflammatory effects that play a critical role in exercise-induced cardioprotection against IH-induced left ventricular function impairment.

## CHANGES OF CARDIOVASCULAR STRESS DURING EACH 5 MIN AND 15 MIN OF COMPETITIVE FOOTBALL MATCH PLAY IN JUNIOR FOOTBALL PLAYERS

Gupta, S.

*University of West Indies, FMS*

**Introduction** Football is a noncontinuous team game where workload on players vary continuously - from standstill condition to short bursts of sprint or explosive jumps or kicks. Continuous recording of heart rate (HR) can be used to assess cardiovascular stress on football players during real match play. **Objectives** Major objectives of the present study were to determine whether the cardiovascular stress on footballers varies significantly for each 5 min and 15 min of play. **Methods** Five junior footballers (16.1±1.3 years), participating in Indian Junior National Football Championship, volunteered in this study. Two players were selected from one team and three from another. Of the 5 players volunteered, two each were midfielders and defenders and the rest was a forward. HR of the footballers were recorded in two league matches (preliminary round) of the tournament. VO<sub>2</sub>max and maximum HR (HR<sub>max</sub>) of the players were measured by graded exercise protocol on treadmill. HR was measured continuously at an interval of 5 s by heart rate telemeter (Sport Tester, PE3000). **Results** VO<sub>2</sub>max and HR<sub>max</sub> of the volunteers were recorded as 52.3±4.1 ml/kg/min and 200.4±2.3 beats/min respectively. Mean HR (HR<sub>mean</sub>) for each 5 min of play frequently differ significantly during the game in all the five players. HR<sub>mean</sub> for each 15 min of play, on the other hand, did not vary significantly in four of the volunteers, although it varied significantly only in one of the players. Analysis of the HRAT shows that players played about 48.5% of the time in the anaerobic zone and 51.5% of the total time in aerobic zone. **Discussion** The study concludes that: (1) although ball possession and attack index can vary tremendously (as supported by other studies) but cardiovascular stress of junior footballers for each 15 min of football match play differs only occasionally, (2) significant variation of cardiovascular stress for each 5 min of football match play occurs frequently, and (3) aerobic and anaerobic systems contribute almost equally in providing energy in junior footballers during competitive match play. **References** Reilly T, Thomas V (1976). *J. ## THE EFFECTS OF VARIOUS CONCENTRATIONS OF CARBOHYDRATE MOUTH RINSE ON CYCLING TIME TRIAL PERFORMANCE IN A FED STATE.

Devenney, S., Shortall, M., Collins, D.K.

*Institute of Technology Tallaght*

**Introduction:** Mouth rinsing with a 6% carbohydrate solution has been reported to enhance cycling and running time trial performances in endurance based events when in a fasted state (Carter et al 2004). The objective of the current study was to identify the effects mouth rinsing with a 6% and 16% carbohydrate solution (CHO) has on time trial performance when compared to a 0% control solution (PLA) when in a fed state. **Methods:** Twelve recreationally active males completed three time trials of a set workload (600 ± 65 W), rinsing a 25ml bolus of a 0% PLA, 6% or 16% CHO (Maltodextrin) every 12.5% of the time trial performance completed. Rating of perceived exertion (RPE), heart-rate and cadence were recorded every 12.5% completion with blood lactate levels recorded at every 25%. Results were analysed using a Two-Way Anova (SPSS 22.0) with p=0.05. **Results:** Performance times significantly improved when using the 6% CHO and 16% CHO versus the PLA trial (6%: 58.82 ± 7.03min v 62.31 ± 7.62min, p = 0.002; 16%: 57.9 ± 7.62min v 62.31 ± 7.62min, p<0.001) respectively. No significance variation was observed when comparing the 6% CHO to 16% CHO (p = 0.244). There was no significant difference between heart rate levels or RPE values across the three trials. **Discussion:** The results of the study indicate that CHO rinsing leads to improvements in performance times in cycling time trial performance while participants were in a fed state. The improvements observed in cycling performance can be associated with the higher levels of power output sustained in both CHO trials. The results support the previous findings by Carter and colleagues (2004). In conclusion mouth rinsing with a 6% or 16% CHO solution has a positive effect in a cycling time trial performance in recreational active males when performed in a fed state. **References:** Carter, J. M., Jeukendrup, A. E., & Jones, D. A. (2004). The effect of carbohydrate mouth rinse on 1-h cycle time trial performance. *Medicine and science in sports and exercise*, 36(12), 2107-2111. ## ELECTROMYOGRAPHY MUSCLE ACTIVITY IN UNILATERAL AND BILATERAL SQUATS WITH RELATIVE LOADS

Olsson, M.C., Frandsen, B.

*Halmstad University*

**Introduction** Unilateral strength training is becoming popular as a complement to bilateral training particularly in athletes active in sports performed primarily on one leg. Some studies have shown improved performance after unilateral compared to bilateral strength training, however the underlying cause for this improvement is unclear. The aim of this study was to compare electromyography (EMG) muscle activity in unilateral and bilateral squats performed with 80% of 1repetition maximum (RM) performed in a smith machine. **Methods** Participants in the study were 12 healthy women and men (mean age 25±2 years) with previous weight-lifting experience. EMG activity was measured during the concentric phase in the muscles vastus lateralis, biceps femoris, gluteus medius and erector spinae during A) a maximal voluntary isometric contraction (MVIC), B) 1RM squat (90 degree knee flexion) bilaterally and unilaterally, and C) 3 repetitions 80% of 1RM for both the unilateral and bilateral stance, where each squat was performed at a set speed with the aid of a metronome. **Results** EMG activities, calculated as percent of MVIC, in thigh and hip muscles (vastus lateralis, biceps femoris, gluteus medius) were significantly higher (p<0.01 for all) in the unilateral compared to the bilateral stance. The highest increase in EMG activity was in the gluteus medius where the unilateral squat elicited a 2.9 increase compared to bilateral stance. Unilateral stance muscle activation was in vastus lateralis 1.2 times higher and in biceps femoris 1.5 times higher compared to the bilateral stance. For the trunk muscle erector spinae, the opposite was apparent. EMG activity was 0.6 times lower (p<0.01) when the squat was performed unilaterally compared to bilaterally. **Discussion** Even when the load is made relative to the 1RM for each stance the muscles in especially the gluteus medius but also vastus lateralis and biceps femoris is activated to a higher degree when performed unilaterally which could be a partial explanation as to why the unilateral stance can be beneficial to include in a strength training regime despite the absolute load being lower. ## ARE SKYDIVING RESULTS DETERMINED BY VO<sub>2</sub>MAX AND AEROBIC PERFORMANCE?

Peric, R., Radosevic, B.

*Institute for Sport Medicine Banja Luka; Medical University Banja Luka, Bosnia.*

**Introduction.** We all know that skydiving is a sport for people with no fear, or at least that's the general opinion but question could be asked: Is skydiving in correlation with fitness level of the jumpers? After 2014 Skydiving championship held in Bosnia, Banja Luka, 10 skydivers were chosen to take part in this study. Five were ranked between top 10 and five ranked between last 20. All subjects were sedentary men, age  $27 \pm 3$ , and weight  $86 \pm 8$ kg, height  $174 \pm 8$ cm. First five had 600+ number of jumps thus second five had no more than 250 jumps. The aim of this study was to examine the fitness level and VO<sub>2</sub>max of skydivers and to see if there is a correlation with their competition results. **Methods.** Research was conducted on Institute for Sport and Occupational Medicine in Banja Luka, on COSMED (Italy) Quark PFT Ergo with real breath by breath gas exchange data analysis (VO<sub>2</sub>, VCO<sub>2</sub>) indirect calorimetry and RS232 ergometer control. Primary parameter that was measured was VO<sub>2</sub>max ml/kg/min and body composition. **Results.** Jumpers from the top five group had a value of 53 ml/kg/min VO<sub>2</sub>max with standard deviation of  $\pm 4$  ml/kg/min. Jumpers from the last five group had a value of 51 ml/kg/min with deviation of  $\pm 3$  ml/kg/min. **Conclusion & Discussion.** As we can see no significant difference between two groups was found. Primary difference was the history of the jumps. If we know that skydiving is associated with increase in anxiety, stress and cortisol levels which lead to increase in blood flow, heart rate rise and blood pressure rise we can conclude that that skydivers suffer from acute cortisol activation and therefore understand their high VO<sub>2</sub>max values although they practice no other activity besides skydiving. No statistical significance was found between skydiving result and VO<sub>2</sub>max either that they possess higher values than average population. We can conclude that number of jumps and experience are the determining factor in competition results. **References.** State anxiety and cortisol reactivity to skydiving in novice versus experienced skydivers, Olivia A. ## INFLUENCE OF ARM CRANK EXERCISE LACTATE INDUCTION ON SUBSEQUENT NUMBER OF REPETITIONS IN LEG PRESS EXERCISE

Almer, C., Müller, A., Korinek, M., Tschakert, G., Hofmann, P.

*University of Graz, Institute of sports science*

**Introduction:** Warm-up is a standard procedure before high intensity exercise but the effects on performance are not well understood (1). Too intense warm up inducing high lactate concentrations is suggested to reduce subsequent performance (2). Applying the lactate shuttle theory high systemic lactate levels inhibit glycolysis and favour aerobic metabolism which should positively influence strength endurance performance (3). The aim of this study was to analyse the influence of a lactate induction by high intensity arm crank exercise on a subsequent two set strength endurance leg press exercise. **Method:** 6 male students ( $25.8 \pm 5.2$  years,  $73.5 \pm 8.3$  weight) performed a 1 RM test to obtain maximal leg press performance. Several days later subjects performed leg press strength endurance exercise at 60% 1RM either with or without hand crank exercise pre-load in a randomized order with at least 1 week between tests. Subjects heart rate (HR) was measured continuously as well as blood lactate concentration (La) before and after a general warm up, the pre start phase with and without a 30s all-out hand crank exercise at 400 W, before and after each of the 2 sets of leg press exercise. Gas exchange data as well as heart rate (HR) were obtained continuously for all tests. **Results:** Number of repetitions was significantly higher after prior arm crank exercise ( $30.7 \pm 5.1$ ,  $29 \pm 6.2$ ) compared to the non-pre-load intervention ( $25.8 \pm 4.1$ ,  $24.2 \pm 3.9$ ) for the first and second set respectively. Net lactate ( $43.6\%$ ), respiratory exchange ratio (RER) ( $1.4 \pm 0.2$  vs.  $1.2 \pm 0.2$ ) and carbon dioxide (VCO<sub>2</sub>) ( $1.033 \pm 0.427$  vs.  $1.017 \pm 0.376$  l.min<sup>-1</sup>) were significantly decreased ( $P < 0.05$ ) using high intensity arm crank exercise pre-load. HR ( $109 \pm 17$  vs.  $135 \pm 11$  min<sup>-1</sup>) but not oxygen uptake ( $0.727 \pm 0.331$  vs.  $0.807 \pm 0.281$  l.min<sup>-1</sup>) was significantly increased ( $P < 0.05$ ) after pre-load. **Conclusion:** As expected from the theoretical assumption, number of repetitions increased significantly and net La increase was clearly diminished due to the La induction by hand crank exercise. Gas exchange data validated the shift to aerobic metabolism with a decreased RER and a lower CO<sub>2</sub> output. These results indicate that knowledge and application of the lactate shuttle theory may give unexpected effects on exercise performance. **References:** 1) Beckenkamp PR, Lin CC.: *Br J Sports Med.* 2011 May;45(6):525-6. 2) Christensen PM, Bangsbo J.: *Int J Sports Physiol Perform.* 2014 Sep 17. 3) Müller A., et al. in: Müller, E., Kröll, J., Lindinger, S., Fusterschmied, J., Stöggl, T. ## A COMPARATIVE STUDY BETWEEN HIGH INTENSITY EFFORTS PLAYERS OF 1ST AND 2ND DIVISION OF A SPANISH PROFESSIONAL SOCCER TEAM

Jimenez-Herranz, E.1, Paredes, V.1, Ramos-Alvarez, J.J.2, Romero, B.1, Naranjo-Ortiz, C.3, Guodemar-Perez, J.1

*1: Health Science Fac. Camilo José Cela University. (Madrid, Spain). 2: University Centre of Sport Medicine. Complutense University. (Madrid, Spain). 3: Nebrija University. Madrid (Spain)*

**Introduction** The ability to repeated sprint ability (RSA) is a prerequisite for performance in soccer (Stolen, 2005), regardless of the technical and tactical skills (Buchheit, 2013). The efforts of maximum intensity above 18-19km/h (Bishop, 2011;Wragg, 2000), however when the recovery periods between sprint are prolonged (>60s) the ability to repeat sprint does not decrease or minimally reduced, whereas when the recovery periods are short (<60s) the yield decreases (Bishop, 2004;Girard, 2011). Some authors have found a higher RSA regarding professional footballers (Impellizzeri, 2008) for both individual RSA could determine that a player from competing in a particular sport level (1st or 2nd division). The aim of this study is to evaluate and compare the duration of the efforts of RSA and recovery times between these players during a match. **Methods** Five players of each category were selected randomly (one per seat). They were placed a GPS during halftime of a training match (45m), the number of efforts of more than 18km/h, the duration thereof and the time elapsed between them was measured and compared the results between the players of 1st and 2nd division. The difference between number of sprints, sprints and recovery time among heart rate and measured with global positioning system was analysed using T-test for two related samples. **Results** The numbers of sprints registered were 32 to first division players and 31 to second division players. The most important results were the recovery time between sprints. The first division players showed minor recovery time between efforts with significant different (first division players:  $1.2 \pm 0.37$  min vs. second division players:  $2.92 \pm 0.58$  min;  $p = 0.04$ ). **Conclusions** Differences in the recovery periods between high intensity efforts among players of 1st and 2nd division, may be a factor to consider in the yields of the players in both categories. **References** Bishop, D., Edge, J., Davis, C., & Goodman, C. ### MOVEMENT PATTERNS AND METABOLIC RESPONSES DURING AN INTERNATIONAL TOURNAMENT OF RUGBY SEVENS

Couderc, A., Thomas, C., Lacome, M., Piscione, J., Robineau, J., Delfour, R., Borne, R., Hanon, C.

*Fédération Française de Rugby*

This study investigated the physical and physiological demands during an European rugby Sevens tournament. In this tournament, twelve elite players of rugby Sevens participated to 7 matches, analysed for each player with Global Positioning System, in order to determine mean movement patterns and to subcategorise players' performance into whole matches (WM) and substitutes (S). Distance covered were categorised with individual maximal sprinting speed (MSS) and maximal aerobic speed (MAS). Blood samples were taken to assess changes in acid-base balance at rest and after each match. During the tournament, mean time of play was  $66 \pm 14$  min ranging from 40 to 86 min; mean total distance covered was  $5846 \pm 1209$  m ranging from 3605 to 8051 m. For all players ( $\pm$  SD): mean relative total distance covered was  $91 \pm 13$  m.min<sup>-1</sup> ranging from 65 to 122 m.min<sup>-1</sup>; Although S players covered significantly more relative distance above MAS than WM players ( $18.8 \pm 8.2$  vs  $14.5 \pm 4.8$  m.min<sup>-1</sup>;  $p < 0.05$ ), there was no significant effect of player's status, time or total distance covered on the significant variation of blood pH, bicarbonate concentration ([HCO<sub>3</sub><sup>-</sup>]) and lactate concentration ([La]) post-match. For all players blood pH and [HCO<sub>3</sub><sup>-</sup>] significantly decreased post-match compared to pre-match (7.41 to 7.26 for pH; 24.5 to 13.8 mmol.L<sup>-1</sup> for [HCO<sub>3</sub><sup>-</sup>];  $p < 0.01$ ). Blood [La] significantly increased post-match compared to pre-match (2.5 to 11.7 mmol.L<sup>-1</sup>;  $p < 0.01$ ). Relative distance covered above MAS was inversely correlated to pH and [HCO<sub>3</sub><sup>-</sup>] ( $r = 0.44$  and  $r = 0.42$  respectively;  $p < 0.01$ ), and correlated to [La] ( $r = 0.36$ ;  $p < 0.05$ ). Relative distance and relative distance covered above 30% of anaerobic speed reserve during the one minute peak activity was correlated to [La] ( $r = 0.39$  and  $r = 0.39$  respectively;  $p < 0.01$ ). For the first time on rugby Sevens, physical demands with individualized velocity thresholds, was observed during European tournament. Moderate relationships were found between match activity and blood metabolic parameters (pH, [HCO<sub>3</sub><sup>-</sup>] and [La]), observed post match, suggesting that post match recovery should be tailored regarding match activity. Also, the peak values observed in this study ([La] up to 19.3 mmol.L<sup>-1</sup>; pH close to 7.05) are questioning about fatigue in rugby Sevens.

### EFFECTS OF COMBINED EXERCISE ON BDNF, FGF, TOTAL-GHRELIN AND ACYLATED-GHRELIN IN OBESE ADOLESCENTS

Kim, H.

*Kyungnam University*

Exercise has been reported to improve cognitive function in humans and rodents, possibly via BDNF (brain-derived neurotrophic factor) and FGF (Fibroblast growth factor) and regulated mechanism. BDNF and obesity-related factors have been reported to be associated. The purpose of this study was to investigate the effects of combined exercise on body composition, blood lipids, BDNF, FGF and ghrelin in obese adolescents. The subjects of this study were 20 boys, who were divided into combined exercise group (EG, n=10), control group (CG, n=10). The combined exercise program conducted 50-60 minutes per day, four times a week, for 12-week. The results of comparative analysis are as follows. The comparison of means difference before and after intervention between group, weight ( $p < 0.05$ ), BMI ( $p < 0.05$ ), Acylated-ghrelin ( $p < 0.05$ ) of EG were more significant decreased than CG. And BDNF ( $p < 0.05$ ), Total-ghrelin were more significant increased than CG. Fat mass, Fat percentage, Muscle mass, Muscle percentage, TC, TG, Glucose, HDL-C and FGF were not different between EG and CG. But in exercise group, Weight, BMI were significant decreased and Muscle percentage was significant increased after 12 weeks. These results indicate that 12 weeks combined exercise decreased Weight, BMI, Acylated-ghrelin and increased concentrations of BDNF, Total-ghrelin in the serum, suggesting a possible functional role for growth of nerve cells and improves energy metabolism and appetite in exercise-induced weight loss in humans.

### RELATIONSHIP AND INTERRELATED FACTORS BETWEEN PHYSICAL PERFORMANCE AND BIOCHEMISTRY PARAMETERS IN COMMUNITY-DWELLING OLDER MEN

Lee, P.X., Chen, J.J.

*National Yang-Ming University*

Introduction: Aging is associated with several morphofunctional changes, which in association with sedentarism reduce the functional capacity and impair the physical performance of older adults. Age related change in biochemistry parameters are of great importance in evaluating the aging conditions. The study aimed to investigate the relationship between biochemistry parameters and physical performance in older men lived in rural community in Taiwan. Method: 1033 men over 65 years old lived in Tianliao District, Southern Taiwan was selected in an epidemiological survey. A total of 414 subjects were enrolled, the respond rate was 60.8%. Not only structured questionnaires were inquired, but also physical activity of weekly, hip bone mineral density and serum biochemistry parameters such as vitamin D, creatinine, GFR-CG (Glomerular Filtration Rate -Cockcroft-Gault), GFR-MDRDs (Glomerular Filtration Rate -Modification of Diet in Renal Disease) and HDLC (High-Density Lipoprotein Cholesterol) were collected. The physical performance tests included grasp test of dominant hand (grip-D, TKK 5401, Japan), muscle strength/endurance (30-s chair stand test), balance (open-eye stand on right foot), flexibility (chair sit-and-reach test), and reaction (8-feet walking test). Results: There were 402 subjects completed the study, the average age was  $74.5 \pm 6.0$  (range=65-98) y/o. Using multiple linear regression models, the independent factors ( $\beta$  coefficient) for different physical performance tests were listed as follows: 30-s chair stand test: age (-0.295), percent body fat (-0.136), socioeconomic state (0.101), smoking (-0.219), physical activity (0.178), creatinine with 1.5ng/ml cut point (-0.099) and GFR-MDRDs with 60 ml/min/1.73 m<sup>2</sup> cut point (0.106); open-eye stand: age (-0.386), BMI (-0.17) and fasting blood glucose (-0.175); chair sit-and-reach test: age (-0.169); 8-feet walking test: age (0.322), BMI (0.156), tea drinking habit (-0.122), physical activity (-0.22) and glucose (0.1); hand grip test: age (-0.386), BMI (0.207), physical activity (0.144), and albumin (0.135). Conclusion: There was no significant association between Vitamin D, HDLC and physical performance. We can use creatinine and GFR-MDRDs to predict the muscle strength and endurance of elderly, and fasting blood glucose may use to predict balance and reaction ability of elderly. These results will provide the general status of physical functions and the value of indicators to show interrelated with biochemistry data. 1. Joane Mattaa, Nancy Mayo et al. ### EFFECT OF DEVELOPMENT OF GLUCOSE INTOLERANCE ON DIAPHRAGM MUSCLE FUNCTION IN TYPE 2 DIABETIC RATS

Ichinoseki-Sekine, N.1,2, Tsuzuki, T.2, Yoshihara, T.2, Takamine, Y.2, Kobayashi, H.2,3, Naito, H.2

1: Faculty of Liberal Arts, The Open University of Japan (Chiba, Japan), 2: Graduate School of Health and Sports Science, Juntendo University (Inzai, Japan), 3: Mito Medical Center, Tsukuba University

**Introduction** Patients with type 2 diabetes may have some respiratory muscle weakness (Correa et al., 2011). However, how respiratory muscle weakness is developed in type 2 diabetes is still unclear. The aim of this study was to investigate the effect of development of type 2 diabetes on diaphragm muscle function. **Methods** Sixteen Otsuka Long-Evans Tokushima Fatty (OLETF) rats, a model of type 2 diabetes mellitus, and 12 non-diabetic control Long-Evans Tokushima Otsuka (LETO) rats were used. Rats were housed in a climate-controlled room and given standard rat chow and water ad libitum from 5 to 25 weeks of age. A strip of diaphragm was used to measure the force production (N/cm<sup>2</sup>) at 1, 15, 30, 60 and 100Hz of stimulation frequencies at 5 and 25 weeks of age and the rest was frozen and stored for histochemical analysis. Results Body weight in OLETF rat was greater than that of LETO rat in both 5 and 25 weeks of age (P<0.01). Blood glucose area under the curve in OLETF rat was greater than that of LETO rat at 25 weeks of age (P<0.01) while no difference was observed at 5 weeks of age. Muscle fiber cross sectional area was larger in OLETF rat than LETO rat in both ages (P<0.05). Diaphragm force production in OLETF rat was lower than LETO rat in both ages (P<0.01). Neutral lipids in muscle fiber was greater in OLETF rat than LETO rat at 5 weeks of age (P<0.01), whereas the difference was disappeared at 25 weeks of age. There was a negative correlation between neutral lipids and force production at 5 weeks of age (30, 60, and 100Hz, p<0.01), however, no correlation was observed at 25 weeks of age. **Discussion** OLETF rats showed type 2 diabetes at 25 weeks of age as same as a previous study (Kawano et al., 1992). In OLETF rat, diaphragm force production was already lower and neutral lipids in muscle fiber was greater at 5 weeks of age, even without glucose intolerance. There was a possibility that high neutral lipid levels might affect lower force production per unit in OLETF rat at 5 weeks of age under tetanized state. Similarly, force production was lower in OLETF rat after onset of diabetes, however neutral lipid did not relate the force production. **References** Correa, A. P., Ribeiro, J. P., Balzan, F. ### THE EFFECT OF VOLUNTARY EXERCISE ON THE COMPOSITION OF GUT MICROBIOTA IN MICE.

Tanimura, Y.1, Aoi, W.2, Naito, Y.3, Takagi, T.3, Mizushima, K.3, Higashimura, Y.3, Yoshikawa, T.3

Aichi Toho University

**Introduction** Recently, it is well-known that the composition of gut microbiota is related to health and illness. Exercise also has health benefits, but that the effect of exercise on the composition of gut microbiota is unclear. Therefore, the aim of this study was to examine the composition of gut microbiota by voluntary exercise in mice. **Methods** Male Balb/c (8 weeks) mice were divided into 2 groups: sedentary and exercise. Mice were individually housed under sedentary condition (SED, n=9) or given free access to a running-wheel (Ex, n=8) for 16 weeks. Fecal samples were collected after 16 weeks for bacterial DNA isolation. We analyzed the samples by using Terminal Restriction Fragment Length Polymorphism (T-RFLP). **Results** The body weight of mice in Ex did not change compared with Sed throughout the experiment. The volume of physical activity in Ex did not show significant change for 16 weeks (average  $1.5 \times 10^5$  counts/week). Ex significantly elevated the proportion of Lactobacillales order compared with Sed, whereas were significantly reduced the proportion of Bacteroides genus. **Discussion** Voluntary exercise for 16 weeks changed the composition of gut microbiota in mice. Ex elevated the proportion of Lactobacillales order. Our result agrees with previous studies in rats (Queipo-Ortuño et al., 2013; Petriz et al., 2014). Most of Lactobacillales order is able to produce the organic acid (ex, lactate or butyrate), which cause lower the pH in intestinal tract due to inhibit the proliferation of destructive fungus. In addition, butyrate has an inhibitory effect of colon cancer (Blouin et al., 2010). Meanwhile, Bacteroides genus reduced in Ex. Generally, it is well known that Bacteroides genus is one of pathogenic bacteria in opportunistic infections. The diversity of gut microbiota reduced in EX. In conclusion, exercise alters the composition of gut microbiota in mice, especially the proportion of Lactobacillales order increase. **References** Queipo-Ortuño MI, Seoane LM, Murri M, Pardo M, Gomez-Zumaquero JM, Cardona F, Casanueva F, Tinahones FJ. ### CAN THE 'REPEATED BOUT EFFECT' AFTER ECCENTRIC EXERCISE BE REMOVED?

Margaritelis, N.V., Theodorou, A.A., Baltzopoulos, V., Maganaris, C.N., Paschalis, V., Kyparos, A., Nikolaidis, M.G.

Aristotle University of Thessaloniki

**INTRODUCTION** An "absolute norm" in eccentric exercise is the "repeated bout effect", which describes a gradual attenuation of muscle damage after repeated eccentric exercise sessions. Although the repeated bout effect is considered as a protection mechanism that allows repeated eccentric exercise without or reduced damage, it is also a barrier for investigating the role of chronic exercise-induced muscle damage in adaptations. Based on evidence that concentric-only exercise renders the muscle more vulnerable to damage after a subsequent eccentric exercise session, we designed a protocol with alternating cycles of concentric-only exercise that exposes the muscles to increased damage during the subsequent eccentric-only exercise. This was an attempt to attenuate and/or remove the repeated bout effect by exploiting muscle mechanic specific adaptations during concentric-only and eccentric only exercise. **METHODS** Seventeen males were assigned into i) the alternating eccentric-concentric exercise group switching between eccentric-only and concentric-only exercise every 4 weeks and ii) the eccentric-only exercise group performing only eccentric muscle actions. The two groups performed 8 weeks of exercise using the knee extensors on an isokinetic dynamometer. Indices of muscle damage (isometric torque, muscle soreness, range of motion and creatine kinase) and inflammation (C-reactive protein) were measured. **RESULTS** Both groups at the first 4 weeks of eccentric exercise exhibited a typical manifestation of the repeated bout effect, namely a marked reduction of muscle damage. However, in the alternating group, the subsequent 4 weeks of concentric-only exercise were sufficient to bring muscle nearly back to its unaccustomed state. In particular, the last eccentric exercise session, which was preceded by a month of concentric-only exercise, induced muscle damage similar to that experienced after the first eccentric exercise session. In the eccentric-only exercise group, the last eccentric exercise session did not cause any alterations in muscle damage and inflammation. **DISCUSSION** Concentric exercise results in

removal of sarcomeres in series previously added by eccentric exercise and that any subsequent eccentric action overstretches the fewer sarcomeres leading to damage. On this basis, we invented an alternating eccentric-concentric exercise scheme, which has successfully overcome the repeated bout effect leading to repeated episodes of muscle damage. This novel exercise scheme will allow investigating the potential role of exercise-induced muscle damage as a stimulus for various potentially beneficial exercise adaptations. ### ANALYSIS OF INTERNAL AND EXTERNAL LOADS IN VOLLEYBALL PLAYERS DURING OFFICIAL MATCHES

Mortatti, A.1, Lima, J.B.1, Costa, E.C.1, Hirabara, S.M.2, Lambertucci, R.H.2

1. Federal University of Rio Grande do Norte; 2. Cruzeiro do Sul University

**Introduction** During a sports competition, it is known that athletes are under pressure for many causes, generating a psychophysiological stress that can directly influence performance. The purpose of this study was to identify and to correlate competitive external load (EL) with internal load (IL) magnitude and with symptoms of stress (SS) during an official competition. **Methods** Eleven volleyball players competing in triangular qualifying competitive matches participated in this study. Specific volleyball motor actions (MA) were filmed to determine EL while PRE session (Foster, 1998) and salivary cortisol (sC) collected after matches were used to analyze IL. DALDA questionnaire (Rushall, 1990) was used to determine SS, being the answers 'worse than normal' from part 'B' of the questionnaire retained for analysis. **Results** Analysis of variance showed effect on sC concentration in 4 moments of analysis, with a significant difference from baseline for matches 1, 2 and 3 ( $p < 0.01$ ); SS values differed from pre moment for matches 2 and 3, and from match 1 to 2 and 3 ( $p < 0.05$ ). MA differed significantly from match 2 to matches 1 and 3 ( $p < 0.01$ ), as well as from session RPE to match 2 to matches 1 and 3 ( $p < 0.05$ ). There was a positive association between MA and quantification of session RPE in 3 matches and significant in match 2,  $r = 0.69$ . **Discussion** Unlike the initial hypothesis, salivary cortisol levels were not influenced by different workloads during the three matches, demonstrating that main stress hormone may be being modulated by psychological factors involved in an official match, corroborating with some authors who indicate that in training matches there is not significant increase in cortisol in athletes very well adapted for the demand for training and competitions (Moreira, et al, 2009; Elloumi, et al, 2003). **In conclusion**, it was demonstrated that stress generated by competitive matches increases salivary cortisol concentrations post match, but this increment is not directly associated with increase of volleyball motor actions. In addition, with the association between volleyball motor actions and session RPE, we conclude that this psychometric instrument is sensitive to determine external load caused by official volleyball matches. **References** Foster C. ### THE EFFECTS OF UPPER BODY SPRINT INTERVALS ON UPPER BODY STRENGTH AND AEROBIC CAPACITY IN FEMALE CROSS-COUNTRY SKIERS

Hovstein Kruken, A., Karlsen, T.1, Vandbakk, K.2, Sandbakk, Ø.1

1 Norwegian University of Science and Technology 2 Nord-Trøndelag University College

**Introduction** Cross-country skiing is regarded as a demanding endurance sport. In classical skiing, the increased race speeds, caused by new competition forms and better prepared race tracks, have led to more use of the double poling technique and, subsequently, greater importance of upper body strength and endurance capacity. The purpose of this study was to compare the effects of 30-s sprint intervals with continuous training of the upper body in improving upper body maximal strength as well as upper- and whole body aerobic capacity among highly trained female cross-country skiers. **Methods** 17 highly trained junior female cross-country skiers (age=18.1±0.8yrs,  $VO_{2max}=3.30\pm0.37$  L/min) performed an 8-week intervention training period where a sprint interval training group (SIT; n=8) added 2 weekly sessions of 6-8x30-s maximal upper-body intervals while poling either using a roller board in a kneeling position or by double poling on roller skis. The control group (CON; n=9) added a weekly session of continuous double poling on roller skis at 70- 80% of their maximal heart rate. Upper body 1RM in a poling specific strength exercise and peak oxygen uptake in isolated upper body poling using a Concept2 Ski-ergometer (Skierg- $VO_{2peak}$ ), as well as in double poling (DP- $VO_{2peak}$ ) and diagonal stride (DIA- $VO_{2peak}$ ) roller skiing was tested pre and post to the intervention. **Results** The groups did not significantly differ at the pre-tests and only the experimental training differed during the intervention training period. Both groups improved all tests from pre- to post-test conditions. SIT improved 1RM more than CON (17.6% vs 9.8%,  $p < 0.001$ ). The improvements in DP- $VO_{2peak}$  (10.8% vs 6.4% for SIT and CON) or Skierg- $VO_{2peak}$  (12.5% vs 9.3% for SIT and CON) did not significantly differ between groups, whereas the increase in DIA- $VO_{2peak}$  improved significantly more for SIT than for CON (8.6% SIT vs CON=2.6%,  $p = 0.003$ ). **Discussion** While both SIT and CON significantly improved all tests by adding upper body session upon their normal training regimes, SIT increased maximal strength and whole body aerobic capacity more than CON. These findings indicate a large potential for female junior skiers to improve their physiological capacities by increased focus on upper body training in general, and that SIT tends to be particularly effective for improving both strength and aerobic capacity over an 8 week period.

### EFFECTS OF ACUTE HYPOXIA AND HYPEROXIA ON ENERGY AND GLUCOSE METABOLISMS DURING INCREMENTAL EXERCISE

Uchimaru, J.

Sendai University

**Introduction** Peak oxygen uptake and/or exercise performance will be reduced during hypoxia and higher during hyperoxia compared with normoxia. Also, energy metabolism mechanisms during exercise under hypoxia have been proposed. That is, previous studies suggested that hypoxia stimulate energy expenditure and glucose metabolisms. However, the mechanisms underlying the energy and glucose metabolisms effect of hyperoxia were not fully understood. **Purpose** Our study focuses on the effect of acute hypoxia and hyperoxia on energy expenditure and glucose oxidation during exercise. **Methods** Nine healthy male subject performed incremental maximal exercise test (15W/min step) under normoxia (Norm: 20.9 FIO<sub>2</sub>), acute hypoxia (Hypox: 14.5% FIO<sub>2</sub>) and acute hyperoxia (Hyper: 28.0% FIO<sub>2</sub>) conditions. The order of each condition was randomized and trials were spaced by 3 days. We measured oxygen uptake on incremental exercise. Energy expenditure rate (EER) and glucose oxidation rate (GOR) were calculated by the formula of Bursztein et al. Continuous data of EER and GOR were collapsed to analyze specific time points of interest, corresponding to 25, 50, 75, and 100% of  $VO_{2peak}$  under three conditions. Repeated-measures ANOVA were performed across treatments. **Results** As expected,  $VO_{2peak}$  decreased in Hypox (38.8±4.6ml/kg/min) and also increased in Hyper (48.4±5.1ml/kg/min) compared with Norm (45.7±5.6ml/kg/min,  $P <$

0.05). EER was progressively increased during exercise at three conditions, but there is no difference among Norm, Hypox and Hyper condition. During Hypox, GOR (from  $0.308 \pm 0.062$  to  $2.276 \pm 0.131$  mg/min/m<sup>2</sup>) as work rate from 20 to 80% VO<sub>2</sub>peak were higher than that of Norm (from  $0.184 \pm 0.081$  to  $1.946 \pm 0.367$  mg/min/m<sup>2</sup>,  $P < 0.05$ ). Conclusion Acute hypoxia would be enhanced GOR during exercise, although there was no difference in EER in comparison with normoxia and/or hyperoxia. Also, It is unlikely that changes in EER and GOR related with increased oxygen uptake in hyperoxia. References Katayama, K., K. Goto., K. Ishida., and F. Ogita. (2010) *Metabolism*. 59: 959-966. ## EXAMINATION OF THE EFFECT OF TRUNK TRAINING ON WEIGHT-LIFTING PERFORMANCE

Amano, K., Kushi, H., Fukada, K., Takashina, T., Yoshida, A.

*Nihon University*

[Introduction] Tests were performed to examine whether trunk training improved weight-lifting performance. [Subjects and Methods] The subjects were 30 high-school students (grades 10–12) who were weight-lifting club members. Eight exercises (three for static training and five for dynamic training) were selected from the popular trunk training program. The subjects trained for 2–4 months, 6 times a week. Before and after the training program, the subjects' snatch (S) and clean and jerk (C&J) weight-lifting performances were evaluated. Changes in the measurements, including growth rate, were compared between the subjects who did and those who did not undergo trunk training. [Results] The results of the trunk training program were as follows: The recorded levels of improvement in the training group were  $6.64 \pm 1.57$  kg for the S lift and  $6.68 \pm 1.50$  kg for the C&J lift, whereas those for the non-training group were  $0.63 \pm 0.38$  and  $1.75 \pm 0.67$  kg, respectively, indicating significant improvements for the subjects who underwent trunk training. [Discussion] Weight lifting is an isometric exercise where the level of performance is high when the movement of the center of gravity is minimized. Trunk training includes isometric exercise, which suggests that this experiment contributed to improved performance. [Conclusion] Through this study, the significant contribution of trunk training on the improvement of weight-lifting performance was clarified.

## PRESERVED CARDIOVASCULAR RESPONSE TO METABOREFLEX ACTIVATION IN NEVER-TREATED HYPERTENSIVE MEN

Barbosa, T.C., Vianna, L.C., Fernandes, I.A., Prodel, E., Secher, N.H., Nóbrega, A.C.L.

*Fluminense Federal University, University of Brasilia, University of Copenhagen*

Introduction Hypertensive rats have exaggerated pressor response to metaboreflex activation (2) but these findings are equivocal in humans (3, 4). Thus, we further assessed whether hypertensive men that had never been treated have increased metaboreflex responsiveness. Due to a possible specificity of pressor response according to muscle groups observed in cardiovascular diseases (1), isometric handgrip and leg cycling were tested. Methods Five never-treated hypertensive (HT;  $48 \pm 3$  years old,  $149 \pm 8/95 \pm 5$  mmHg) and 6 normotensive (NT;  $47 \pm 5$  years old,  $124 \pm 4/78 \pm 2$  mmHg) men had intra-arterial blood pressure (BP) and heart rate (ECG; HR) measured during muscle metaboreflex activation by post-exercise ischemia (PEI) after: 1) isometric handgrip at 40% maximal voluntary contraction; 2) leg cycling at 80 W. Responses to exercise were the difference between the last 30 s of PEI and resting baseline (BL). Results During PEI following handgrip, BP remained elevated (HT:  $+32 \pm 3$  mmHg vs. NT:  $+35 \pm 3$  mmHg;  $P < 0.05$  vs. BL), while HR returned to BL (HT:  $-1 \pm 2$  bpm vs. NT:  $-1 \pm 2$  bpm;  $P > 0.05$  vs. BL). During PEI following cycling, BP (HT:  $+28 \pm 4$  mmHg vs. NT:  $+24 \pm 4$  mmHg;  $P < 0.05$  vs. BL) and HR (HT:  $+28 \pm 7$  bpm vs. NT:  $+27 \pm 6$  bpm;  $P < 0.05$  vs. BL) remained elevated above BL. These responses to PEI of forearm and leg muscles were similar between groups ( $P > 0.05$ ). Discussion In line with a previous finding in humans (3), we showed that cardiovascular responses to metaboreflex activation of hypertensive men were not exaggerated compared to normotensive men, regardless of the muscle group involved. In comparison to conflicting evidence (4), we suggest that antihypertensive treatment and aging are important factors affecting metaboreflex responsiveness. References 1. ## CAN TRANSCRANIAL DIRECT CURRENT STIMULATION CHANGE CARDIOVASCULAR RESPONSES AND GUN-SHOOTING PERFORMANCE IN POLICE OFFICERS?

Elsangedy, H., Nascimento-Neto, L., Machado, D., Agricol, P., Farias Junior, L., Nascimento, P., Silva, S., Sabino, M., Ribeiro, L., Pereira Junior, A., Fontes, E., Okano, A.

*Rio Grande do Norte University*

Introduction: Police officers need to improve precision and accuracy of shooting to minimize crime risks. Cardiovascular variables, such heart rate (HR) and blood pressure (BP), are controlled by autonomous nervous system and has been related to shooting performance. Transcranial direct current stimulation (tDCS) has shown to increase parasympathetic activity and decrease sympathetic activity. Therefore, tDCS might be able to improve shooting performance since it can changes autonomous nervous activity and decrease HR and BP. Purpose: Here we tested whether tDCS is able to affect cardiovascular responses and shooting performance in police officers. Methods: The sample was composed by 13 male police officers ( $33.2 \pm 4.3$  years;  $1.72 \pm 0.5$  m;  $79.5 \pm 7.2$  kg;  $26.7 \pm 1.4$  kg/m<sup>2</sup>;  $41.3 \pm 10.2$  ml.kg.min<sup>-1</sup>). After two sessions of familiarization of the gun (air shot gun 4,5 mm, Taurus®, Gamo P-900, 0,55 Kg) and test procedures, participants randomly performed three sessions with different tDCS conditions in a cross over design: anodal single lateral tDCS (A-tDCS), anodal bilateral tDCS (B-tDCS), and a sham tDCS (S-tDCS). An electric current of 2  $\mu$ A for 20 min using 35 cm<sup>2</sup> electrodes embedded in a salty solution applied in A-tDCS and B-tDCS conditions. In the S-tDCS session, the device was turned off after 30 seconds in order to deceive subjects. Before and after tDCS, heart rate variability (HRV), HR (Polar® RS800cx), BP (Omron® 742 INT), as well as gun-shooting accuracy, precision, score, and time were assessed. Results: A two-way repeated measure ANOVA (condition X time) showed that there was an effect of time in all conditions, with decreased HR ( $P \leq 0.003$ ) and increased DBP ( $P \leq 0.004$ ). There was no change in any index of HRV ( $P \geq 0.05$ ), SBP ( $P \geq 0.05$ ) as well as there was no effect on shooting accuracy ( $P \geq 0.2$ ), precision ( $P \geq 0.06$ ), score ( $P \geq 0.06$ ), and time ( $P \geq 0.3$ ). Conclusions: tDCS has no effect on cardiovascular measures and shooting performance of police officers. It is possible that the physical fitness level and the specific work context of police officers have influenced the tDCS effect.

## HEART RATE VARIABILITY AS A PREDICTOR OF FAILURE IN COGNITIVE PERFORMANCE

Wale, R.1, Thatcher, R.2, Hudson, J.3

*Aberystwyth University*

**Introduction** Heart Rate Variability (HRV) is a reliable reflection of the autonomic nervous system's (ANS) influence on heart rhythm, and is sensitive enough to identify physiological and psychological responses (Strauss, 2003). Few studies have examined if HRV is sensitive enough to predict failure in cognitive performance under high levels of physiological and psychological stress. The aim of the study was to identify if HRV can predict performance failure in healthy males performing under stress. **Method** Eight healthy male subjects took part in a within subject, repeated measures design study. Subjects completed two experimental trials (low cognitive anxiety (LC); high cognitive anxiety (HC)) where the threat of shock was used to induce cognitive anxiety (Svebak et al., 1982). Pre and post testing subjects completed the Revised Competitive State Anxiety Inventory-2 (CSAI-2R; Cox et al., 2003). A 3-lead ECG was used to measure HRV (AD Instruments, PowerLab, Oxford, England). Subjects were submerged in water at 42°C up to the chest for up to 30 min to induce physiological stress. Cognitive performance was measured via the trail making test (Reiten, 1955) which was completed every 5 min. **Results** A 2-way-repeated measures ANOVA identified no significant difference between LC and HC conditions in HRV and performance measures ( $p > 0.05$ ); CSAI-2R did not differ significantly between the LC and HC conditions ( $p > 0.05$ ). A significant main effect was found in HRV over time with a decrease in SDNN, RMSSD, LFnu, SD1, SD2, and an increase in HFnu. Only three of the eight subjects suffered performance failure; in these subjects correlations were found between performance decrement and decreases in the HRV parameters SDNN ( $r = -0.4$ ), LF ( $r = -0.57$ ) and HF ( $r = -0.45$ ). **Discussion** Physiological stress was identified by decreased SDNN, RMSSD and HF(nu) over time, indicating parasympathetic nervous system withdrawal. Furthermore, increased LF(nu) over time illustrates increased SNS influence (Armstrong et al., 2012). Negative correlations were found between SDNN, LF, and HF and performance of subjects who suffered performance failure, providing support for the proposal that HRV can successfully predict performance change. Findings were limited by the cognitive performance test, which was not sensitive enough to identify performance change in all participants, and, by the stress protocol, which was not sufficient to induce changes in cognitive anxiety. **References** Armstrong R, Ahmad S, Seely A, Kenny G. ## OXYGEN UPTAKE KINETIC IN WELL TRAINED ROAD- AND CROSS-COUNTRY CYCLISTS

Slettaløkken, G., Rønnestad, B.R.

*Lillehammer University College*

**Introduction** While road-cycling is mostly performed at a steady pace over an extended duration of time, the hilly terrain in cross-country cycling results in rapid shifts in exercise intensity. As a fast kinetic of oxygen uptake ( $\dot{V}O_2$ ) is essential for avoiding oxygen deficiency during the transient from low to high intensity (I), rapid  $\dot{V}O_2$  kinetics may be more important for performance in cross-country cycling than road cycling. We hypothesized that among cyclists of high national level and similar aerobic fitness, cross-country cyclists (CC) would have a faster  $\dot{V}O_2$  kinetic than road cyclists (RC). **Method** Eleven CC (17±1 years, 66±9 kg, 178±7 cm, 1 female) and nine RC (17±1 years, 70±9 kg, 182±8 cm, 1 female) participated in the study. All tests were performed on an ergometer cycle while respiratory gases were measured pulmonary. Blood lactate was sampled from the fingertip. Lactate threshold (LT) was defined as work intensity equal to blood lactate concentration of 4.0 mmol/L.  $\dot{V}O_{2max}$  and maximal aerobic power (MAP) was measured during a stepwise incremental test until exhaustion.  $\dot{V}O_2$  kinetics was measured as rate of increase in  $\dot{V}O_2$  when the cycling intensity increased from 20W to moderate intensity defined as 80% of LT. **Results** LT,  $\dot{V}O_{2max}$  and MAP were not different between the groups (CC: 264±56 W, 4.8±0.9 L/min and 339±67 W, respectively. RC: 268±66 W, 4.8±0.9 L/min and 344±69 W, respectively. All  $p > 0.05$ ).  $\dot{V}O_2$  at 20 W was 0.97 ±0.12 and 0.99 ±0.18 L/min for CC and RC, respectively ( $p > 0.05$ ). Exercise load at moderate intensity was 211±45 W and 215±53 W for CC and RC, respectively ( $p > 0.05$ ). Steady state  $\dot{V}O_2$  at moderate intensity was 2.1±0.5 and 1.9±0.6 L/min for CC and RC, respectively ( $p > 0.05$ ). The rate of increase in  $\dot{V}O_2$  from 20 W to moderate intensity (time taken to reach 63% of steady state,  $\tau$ ) was 10.3±2.4 and 11.7±2.9 s for CC and RC, respectively ( $p > 0.05$ ). Effect size measured as Cohen's d, was 0.53 between groups, which is considered as moderate effect for highly trained athletes (2).  $\tau$  did not correlate with  $\dot{V}O_{2max}$  ( $r = -0.26$ ), MAP ( $r = -0.01$ ) or LT ( $r = -0.05$ ). **Discussion** Though these results do not show a statistical difference, the numeric 12% faster  $\dot{V}O_2$  kinetic in the CC group together with the moderate effect size of difference in  $\dot{V}O_2$  kinetic, indicates that the rapid shifts in exercise intensity during cross-country cycling compared to road cycling may lead to a faster  $\dot{V}O_2$  kinetic in CC that is of practical importance. **References** 1 Burnley and Jones, *EJSS*, 2007; 7:63-79 2 Rhea, *JSCR*, 2004; 18:918-920

## PULSATING ELECTROSTATIC FIELD APPLICATION AND MUSCLE SORENESS DEVELOPMENT AFTER ECCENTRIC EXERCISE

Gatterer, H., Peters, P., Mittermair, G., Philippe, M., Burtcher, M.

*University Innsbruck*

**Introduction** The aim of the study was to establish whether pulsating electrostatic field (PESF) application, shown to increase blood flow, metabolic activity and to function as an ion pump (Liani et al., 2014, De Lorenzo et al., 2004), is able to reduce muscle pain after exercise induced muscle damage. **Methods** Six participants (3 males, weight: 74.0±6.9 kg, height: 185.7±10.2 cm, age: 27.0±2.6 years; 3 females, weight: 71.0±5.3 kg, height: 172.3±6.4 cm, age: 24.3±1.2 years) performed two sessions of downhill running separated by at least 4 weeks. After the running sessions participants were either treated for 45 min with a negative PESF (NewHealth 9000 device, Akern srl, Pontassieve, Italy) at 9000V (current level: < 9mA, pulsatile frequency: 50Hz) or got a sham treatment. The order of the intervention was random and condition was blinded for the participants. Muscle soreness score (MSS) was established before, immediately after the run, immediately after the treatment and 24 and 48 hours after the run. Creatine kinase was measured before and 48 hours after the run and jump ability was assessed before, immediately after the treatment and 48 hours after the run. **Results** 48 hours after the downhill run, MSS tended to be less increased after PESF administration when compared to the sham setting ( $\Delta$  MSS: 3.2±2.2 vs. 5.7±3.4 after 48 h;  $p = 0.083$ ). No further differences were detected. **Discussion** Outcomes show that PESF might be a promising application to reduce muscle soreness after exercise induced muscle damage. PESF application might have induced some beneficial effects due to an increased blood flow caused by an augmented vasomotor activity (Liani et al., 2014). The increased blood flow might have enhanced the removal of edema, limited inflammation and reduced perception of pain (Hausswirth et al., 2011). Furthermore, PESF might have functioned as an ion pump and moved calcium ions. Increased calcium concentrations within the sarcoplasm may activate many different molecular pathways leading to breakdown of the cell membrane and myofibrils (McKune et al., 2012). However, further studies are needed to confirm

present outcomes and to establish the exact mechanism by which PESF may reduce muscle pain. References De Lorenzo A, Martinoli R, Carbonelli MG, Monteleone G, Di Lorenzo N, Di Daniele N. ### **A COMPARISON OF BODY MASS INDEX SCORES TO BODY FAT PERCENTAGE DERIVED FROM SKINFOLD MEASURES WITHIN THE AUSTRALIAN DEFENCE FORCE**

Guajardo, S.

*Charles Darwin University*

**Introduction** Body Mass Index (BMI) scores have been used within the Australian Defence Force for decades, it's claimed to be the most effective means of assessing possible health related issues that may appear within an ADF career. Recruitment limits BMI at a ceiling of 32.9 in relation to health care expenses (Peake et al 2012) although this does not distinguish between lean muscle mass and body fat (De Lorenzo et al 2011). Therefore the aim of this study was to compare BMI and body fat percentage scores of current full-time ADF personnel to ascertain if BMI is an out-dated method of assessing health risks and body composition. **Methods** The study included 16 ADF personnel (8 males and 8 females) between the ages of 18-44 from all three services including the Royal Australian Air Force, Royal Australian Navy and Australian Army Corps. The participants had anthropometric measurements taken with Harpenden skinfold calliper's at 8 anatomical sites and BMI was derived from a stadiometer and Tanita scales with the formula weight/height<sup>2</sup>. The BMI scores were then further calculated to form body fat percentage (BF %) estimations. Pearson's correlation coefficient (r) was calculated using SPSS 19 to find any relationships between BMI, BF% calculated from BMI and BF% calculated from skinfold measures. Results A significant positive correlation was observed between BMI and BF% calculated from BMI and BF% calculated from skinfold measures in male participants (r=.95, p<.000 and r=.90, p<.002) however no correlations between BMI and calculated BF% from other methods were observed amongst females. The effect of age was significant in both groups relating to BF% calculated in females (r=.78, p<.023) and skinfold in males (r=.74, p<.036) and as a combined group to BF% from BMI (r=.76, p<.001). **Discussion** The use of BMI in the ADF as means of quantifying body fat estimations may have been valid when predominantly males enlisted; the modern defence force is diverse in culture and gender and measurement of body composition should reflect the changes. This study observed BMI calculated estimations of body fat percentages to be significantly correlated with the male personnel but not with the females, which in many cases over-estimated the body fat percentages of personnel with lower skinfold scores. BMI is therefore not an accurate reflection of body composition or health risk in the modern defence force. ### **MALE JUDO ATHLETES WITH HIGHER BODY FAT PERCENTAGE CONTINUE TO HAVE HIGH SKIN TEMPERATURES AFTER THE MATCH**

Takashina, T., Kushi, H., Fukada, K., Amano, K., Yoshida, A., Konno, J.

*Nihon University*

**[Introduction]** Competitive Judo is divided into 7 classes according to weight, with men divided into the following classes: <60 kg, 66 kg, 73 kg, 81 kg, 90 kg, 100 kg, and >100 kg. Body fat percentage increases with increasing weight class, with a particularly rapid increase in the >90 kg classes. The purpose of this study was to compare physiological changes before and after a Judo match between men <90 kg group and >90 kg group. **[Subjects and Methods]** This study included 15 men with >10 years of Judo experience who were divided into 2 groups: one is "<90 kg (n = 7)" and ">90 kg (n = 8)". Body composition (body fat percentage, skeletal muscle percentage, and extracellular water) was measured before the match, while heart rate, tympanic temperature, and skin temperature (Thigh, Tsurite, and Hikite temperatures) were measured before and 1, 10, and 20 min after the match. **[Results]** Body fat percentage in the >90 kg group (20.8 ± 2.3%) was significantly higher than the <90 kg group (11.6 ± 1.4%) (p < 0.01), while skeletal muscle percentage (p < 0.01) and extracellular water (p < 0.05) in the <90 kg group (50.1 ± 1.3% and 0.20 ± 0.003 L/kg, respectively) were significantly higher than the >90 kg group (43.7 ± 1.6% and 0.17 ± 0.007 L/kg, respectively). The Thigh, Tsurite, and Hikite temperatures measured 10 min after the match were significantly higher in the >90 kg group than the <90 kg (p < 0.05). There was significant correlation between body fat percentage and rate of change of Thigh (R<sup>2</sup> = 0.6288, p < 0.01), Tsurite (R<sup>2</sup> = 0.4173, p < 0.01), and Hikite (R<sup>2</sup> = 0.5372, p < 0.01) temperatures between 1 and 10 min after the match. **[Conclusions]** The results of this study demonstrate that male Judo athletes with higher body fat percentage continue to have high skin temperatures after the match.

### **EFFECT OF MUSCLE ACTIVITY ON ERECTOR SPINE, RECTUS FEMORIS, BICEPS FEMORIS, AND GASTROCNEMIUS IN ACCORDANCE WITH THREE FORWARD BENDING POSTURES DURING CYCLE-ERGOMETER EXERCISE**

Hu, Z., Park, J., Lee, H.

*Sangmyung University*

**Introduction** The purpose of this study is to examine the differences of muscle activity on Erector spine, Rectus femoris, Biceps femoris, and Gastrocnemius according to three forward bending postures during aerobic exercise with cycle ergometer. **Methods** For achieving this purpose, 9 active male students in Sangmyung University were performed. This experiment was carried out with two measuring equipment. 9 subjects were asked to maintain three postures in bending angles from 0 to 90 degrees, performing the exercise at a given time. First posture is upright sitting posture. Second posture is forward bending posture. Third posture is upright standing posture. Three postures that the participants were going to perform were applied to each participant in the same order. Prior to placing the electrodes on the skin, the skin over the targeted muscle was shaved and cleaned with ethanol for the accurate muscle activity measurement (Albertus-Kajeeet al., 2010). As the EMG activity of the targeted muscles was recorded, subjects pedaled for 60 seconds at 70 rpm. TeleScan program by Laxtha was used to analyze the values of muscle activity and the values of MVIC (Kang al., 1999). Data on calculated values through TeleScan were calculated by SPSS/PC ver.18.00, analyzed using one-way analysis of variance to detect significant differences. Statistical significance was defined as p < 0.05. **Results** The data of three postures suggested that only Rectus femoris values in accordance with three postures showed significant differences statistically (p < .05). In case of upright standing posture, its posture more contributed to Rectus femoris than the other postures did during cycling. Also, this study demonstrated that no matter what postures subjects

biked in, four targeted muscles were significant differences in muscle activity. Conclusion In conclusion, as this study showed targeted muscle activity by each posture, three postures help Rectus femoris to use more than the other muscles. The results of this study supported to reconfirm the results of a preceding research by showing Vastus lateralis runs as one of major muscle groups during pedaling, and training volume remarkably increases during measuring EMG [Ericson et al., 1986; Komi et al., 1975]. Therefore, we recommend that trainers in the field should consider this result when they train people with cycle exercise (Lee et al., 2010). Furthermore, when we explore which posture burns more calories during cycle-ergometer exercise, the pre-study will help to measure up training volume. ### THE EFFECTS OF ENDURANCE EXERCISE AND CALORIC RESTRICTION ON GEOMETRY AND DENSITOMETRY OF CORTICAL BONE IN ADULT MALE RATS

Tsai, T., Tsai, C., Chang, M., Yang, R., Huang, T.

*National Cheng Kung University*

Objective: The purpose of this study was to investigate the effects of calorie restriction and endurance exercise on cortical bone mineral density and geometry in adult male rats. Method: Sixty 26 weeks male Sprague Dawley rats (n=60) were randomly assigned to control (CON), 40% and 20% caloric restriction (CR40% and CR20%), endurance training (EXE) and pioglitazone (PIO) groups (n=12 for each group). The exercise intervention was consisted of a treadmill running training regime with running speed at 16 m/min, training duration 60 min/day and a training frequency of 5 days/week for nine weeks. Animals of the PIO group were oral fed by pioglitazone at a dose of 10mg/kg b.w./day. After euthanasia, femoral bones were collected and subjected micro computed tomography (microCT) scanning for densitometric and midshaft cross-section geometric analyses. Result: The CR40%, CR20% and EXE groups were significant lower in body mass as compared to the CON and PIO group (p <0.05). There is no difference in the absolute bone mineral density (BMD, g/cm<sup>3</sup>) and bone mineral content (BMC, mg). And, none of cross-sectional geometry measurements showed difference among groups. However, when indices further normalized to the body mass, the CON and PIO groups showed relatively lower values in most indices of densitometry (relative total and cortical BMD and BMC) as well as relatively lower cross-sectional parameters in midshaft femur (including: cross-sectional area, cortical thickness and moment of inertia, etc.) (p <0.05). Conclusion: Absolutely, adult male rats subjected to exercise, CR and pioglitazone treatment showed no different effects on cortical bone geometry and densitometry. However, the body weight reduction shown in exercise and CR groups made the bones of those animals relatively higher in cortical bone dimension and density.

### CAN A GENETIC PREDISPOSITION SCORE PREDICT CHANGES IN MUSCLE FUNCTION OVER A TEN-YEAR FOLLOW-UP PERIOD IN FLEMISH MIDDLE-AGED ADULTS?

Charlier, R., Mertens, E.2, Lefevre, J.1, Thomis, M.1

*1. KU Leuven, 2. VUB (Brussels, Belgium)*

Introduction Ageing is a complex process that is accompanied with changes in both muscle mass and muscle function (strength and performance). These changes initiate in middle-age and are characterized by large inter-individual differences, determined by environmental and genetic factors. The aim of this study was to examine the power of a genetic predisposition score (GPS), based on 18 candidate polymorphisms linked with muscle phenotypes (a.o. ACTN3, GDF8, VDR), to predict changes in muscle function over a 10-year follow-up period in Flemish middle-aged adults. Methods Data were assessed within the framework of the first (2002-2004: baseline) and third generation Flemish Policy Research Centre Sport (2012-2014: follow-up). A total of 117 healthy, Flemish Caucasian adults (39-49, 73.5% men) were measured during a follow-up period of  $9.59 \pm 0.47$  years (Mean  $\pm$  SD). Force and velocity characteristics of the knee extensors were measured using the Biodex Medical System 3® dynamometer. Isometric strength of the knee extensors (Nm) was assessed at a knee joint angle of 120° (ISOM120°). Isometric knee extension strength (Nm) was examined at a low velocity of 60°/s (ISOK60°) and at a high velocity of 240°/s (ISOK240°). Two models for a genetic predisposition score (GPS) were designed: a total GPS (based on the sum of all 18 variants, each favorable allele = score 1) and a data-driven GPS (sum of favorable alleles of those variants with significant b-coefficients in stepwise regression). Both GPS models were used to predict 10-year changes in muscle function via linear regression analysis. Results The total GPS was able to explain 26.8% of the variance in changes in ISOM120° in women (beta = -0.52, P = 0.0034), but not in men. The regression equation of the data driven GPS for ISOM120° was based on two polymorphisms (CNTFR rs3808871, PPP3R1 rs11692815). This regression model was able to predict changes in ISOM120° (beta = -0.18, P = 0.0486, r<sup>2</sup> = 0.0334, total group), with up to 13.8% explained variance in women separately (beta = -0.37, P = 0.0396). No GPS model was able to predict changes in isokinetic strength at either of both speeds. Conclusions A GPS based on 18 gene variants contributes to predict age-related changes in isometric strength, however only in women. Furthermore, gene variants in PPP3R1 (calcineurin B) and CNTFR (Ciliary Neurotrophic Factor Receptor) are significantly related to loss of isometric strength in both men and women. ### EFFECT OF MODERATE AEROBIC EXERCISE ON MOTOR LEARNING

Perini, R.1, Capogrosso, M.1, Bortoletto, M.2, Miniussi, C.1,2

*1 Università di Brescia, Dept. of Clinical and Experimental Sciences*

Introduction Regular participation in physical activity has been associated with improved cognitive functions across the lifespan and would help in preventing cognitive decline and dementia. Aerobic exercise of moderate intensity has been shown to elicit increment in concentrations of brain-derived neurotrophic factor, that would enhance brain plasticity. Executive functions, learning and memory processes could therefore result improved. Our aim was thus to evaluate the effect of a single bout of aerobic exercise on motor learning, as measure of brain plasticity. Methods Thirty-eight healthy males (age:  $23 \pm 2$  yrs, mean  $\pm$  SD) were randomly assigned to an exercise-group (exe-group; n=19) or a control group (ctrl-group; n=19). All subjects exercised on a cycle-ergometer for 30 min: exe-group pedaled at an intensity eliciting 70% of individual maximal heart rate (HR), ctrl-group pedaled at 20 W, i.e. an almost unloaded task. The subjects were administered a motor task (MT), which consisted of performing a sequence of 64 abduction movements with the left thumb as fast as possible. MT was carried out before (block-pre) and six times after the exercise (block1, 2, ..., 6). Movement acceleration was continuously recorded, then the mean peak value for each block was calculated and normalized to block-pre. HR was continuously recorded throughout the experiment. Results At the end of cycle task HR in exe-group was  $148 \pm 13$  b/min, corresponding to a mean increase of 75 b/min above resting value. In the initial 2 min of recovery HR dropped by about 50 b/min and then further slowly decreased. In ctrl-

group, a slight increase in HR (10-12 b/min) was observed during pedaling. In exe-group, movement acceleration showed a continuous increment from block1 to block6 (+ 30% on average;  $p < 0.05$ ). In contrast, in ctrl-group only a tendency to improve the motor performance was found, being movement acceleration in all blocks significantly lower than in exe-group. Discussion Performance in motor task progressively enhanced in the recovery after the dynamic exercise. This would indicate that a single bout of aerobic muscular work does boost the process of motor learning. Thus, suggestion can be made that acute exercise, at least of moderate intensity, can have an influence on brain plasticity. [renza.perini@unibs.it](mailto:renza.perini@unibs.it)

## EFFECTS OF INTERVAL VS. CONTINUOUS EXERCISE ON ACUTE PHYSIOLOGICAL RESPONSES IN PATIENTS WITH TYPE 1 DIABETES MELLITUS

Tschakert, G.1, Moser, O.1,2,3, Mueller, A.1, Groeschl, W.1, Pieber, T.R.2, Obermayer-Pietsch, B.2, Koehler, G.2, Hofmann, P.1

*1University of Graz (Graz, AUT) 2Medical University Graz (Graz, AUT) 3University of Potsdam (Potsdam, GER)*

**Introduction** Aerobic high-intensity interval exercise (HIIE) is an integral part of prevention in individuals with Type 1 Diabetes Mellitus (T1DM). The aim of this study was to compare the acute metabolic and cardiorespiratory response to short HIIE vs. moderate continuous exercise (CE) in T1DM patients. **Methods** 7 trained male subjects with T1DM (age:  $24.7 \pm 5.3$  years, height:  $1.76 \pm 0.40$  m, weight:  $74.0 \pm 5.1$  kg) adapted to ultra-long-acting basal insulin initially conducted an incremental exercise test (IET) to determine maximal power output ( $P_{max}$ ) and the first (LTP1) and second (LTP2) lactate turn point. Then they performed short HIIE and CE matched for mean load ( $P_{mean}$ ) and duration (30 min) at three different mean loads: 5 % of  $P_{max}$  below PLTP1 (A), 5 % of  $P_{max}$  above PLTP1 (B), and 5 % of  $P_{max}$  below PLTP2 (C). In HIIE, peak workload ( $P_{peak}$ ) was  $P_{max}$  from IET, peak workload duration ( $t_{peak}$ ) was 20 s, and recovery duration ( $t_{rec}$ ) was 120 s for A, 60 s for B, and 20 s for C. Recovery load ( $P_{rec}$ ) was calculated. Blood lactate concentration (La), heart rate (HR), and gas exchange parameters were measured. Insulin and bread units were adapted according to standard guidelines. For comparison between CE and HIIE, a paired t-test was used. **Results** Mean values for La and respiratory exchange ratio (RER) were significantly higher in HIIE compared to CE ( $P < 0.05$ ) in A (La:  $1.67 \pm 0.50$  vs.  $0.96 \pm 0.41$  mmol/l; RER:  $0.92 \pm 0.03$  vs.  $0.87 \pm 0.03$ ) and B (La:  $2.08 \pm 0.64$  vs.  $1.33 \pm 0.48$  mmol/l; RER:  $0.93 \pm 0.03$  vs.  $0.89 \pm 0.03$ ) but not in C (La:  $4.93 \pm 1.80$  vs.  $4.75 \pm 1.53$  mmol/l; RER:  $0.94 \pm 0.03$  vs.  $0.93 \pm 0.03$ ). In each test, a La steady state was found. There were no significant differences between HIIE and CE at all mean intensities for average HR (A:  $106.4 \pm 11.1$  vs.  $105.8 \pm 7.0$ ; B:  $117.5 \pm 9.3$  vs.  $120.2 \pm 7.6$ ; C:  $161.8 \pm 8.8$  vs.  $164.7 \pm 9.6$  b/min) and oxygen uptake (A:  $1.32 \pm 0.25$  vs.  $1.33 \pm 0.23$ ; B:  $1.59 \pm 0.29$  vs.  $1.61 \pm 0.35$ ; C:  $2.94 \pm 0.40$  vs.  $3.01 \pm 0.40$  L/min). All subjects were euglycemic before, during, and after all tests. **Discussion** Despite markedly higher  $P_{peak}$  in short HIIE, this exercise mode gave similar acute physiological responses compared to moderate  $P_{mean}$ -matched CE, particularly for high mean load (C). The similar RER values in HIIE vs. CE for C suggest that the overall response is the same for short HIIE and CE although markedly higher peak workloads in the intervals. Acute responses and training adaptations induced by HIIE applying different peaks vs. CE have to be investigated in further mechanistic and randomized controlled training studies. ## BIOCHEMICAL ASSESSMENT OF MUSCLE DAMAGE AFTER MOUNTAIN TRAIL RACES

Cadefau, J.1,3, Carmona, G.1, Roca, E.2, Guerrero, M.3, Illera, V.1, Bedini, J.I.4, Cussó, R.3

*1:INEFC-UB (Barcelona); 2:University of Girona (Girona); 3:Dep. Physiol. Sci. I, University of Barcelona (Barcelona); 4:Hospital Clínic (Barcelona)*

**Introduction** Mountain trail races (MTR), or >42km Mountain Ultramarathons (MUM); are competitive runs that involve a great cumulative elevation gain (Easthope et al., 2011). There is general agreement that MTR leads muscle damage, due to strenuous competitive conditions and the eccentric contractions during the downhill phases (Millet et al., 2012). This study aimed to test the effects of different distances in the induction of muscle damage. **Methods** One group ( $n=10$ ) of amateur trained men who ran a 35km MTR and another group ( $n=6$ ) of highly trained men who ran a 55km MUM volunteered for the study. Serum biomarkers of muscle damage, including CK, CK-MB, Mitochondrial-CK (Mt-CK), AST, ALT, cardiac troponin I (cTnI) and slow myosin (SM) and fast myosin (FM) isoforms were assessed before (pre), 1 hour after finishing (post), and 24 and 48 hours after the beginning of the races. A repeated measures analysis of covariance (ANCOVA) was done, including training hours per week as covariate. **Results** CK, CK-MB, Mt-CK and AST activity of both groups showed significant increases ( $p < 0.01$ ), peaking between 24h – 48h. The response was much higher in the 55km group than in the 35km group, for CK (164%) at 1h post, and for CK-MB (251% and 147%) at 1h and 24h respectively. Increases of CK, CK-MB and AST registered 1h after the competition, were correlated to SM serum values obtained at 24h. SM was significantly increased at every time point analysed following competition for the 55km group, with a peak at 48h; but no significant changes from baseline were seen in the 35km group. FM showed no significant changes from baseline values in both groups; however, values were significantly higher in the 55km group throughout the experimental period, even at the pre value. A significant cTnI peak was found in the 55km group at 1h post, returning to baseline values at 24h. No significant changes were seen in the cTnI for the 35km group at any time point. **Discussion** Distance was the main determinant of SM release, signifying sarcomere damage of slow fibres following a MUM, even when highly trained athletes perform it. SM serum first changes obtained at 24 hours were correlated to CK, CK-MB and AST activities registered 1h post competitions. cTnI was only significantly elevated following the 55km MUM. **References** Easthope CS, Hausswirth C, Louis J, Lepers R, Vercruyssen F, Brisswalter J. ## ASSOCIATION BETWEEN RIGHT VENTRICULAR METABOLISM AND EXERCISE CAPACITY IN HEALTHY MIDDLE-AGED MEN

Leskinen, T., Heiskanen, M.A., Eskelinen, J.J., Hakala, J., Pärkkä, J., Heinonen, I., Hannukainen, J.C., Kalliokoski, K.K.

*University of Turku*

**Introduction** Previous cross-sectional studies have shown that athletes with high exercise capacity have lower insulin-stimulated left ventricular (LV) glucose uptake (GU) yet rather similar LV free fatty acid uptake (FFAU) compared to sedentary individuals (Nuutila et al. 1994, Takala et al. 1999a, Takala et al. 1999b). However, it is not known whether also right ventricular (RV) metabolism is similarly related to exercise capacity. Here we aimed to study the association between RV metabolism and exercise capacity in healthy sedentary middle-aged men. **Methods** Overall 28 healthy, previously sedentary middle-aged men were recruited for the study (age 40 to 55 years, mean BMI  $26.1$  kg/m<sup>2</sup>). A maximal-graded exercise test with direct respiratory measurements was performed on a bicycle ergometer. The RV

GU was measured using FDG-PET during euglycemic hyperinsulinemic clamp, and RV FFAU was determined by FTHA-PET. Structural and functional parameters were determined by cardiac magnetic resonance (CMR). Results The mean VO<sub>2</sub>max for the study subjects was 34 ml/kg/min (95% CI 33,36), mean RV GU during clamp 12 μmol/100g/min (11,14), and the mean RV FFAU at rest 1.7 μmol/100g/min (1.5,1.9). CMR-assessed mean RV end-diastolic volume (EDV) for the study subjects was 170 ml (159,180), mean RV end-systolic volume (ESV) 66 ml (59,73), and mean RV ejection fraction (EF) 62% (59,64). RV GU correlated negatively with age ( $r=-0.43$ ,  $p=0.03$ ) but not significantly with VO<sub>2</sub>max, RV FFAU, BMI, RV EDV, RV ESV, or RV EF%. RV FFAU correlated positively with HR<sub>rest</sub> ( $r=0.44$ ,  $p=0.03$ ), RV EF% ( $r=0.51$ ,  $p=0.02$ ) and negatively with RV ESV ( $r=-0.46$ ,  $p=0.03$ ) and VO<sub>2</sub>max ( $r=-0.44$ ,  $p=0.03$ ). Discussion Our results show that resting RV FFAU, rather than RV GU, correlates negatively to exercise capacity in sedentary middle-aged men. This adds to previous findings of lower LV GU and similar LV FFAU in trained compared to sedentary subjects. However, more confirmatory studies including exercise interventions in sedentary subjects are needed to better clarify the real training effects on RV glucose and fat metabolism. ### EFFECTS OF HIGH-INTENSITY INTERVAL TRAINING ON THE RIGHT VENTRICULAR GLUCOSE AND FATTY ACID METABOLISM IN HEALTHY MIDDLE-AGED MEN

Heiskanen, M.A., Leskinen, T., Eskelinen, J.J., Hakala, J., Pärkkä, J., Heinonen, I., Hannukainen, J.C., Kalliokoski, K.K.  
*University of Turku*

Introduction The adaptations to exercise training in the heart have mostly been studied regarding the left ventricle (LV) and the effects on right ventricle (RV) are incompletely known. A recent meta-analysis showed that in prolonged intense exercise, especially the right ventricular function is compromised while the left ventricle remains relatively unaffected (Elliott & La Gerche, 2014), underlining the need to study RV adaptations to exercise. We compared the effects of short-term high-intensity interval training (HIT) and moderate-intensity training (MIT) on right ventricular glucose and fatty acid metabolism and function in healthy middle-aged men. Methods Twenty-eight untrained, lean and healthy men of age 40-55 years were randomized into HIT ( $n = 14$ ) and MIT ( $n = 14$ ) groups. Both groups had six training sessions within two weeks. Within a session HIT group performed 4-6 x 30 s "all out" cycling effort with 4 min recovery between bouts (Burgomaster et al, 2005) and MIT group cycled for 40-60 min at 60% VO<sub>2</sub>max. Glucose uptake (GU) of the free wall of the RV was measured using FDG-PET (during euglycemic hyperinsulinemic clamp) and free fatty acid uptake (FFAU) was measured with FTHA-PET (without clamp) before and after the training intervention. Cardiac MRI was performed to measure structural and functional parameters of RV. Results RV GU decreased ( $p=0.001$  for the training effect) after both HIT (-22 %) and AET (-15 %), but not statistically differently between the groups ( $p=0.6$  for the group\*training interaction). FFAU was not affected by training (HIT 0 %, MIT +1 %,  $p = 0.97$  for the training effect). Also RV ejection fraction (EF) and end-diastolic and end-systolic volumes (EDV and ESV) did not change significantly ( $p>0.05$  for the training effect). Discussion Correspondingly with the cross-sectional studies showing decreased insulin-stimulated glucose uptake in the left ventricle in the trained state (Takala et al 1999), also RV GU decreased by training and similarly between HIT and MIT. In line with our previous study (Hannukainen et al. 2007), we did not observe changes in FFAU neither by HIT or MIT. Also RV EF, RV EDV, and ESV remained unchanged after the training. The results suggest that in the RV glucose metabolism adapts to training first, thereafter possibly followed by structural and functional adaptations. ### EFFECTS OF UPHILL AND DOWNHILL WALKING ON THE DEGREE OF MUSCLE PAIN OF THE LOWER EXTREMITIES AFTER EXERCISE

Tamari, Y.1, Wada, T.1, Yoshida, N.1, Kremenec, M.J.2, Nishimura, K.3, Onodera, S.2

*1 Graduate school, kawasaki university of medical welfare, 2 Kawasaki university of medical welfare, 3 Hiroshima institute of technology*

Purpose: The purpose of this study was to clarify the effects of uphill and downhill walking on the degree of muscle soreness after exercise. Methods: The subjects were six healthy Japanese males (age: 22.2±1.8 years, height: 169.9±6.9 cm, weight: 65.0±8.1 kg, BMI: 22.6±3.3). Each subject signed an informed consent form. The subjects were holding the rest sitting position of five minutes. Then, the subjects walked on treadmills for 30 minutes (Walking speed: 3.0 km/h, the weight of the backpack: 15% of body weight). The exercise conditions were the uphill-condition (slope: 10%) and downhill-condition (slope: -10%). Measurement items were heart rate, oxygen uptake, blood pressure, Rate of Perceived Exertion (RPE) and rectal temperature. We carried out a measurement every 5 minutes from the time the subject started the exercise. Fatigue and muscle soreness of the lower extremities were measured before exercise and after exercise (immediately after, one day later, two days later, three days later, four days later and five days later). Measurement of fatigue and muscle soreness of the lower extremities was carried out using the visual analog scale. Results and Discussion: The weight of the backpack during exercise was 9.7±1.2 kg. Heart rate and oxygen uptake during the downhill-condition were significantly lower than the uphill-condition ( $p<0.05$ ). Systolic blood pressure, RPE and rectal temperature showed no significant differences between the two conditions. Diastolic blood pressure during the downhill-condition of exercise at 15 and 20 minutes were significantly lower than the uphill-condition ( $p<0.05$ ). Fatigue of the lower extremities showed no significant difference between the two conditions. Muscle soreness in the uphill and downhill-conditions appeared immediately after the end of the exercises. Muscle soreness in the uphill-condition disappeared after one day of exercise. On the other hand, muscle soreness in the downhill-condition disappeared after two days of exercise. Moreover, the degree of muscle soreness immediately after exercise in the downhill-condition was significantly higher than in the uphill-condition ( $p<0.05$ ). From these results one can say that it is necessary to ensure for more rest after downhill walking than for rest after uphill walking. Conclusion: Loss of muscle soreness during downhill walking was delayed as compared to uphill walking. Moreover, the degree of muscle soreness immediately after downhill walking was significantly higher as compared to the uphill walking.

### THE AEROBIC CAPACITY AND IT'S RELATIONSHIP WITH ANTHROPOMETRIC MEASUREMENTS AND HEART RATE RESERVE FOR SECOND STAGE STUDENT OF SPORT SCIENCE COLLEGE

Mathkor, F.

*college of physical education*

the purpose of this study was to estimate VO<sub>2</sub>max and it's relationship with anthropometric measurements and heart rate reserve for second stage student of sport sciences college to identify the role of the subjects in college and its impact to development the fitness

level. Methods :Two groups of seventeen Males and sixteen females university student at the second stage of sport college , thirty of them were completed the study, the characteristics of males (age  $21.4 \pm 1.57$  years; mass  $65.5 \pm 6.16$  kg;high  $176.8 \pm 5.97$ ) mean  $\pm$  s.d, and the characteristics of females,(age  $20.42 \pm 1.39$  years; mass  $60.42 \pm 2.63$  kg;high  $164.28 \pm 4.85$ ) mean  $\pm$  s.d. Measurements were made of VO<sub>2</sub>max, somatotype (SPE),heart rate reserve(HRR),body mass(BM), body fat(BF) and energy consumption by calorie(CAL).This study was performed according to the guidelines set by the single stage treadmill walking test is a sub maximal aerobic fitness test. Results :There are no significant differences between males and females in all the study variables except (BF) that found greater in females than in males at level ( $P < 0.05$ ). on the other hand positively correlated with both VO<sub>2</sub>max and CAL in female, However, VO<sub>2</sub>max was not correlated in female with another variables, but there are many positively correlated in this study between each of the SPE and (HRR ,BM,BF and CAL ). While VO<sub>2</sub>max positively correlated were found in male with HRR, however VO<sub>2</sub>max was not correlated in male with another variables, but there are many positively correlated in this study between SPE with (HRR and BM),and BM with BF. Conclusion: there were significant differences between male and female of BF measures .Furthermore, it has been identified that mesomorphy is positively correlated with level of ability. We found that VO<sub>2</sub>max related with the amount of calorie spending during the physical effort in female.

#### VARIABILITY OF HEART RATE OF ELITE ATHLETES AT THE VALSALVA TEST

Sukhov, S.

*National Anti-Doping Centre*

Introduction Vegetative nervous system (VNS) plays important role in regulation of adaptation to intensive physical load. One of the informative noninvasive methods of study of VNS is analysis of variability of heart rate at the Valsalva test (VHR at VT). This test is an integral indicator of sympathetic and parasympathetic mechanisms of the baroreflex. Goal of the study was to compare VHR at VT of elite athletes and young male non-athletes. Methods Twenty-five elite judoists (experimental group) and fifteen healthy young male non-athletes (control group) have been examined. VHR at VT was registered with use of hard- and software complex VNS-Spectrum The study protocol included a 65-second registration of ECG in supine position. A few seconds after the start of ECG recording a person took a breath and made an effort for 20 seconds maintaining the intra-lung pressure at the level of 40 mm Hg under the control of manometer. Valsalva coefficient was calculated at processing of the rhythmogram (ratio of R-Rmax interval after the test to the R-Rmin during the test). A normal finding should be above 1.7. Lower tolerable values are around 1.30-1.70. Results In athletes the Valsalva coefficient was  $1.83 \pm 0.06$  which corresponds to optimal status of VNS. The control group had the Valsalva coefficient of  $1.57 \pm 0.11$ . This value shows the necessity of improving the functional status of individuals in the control group. VHR at VT was higher in the experimental group that evidences to the better adaptation of athletes to the changing conditions of external and internal environment. Simplicity and quickness of the procedure makes this method quite useful for effective control of workout process. Conclusion Follow-up of the test results provides a correct assessment of variations of the body's functional status and its adaptation reserves. The test allows identifying among the athletes those with excess stress of regulatory systems and increased risk of adaptation failure.

#### RELATIONSHIP BETWEEN BONE MINERAL VALUES AND LEG ANAEROBIC POWER IN PROFESSIONAL WRESTLERS AND UNTRAINED MEN

Hu, M.

*Guangzhou Institute of Physical Education*

Introduction In human, the absolute lean mass of the lower extremities was linearly related to the peak and average power. However, little is known about the relation between anaerobic power and bone mineral values in professional wrestlers. Therefore, the purpose of the present study was to investigate the relation between bone mineral values and anaerobic power in professional wrestlers. Methods A total of 14 male wrestlers ( $22.9 \pm 3.4$  yr) and 11 untrained men ( $24.5 \pm 1.6$  yr) were studied cross-sectionally. A total body scan was performed using dual-energy X-ray absorptionmetry (QDR-Explorer, Hologic, USA) to determine total and regional body composition. A 30-s Wingate test was conducted to measure performance of peak and average power. Pearson's correlation was calculated to explore the association between anaerobic power and bone mineral values as well as lean mass for both legs. Results Compared to the untrained men, the wrestlers had greater leg lean mass, BMC and BMD, and lower fat percentage. The average power (W and  $W \cdot kg^{-1}$ ) in untrained men was significant lower than wrestlers (both  $p < 0.01$ ). Average power (W) was correlated with leg lean mass in both groups. Peak power and average power (W) were notably associated with leg BMC and BMD in wrestlers ( $r = 0.608-0.717$ ,  $p = 0.021-0.004$ ), but less significant in untrained men. Peak power and average power ( $W \cdot kg^{-1}$ ) were associated with leg BMD in wrestlers ( $r = 0.616$ ,  $p < 0.05$ ;  $r = 0.641$ ,  $p < 0.05$ , respectively), but not in the control group. The positive relation between peak power and average power ( $W \cdot kg^{-1}$ ) variables and leg BMC exhibited a reliable trend in the wrestlers. Discussion It was well documented that the absolute measure of leg maximal power was associated with BMC and BMD at different sites in the adolescent girls (Witzke and Snow, 1999). Previous study (Haydari et al., 2010) showed a positive relationship between femoral neck and trochanter BMC and BMD variables and anaerobic power (Sargent jump test) in professional jumpers. It was also reported that 300-m running speed correlated with BMC and BMD variables in young female handball players (Vicente-Rodriguez et al., 2004). In the present study, we found the professional wrestlers' anaerobic power positively associated with bone mineral values, especially BMD; The positive association between BMD and anaerobic power were exhibited not only in the absolute measure of power but also in the relative values. Hence, our data provided support for this notion, and further contribute to, existing observations showing that the wrestlers showed positive correlations between BMD and anaerobic power in the relative values. #### CONTROVERSIES IN ATHLETES ELECTROCARDIOGRAPHIC INTERPRETATION ACCORDING TO THE MAJOR GUIDELINES - THE SEATTLE CRITERIA AND THE RECOMMENDATIONS FOR INTERPRETATION OF 12-LEAD ECG IN THE ATHLETE, 2010

Stoian, I.M.1,2, Antonescu, S.3

*1. Prof.C.C.Iliescu" Cardiovascular Diseases Institute, Bucharest, Romania 2. National Institute of Sports Medicine, Bucharest, Romania \*\*\* Medical Centre, Prevention,Diagnosis, Bucharest, Romania*

Introduction. To measure the QTc interval in elite endurance athletes, and to compare the electrocardiographic interpretation according to the two major screening methods - The Seattle Criteria(2) and the Recommendations for Interpretation of 12-Lead Electrocardiogram in

the Athlete 2010.(1) Method. Preparticipation Screening: 347 highly trained athletes ( 285 M, 73 %) age  $21 \pm 3$ yo. Caucasians. Sports: rowing, canoeing. Clinical exam and personal/family history. 12 lead electrocardiogram(ECG). Each ECG was read according to the (A) the Seattle Criteria and (B) the Recommendations for Interpretation of 12-Lead Electrocardiogram in the Athlete. Long QTc (A):  $\geq 470$ ms(M),  $\geq 480$ ms(F); (B):  $\geq 440$ ms(M),  $\geq 460$ ms(F). Short QTc: (A)  $\leq 320$ ms; (B):  $\leq 380$ ms. Echocardiography (2D,Doppler, TDI). Cardiology exam and specific tests when required. Results: Height  $176.27 \pm 6.74$ cm; weight  $70.37 \pm 8.88$  kg; BMI  $1.59 \pm 0.15$ . Long QTc interval 2010 Recommendations ( $\geq 440$ ms) vs  $\geq$  Seattle ( $\geq 470$ ms): 9c vs 5c. Short QTc interval 2010 Recommendations ( $\leq 380$ ms) vs Seattle ( $\leq 380$  ms): 53c vs 13c. Discussion. According to (A) and (B), 80 athletes had abnormal QTc interval. The most frequent abnormalitie was the short QTc int (66 cases) from which, 53, were diagnosed by the 2010 Recommendations (QTc  $\leq 380$ ms). The cardiac evaluation performed in all athletes, revealed only one athlete with congenital short QT syndrome. References 1. Corrado D, et al. ## ATTITUDES & PRACTICES OF RECOVERY IN ASIAN YOUTH ATHLETES

Murray, A.1,2, Sproule, J.2, Turner, A.P.2

1 Aspire Academy, Doha, Qatar. 2 University of Edinburgh, Edinburgh, UK.

Introduction Exercise adaptations to training and recovery have been extensively studied in adults. Studies in youth populations are limited for ethical and practical reasons. Furthermore, sports academies have developed to provide full time coaching structures to developing athletes. Recovery practices in youth athletes across the world are often influenced heavily by coaches and their experiences of training adults or imparting adult practices upon youths. Therefore, the purpose of this study was to establish current practice and attitudes towards recovery in youth athletes. Methods Athletes were surveyed during participation in an Asian Olympic Youth Athletics Camp (n=48) or within their training environment at the Aspire Academy (n=41). A comparative sample of athletes of similar ages in the UK was made via email (n=53). Athlete's ages ranged from 13-18 years with 86% male across the groups. An online questionnaire was conducted with the three groups to assess practice and attitude to recovery. Results Athletes in Asia and the UK believe sleep and nutrition to be the most important recovery factors compared to contrast, active recovery, ice and compression. Attitudes towards recovery differed between athletes in Asia and the UK with the respect to the perceived benefits of sleep (88% believe in it in the UK v 67% in Asia, X2 16.5, p<0.01, ES=0.9), nutrition (92 v 58%, X2 19.0, p<0.01, ES=0.66), active recovery (70 v 51%, X2 5.09, p=0.02, ES=0.28) and compression (43 v 25%, X2 5.0, p=0.02, ES=0.46). The number of recovery techniques used with Asian athletes is higher after training (ES=0.5) and competition (ES=1.49). There is no increased use of technology to measure recovery in either the Asian or UK groups (X2 0.74, p=0.39). An analysis of open answers suggests Asian athletes rely more on 'feel' to justify recovery. Cluster analysis of the combination of techniques suggests that recovery attitudes can be clustered into 4 main groups at a similarity level of 50%. These can be summarised as; Traditional (where using active recovery, nutrition & sleep predominate), Intervention-based (stretching, cold & compression), Nutrition-based (stretch & nutrition) and Basic (sleep & active recovery). Within Asia, the Traditional approach dominates (76%) whereas in the UK Nutrition-based (38%) just exceeds Traditional (34%; X2 28.0, p<0.01). The reasons why these groups do what they do differs (X2 8.5, p=0.01) with 49% favouring experience in Asia and 60% in the UK favouring a combination of evidence and experience. Analysis of the open answers suggests behaviour in Asia is ruled by what the coach says and in the UK by educated self-decision. Discussion There are different beliefs in the benefits of sleep, nutrition, active recovery and compression but it seems that youth athletes still favour active recovery, nutrition and sleep. They may do this for different reasons as coaches seem to dictate to athletes more in Asia. This suggests there is a need to understand the evidence base for current recovery practices in a youth population.

## CLINICAL EFFECTS OF TRIATHLON EVENT ON CARDIAC BIOMARKERS

Kwak, Y.

DONG-EUI UNIV

The purpose of the present study was to investigate cardiac damage biomarkers after a triathlon race in elite and non-elite athlete groups. Fifteen healthy men participated in the study. Based on performance, they were divided in elite athlete group (EG: n= 7) and non-elite athlete group (NEG: n= 8). Participants blood samples were obtained in four periods: before, immediately, 2 hours and 7 days after finishing the race. Creatine kinase (CK), creatine kinase-myoglobin (CK-MB), myoglobin, and lactate dehydrogenase (LDH) were significantly increased in both groups immediately, and 2 hours after finishing the race (p<.05). CK, CK-MB, and myoglobin were completely recovered after 7days (p<0.05). Hematocrit was significantly decreased in both groups (p<0.05) 7 days after the race. LDH was significantly decreased in the EG (p<0.05) only 7 days after the race. Although cardiac troponin T(cTnT) was significantly increased in the EG but not in the NEG 2hours after the race (p<.05), there was no group-by-time interaction. cTnT was completely recovered in both groups 7 days after the race. In conclusion, cardiac damage occurs during a triathlon race and, is greater in elite than in non-elite. However, all cardiac damage markers return to normal range within 1 week.

## FORCE PRODUCTION AND COINCIDENT TIMING ACCURACY DURING RAPID GRIPPING AT DIFFERENT TARGET VELOCITIES IN BALL GAME PLAYERS

Ohta, Y.

Aichi Shukutoku University

Introduction Many ball game sports require precise rapid force production and accurate timing to hit or catch an oncoming target. This study aimed to clarify the accuracy of force production and coincident timing during rapid gripping at different oncoming target velocities of ball game players and non-players. Methods Twenty young adults (12 ball game players and 8 non-players) participated in this study. The participants performed rapid gripping to coincide with the arrival of a moving target using a horizontal electronic trackway (length, 4 m). The target moved at a constant velocity, and three different velocities (4 m/s, 8 m/s, and 12 m/s) were randomly produced. The grip

force required was 30% of the maximal voluntary contraction (MVC). The peak grip force (PF) and time to peak force (TP) were measured. The two types of errors observed in the force and timing were analysed to evaluate the accuracy of force production and coincident timing. A constant error (CE) of force and timing was obtained by subtracting the PF from the target force (30% MVC) and the target arrival time from the TP, respectively. An absolute error (AE) was obtained from the absolute values of the differences between the PF and target force and between the target arrival time and TP. Results The CE and AE of both timing and force were increased in both groups with an increase in the target velocity, and the values for ball game players in both instances were significantly smaller than they were for non-players. Discussion The CE of timing values indicated that a delay in the timing of peak force production compared to the arrival of the target was increased with increasing target velocity in both groups. The AE in timing values suggested that the coincident timing accuracy was reduced with increasing target velocity in both groups. In force production, the CE value indicated that the degree of greater gripping than target force (30 % MVC) was increased with increasing target velocity. Further, the result of the AE in force suggested that the force production accuracy decreased with increasing target velocity in both groups. However, these errors of force and timing were smaller in ball game players than in non-players. Therefore, the results of the present study suggest that the accuracy of force production and coincident timing during rapid gripping was higher in ball game players than it was in non-players.

### THE IMPACT OF TRAINING IN NATURAL HYPOXIA ON TOTAL HAEMOGLOBIN MASS IN MALE CYCLISTS

Malczewska-Lenczowska, J., Sitkowski, D., Orysiak, J., Pokrywka, A., Szczepanska, B.

*Institute of Sport, Warsaw, Poland*

**Introduction** Conventional altitude training may increase in tHb-mass although the reported results are inconclusive and, moreover, not much is known about the persistence of tHb-mass after descending from altitude. The aim of this study was thus to examine the impact of classical altitude training camp on tHb-mass and to evaluate its stability throughout the following 3 weeks at the sea level. **Material and Methods** Six male road cyclists (age: 20.0±2.23 years, height: 184±9 cm, body mass: 71.5±8.36 kg) participated in the study. All cyclists resided at 1920 m and trained at about 1600-2300 m above the sea level for 20 days. The tHb-mass was determined by optimised CO-rebreathing method. Haemoglobin concentration (Hb) and hematocrit (Ht) were measured and plasma volumes (PV) were computed. The concentrations erythropoietin (EPO) and hypoxia-inducible factor 1alpha (HIF-1alpha) were assayed in serum. All measurements were done at baseline, on the last day of training camp, as well as twice thereafter – in the 2nd and 4th weeks. Additionally, EPO and HIF-1alpha concentrations were measured twice during the training camp – in the first and second weeks. Changes in mean values of all those indices were expressed as differences vs. baseline values ( $\Delta\%$ ). All data were subjected to ANOVA with repeated measures followed by post-hoc LSD test, the level of  $p < 0.05$  being considered significant. **Results** Altitude training resulted in significant increases in tHb-mass and Hb concentrations, by 4.9% ( $p < 0.01$ ) and by 8.3% ( $p < 0.001$ ), respectively. After returning to the sea level, tHb-mass decreased slightly, but remained significantly elevated in the second week (by 2.9%;  $p < 0.05$ ) and 20-24 days post-camp (by 3.9%;  $p < 0.01$ ); Hb concentration decreased significantly in the fourth week after descending from altitude by 6% ( $p < 0.01$ ) with respect to the last day of the camp. Furthermore, significant increases in HIF-1alpha concentrations in the first ( $p < 0.01$ ) and in the second week of training camp ( $p < 0.05$ ) was noted; a nearly significant ( $p < 0.06$ ) increase in EPO concentrations was also observed but both HIF-1alpha and EPO concentrations decreased significantly ( $p < 0.05$ ) 20-24 days post-camp. There were no significant differences in PV, either during or after the training camp. **Conclusions** Training under natural hypoxia conditions brought about an activation of erythropoiesis that resulted in increased tHbmass. No significant changes in tHbmass were noted after descending from altitude; its level remained significantly higher during the 3 weeks post-camp. email: jadwiga.malczewska@insp.wa.wpl

### REPEATED SHORT-TERM EXPOSURES TO NORMOBARIC HYPOXIA DO NOT PREVENT ACUTE MOUNTAIN SICKNESS IN SUSCEPTIBLE INDIVIDUALS

Faulhaber, M., Pocecco, E., Gatterer, H., Duennwald, T., Burtcher, M.

*University Innsbruck*

**Introduction** Ascents to high altitude are associated with the risk of acute mountain sickness (AMS) (Netzer et al., 2013). Pre-acclimatization by repeated short-term exposures to normobaric hypoxia (7 x 1 hour at 4500 m) has been shown to reduce the severity of AMS during a subsequent exposure to normobaric hypoxia (Wille et al., 2012). However, recently the effects of pre-acclimatization in normobaric hypoxia were put into question (Fulco et al. 2013). Therefore, the present study tested the effects of pre-acclimatization in normobaric hypoxia on the prevalence and severity of AMS during a subsequent exposure to real high altitude in persons susceptible to AMS. **Methods** Thirty-two healthy persons, susceptible to AMS, participated in this study. Participants were randomly assigned to the hypoxia group (HG) or the control group (CG) before the pre-acclimatization program (7 passive 1-hour sessions within 7 consecutive days). The HG was exposed to a simulated altitude of 4,500 m (FIO<sub>2</sub> 12.6%) whereas the CG breathed sham hypoxia (normoxic air, FIO<sub>2</sub> 20.9%) during the sessions. After finishing the pre-acclimatization program, participants were exposed to real high altitude (Mönchsjoehut, Switzerland, 3650 m) for 45 hours. AMS (Lake Louise score) and resting ventilation (MetaLyzor, Cortex, Germany) were assessed before ascending to high altitude (baseline values) and during the high-altitude exposure (AMS after 3, 6, 9, 21, 30, and 45 hours; ventilation after 21 hours). Overall AMS incidence was compared by Chi-square-tests and a two-way ANOVA for repeated measurements was applied for the severity of AMS and resting ventilation. **Results** Overall AMS incidence was 59 % in the HG and 67 % in the CG respectively and did not differ between groups ( $p = 0.65$ ). There were no differences in AMS severity between groups (ANOVA interaction  $p = 0.76$ ). Changes in resting ventilation from baseline to high altitude tended to be more pronounced in the HG compared to the CG ( $+2.0 \pm 2.5$  l/min vs.  $+0.3 \pm 2.3$  l/min;  $p = 0.06$ ). **Discussion** The applied pre-acclimatization program seems to have resulted in moderate ventilatory adaptation. However, these adaptations did not prevent AMS during an exposure to real high altitude in AMS susceptible individuals. Further studies should investigate if a higher dose of normobaric hypoxia effectively prevents AMS during after a rapid ascent to high altitude. **References** Fulco CS, Beidleman BA, Muza SR. ## THE EFFECTS OF ARM WARMERS ON THERMAL AND METABOLIC RESPONSES WHILE RUNNING IN A COLD ENVIRONMENT.

Ito, R., Yamashita, N., Matsumoto, T.

*NIHON FUKUSHI UNIVERSITY*

**Introduction** Individuals who exercise outdoors (e.g., participate in soccer, rugby, marathons) in winter can expose themselves to cold conditions and cooling of the body may result. Cold exposure often produces detrimental effects on physiological responses and exercise performance. In recent marathons held in winter, many runners have worn arm warmers as a measure against the cold. Tight-fitting 100% polyester sleeves worn over the arm have been believed to prevent heat loss from the body to the surrounding environment and to provide thermal comfort. **Purpose** The purpose of this study was to investigate the effects of arm insulation on physiological responses during exercise in the cold. We hypothesized that arm insulation would suppress decreases in body temperature and improve cold strain during sustained exercise. **Methods** Seven healthy men (mean ( $\pm$  standard deviation) age,  $22.4 \pm 3.9$  years; height,  $170.6 \pm 6.5$  cm; mass,  $66.9 \pm 8.1$  kg;  $VO_{2max}$ ,  $52.3 \pm 4.79$  mL/kg/min) who were non-smokers and not currently taking medication participated in this study. Participants rested for 5 min and exercised on a treadmill at 70% $VO_{2max}$  intensity for 30 min wearing the arm warmer (ARM) or not (CON) at 5°C and 40% relative humidity. Head wind equal to running speed was blown on the participant during exercise. Trials were randomly assigned and balanced for order. **Results** Rectal temperature was significantly higher in ARM than in CON at 5 min ( $p < 0.05$ ). Mean weighted skin temperature was significantly higher in ARM than in CON from 15 to 30 min ( $p < 0.05$ ). Upper arm temperature was significantly higher in ARM than in CON from 15 to 30 min ( $p < 0.05$ ). Chest, thigh and calf temperatures as well as oxygen consumption and heart rate did not differ significantly between groups. Plasma lactate and plasma norepinephrine levels were significantly lower in ARM than in CON at 10 min ( $p < 0.05$ ). Thermal sensation was significantly higher in ARM than in CON at 0 min ( $p < 0.05$ ). Plasma glucose, plasma epinephrine, serum triglyceride and serum free fatty acid levels were not significantly different between conditions. **Discussion** The higher rectal temperature and thermal sensation and lower plasma norepinephrine levels indicate that the arm warmer suppressed heat loss during the early phase of exercise in the cold. In addition, attenuated sympathetic nerve activity might have suppressed plasma lactate levels by decreasing intermuscular glycogenolysis. **Conclusion** Arm warmers are effective against cold stress, particularly during the early phase of exercise.

## CHANGES IN CIRCULATING MICRORNA'S BETWEEN HIGH AND LOW RESPONDERS TO A 16-WK DIET AND EXERCISE WEIGHT LOSS INTERVENTION

Parr, E.B.1, Camera, D.M.1, Burke, L.M.1,2, Coffey, V.G.3, Hawley, J.A.1,4

*Australian Catholic University*

**Introduction** MicroRNAs (miRNAs) are small non-coding RNAs that regulate the expression of target mRNAs and proteins. Certain miRNAs can be released into the circulation (c-miRNAs) for transport to selected recipient cells and have been shown to be altered in response to acute exercise and chronic training (Flowers, Won & Fukuoka, 2015), as well as energy-restricted weight loss (Milagro et al., 2013) or surgery-induced weight loss (Ortega et al., 2013). The aim of this study was to determine the expression profile of selected c-miRNAs following a 16 week exercise and high dairy protein diet program in individuals who either lost a large (high responders; HiRes) versus a small (low responders; LoRes) amount of body mass (BM) post intervention. **Methods** From a data set of 89 male and female overweight/obese participants who completed the intervention (500 kcal energy restriction from diet [250 kcal] and exercise [250 kcal]), a subgroup of HiRes (>10% BM loss,  $-11.0 \pm 2.4$  kg,  $n=22$ ) and LoRes (<5%,  $-3.0 \pm 1.3$  kg,  $n=18$ ) were identified. RNA was extracted, quantified and reverse transcribed from fasted plasma samples collected pre and post intervention. Quantification of miRNA was performed on a customized 96-well miScript miRNA PCR Array (Qiagen). **Results** Loss of BM (8.0 kg) and fat mass (FM; 7.7 kg) was greater for HiRes than LoRes ( $P < 0.001$ ). Of the 13 c-miRNAs investigated, there was a higher baseline expression of miR-935 in LoRes compared HiRes ( $1.06 \pm 0.52$  vs  $0.72 \pm 0.35$ ;  $P=0.025$ , 95%CI: 0.044 – 0.633). The miR223 increased post intervention in HiRes only (Pre:  $0.88 \pm 0.89$  vs Post:  $1.67 \pm 1.48$ ;  $P=0.041$ ). There were no post-intervention changes in the other c-miRNA's measured in either groups. **Discussion** This is the first study to quantify the expression profile of selected c-miRNA's following a combined diet and exercise intervention to achieve BM loss. The higher baseline expression of miR-935 in LoRes supports previous findings from a diet-only intervention (Milagro et al., 2013) suggesting miR-935 may be an important baseline prognostic biomarker for assessing individual responsiveness to energy restricted dietary and exercise-induced weight loss. Further, the selective increase in miR-223 expression in HiRes suggests it may regulate putative downstream targets that positively influence weight loss with diet and exercise. **References** Flowers E, Won GY, Fukuoka Y. ## TCD4+ LYMPHOCYTE ARE RELATED TO MUSCLE STRENGTH PARAMETERS IN HIV-1 POSITIVE ADOLESCENTS

Ornellas, F., Bacurau, R.F.P., Negra, M.D., Lancellotti, C.L.P.

*Federal University of Sao Paulo-UNIFESP/EPM*

**Introduction:** Catabolism of muscle and loss of function are complications that can occur during the course of Human Immunodeficiency Virus-type 1 (HIV-1) infection and are commonly seen in a majority of adolescents with vertically transmitted HIV. The levels of CD4+ and CD8+ lymphocytes, reference markers for the treatment of vertically transmitted HIV-1, also decline as the disease progresses. Alterations of these reference markers may be associated with neuromuscular force parameters in sedentary adolescents that have potential as prognostic indicators for treatment administration. **Objective:** To investigate the relationship between maximal isometric muscular contraction force and levels of CD4+ and CD8+ lymphocytes in sedentary, vertically transmitted HIV-1 positive adolescents. **Methods:** The sample consisted of twenty adolescents (N= 9 males, 11 females, age 15-17 years) with vertically transmitted HIV-1. All patients were from the Institute of Infectious Diseases Emilio Ribas in São Paulo, Brazil undergoing HAART therapy and were randomly selected to participate in the study. The number of CD4+ and CD8+ cells was determined by flow cytometry using BD FACS Calibur Multitest Equipment, and Multiset-BD software. Viral load was determined using b-DNA methodology, on Siemens System Versatil 440 equipment. All analyses followed standard procedures approved by the Brazilian Ministry of Health. Muscular strength measurements were completed in the morning after blood collection along with weight and height measurements. Prior to starting, patients were familiarized with all testing procedures and strength exercises that were used for testing. After the warm up, maximum voluntary isometric muscular strength of the elbow flexors and knee extensors were assessed using an electric dynamometer (EMG210C, EMGLAB). Each patient made three attempts

with a rest interval of two minutes between trials. The highest isometric force and torque value were recorded and used for analyses. Results: Upper body force ( $r=0.70$ ,  $p=0.001$ ) and maximal torque ( $r=0.69$ ,  $p=0.001$ ) were significant correlated with CD4+ count. Similar observations between CD4+ count and lower body muscular force ( $r=0.62$ ,  $p=0.005$ ) and maximum torque ( $r=0.61$ ,  $p=0.007$ ) were also observed. CD8+ was not associated with any strength measures. Conclusion: CD4+ lymphocytes showed a strong correlation with force parameters in sedentary HIV-1 positive adolescents. Given that those individuals with higher TCD4+ counts showed a tendency towards manifesting higher muscle strength, this may be used as a predictor to indicate the level of physical capacity of patients and consequently help optimize treatment.

### SIX WEEKS OF HIGH-INTENSITY INTERVAL TRAINING REDUCES FAT MASS IN HEALTHY MALES

Guppy, F.M.1, Thatcher, R.2, Wallace, J.A.2

*1University of Brighton 2Aberystwyth University*

**Introduction** High-intensity interval training (HIIT) has been shown to improve numerous health parameters including improvements in body composition (Gillen et al., 2013; Terada et al., 2013; Hazell et al., 2014) as well as glucose tolerance and insulin sensitivity (Babraj et al., 2009). Creatine supplementation has been shown to play a role in improving body composition (Gualano et al., 2010). This study aims to examine the effects of a 6-week HIIT programme, both independent of and combined with creatine supplementation, on body composition. **Methods** Twenty-eight male participants ( $23.2 \pm 5.8$  y;  $1.78 \pm 0.10$  m;  $78.7 \pm 14.4$  kg;  $24.8 \pm 2.7$  kg/m<sup>2</sup>) made a single fasted visit to the laboratory, pre and post a 6-week HIIT and/or supplementation intervention, where they underwent a whole body DXA scan (Hologic Discovery A, Hologic Inc., Bedford, MA, USA). HIIT involved repeated 30-second sprints (4 in weeks 1 & 2, 5 in weeks 3 & 4 and 6 in weeks 5 & 6) with resistance set at 7.5% body mass. Supplementation involved 5 g/day of either Creatine Monohydrate (CreaPure, AlzChem, Trostberg, Germany) or Placebo (Microcrystalline Cellulose, Blackburn Distributions Ltd, Lancashire, UK). A factorial analysis of covariance (SPSS v20, an IBM Company, New York, USA), with baseline values used as a covariate was used, with data combined when no interaction effects between HIIT and Creatine was observed. **Results** HIIT caused significant reductions in sub-total (-5.85 -v- 0.75%  $p<0.05$ ), and lower limb (-6.80 -v- -1.34%  $p<0.05$ ), fat mass with no observed effects on lean mass compared with non-exercising controls. Creatine supplementation had no effect on body composition. **Discussion** This study supports the use of short duration high intensity interval training as a potent method of reducing fat mass. This coupled with metabolic adaptations seen in glucose tolerance and insulin sensitivity (Babraj et al., 2009) means that HIIT has potential clinical adaptations, however the optimum intervention protocol needs to be established. The lack of adaptation due to creatine supplementation suggests that interventions of greater than six weeks in duration are needed in order to induce changes in body composition. **References** Babraj J., Volvaard N., Keast C., Guppy F., Cotterell, G., Timmons, J. ## Psychology

### BRIEF GROUP INTERVENTIONS FOR YOUNG ATHLETES' PSYCHOLOGICAL FLEXIBILITY, RESILIENCE AND WELL-BEING

Lundqvist, C., Sjöström, M.

*The Swedish School of Sport and Health Sciences*

**Introduction/aim** To evaluate effects of brief group interventions (Mindfulness Acceptance Commitment (MAC; Gardner & Moore, 2007) and traditional sport psychology (goal-setting, arousal regulation, imagery, self-talk and concentration skills) on young athletes' psychological flexibility, resilience and well-being. **Method** All participants were studying at a national sports program for athletes in upper secondary school (Mean age = 16.7 ( $\pm .9$ ); 91% men). A total of 42 athletes completed the MAC intervention and 14 athletes completed the traditional sport psychology intervention. One baseline (BL) and one post-intervention (PI) assessment was performed with The Satisfaction of Life Scale (SWLS; Diener, Emmons, Larsen, & Griffin, 1985), the Acceptance and Action Scale (AAQ; Bond et al., 2011), the Mindfulness Attention Awareness Scale (MAAS; Brown & Ryan, 2003) and the Resilience Scale (RS; Wagnild, 2011). Both interventions included one seminar + one hour/week during five weeks with homework exercises. **Results** Significantly higher scores in the AAQ (Mean: BL = 13.12 ( $\pm 6.92$ ), PI = 15.22 ( $\pm 6.74$ ),  $t(40) = -2.79$ ,  $p<0.01$ ), lower scores in the MAAS (Mean: BL = 61.46 ( $\pm 12.86$ ), PI = 58.42 ( $\pm 11.99$ ),  $t(40) = 2.31$ ,  $p<0.03$ ) and RS (Mean: BL = 126.83 ( $\pm 17.49$ ), PI = 118.17 (23.76),  $t(41) = 2.86$ ,  $p<0.01$ ) but no significant differences in SWLS were displayed after the ACT intervention. The traditional sport psychology intervention showed no significant effects, which may also be a consequence of few participants in the sample. **Discussion** Results indicate positive effects of the brief group intervention of ACT on young athletes' psychological flexibility. Surprisingly, lower mindfulness and resilience scores were displayed which could indicate a true decrease but, considering methodological limitations with self-rate assessments, could also be a result of a higher awareness of thoughts and emotions among participants post- compared to pre-intervention. **References** Bond, F.W., et al., (2011). ### VALUES AND MOTIVATION IN HIGH PERFORMANCE ATHLETES

Galilea, B.1, Castillo, I.2, García-Merita, M.2, Soler, M.J.2, Balaguer, I.2

*consell catala de l'esport*

1: Unitat d'Esport i Salut. Consell Català de l'Esport (Spain) 2: Unidad de Investigación de Psicología del Deporte. University of Valencia (Spain) **Introduction** Values has been considered as having an impact on motivation (Schwartz, 1994) and their relation to motivational processes would provide insight on how human functioning can be optimised (Parks & Guay, 2009). In the sport context, these relationships have received scant attention. Among the few papers on the subject, Balaguer and her colleagues have studied the association between personal values and motivational orientations and regulations in young amateur athletes and have analysed gender differ-

ences in values and motivation (Balaguer, Castillo, Quested & Duda, 2013). In this research, the aim was to replicate the study of Balaguer et al. with high performance athletes. Methods A total of 139 high level Spanish athletes from different sports (52 men and 87 women) ranging in age from 14 to 20 years ( $M = 15.7 \pm 1.12$ ), participated in this study. All participants practice sport five days a week ( $M = 5.35 \pm 0.66$ ), for over four hours per day ( $M = 3.78 \pm 1.04$ ). Participants completed a questionnaire package tapping the variables of interest. Results The results of the regression analysis showed that ego orientation was negatively predicted by benevolence ( $\beta = -.28, p < .01$ ) and positively by hedonism ( $\beta = .19, p < .05$ ). Intrinsic motivation was negatively related to achievement values ( $\beta = -.25, p < .05$ ). Finally, external regulation was positively predicted by power ( $\beta = .26, p < .01$ ). Multivariate analysis of variance for each variable of interest indicated statistically significant differences between gender on benevolence, power, task orientation, ego orientation, intrinsic motivation and external regulation. Follow-up univariate analyses showed that women scored higher than men on benevolence, task orientation and intrinsic motivation; whereas men scored higher than women on power, ego orientation and external regulation. Discussion Results of this study with elite athletes are similar to those obtained with young amateur athletes in the research of Balaguer et al. (2013). These findings suggest that value systems can impact the meaning of and reasons for engagement in sporting pursuits. References Balaguer, I, Castillo, I, Quested, E, Duda, JL (2013). ### THE EFFECT OF GAME PERCEPTION ON PLAYERS' MULTIDIMENSIONAL PERFORMANCE WITH SPECIAL FOCUS OF TEAM IDENTIFICATION AND ENTITATIVITY MODERATING EFFECT

Guraj, K.

*University of Warsaw*

Introduction: The factors having the biggest impact on athletes' performance have been under discussion for several years if not decades. One of the most recent approaches puts the emphasis first on whether the game is perceived as a threat or a challenge which is then said to affect the other aspects of performance. The most thorough examination of this have been presented by Jones, Meijen et al. (2009) in the Theory of Challenge and Threat States in Athletes. However, it hasn't given much attention to the role of intra- and intergroup relations among the team players. The aim of this study is therefore to examine the effect of game perception (threat vs. challenge) on players' multidimensional performance and how much do variables such as group identification and entitativity modify that effect. Methods: A questionnaire study was conducted in a repeated measures design with 2 conditions included – control (at practice) and experimental (before the game). We examined responses from 22 male elite volleyball players from Polish first and second division. Variables assessed: entitativity, overall and specific skills perception, team identification, perceived control, collective self-efficacy, attitude towards the outcome of the game, perception of the game (threat vs. challenge) and mood. Results: Perceiving upcoming game as a threat was followed by a significant decrease in optimism towards the outcome of the competition as well as a decrease in the overall competence perception (specific skills perception decrease only on a level of a tendency). An increase in the level of pessimism towards the outcome was also observed. However, perceiving the game as a challenge had no influence on mentioned variables. Nonetheless, a statistical tendency to report higher energetic arousal and perceive emotions as helpful for performance followed the "challenge approach". Further analysis of the possible moderations showed only one significant relation – the level of team identification moderated the impact of "challenge approach" on perceiving the emotions as helpful for performance. Conclusion/Discussion: The study didn't show many group related moderating effects. However, the results seem to suggest that different ways of perceiving the competition affect different aspects of performance related variables. While "threat approach" is connected with the lack of confidence about having the means to win, "challenge approach" seems to have an impact only on physiological and physical aspects of performance. Therefore, further research on those connections and a deeper analysis of group-related variables impact is a must. Selected references: Cerin, E. (2003). *J. of Applied Sport Psych.*, 15, 223-238. ### A QUALITATIVE EXAMINATION OF MENTAL SKILLS IN ELITE REFEREES

Murakami, K., Hirata, D., Sato, S.

*Tokyo University of Science*

Introduction Sports umpires, referees and their assistants are responsible for ensuring that the competitive efforts of athletes take place within the rules of the game, and that match results are obtained fairly. Referees must continuously endure physical pressure; they should, however, also be willing to psychologically endure various stressors. As the best performance cannot be expected from athletes and coaches who are under a great deal of stress, referees are sometimes unable to demonstrate proper performance (Reilly and Eregson, 2006). One key factor in referees working to their capabilities in regard to performance is use of appropriate mental skills. The purpose of this study, therefore, is to investigate the mental skills of elite referees, and to drive home the impact of mental skills on performance. Methods Eight elite referees, representing four different sports (soccer, basketball, baseball, and tennis), served as participants. At the time of the interview, the average age of the participating referees was 39.1 years, with a range of 32 to 48 years. These referees had arbitrated sporting events at a top level for 10 to 24 years, with a mean of 16.3 years of refereeing experience. An interview guide, comprised of a series of open-ended and guided questions, was developed for this investigation. Qualitative interviews were between 35 and 60 minutes long, and were transcribed, coded, and analysed by three experienced qualitative researchers. Results Participants were asked the general question, "What mental skills helped you to succeed as an elite referee?" One hundred sixty-one raw data responses resulted from the answers to this question. These raw data responses were content analysed; the three researchers discussed and came to a consensus on the grouping of the raw data responses, transforming them into meaningful subcategories and larger groupings. This procedure resulted in 22 subthemes that were grouped into 20 higher-order themes; these were then summarized with seven overall mental skills categories: 1) emotional control, 2) communication, 3) resolute attitude and look, 4) concentration, 5) confidence, 6) decisive thinking, and 7) motivation. Discussion After an extensive review of the literature, we found that Weinberg and Richardson (2002) identified a number of psychological characteristics that are true of highly successful referees. Furthermore, mental skills that were used to achieve an optimal psychological state were identified. The qualitative results collected from our participants paralleled these results exactly. The information gathered from this work also provides insight into how we can better create mental skills training program for this population. Reference Reilly, T. and W. Eregson, 2006 *Special populations: The Referee and Assistant Referee.*

### **TIME AND BALL MOVEMENT ANTICIPATION AND ITS RELATIONSHIP WITH THE AFFECTIVITY OF SOME ARTISTIC SKILL ACCORDING TO SPECIALIZATION IN VOLLEYBALL**

Alagha, A.Y.H.

*Baghdad University-iraq*

The importance of the study lies in finding a relationship between time and ball movement anticipation as a mental ability with the affectivity of skill performance of some artistic skill according to players' specialization. Anticipation can be detected by using high accuracy programs that provide intensive data about the players any coach will need. The problem of the study lies in the lack of using psychological labs for measuring mental abilities including ball movement and time anticipation for volleyball players. These anticipation tests are considered very important in determining the time of response. Ball movement anticipation is also important in determining where the ball's path and to which player or position so as each player can benefit from it according to his specialization. The researcher used the descriptive method. The subjects were (40) elite Iraqi club players for volleyball specialization (setter, libero and spiker). The apparatuses used in the research were time and ball movement anticipation apparatuses as well as skill performance affectivity program analysis according to the players' specialization. The affectivity of play was detected through shooting (16) match for each team that is two matches for each team. Correlation relationships were used to identify the degree of correlation between tests. researcher recommended the following: Using these special tests to anticipate time and motion to measure skill performance of players according to their specializations. Using Vienna system to compare among players' specializations. Using the curriculum of the proposed training program and generalization it on all coaches to achieve better results.

### **FREQUENCY, INTENSITY AND DIRECTION OF ANXIETY AND ITS RELATIONSHIP TO GROUP COHESION IN A JUVENILE VOLLEYBALL TEAM**

Facco Stefanello, J., Paes, M.J., Berbetz, S.R., Fernandes, G.J., Machado, T.A.

*Federal University of Parana*

Introduction It is observed to be increasingly important group processes related to sports performance, among which stands out the group cohesion. The objective of this study was to analyze the relationship between the level of group cohesion and pre-competitive anxiety athletes of a volleyball team in the competitive situation. Methods The study included 12 volleyball athletes male, mean age  $16.33 \pm 0.65$  and practice time of  $1.29 \pm 0.89$ , one of the teams participating in the Final Phase of Paraná State School Games 2013. The Group Environment Questionnaire (GEQ) was validated for the Portuguese language, for evaluation of group cohesion level of the team. Already pre-competitive anxiety was assessed by Competitive State Anxiety Inventory (CSAI-2R). Results Significant correlations were found for the frequency ( $p = 0.02$   $r = 0.66$ ) and intensity ( $p = 0.04$   $r = 0.61$ ) anxiety only between the dimension of self-confidence and individual attraction dimension to the group-social (AI-S). Considering the direction of anxiety, it was observed that the somatic anxiety showed significant correlation of moderate intensity, with the integration of dimensions for the social group ( $p = 0.02$   $r = 0.67$ ) and individual attraction to the group -social ( $p = 0.03$  and  $r = 0.62$ ). Self-confidence, also correlated in a moderate way, with the integration of dimensions for the social group ( $p = 0.03$   $r = 0.61$ ) and individual attraction to the social group ( $p = 0.02$   $r = 0.67$ ). It was observed that the athletes experienced the symptoms of anxiety in a positive way and showed high levels of group cohesion, promoting their sport performance. Discussion The results corroborate the findings with amateur athletes of different individual and team sports (Fernandes et al., 2014), which also perceived the anxiety scales (cognitive, somatic and confidence) as facilitators of sports performance, suggesting a positive correlation between intensity and direction of anxiety (Lundqvist et al., 2011). Cohesion task-group reflects the degree to which group members work together to achieve common goals (Carron et al., 2002), which can be seen in the tactic of volleyball game, in which the actions for the construction of play depend on the joint efforts of the athletes. ### **THE RELATIONSHIP BETWEEN STRESS RESPONSE AND WEIGHT MANAGEMENT AMONG UNIVERSITY STUDENTS**

Ikeda, T.

*1 Nishikyushu University, 2 Fukuoka Prefectural University*

Introduction Compared to males, more female youths practice weight management (Ikeda & Ikeda, 2004). A slim body has long been an objective for many female youths (Ministry of Health, Labor & Welfare, 2001). There are however associated risks relating to physical and mental health, especially if the methods of controlling one's weight are too severe. The aim of the present study was therefore to investigate the relationship between stress response and weight management among university students. Methods The participants were 411 university students (males: 169, females: 242). All participants completed the Stress Response Scale consisting of 7 inferiority factors; Depression, Anxiety, Anger, Emotional instability, Social withdrawal, Physical fatigue, and Autonomic nervous system (Ozeki, 1990), and the European Health and Behavior Survey (Wardle & Steptoe, 1991) in its Japanese version (Tsuda et al., 2005). Results The results of the t-test showed a significant gender difference of approximately 5% in the sub-totals for mental ( $t = 2.5$ ) and physical ( $t = 2.6$ ) stress response, and for their inferiority factors: Depression ( $t = 3.5$ ), Anger ( $t = 2.4$ ) and Physical fatigue ( $t = 3.4$ ). Scores pertaining to females were consistently higher than those pertaining to males. In the chi-square test, the proportion of females managing their weight (75.3%) was significantly higher than the proportion of males (42.9%). In the two-way layout ANOVA with general linear modeling, there was no discernible relationship between weight management and exercise. In terms of the main effects, the group managing their weight showed a higher stress score in the Social withdrawal and Physical fatigue categories, and the group doing exercise showed a lower stress score in the sub-total of mental stress and its inferiority factors of Depression and Social withdrawal. Discussion The results of the present study were similar to those of previous studies on the high probability of a high stress response among female youths practicing weight management (Ozeki, 1999; Ikeda & Ikeda, 2004). Moreover, weight management was found to relate to Social withdrawal as a symptom of mental stress and to Physical fatigue as a symptom of physical stress. However, weight management through exercise was shown to reduce mental stress. These results demonstrate that weight management through exercise is the most beneficial method for

the mental and physical wellbeing of youths. References Ikeda, T. and Ikeda, T. (2004). J Nishi-Kyushu University & Saga Junior College, 34, 135-139. Ministry of Health, Labor & Welfare (2001). ### ATTITUDES TOWARDS PHYSICAL ACTIVITY OF ELEMENTARY AGE CHILDREN AFTER AN 8 WEEK AFTER-SCHOOL PROGRAM

Celeski, L., Flink, T.

*Gannon University*

**Introduction** Young children enjoy physical activity (PA) during play but often in today's society become increasingly sedentary as they age due to a variety of factors such as attitude toward PA. School settings have shown to be optimal environments to incorporate PA (Rickwood, 2013). This study examined if the environment of an after-school program was conducive to cause changes in attitudes towards PA. **Methods** The intervention consisted of an eight week after-school program in which 43 students (age=9.29±.67yrs) met three times per week for one hour to engage and self-regulate their activity level in various games and running activities aimed at increasing overall fitness with an emphasis on cardiovascular conditioning. Self-regulation and autonomy toward exercise has shown to be successful (Teixeira et al, 2012). A Subjective Exercise Experiences Scale (SEES) survey was also administered at the onset and culmination of the intervention (weeks 1 and 8) to assess positive attitudes, psychological distress and fatigue related to PA. Independent t-tests were used to analyze subscale outcomes pre vs. post intervention, male versus female, 3rd grade versus 4th grade and also individuals who ran laps at recess and those who did not. **Results** The responses for distress were significantly higher for girls than boys (17.42±4.68 vs 19.92±2.00 t=2.36, p=0.014). There was no significant difference in responses to the SEES for grade level (p>0.05) or recess lap participation (p>0.47). There was a non-significant increase in the fatigue (15.45±4.75 vs 16.53±4.60) and positive attitude (23.55±4.22 vs 25.24±2.91) subscales from pre to post of 6.94% and 7.23% respectively. **Discussion** At this level, there are many developmental differences between boys and girls (Kantsios, 2010). The subscale responses to distress indicated that male students showed a more favorable response to exercise than the females. In addition, there was no significant changes in any of the SEES subscales with the increase in PA. The lack of change in distress and fatigue subscales while significantly increasing PA over an eight week period may be an indication that the environment in the intervention was conducive to a positive experience for PA. **References** Allender S, Cowburn G, Foster C (2006). ### THE EFFECTS OF EIGHT WEEK AEROBIC EXERCISES ON MENTAL HEALTH AND SELF-ESTEEM OF TYPE 2 DIABETES MELLITUS

Mousavi Gilani, S.R., Jalili, A., Khazaei Feizabad, A.R., Nakhae, H., Ziaee, F.

*Zahedan University of Medical Sciences, Zahedan, IR, Iran.*

**THE EFFECTS OF EIGHT WEEK AEROBIC EXERCISES ON MENTAL HEALTH AND SELF-ESTEEM OF TYPE 2 DIABETES MELLITUS** **Introduction** Mental health and physical health are very closely tied together, and each can exert a significant effect on the other (Cohen and Shamus, 2009). Mental health is one of the most important general public health and government policy in recent years (Health, 2011). Type 2 diabetes mellitus is a disease that has seriously endangered the health of many people. This study aimed at investigating the effects of 8 week aerobic exercise on mental health, including the aspects of physical symptoms, anxiety and insomnia, social functioning and depression and also self-esteem in men with type 2 diabetes mellitus. **Methods** This clinical trial study was performed on forty six male with type 2 diabetes mellitus selected and classified randomly into experimental (n=23) and a control group (n=23). GHQ-28 and Rosenberg test were used before and after intervention to assess general health and self-esteem. The experimental group performed aerobic exercise 45 minutes at 60-70 percent of heart rate three times a week for 8 weeks, while the control group did not do any special extra activity then. **Inferential statistical**, such as the t-test in the form of independent samples, the Mann-Whitney test and Cronbach's Coefficient Alpha, were used to determine the reliability of the measuring tools. Differences at p<0.05 were considered significant. **Results** Statistical analysis showed that aerobic exercise had significant effects on mental health (P=0.020), subscales of physical symptoms (P<0.001), depression (p=0.044). It had no significant effect on subscales related to social functioning (P=0.207) and anxiety and insomnia (P=0.078). The dependent T-test showed a significant increase in the average scores of self-esteem in the experimental group (P<0.001). **Discussion** According to the results, aerobic training had a significant effect on the mental health and self-esteem of diabetics. So the results are in line with the findings offered by (Madden, 2013). Generally, we can conclude that physical exercises can be mentally beneficial for both healthy and sick people. Aerobic exercise is considered as an effective strategy and approach for improve mental health and self-esteem of the people with type 2 diabetes mellitus. **References** Cohen G, Shamus E. (2009). ### DOES PHYSICAL ACTIVITY CONTRIBUTE TO A DECREASE IN LONELINESS? A SYSTEMATIC REVIEW

Pels, F., Kleinert, J.

*German Sport University Cologne*

**Introduction** It is a common presumption that being physically active in groups can reduce loneliness by enhancing social contacts. With regard to social contacts, the magnitude of loneliness depends on qualitative (e.g., social support) rather than quantitative (e.g., number of social contacts) relationship characteristics (De Jong Gierveld et al., 2006). Thus, when regarding the physical activity (pa) context, we hypothesize that only positively characterized pa group relationships reduce loneliness. To our knowledge, this effect has not been evaluated systematically prior to this work. Therefore, this work aims at providing an overview of the existing research on the relationship of loneliness and pa. **Methods** A systematic literature search was conducted in the databases SportDiscus, PsycInfo, PsycArticles and Psyn-dex. The search term loneliness was combined with each of the search terms physical activity, exercise and sport. Non-peer-reviewed articles and publications in languages other than English were excluded. A total of 27 studies were included in the review. **Results** The majority of the 27 studies addressed adolescent or elderly samples. Nineteen studies were cross-sectional, four longitudinal (two exam-

ining the influence of pa on loneliness, two examining the influence of loneliness on pa) and four intervention studies (examining the influence of pa-interventions in a group setting on loneliness). Eleven cross-sectional studies found a direct, negative association between pa and loneliness. Two cross-sectional studies investigating indirect relationships found social support and social competence to mediate this association. The longitudinal studies found a negative influence of loneliness on pa, but no influence of pa on loneliness. However, each of the intervention studies found pa to reduce loneliness. One of these indicated that the decrease in loneliness was related to a positive change in social support by the other pa course participants. Discussion Overall, the studies imply a potential loneliness-reducing effect of pa in a group setting. However, this seems to be dependent on the quality of personal relationships in pa groups. Therefore, exercise instructors should, for example, consider creating a socially supportive climate in order to reduce loneliness. Studies further suggest that loneliness itself might lead to a reduced probability of engaging in pa. This could be attributed to low volitional control for initiating pa due to high stress, as loneliness is a stressful experience (McHugh & Lawlor, 2013). ### COMPARISON OF EMOTIONAL INTELLIGENCE IN ATHLETES WITH DOPING HISTORY IN COMPARISON WITH GENERAL POPULATION

Same Siahkalroodi, L., Saeedi, A.R., Pourkazemi, L.A.

*Sport Medicine Federation of Iran*

Background: Regarding increasing and concerning worldwide trends of doping and lack of definite information about contributing factors in this era, this study was performed to determine the emotional intelligence in athletes with doping history in comparison with general population. Methods and materials: In this case-control study 30 subjects were enrolled including two groups of professional athletes with doping history and general population. In each group 15 subjects were present. The emotional intelligence was assessed by Bar-On Emotional Questionnaire. Results: The highest and lowest total scores in athletes group were 401 and 197 and in normal population group 410 and 243 were highest and lowest obtained scores and there was significant difference between total scores of two groups ( $P=0.001$ ), and also in some subscale items including stress tolerance, optimism, self-regard, impulse control, and assertiveness ( $P < 0.05$ ). Conclusions: Totally, according to the obtained results in this study, it may be concluded that there is significantly lower emotional intelligence in athletes with doping history in comparison with general population.

### COLLEGE FOOTBALL PLAYER'S COGNITIVE STRUCTURE OF TEAM TACTICS

Akihito, K., Hasegawa, N., Yao, N.

*National Defense Academy of Japan*

Introduction Team tactics is a very important factor in football games. It is also essential for coaches to grasp player's cognitive structure of team tactics. This study aims to develop a cognitive scale and demonstrate a structure of team tactics for college football players. Methods The study used a questionnaire answered by 310 male college Football players (age:  $19.9 \pm 1.2$  years, experience:  $12.4 \pm 2.9$  years). The questionnaire consisted of 44 questions about team tactics. The data collected was subjected to exploratory factor analysis, reliability analysis and confirmatory factor analysis by structural equation modeling. Results Five factors were extracted from the results using exploratory factor analysis. In the next exploratory factor analysis, the number of items of each factor is made equal, and each item was subordinated to each factor. The result also showed that each item had a factor loading amount over .40 and a simple structure. The Cronbach's  $\alpha$  of each factor was .76, .72, .67, .70 and .67, starting from factor 1. The fit coefficients by confirmatory factor analysis were sufficient (GFI=.945, CFI=.949, RMSEA=.049). All pass coefficients that observed variables from latent variables were significantly ( $p < .001$ ) and showed positive values more than a medium level (.48–.85). Discussion The factors extracted by exploratory factor analysis were called Understanding of the concept, Mastery, Importance, Difficulty and Emphasis of the result. We judged that the scale was sufficiently reliable, because the Cronbach's  $\alpha$  was over or near .70. The result of confirmatory factor analysis showed sufficient construct validity of the model, which comprised of 15 items of the five factors. College football player's cognitive structure of team tactics consisted five factors. The resulting scale had sufficient reliability and validity, and we provided suggestions about using this scale. ### GENERALIZED SELF-EFFICACY AND PHYSICAL ACTIVITY IN CHILDREN

Li, Y.C.1,2, Hay, J.3, Fought, B.3, Joshi, D.2, Cairney, J.1,2

*McMaster University*

1: Department of Kinesiology, McMaster University (Hamilton, Canada), 2: Infant and Child Health (INCH) Lab, Department of Family Medicine, McMaster University (Hamilton, Canada), 3: Faculty of Applied Health Sciences, Brock University (St. Catherine, Canada) Introduction Our understanding of the long-term relationship between self-efficacy and physical activity is limited. The purpose of this study was to investigate the effect of self-efficacy on sedentary behaviours and physical activity patterns in school-aged children over time. Methods 2278 10-year-old children (1120 girls and 1158 boys) were followed up seven waves from 2005 to 2008. All children completed two questionnaires in each wave measuring self-efficacy (adequacy, predilection, and enjoyment) and physical activity patterns (sedentary behaviours (SED), free play (FRE) and organized activity (ORG)), respectively (Hay, 1992). Mixed-effects models were used to estimate changes in physical activity and self-efficacy within individuals over time, controlling for gender and motor ability. Results A significant time effect was found in FRE and ORG, indicating that FRE increased and ORG decreased over time. There were significant time by adequacy and time by predilection interactions for both FRE and ORG. Although children with high adequacy had higher FRE relative to other children, this effect diminished over time. Children with high predilection also had higher ORG, but the gaps between groups widened over time. Significant time by predilection and time by enjoyment interactions were found in SED. While SED was lower over time in children with high prediction, it was consistently higher in children with high enjoyment. The differences in SED between groups increased over time for both predilection and enjoyment. Discussion This study found that higher self-efficacy is related to greater participation in physical activity (Cairney, et al., 2005), and that the impact of predilection increases over time, which either facilitates the participation in free play, or buffers the decrease in organized play and the increase in sedentary behaviours. However, adequacy seems to be more important in explaining differences in young children. Interestingly, children with higher enjoyment were more to be sedentary over time, suggesting enjoyment of physical education does not translate into increased physical activity. Overall, this study highlighted the im-

portance of different components of self-efficacy on physical activity patterns. In addition, in order to improve children's physical health, interventions targeting on the enhancement of predilection may facilitate physical activity and reduce sedentary behaviours. ### SWEDISH SWIMMERS' PERCEPTION OF PARENTAL INVOLVEMENT

Rodis, A.

*Lund University*

**Introduction** Parents play a critical role in children's sport involvement and throughout their sporting lives. Parental level of involvement can influence positively or negatively their children sport participation. Therefore, it is essential to explore the young swimming athletes' satisfaction in relation to parental level of involvement in their sport. The aim of this study was to investigate the style and the influence of perceived parental involvement on enjoyment and competitive anxiety in young Swedish swimmers. **Methods** Perceived parental involvement using the Parental Involvement in Sport Questionnaire (Wuerth et al., 2004), enjoyment (a questionnaire with 3 items that assess enjoyment in swimming) and competitive anxiety, SAS-2 (Smith et al., 2006) were assessed in 104 (61 female & male 43) Swedish swimmers, aged 9-18 years old (Mean age 13.7, SD 2.5). All participants were members of a swimming club at various competitive levels, spending an average of 10.5 months training for swimming per year. **Results** The athletes were satisfied with their parents' directive behavior and praise/understanding, but were slightly dissatisfied with their parents' level of active involvement and pressure. The negative discrepancy scores in active involvement and pressure revealed that athletes desire slightly more active involvement and pressure from their parents. A positive correlation was also found between perceived parental pressure and directive behavior. But, no correlations were found between athletes' perceived parental involvement and enjoyment or competitive anxiety. **Discussion** The young swimmers showed that they enjoyed their sport and were free of competitive anxiety in relation to their parents' involvement. Enjoyment can be decline when parents over-involved to their kids sport participation and young athletes have reported over-involved parents as a source of stress (Reeves et al., 2009) and most importantly, on contributing to kids burning out or dropping out of sport (Goodger et al., 2007). On the whole, young Swedish swimmers were satisfied with their parents' level of involvement in their sports, indicating the moderate and caring nature of Swedish parents in relation to the sport of swimming. **References** Goodger K, Gorely T, Lavalley D, Harwood C. (2007). *The Sport Psychologist*, 21, 127-151. Reeves, C. W, Nicholls A. R, McKenna J. (2009). *Journal of Applied Sport Psychology*, 21, 31-48. ### THE SUSTAINABILITY OF ACHIEVEMENT MOTIVATION IN YOUTH SPORT

Ingrell, J.

*Malmö University*

**Introduction** Participation in organized youth sport could be one context for identity development. For some athletes this could be one part in a multifaceted identity but for others (e.g. young high level athletes) the social organization of high-performance sports could cause burnout in athletes due to a lack of control and identity constrictions (Coakley, 1992). One social organization of high performance youth sport that has since mid-90's in Sweden grown in population is elementary sports schools. Further down the ages the demonstration of high competence and emphasis placed on sporting achievement could be essential and such pressure and/or expectations needs further investigation. The aim of this study is to examine the relationship among achievement goals, perceived competence and possible burnout components in (elite) adolescent-age athletes over time. **Methods** A longitudinal design based on three cohorts and on a convenience sample with youth athletes, age 13-14, from various team and individual sports, attending a sports school and regular elementary schools. The athletes will during a one year follow up respond to a number of questionnaires assessing achievement motivation and affective responses in youth sport. One cohort contains youth athletes who were selected to go to an elementary sports school in south of Sweden. The second cohort contains youth athletes who applied to that special elementary sports school but weren't selected. The third cohort contains youth athletes from an elementary school in a district that, by 40 socio-economical variables, could act as a "mini-town" regarding the town where the sports elementary school is located. **Structural equation modeling procedures** will be employed to evaluate the hypotheses. **Results** While the study is in the initial stage results have not yet emerged. However, some preliminary findings regarding the study will be presented and discussed during the conference. **Discussion** Results will be analyzed and discussed according to the purpose and the theoretical framework based on achievement goal theory in sport originated from Nicholls' (1989) two conceptions of ability (task and ego), Coakley's (1992) view on identity development in (elite) sport, and the multidimensional definition of athlete burnout (Raedeke & Smith, 2009). **References** Coakley, J. ### PERCEIVED EXERCISE BENEFITS FROM DIFFERENT AGE POPULATIONS

Ping-Kuei, C.

*University of Taipei*

**Introduction** Exercise participation nowadays has become people's regular habit in daily life. When doing exercise, most of the participants would gain psychological and physiological benefits such as a sense of well-being. Previous studies have emphasized that exercise in leisure time can play a significant part in enhancing the quality of life (Iso-Ahola, 1997). However, few studies have compared the differences in perceived exercise benefits among different age groups because different age populations might have different demands towards exercise. **Methods** Three participants representing different age populations, including a college student, a white collar, and a retired person, were recruited. Semi-structured interviews were conducted to collect data. **Results** The results found that all the three participants revealed a sense of well-being and social relationships were the best benefits of leisure-time exercise. Further, for the college student, exercise could meet the needs of seeking fun. For the white collar, participation in physical exercise was beneficial to mental and physical relaxation. For the retired person, physical and mental health was the first concern to engage in exercise. **Discussion** The findings indicated that different age groups would have different expected benefits they might want to obtain from physical exercise. For

different populations, exercise experience is particularly important for supporting well-being and building a meaningful life. Similar to previous research, participating in physical exercise can be helpful for an individual to gain benefits including the experience of happiness, positive emotion, and the development of one's full potential (Carruthers & Hood, 2007). Finally, professionals in exercise promotion are suggested to design different exercise programs that meet various demands of different age populations. ### **RELATIONSHIPS AMONG PERSONALITY TRAITS, COPING STRATEGIES, AND CAREER BARRIERS OF COLLEGE STUDENT-ATHLETES**

Huang, C.J., Ku, W.W., Wong, T.L.

*University of Taipei*

**Introduction** College student-athletes are expected to invest in the athlete and student role identities simultaneously. However, combining these two pursuits may limit their exploration of out-sport career options. Previous studies have reported that neurotic personality related to a negative perspective toward the life after retirement, while conscientious personality related to aspirational reasons for retirement (Robinson, Demetre, & Corney, 2010). Besides, coping strategies which can help individuals match the transition demands and individuals' resources are viewed as a key factor for successful transition (Stambulova, 2003). Little literature has previously linked the relationships between personality, coping strategies, and out-sport career barriers of college student-athletes. **Methods** This study recruited 356 junior and senior college student-athletes (224 males, 132 females, age = 21.21 years) to investigate the relationships between personality, coping strategies, and career barriers. Participants completed the Mini-Markers (a brief version of big-five markers), Career Coping Strategies Inventory, and Student-Athlete Career Situation Inventory-Career Barrier subscale. Multiple regression was conducted to examine the predictive effects of five personality sets and coping strategies on perceived barriers toward out-sport career explorations in college student-athletes. **Results** The multiple regression indicated that personality sets and coping strategies could totally accounted for 14.30% of the variance of career barriers ( $F(9,346) = 6.43, p < .05$ ). Particularly, emotional stability ( $\beta = -.18$ ) negatively predicted career barriers, whereas negative-emotional coping strategy ( $\beta = .26$ ) positively predicted career barriers. **Discussion** Consistent with previous research (Savickas, Briddick, & Watkins, 2002), the finding suggests that student-athletes who are low on emotional stability are more likely to perceive higher career barriers due to fewer career exploration behaviors. Those student-athletes who always deal with career difficulties using negative strategies, such as anger and avoidance, are more likely to face career barriers. This study supports the important relationships among personality, coping strategies and career barriers, indicating a close association between personal characteristics and career exploration behaviors in college athletes. Parents, coaches and guidance counselors might facilitate the career development of student-athletes by encouraging emotional stability and less usage of negative coping strategies, which could impact career-related behaviors, such as thinking about seeking knowledge and exploring career options. **References** Robinson OC, Demetre JD, Corney R. ### **SPORT ADDICTION AMONG HUNGARIAN UNIVERSITY STUDENTS**

Kiss-Geosits, B.

*University of West Hungary*

**Introduction** Recent decades saw thousands of research prove that the regular sport activity with adequate intensity and amount significantly contributes to maintaining one's health, while inactivity and the lack of fitness might fundamentally make one unhealthy. According to researchers, sport activities with sufficient quality and amount have a positive effect on the physical and mental health of adults as well as children and adolescents. When it comes to maintaining fitness and health, physical activity is the key factor along with dieting and nutrition. Nevertheless, sport can show that taking it too far may cause problems. **Method** Presently there are only few research on compulsive physical training and exercise addiction. These research mainly focus on running, aerobic sports and body building; only few deal with triathlon, dancing, weight lifting and other sports. For our study we looked for questionnaires that examine exercise addiction in general, define the psychic background, assess the ratio of physical activity, and do not concern any given kind of sport or form of motion. We used two questionnaires that met the criteria: Hausenblas and Downs' 21-item questionnaire, the Exercise Dependence, that uses the 7 scales consistent with the DSM-IV criteria: Tolerance; Withdrawal; Intention Effect (exercise is often taken in larger amounts or over a longer period than was intended); Lack of Control; Time (a great deal of time is spent in activities necessary to obtain exercise); Reductions in Other Activities (social, occupational or recreational activities are reduced); Continuance (exercise is continued despite knowledge of having a persistent or recurrent physical or psychological problem) The other questionnaire used is the Exercise Addiction Inventory, a short but very reliable and valid fill-out form. **Results** Surprisingly, the results gained by Griffiths and his peers showed that 3 % of the interviewees were addicted to exercising. Our study showed that 7,4 % of university students are highly, while 63 % are moderately addicted to physical exercise. According to international research, exercise dependence is more likely to manifest for men. Domestically, 4,9 % of men and 8,9 % of women are addicted in this regard. The detailed results of the 270-subject pool will be presented in the sports science conference. **References** Demetrovics Zsolt & Kurimay T (2008) - *Testedzsfüggőség: a sportolás mint addikció*, *Psychiatria Hungarica*, 23(2), 129-141. ### **THE PERFORMANCE OF MULTIPLE OBJECTS TRACKING OF BASEBALL ATHLETES IS BETTER THAN PEERS IN DIFFERENT OBJECT MOVING**

Wu, S.K., Chen, W.Y., Yang, H.H., Wu, S.Y., Chiang, C.H.

*National Taiwan University of Sport*

**Introduction** Attentively tracking multiple targets plays an important role for baseball athletes. Taking the outfielder as an example to avoid missing a flying ball, the experienced outfielder has to attentively track the ball, teammates and the base runner at the same time with the higher tracking accuracy. The present study was to investigate whether the baseball athletes have better performances of simul-

taneously tracking multiple objects than the peers. Method Thirty-nine elite collegiate baseball athletes ( $23.13 \pm 2.7$  y/o) and 39 undergraduate students ( $19.97 \pm 1.06$  y/o) were recruited. The multiple object tracking (MOT) task (Pylyshyn & Storm, 1988) was used to measure their ability of tracking multiple objects. In this task, participants were asked to simultaneously track three of eight objects, which independently and randomly wander about the screen for 4-5 seconds. In the end of each trial, participants reported which three objects were targets and the proportion of correct (%) was collected. If missing any target, the trial was marked as an error trial. Four different object-moving speeds (0.3, 0.6, 0.9, 1.2 deg/s) were manipulated in the study, and each speed conditions have 20 trials. To investigate the tracking performances between the baseball athletes and peers, a mixed designed repeated-measures ANOVA was conducted with speed as the within-subject independent variables and group as the between-subject independent variables. Result The proportion of correct for baseball athletes was significantly higher than their peers,  $F(1,76) = 4.69$ ,  $p = 0.033$ , and the main effect of speed was significant in proportion of correct,  $F(3,228) = 804.631$ ,  $p < 0.001$ . However, the interaction between groups and speeds was not significantly difference,  $F(3,228) = 0.036$ ,  $p = 0.991$ . Conclusion The result revealed that baseball athletes have a better performance of tracking multiple objects in most speed conditions than peers. This finding might provide the coach a useful information to improve the performance of baseball athletes or to select the potential elite baseball athletes. References: Pylyshyn Z, Storm R. (1988). *Spatial Vision*, 3(3), 179-197.

### **A COMPARATIVE STUDY OF THE IMPACT OF INDIVIDUAL AND GROUP SPORT ACTIVITIES ON THE MENTAL HEALTH OF CHAOXIAN NATIONALITY COLLEGE STUDENTS**

Hou, H.

*Minzu University of China*

Introduction Utilizing Mood Scale (BFS), this paper investigates the psychological impacts of selected individual and group sport activities among Chaoxian nationality college students, with a focus on the "instant" effect. The analysis provides theoretical support, methodological guidance, and new evidence for improving the mental health of Chaoxian nationality college students – and to a wider extent of ethnic minority students in general – through physical activities. Methods Based on an extensive literature review, the author designed and carried out an experiment among a sample of 135 Chaoxian nationality college students, utilizing Mood Scale (BFS) to measure psychological effects of individual and group sport activities. Examples of individual sport activities in this study include martial arts, aerobics, yoga, rope skipping, skating, and taekwondo. Examples of group activities include football, basketball, and volleyball. Data collected from the experiment was processed and analyzed by using statistical methods including T-test and covariance analysis. Results Results show that physical activities have positive effect on the mood status of Chaoxian nationality students. To be specific, individual sport activities have certain effect on the whole and relatively significant effect on female students; Group sport activities have negative effect on male students but positive effect on female students; Different sport activities have different psychological effects on college students of Chaoxian nationality. Discussion This paper is a primary attempt to study the differentiated effects of individual and group sport activities on the mental health of ethnic minority college students in China. Though its findings are exploratory in nature, the analysis further confirms the conclusion drawn from previous research: physical activities do influence mental health (e.g., Hou, 2012; Huang, 1997; Huang et al., 1995). If expanding the sample quantitatively and spatially in this study, it is very likely to attain more compelling evidence on the differentiated psychological effects of different physical activities among ethnic minority college students, providing theoretical foundation for China's national physical fitness program. ### **THE RELATIONSHIP BETWEEN MOOD STATE AND ARTISTIC GYMNASTICS COMPETITION RESULTS**

Boldizsár, D.1, Soós, I.2, Hamar, P.1

*University of Physical Education*

1Hungarian University of Physical Education, Budapest, 2University of Sunderland, UK Introduction A substantial number of investigations have highlighted that emotion is an inherent part of the competitive experience and influences performance (Beedie et al., 2000; Scott et al., 2002; van Wijk, 2011). The aim of this study was to examine the relationship between pre-competition mood state and gymnastics competition performance. Methods The Brunel Mood Scale (BRUMS) (Terry, Lane, Lane and Keohane, 1999; Terry, Lane and Fogarty, 2003) was filled out by 119 Hungarian gymnasts in 2013. Participants ranged in ability from international ( $n=20$ ), elite ( $n=43$ ) to second class ( $n=53$ ). Performance was determined based on the gymnastics competition score, and the final position. Results Of the investigated psychological factors, anger ( $r=0.231$ ,  $p=0.013$ ) tension ( $r=0.187$ ,  $p=0.045$ ) fatigue ( $r=0.258$ ,  $p=0.005$ ) were associated with the achieved result in the main event. Significant differences were found in the anger factor between groups. The international group showed significantly higher anger by the Post Hoc test. Discussion According to Pieter et al. (2006) athletes who have higher tension and anger before competition demonstrate decreased performance. In our study significant correlations were found between anger, fatigue and performance. According to Lane's (2002) findings, pre-competition anger and tension, on one hand, usually decrease individual performance. Higher achievement expectation of the international group results in higher levels of anger as opposed to the second class group that is related to the enhanced arousal requirement in elite performers. ### **ACL REHABILITATION: HOW TO SUPPORT HIGH MOTIVATION IN FOOTBALL PLAYERS AFTER INJURY AND SURGERY**

Vago, P., Danelon, F., Colombo, L., Casolo, F., Gatti, M.

*Catholic University, Milan / Isokinetic Rehab Centre, Milan*

Introduction Rehabilitation and full sport recovery after Anterior Cruciate Ligament (ACL) injury and reconstructive surgery need perseverance and willpower. The difficulties normally experienced by patients after injury can be overcome with high motivation during the recovery period (1, 2). The aim of this study was to explore which motivational factors were linked to a good compliance of a rehabilitation path, in order to better understand how professionals could support patients in coping with difficulties. Methods Five male football players

(aged 13 to 38 years) ranging from recreational to competitive athletes, previously undergone ACL surgical reconstruction followed by knee rehabilitation were recruited for this qualitative study. We conducted semi-structured interviews, specifically focusing on: 1) relationship with football 2) the injury 3) the recovery process with particular attention to surgery and rehabilitation. The interviews were conducted by a psychologist in the Rehabilitation Centre Isokinetic of Milan, in the winter months of 2014-15. We were interested in understanding their decision to opt for surgery, what information they had, what were their expectations. Moreover, we wanted to know how the rehabilitation period was. We applied a semi projective tool (fill in a graphic line that represents their feeling in the main steps of the path, starting from before the injury and arriving to the present). Results The injury was a different experience for the patients, in some cases it was described as a trauma, in other cases they did not appreciate its severity. They were quite worried about undergoing rehabilitation post- the surgery but their will to return to play football was the main helping factor. Finally, the football players reported this experience (the injury and the care process) as a very formative moment of their life which also helped with their self-esteem. Conclusion The interviews clearly show the importance of understanding the patient, his experience, his targets and his needs in order to provide better support during the rehabilitation process and achieve full recovery. A motivational speech before starting the rehabilitation process could be useful to better know the patient and his needs. References 1. Langford JL, Webster KE, Feller JA. ## THE RELATIONSHIP BETWEEN THE LEADERSHIP AND SELF-CONFIDENCE QUALITIES THE STUDENTS OF SPORT MANAGEMENT

Aldemir, G.Y., Bayram, A., Tanyeri, L., Bilir, G.S.

*Marmara University, Trakya University*

The relationship between the leadership and self-confidence qualities of the students of sport management. In order to examine on the leadership qualities, the sport with leadership scale, which had been improved by Chelladurai and Saleh in 1980, has been used. This scale has been adapted into Turkish by Toros and Tiryaki in 2011 and improved and validity and reliability tests have been carried out. The scale consist of five lowest stage. There are 40 clauses in the scale in total. In order to examine on the self-esteem qualities, the self-confidence scale, which had been improved by Coopersmith in 1967, has been used. This scale has been adapted into Turkish by Akin in 2007 and improved and validity and reliability tests have been carried out. The scale consist of two lowest stage. There are 33 clauses in the scale in total. Furthermore, face-to-face questionnaire method has been used and 189 students studying in different branches have been interviewed. After the questionnaires have been examined, the default ones were eliminated and 184 questionnaires have been subject to the analysis. Out of 184 students, 75 were female and 109 were male students. The reliability of the question prepared in accordance with the Likert scale, have been scaled with the Cronbach Alpha reliability scale. According to the analysis, the Cronbach Alpha rate has been found as 0,97 This rate is highly reliable. The leadership and self- confidence qualities scales of the students of sport management has been applied and in the light of the obtained data, the results have been evaluated and it has been determined that there is a significant relation between the lowest stages of leadership qualities and self- confidence qualities. The pearson correlation factor between democratic behavior low stage (,611), authoritarian behavior low stage (,029), social support low stage (,745), positive feedback low stage (,594), education and training low stage (,728) and inner self confidence low stage calculated. The pearson correlation factor between democratic behavior low stage (,633), authoritarian behavior low stage (,009), social support low stage (,741), positive feedback low stage (,616), education and training low stage (,703) and external self confidence low stage calculated.

## Rehabilitation and Physiotherapy

### DIFFERENCES IN KINESIOPHOBIA FOLLOWING TWO WEEK OF HOSPITAL-BASED CARDIAC REHABILITATION PROGRAM IN PATIENTS WITH CARDIOVASCULAR DISEASES

Brdak, M., Utykanski, H., Utykanska, A.

*Univesity of Physical Education*

Differences in kinesiophobia following two week of hospital-based cardiac rehabilitation program in patients with cardiovascular diseases Introduction Kinesiophobia is defined as irrational, weakening and devastating fear of movement stemming from the belief of fragility and susceptibility to injury (Kori et al. 1990). The key element of cardiac rehabilitation is the sufficient level of patient's physical activity – the element of Ideal Cardiovascular Health (Donald et al., 2010). Knowledge of psychological barriers in taking physical activity by patients and it's changes during cardiac rehabilitation are required to set the right education in prevention the cardiovascular diseases. Methods The study involved 39 people with cardiovascular diseases (23 female, 15 male, mean age 56.84 ± 7.89 years) participants of cardiac rehabilitation program. The program of rehabilitation include the physical exercises on the ergometers and health education episodes. The level of kinesiophobia at males and females was assessed twice, at the beginning and at the end of second week of rehabilitation program. A Polish version of Kinesiophobia Causes Scale questionnaire (Knapik et al 2012) was used. The scores of kinesiophobia were compared using the T-Student. The statistical significance was assumed at the level of p≤0.05. Results After two week of rehabilitation program, females achieved significant lower scores in all factors of kinesiophobia except morphological parameters where score was lower and the strength of biological drives where score was higher but the differences in those factors wasn't significant. Significant higher scores females achieved in the level of self – acceptance (p=0,016) and self – assessment of motor abilities (p=0,033). Males achieved significant lower scores in almost half of the factors of kinesiophobia: the level of energy resources (p=0,026), mood (p=0,011), susceptibility to social influence (p=0,021), biological domain (p=0,026) and general index of kinesiophobia (p=0,014). Only one factor have higher score , the level of biological drives but the difference wasn't significant. Discussion This study underline the differences in kinesiophobia between males and females at the beginning and at the end of cardiac rehabilitation program. Participation in physical exercises connected with educational episodes during cardiac rehabilitation program are enough factors to reduce most scores of kinesiophobia factors but the women are more sensitive on those influences than men. That suggest the rehabilitation program should be more individualized what is highlighted in The European Guidelines for prevention the cardiovascular diseases References Kori SH et al (1990) Pain Management, 3, 35-43 Donald M et al (2010) Circulation, 121, 586-613 Knapik A et al (2012) Med. Review of University In Rzeszow, 3, 277-287 European Association for Cardiovascular Prevention and Rehabilitation (2012) Polish Cardiology, 70, supl. I, S1-S100 Contact mbrdak@awf.poznan.pl

## EFFECTIVENESS OF TRAINING SQUAT IN THE NEUTRAL SPINE IN TREKKERS HAVING ANTERIOR PELVIC TILT AND KNEE PAIN

Cutlerywala, A.

*Rajiv Gandhi University of HealthSciences*

Background Knee pain is a very common sight among trekkers, increased with walking downhill. Walking downhill has shown to exaggerate the anterior pelvic tilt, therefore, the aim of the study was to analyze the effectiveness of training squat pattern in the neutral zone of spine and hypothesize whether it will be effective in the management of knee pain in the trekking group. **METHODOLOGY** 19 subjects were screened and selected for the study through purposive sampling. The subjects were taught to maintain the neutral spine. Within the neutral spine they were asked to draw in the lower portion of the belly. The subjects were asked to lower themselves into the squat position maintaining the neutral spine and their abdominal muscle contraction. They were asked to contract their gluteal muscles consciously (30%-40% of their total strength) and raise themselves up in the starting position. Breathing cues were also given, subject inhales while lowering into a squat and exhales to lift himself up. Once the subjects mastered the correct squat pattern they were progressed into other squat patterns over a period of 3 months. Results: Paired t test was performed to statistically evaluate the overall change in the pain symptom. The p value at the end of the test showed  $p < 0.05$ , thus proving the test significant. Paired t test was performed to statistically evaluate the overall change in the movement pattern. The p value at the end of the test showed  $p < 0.05$ , thus proving the test significant. Discussion Trekkers have vague knee pain with no or minimal radiological changes. The purpose of this study was to analyze the effectiveness movement pattern correction (anterior pelvic tilt- neutral spine) in the squatting activity and its effect on the knee pain. The study demonstrated that there is a significant difference in the pain and functional movement. This may have been the result because, it's not activity but it's the lack of mobility and stability that gives rise to a problem. Repeated functional activities on a faulty base can cause overuse, compensation, postural changes and musculoskeletal imbalances. If left unchecked, symptoms of pain and inflammation develop. The best way to avoid accumulation of problems is to impose balancing and contrasting activities to counteract the effect of high volume unnatural patterning. References Veerle K. ## ACUTE CELL SWELLING IN GASTROCNEMIUS WITHOUT CHANGES ON ACHILLES TENDON AFTER OCCLUSIVE

Cortell-Tormo, J.M., Chulvi-Medrano, I., Alakhdar, Y., Manchado, C.

*University of Alicante*

Introduction Occlusive strength training (OST) is shown like an alternative to intensive training in a previous results have shown a marked increase in muscular size and strength. OST combine low-intensity exercise (20-30% 1-RM) with blood flow restriction (BFR) (Pope et al., 2013). However there is not many papers about the effects of this training on tendon. It is know that the tendon suffers some adaptation to physical loading (Heinemeier & Kjaer, 2011) and recently Kubo et al. (2006) reported that after 12-weeks of OST specific tendon and tendon properties remain without changes. Present study show acute Achilles tendon responses and muscle changes to OST. Methods 12 male aged 24 (4) years and 3 female aged 27 (3) with a minimum of 1 year of strength training experience were recruited. OST (30% 1RM and 30% of maximum pressure occlusion) was applied in dominant leg during 3 sets of 15 repetitions in plantar flexion using a leg press machine. The contralateral leg was used as a control group. The thickness of Achilles tendon was measure in each subject before the testing, immediately after exercise and 24 hours after exercise by ultrasound (Mindray, Z6). Results After apply the Wilcoxon test we didn't find a significant different ( $p > 0.05$ ) between groups or between inter-group for Achilles tendon thickness OST pre 0.51 cm; OST post 0.43 cm; OST post24 0.50 cm; Control pre 0.50 cm; Control post 0.46 cm; Control post24 0.51 cm. We notice a significant difference in gastrocnemius thickness OST pre 1.77 cm; OST post 2.04 cm ( $p < 0.05$ ); OST post24 1.96 cm; Control pre 1.73 cm; Control post 1.86 cm; Control post24 1.84 cm. Discussion There is not significant difference between the control group and the occlusive group. Therefore, it is suggest that the occlusive condition does not produce any acute disturbance on tendon. Our data are consistent with Kubo's data (2006). We find acute and transient increase in cross-sectional area attributable to modifications in water content (Loennecke et al., 2012). Taking these data together it can be suggested that OST maybe a potentially useful protocol to improve muscular fitness without tendon impairments and for this could be useful for individuals who cannot lift sufficiently high loads to increase muscle size and strength. ## EFFECTS OF REHABILITATION EXERCISE AND TAPING ON MUSCLE ELECTROMYOGRAPY, PAIN AND RANGE OF MOTION IN JUDO ATHLETES WITH SHOULDER SUBLUXATION

Ji, J.G., Kwak, Y.S.

*Dong Eui univ*

The purpose of this study is to clarify the effect of Rehabilitation exercise and taping on joint muscle activity, joint working range, and joint pain. The study is evidenced by rehabilitation program on patients with shoulder joint subluxation patient of judo player, which the patients underwent taping and rehabilitation exercise. In case of internal rotation, taping showed noticeable interaction with supraspinatus tendon. For deltoid and latissimus dorsi, however, there were increase of numbers but not critical. External rotation, on the other hand, while the taping did not appeared to be interactive with supraspinatus tendon though there were increase of numbers, it demonstrated noteworthy interactions with deltoid and latissimus dorsi. Statistically noticeable result was shown from the change on joint working range of motion, abduction, and extension with increasing of ROM after the taping. Self-awareness of pain was decreased among taping group, but not critical. The study showed positive result on both rehabilitation exercise group and taping group of judo subluxation patients, but the group with two method combined together demonstrated the best result. As a result, mix of the two program offers the best resolution for subluxation patients. It is suggestive that more specified experiment through isokinetic equipments should be accompanied to research myofunction restoration in depth.

## CHRONIC EFFECTS OF WHOLE BODY VIBRATION ON EMG AND TORQUE PRODUCTION OF KNEE EXTENSOR MUSCLES IN ACUTE STROKE PATIENTS

Péter, A., Hegyi, A., Tihanyi, T., Tihanyi, J.

*University of Physical Education, Budapest, Hungary*

**Introduction.** Vibration exercise is a novice method to restore muscle balance and neuromuscular problems of stroke patients. It was found previously that the isometric and concentric torque of the knee extensors increased significantly after six weeks of WBV intervention on stroke patients (Tankisheva et al., 2013). However, in another study 17 sessions of WBV training did not improve the strength parameters of stroke patients (Marín et al., 2013). The aim of this study was to examine the chronic effect of WBV on the isometric and eccentric torque and activity of the knee extensor muscles and the co-activation pattern. **Methods.** 16 voluntary stroke patients participated in this study, 8 women and 8 men (age= 58.2± 9.4 yrs). Subjects were divided randomly in two equal groups: vibration group (V) and control group (C). Subjects in V received 4 weeks (3 times a week) of WBV intervention. The vibration frequency ranged between 15-25 Hz, with 5 mm amplitude. Unilateral (UL) and bilateral (BL) isometric (IC) and eccentric (EC) torque of knee extensor muscles were measured by Multicont II dynamometer, and the corresponding EMG activity of the vastus medialis (VM) and vastus lateralis (VL) and biceps femoris (BF) muscles were recorded simultaneously before and after the 4-week intervention. **Results.** The UL and BL maximal IC increased by 45.2% and 45.6%, respectively in the paretic leg of the V group. The bilateral deficit decreased significantly in the V group ( $p=0.010$ ). The UL and BL EC torque of paretic leg increased by 26.3% and 31.9%, respectively in the V group. The changes were not significant at C group neither in the strength nor in the EMG activity parameters ( $p>0.05$ ). The EMG activity of the VM and VL muscles significantly improved, while the co-activation decreased during the contractions ( $p\leq 0.05$ ) in the injured leg in the V group, while remained unchanged in the C group ( $p>0.05$ ). **Discussion.** Our results suggest that the WBV caused significant changes in the paretic knee extensors. Increased strength parameters seem to be resulted from the changes in the activity pattern of the muscles around the knee. In this way, presumably the transmission of the functions of the motor area can be accelerated via the WBV. **References** Marín, PJ, Ferrero, CM, Menéndez, H, Marín, J, Herrero, AJ. ## THE EFFECTS OF DRY NEEDLING VERSUS MANUAL PRESSURE RELEASE OF MYOFASCIAL TRIGGER POINTS ON HIP MUSCLE LENGTH AND STRENGTH

Kennedy, M., Wallace, J., Dowling, M., McCarthy Persson, U.

*Institute of Technology, Carlow*

**Background:** It is widely accepted by clinicians and researchers that myofascial trigger points (MTrPs) can cause pain and provoke motor dysfunctions such as muscle weakness, muscle imbalance and altered motor recruitment. Muscle length and strength imbalances and flexibility impairments at the hip can cause abnormal distribution of forces and stress across the joint, resulting in injury to the hip, low back and pelvis (Sahrmann, 2002; Van Dillen et al, 2008). MTrP treatment methods are proposed to improve muscle flexibility, strength, function and pain. There is little evidence as to whether these methods are effective in treating these issues around the hip and buttock region, or which method is more effective. The purpose of this study was to investigate the effectiveness of dry needling versus manual pressure release of MTrPs on the length and strength of two hip muscles. **Methods:** 36 subjects were recruited from male athletes that participate in a multidirectional sport at least three times per week. Subjects were required to have MTrPs in their piriformis and gluteus medius muscles and reduced flexibility on hip flexibility tests. Subjects were randomly divided into two groups; group 1 would receive dry needling and group 2 would receive manual pressure release. Once recruited, subjects attended 2 testing sessions. At session 1 the subject received their allotted intervention to their piriformis or gluteus medius muscle. Seven days later, at session 2 the subject received their allotted intervention to the muscle not treated on session 1. Muscle length, muscle strength, pressure pain threshold (PPT) and stretch location was assessed immediately before and immediately after the intervention. **Results:** Data was analysed for significance ( $p<0.05$ ) between pre and post intervention within the groups as well as between groups. Results indicate both treatments cause a significant increase in muscle length. There are observable decreases in muscle strength following both treatments, with dry needling of the gluteus medius muscle resulting in a significant decrease in hip abduction strength. Only manual pressure release significantly improved PPT. Between groups, strength decreased significantly more following dry needling than manual pressure release. **Discussion:** Dry needling and manual pressure release appear to increase muscle length and decrease isometric muscle strength immediately post treatment. Further investigation is required to establish if these effects translate into performance changes. **References:** Sahrmann, S. (2002). *Diagnosis and Treatment of Movement Impairment Syndromes*. ## BACK TO WORK AS FIREFIGHTER WITH A STOMA AFTER RECTAL CARCINOMA: A CASE REPORT ON EXERCISE AND CANCER

Scharhag-Rosenberger, F., Wiskemann, J.

*National Center for Tumor Diseases (NCT) Heidelberg, University Hospital Heidelberg*

**Background:** A stoma is a surgically created opening of the abdomen to discharge stool. It is associated with weakened abdominal muscles and an increased risk of hernia (H) during physically demanding tasks like fire fighting. Colorectal cancer patients with a stoma are furthermore deconditioned through anti-cancer therapy. This case study reports how a firefighter with rectal carcinoma and a permanent stoma was trained to regain operational fitness. **Case study:** A 44 year old firefighter (178 cm, 82 kg) with an adenocarcinoma of the rectum (diagnosed 24 months before) was submitted to the exercise expert consultation of our comprehensive cancer center. He had received neoadjuvant radiochemotherapy and surgery. After two temporary ileostomies, a permanent colostomy was performed 12 weeks before baseline assessment. The patient was physically inactive since diagnosis and unable to work. To regain occupational fitness, we administered a 6-month training program consisting of three phases: a 2-month preparation phase, a 2-month individually supervised training phase, and a 2-month group based training phase. The program included sensorimotor, aerobic and resistance training of increasing volume and intensity. Cardiopulmonary exercise tests (CPET) and isometric strength tests were performed at baseline and after each phase. Training frequency varied from 1–3 sessions/week, although 2–5 sessions/week were prescribed. A psychosocial counselling slightly improved the situation. Peak power output in the CPET was 150, 158, 167, and 192 W at baseline, 2, 4, and 6 months. Peak oxygen uptake (VO<sub>2</sub>peak) increased from 1.56 l/min (19 ml/min/kg) to 2.39 l/min (29 ml/min/kg). Maximal isokinetic peak torque (MIPT) of the knee extensors was 138.0, 165.5 and 196.5 N at baseline, 4 and 6 months. MIPT of the elbow and hip flexors in-

creased from 51.8 to 66.0 Nm and 213.8 to 239.7 Nm, respectively. The firefighter passed a test for occupational fitness shortly after the 6 months test and was permitted to work in an exterior crew on a pump truck. Conclusion: Regaining occupational fitness for physically demanding tasks like firefighting is possible in cancer survivors with a stoma through an individually tailored and supervised exercise program. Training can therewith prevent from unemployment. However, sufficient time and psychosocial support might be needed depending on the individual situation. References: (1) Turnbull GB. Exercise and ostomy. *Ostomy Wound Manage*, 50(3):22-4, 2004.

### **AEROBIC EXERCISE IMPROVES THE EXPRESSION OF ACTIVITY-RELATED CYTOSKELETON ASSOCIATED PROTEIN IN THE HIPPOCAMPUS OF LACTATIONAL DEHP-EXPOSED RATS**

Lee, Y., Wang, D.C.

*Kaohsiung Medical University*

Introduction Exercise can provide beneficial effects on brain function (Singh and Staines, 2015). Di-(2-ethylhexyl)-phthalate (DEHP), an endocrine disruptor, has been found to exert toxic effects by reducing the levels of BDNF and hippocampal atrophy in rats. (Smith and Holahan, 2014). In this study, we conducted an experiment regarding the effects of aerobic exercise on novelty-induced expression of activity-related cytoskeleton associated protein (Arc), an important immediate-early gene involved in synaptic plasticity, in the hippocampus of young male rats receiving postnatal DEHP exposure. Method Rat dams were fed with vehicle or DEHP (10mg/kg per day) during lactation. After weaning, the male offspring were divided into 4 groups: control (C), DEHP (D), exercised control (Cex), and exercised DEHP (Dex). Exercised rats were trained on treadmill every day from 3 weeks of age for 5 weeks. At the age of 8 weeks, the rat were exposed to a novel environment for 5 min and then returned to their home cage for 60 min to induce the expression of Arc in the hippocampus. After novelty exploration, the hippocampus was collected for Western blotting. Result The expression of Arc was significantly decreased in the D group compared to the C group, in addition, the novelty-induced Arc expression was improved in the Dex group compared to D group. Discussion According to the result, lactational DEHP exposure may impair the novelty-induced Arc expression in the hippocampus, suggesting an impairment of synaptic plasticity in the DEHP-exposed rats. Meanwhile, aerobic exercise during the childhood-adolescence can restore the synaptic plasticity by improving the novelty-induced Arc expression in the hippocampus of DEHP-exposed young male rats. Reduced hippocampal dendritic spine density and BDNF expression following acute postnatal exposure to di(2-ethylhexyl) phthalate in male Long Evans rats. *PLoS One*. 2014, 9(10):e109522.

### **AEROBIC EXERCISE IMPROVES THE EXPRESSION OF CANNABINOID RECEPTORS TYPE 1 RECEPTOR IN LACTATIONAL DEHP-EXPOSED RATS**

Huang, C., Wang, D.C.

*Kaohsiung Medical University*

Introduction Studies indicate that aerobic exercise improves the learning and memory, as well as reduces the risk of neurodegenerative diseases. Cerebellum, an important role in motor coordination and motor skill learning, is also benefited by exercise (Kim et al., 2013). Di-(2-ethylhexyl)-phthalate (DEHP), a plasticizer applied in polyvinyl chloride manufacture, is regarded as an endocrine disruptor. It has been reported that perinatal treatment of DEHP leads to impairment of nervous system (Smith et al., 2011). Because the function of cerebellum is modulated precisely by cannabinoid receptor type 1 (CB1R), an attempt was made to reveal the effect of exercise on the cerebellar expression of CB1R in the lactational DEHP-exposed young male rats. Method Rat dams were fed with vehicle or DEHP (10mg/kg per day) during lactation. After weaning, the male offspring were divided into 4 groups: control (C), DEHP (D), exercised control (Cex), and exercised DEHP (Dex). Exercised rats were trained on treadmill every day from 3-weeks of age for 5 weeks. At the age of 8 weeks, animals were subjected to rotarod test to assess the motor coordination and then their cerebellar CB1R were analyzed by Western blotting. Result The performance on rotarod was impaired in the D group, which indicated the impairment of motor coordination in these rats. Exercise improved the motor coordination in the Dex group. The cerebellar Purkinje cell marker calbindin-D28K was not affected by lactational DEHP exposure. An upregulation of cerebellar CB1R was observed in the D group, whereas a normalization of cerebellar CB1R in the Dex group was found when compared to the C group. Discussion Because the expression of calbindin-D28K is not affected by lactational DEHP exposure, the reduction of Purkinje cells may be not responsible for the impairment of motor coordination in the DEHP-exposed rats. However, the upregulation of cerebellar CB1R in the DEHP-exposed rats suggests that interference of endocannabinoids system in the cerebellum of DEHP-exposed animal. Exercise during childhood-adolescent period may improve the motor coordination by normalization of the endocannabinoids system in lactational DEHP-exposed rats. These evidence show that aerobic exercise may provide beneficial effects on protection of cerebellar function against DEHP exposure. References 1. ### **AEROBIC EXERCISE IMPROVES THE ACTIVATION OF AKT AND ERK SIGNALING IN THE MOTOR CORTEX OF LACTATIONAL DEHP-EXPOSED ADULT MALE RATS**

Zeng, Y., Wang, D.C.

*Kaohsiung Medical University*

Introduction Di-(2-ethylhexyl)-phthalate (DEHP), a plasticizer usually applied in polyvinyl chloride manufacture, is regarded as an endocrine disruptor to exert adverse effects on the brain function (Sun et al., 2014). Exercise has been identified as a strategy for ameliorating a range of cognitive dysfunction in humans and animals (Singh and Staines, 2015). In this study, we conducted an experiment regarding the effects of aerobic exercise on motor skill-induced activation of Akt and Erk signaling in the cortex of young adult male rats receiving postnatal DEHP exposure. Methods SD rat dams were fed with vehicle or DEHP (10mg/kg/day) during lactation. After weaning, the male offspring were divided into 4 groups: control (C), DEHP (D), exercised control (Cx), and exercised DEHP (Dx). Exercised rats were trained on treadmill every day from 3-weeks of age for 5 weeks. At the age of 8 weeks, rats were trained to traverse a runway apparatus for 5 times to induce the activation of Akt and Erk signaling in the motor cortex. After one hour of behavioral stimulation, rats were sacrificed and their motor cortices were analyzed by Western blotting to detect the phosphorylations of Akt and Erk. Results Traverse time of crossing the runway apparatus was increased in the lactational DEHP-exposed rat. Exercise decreased the traverse time in the exercised DEHP-exposed animals, indicating an improvement of motor skill in these rats. Western blotting showed decreased phosphorylations of Akt

and Erk in the motor cortex of DEHP-exposed rats. After exercise for 5 weeks, the phosphorylations of Akt and Erk were improved in the exercised DEHP-exposed animals. Discussion After motor skill learning, the phosphorylation of Akt and Erk signaling indicates the activation of neural plasticity in the motor cortex. In this study, the phosphorylation of Akt and Erk signaling was decreased in the DEHP-exposed rats, suggesting the impairment of neural plasticity in the DEHP-exposed rats. Aerobic exercise during early life may ameliorate the adverse effects of lactational DEHP exposure on motor skill learning-induced neural plasticity, which is revealed by the improvement of phosphorylation of Akt and Erk signaling in the motor cortex after exercise in the DEHP-exposed rats. ### THE IMPAIRED CEREBRAL EXPRESSION OF ACTIVITY-RELATED CYTOSKELETON ASSOCIATED PROTEIN IN PHTHALATE-EXPOSED RATS CAN BE AMELIORATED BY AEROBIC EXERCISE

Tsai, K., Wang, D.C.

*Kaohsiung Medical University*

Introduction Di-(2-ethylhexyl)-phthalate (DEHP), a plasticizer usually applied in polyvinyl chloride manufacture, is regarded as an endocrine disruptor to exert adverse effects on the brain function (Sun et al., 2014). Exercise has been proposed as a strategy for ameliorating a range of cognitive dysfunction (Singh and Staines, 2015). In this study, we conducted an experiment regarding the effects of aerobic exercise on motor skill-induced activity-related cytoskeleton associated protein (Arc) expression in the motor cortex of young adult male rats receiving postnatal DEHP exposure. Methods SD rat dams were fed with vehicle or DEHP (10mg/kg) during lactation. After weaning, the male offspring were divided into 4 groups: control (C), DEHP (D), exercised control (Cx), and exercised DEHP (Dx). Exercised rats were trained on treadmill every day from 3-weeks of age for 5 weeks. At the age of 8 weeks, rats were trained to traverse the runway apparatus for 5 times to induce the expression of Arc in the motor cortex, and were sacrificed to collect proteins from their motor cortex. Western blotting was used to reveal the level of Arc expression in the motor cortex. Results Traverse time of crossing the runway apparatus was increased in the lactational DEHP-exposed rat. Exercise decreased the traverse time in the exercised DEHP-exposed animals, indicating an improvement of motor skill in these rats. Western blotting showed decreased motor skill learning-induced Arc expression in the motor cortex of DEHP-exposed rats. After exercise for 5 weeks, the expression of Arc was improved in the exercised DEHP-exposed animals. Discussion The reduced activity-induced Arc level in the motor cortex of lactational DEHP-exposed rats suggests an adverse effect of DEHP on the synaptic plasticity. Aerobic exercise during early life may ameliorate the adverse effects of lactational DEHP exposure on motor skill learning-induced neural plasticity, which is revealed by the improvement of Arc expression in the motor cortex after exercise in the DEHP-exposed rats. Perinatal exposure to Di-(2-ethylhexyl)-Phthalate leads to cognitive dysfunction and phospho-tau level increase in aged rats. *Environ Toxicol.* 2014, 29(5):596-603.

### PATIENT-REPORTED OUTCOMES BUT NOT DEMOGRAPHIC FACTORS ARE ASSOCIATED WITH NORMAL MUSCLE FUNCTION 2-5 YEARS AFTER ANTERIOR CRUCIATE LIGAMENT INJURY: A CROSS-SECTIONAL STUDY

Cederström, N.1, Roos, E.M.2, Ageberg, E.1

*(1) Lund University, Lund, Sweden; (2) University of Southern Denmark, Odense, Denmark*

Background Treatment after anterior cruciate ligament (ACL) injury includes rehabilitation, with or without reconstructive surgery. Reaching normal muscle function is considered important, as it is associated with return to sports and preventing long-term joint problems. The influence of demographic and patient-reported outcomes for achieving normal muscle function is largely unknown. Purpose In a cross-sectional cohort study, examine associations of patient-reported outcomes and demographic factors with muscle function after ACL injury/reconstruction. Methods Fifty-four patients were measured mean 3 years (SD 0.85) after ACL injury/reconstruction to determine whether knee muscle power (leg extension, leg flexion, and leg press) and hop performance (single-leg vertical jump, single-leg hop for distance, and side-hop) scores had normalized. A Limb Symmetry Index (LSI; injured leg divided by uninjured and multiplied by 100)  $\geq 90\%$  was considered normal. Age, gender, body mass index (BMI), activity level (Tegner Activity Scale [TAS]), and the Knee Injury and Osteoarthritis Outcome Score subscales (KOOS; Pain, Symptoms, Activities of Daily Life [ADL], Activities in Sport and Recreation [sport/rec], Quality of Life [QOL]) were analyzed using simple logistic regressions to determine their association with muscle function. Results A higher TAS score (odds ratio 1.40, 95% CI 1.0-1.9,  $p = 0.02$ ) and better scores on KOOS QOL (odds ratio 1.03, 95% CI 1.0-1.1,  $p = 0.02$ ) were significantly associated with normal knee extension LSI; i.e., with each unit increase of TAS and KOOS QOL, the likelihood of reaching normal LSI increased 40% and 3%, respectively. Each increase in TAS score (odds ratio 1.42; 95% CI 1.0-2.0,  $p = 0.03$ ), and better scores on KOOS subscales (odds ratio increases of 4-15%) were associated with normal LSI for vertical jump. Better scores on KOOS sport/rec (odds ratio 1.03, 95% CI 1.0-1.1,  $p = 0.02$ ;) and KOOS QOL (odds ratio 1.03, 95% CI 1.0 - 1.1,  $p = 0.03$ ) were associated with normal LSI of the side-hop test. Age, gender or BMI showed no associations with muscle function. Conclusions Higher activity level and better self-reported outcomes on the disease-specific questionnaire KOOS were associated with normal LSI of knee extension power and single-leg hop performance mean 3 years after ACL injury. Demographic variables showed no such association. These results warrant the need for future research into the psychological factors involved in ACL injury rehabilitation; their relation to outcomes commonly used to measure success and to improve treatment. ### THE ANALYSIS OF NEUROMUSCULAR ACTIVITY AND MUSCULAR OXYGENATION THROUGH DIFFERENT MOVEMENT CADENCES DRUING IN-WATER AND ON-LAND KNEE EXTENSION EXERCISE

Chien, K.Y., Kan, N.W., Li, Y.L., Chang, F.Y., Chen, W.C.

*National Taiwan Sport University; Taipei Medical University; National Penghu University of Science and Technology; University of Taipei*

Introduction The prevalence of sport injuries is relatively higher in lower extremity (Hootman et al., 2007). Thus, appropriate rehabilitation training strategies are substantial for injured athletes who need to quickly return the field. The physical properties of water allow it to provide a number of rehabilitation and exercises that accelerate recovery, train muscular strength, and permit a larger range of movements. Previous exercises in aquatic therapy research focused on isometric or upper limbs dynamic exercise model (Pöyhönen et al., 1999; Castillo-Lozano et al., 2013). To our knowledge, there has yet to be any studies investigating neuromuscular activity, oxygen saturation, and perceived exertion in lower-extremity dynamic aquatic exercise models. The lack of these investigations restricts the design of

aquatic exercises and training and clinical applications. The purpose of this study was to compare the different cadences of knee extension exercises in water and on land, and differences in the neuromuscular activation of quadriceps femoris, muscular oxygenation and rating of perceived exertion. Methods Seventeen young women participated in this study, and the subjects were randomly allocated to perform loaded knee extension/flexion exercises (2.4 kg load) in water and on land at four different cadences of 30, 50, 70, and 90 beats per minute (bpm). Heart rate (HR), rating of perceived exertion (RPE), electromyography for the extent of muscular activity (EMG), blood flow (BF) and total saturation index of oxygen(TSI) were measured. Response values of measured parameters at each cadence were obtained by subtracting the resting values from the indicator values measured at the respective cadences. A two-way ANOVA repeated measurement analysis was used to evaluate the differences in response values of EMG, HR, RPE, BF and TSI under different conditions (in water or on land) and cadences. Results RPE and muscular activation at 30 bpm in water were lower than those on land. EMG, RPE, and BF in water at 90 bpm were comparable to that on land. However, HR and TSI changes were higher in water compared to on-land. Discussion This study showed that the neuromuscular activity when performing knee extension exercises at 90 bpm in water was comparable to that of on-land. However, exercising in water at the same cadence evoked higher TSI responses and greater cardiovascular challenges. We recommend using the properties of water to alleviate the swelling around the injured area and enhance regional blood circulation and metabolism at early stages of rehabilitation. Exercise may start from a more comfortable pace of 30 bpm and then gradually increased as needed to reach 90 bpm for effective training. References Hootman, J.M., Dick, R., Agel, J.. ### **ACUTE SUPPLEMENTATION WITH RESVERATROL DOES NOT IMPROVE FLOW-MEDIATED DILATION IN CORONARY ARTERIAL DISEASE ELDERLY PATIENTS**

Diaz, M., Avila, A., Coeckelberghs, E., Degens, H., Azzawi, M., Vanhees, L., Cornelissen, V.

*KU Leuven & Manchester Metropolitan University*

Coronary arterial disease (CAD) is characterized by the building up of plaque in the arteries of the heart and is a serious cause of morbidity and mortality. Abnormal constriction of the heart arteries might lead to ischemia and myocardial infarction. Common risk factors for the development of CAD include hypertension, hyperlipidemia, obesity and lack of exercise. Betablocker agents or nitrate preparations are routinely prescribe to CAD patients aiming to reduce blood pressure and improve dilation of the artery. Resveratrol (RV) is a polyphenol with multiple cardiovascular and metabolic effects. In humans, RV has been shown to increase nitric oxide bioavailability and as a consequence enhance endothelium-dependent vasodilation. Methods: The study was performed in a randomized double blind placebo controlled trial. After screening and signing informed consent, 15 CAD patients (aged  $67.75 \pm 7.07$  years;  $80.5 \pm 13.6$  kg;  $172.1 \pm 7.07$  cm and BMI of  $27.1 \pm 3.65$  kg/m<sup>2</sup>), routinely referred for cardiac rehabilitation at University Hospital Leuven were assigned to flow-mediated dilation (FMD) measurements under acute supplementation with RV (21st century alternatives, UK) and placebo. The subjects were required to consume 330 mg of RV or placebo (in the forms of pills) with each meal during the three days (1g/day) prior to testing. All of the tests were performed between 08:00 and 10:00 am with a seven-day rest and washout period in-between. Results: All calculations were analyzed using GraphPad Prism. To compare parameters before and after RV a paired-sample t test was used. Statistical significance was set at  $p < 0.05$  (2-tailed). No difference in initial diameter was observed between treatments ( $p = 0.75$ ). Further, treatment with RV resulted in no increased FMD ( $p = 0.68$ ). Conclusion: Doses of 1mg/day of RV are considered to be high while having no secondary adverse effects in humans. In our study, endothelial function as evaluated by FMD was not enhanced by acute supplementation with RV in CAD elderly patients.

### **OUTCOMES FOLLOWING THE INTERVENTION OF THE MULTIDISCIPLINARY APPROACH FOR A PATIENT WITH KNEE JOINT OSTEOARTHRITIS IN TAIWAN: A CASE REPORT**

Hsu, C.

*Cheng Ching Hospital*

Introduction Osteoarthritis is the most common cause of musculoskeletal pain and disability in the knee joint. The increased loading in the knee joint causes further deterioration of the joint cartilage and produced the symptom. Pain relief and excessive load removed are very important principles in OA knee management. The purpose of this study is to describe outcomes from the multidisciplinary approach for a patient with severe knee pain caused by orthoarthritis in Taiwan. Methods A 46-year-old female presented L't knee pain and had difficulty to perform functional activities. The X ray finding showed OA change and narrowing joint space. According to Kellgren and Lawrence system, the severity is grade 3. The score of the Western and McMaster Universities Index(MOMAC) indicated disability and the knee flexion ROM was slightly limited. Treatment consisted of the low intensity laser therapy for cartilage. The application of therapeutic taping supported knee joint and decreased the pressure in the joint space. Finally, the strengthening exercise of lower extremity was instructed especially in gluteus maximum and medius. This case accepted 12 treatment visits over 4 weeks. Results The pain scale and the scores of WOMAC showed significant improvement. The pain scale decreased from 7 to 1. The scores of WOMAC improved from 66% to 8% after treatment. Discussion The laser therapy provides an analgesic and anti-inflammatory effect by increasing pain threshold in sensory nerve endings. In addition, laser irradiation stimulates collagen production and alters DNA synthesis. The therapeutic taping technique protected the knee joint and decreased the abnormal stress on the cartilage in weight bearing condition. The strengthening exercise of gluteus muscles improved the alignment and movement quality of pelvis and lower extremity. Appropriate alignment and movement of lower extremity maintained the effect of the multidisciplinary approach. ### **MORPHOLOGICAL CHARACTERISTICS OF MUSCLE FASCICLE IN THE MEDIAL GASTRONEMIUS DURING RAMPING CONTRACTION WITH AND WITHOUT AN ACHILLES REPAIR**

Peng, W.C.1, Wang, H.K.1, Chang, Y.P.1, Shih, K.S.2, Ma, H.L.3, Lin, L.C.4

*1.National Taiwan University(Taipei, Taiwan) 2.Shin Kong Wu Ho-Su Memorial Hospital(Taipei, Taiwan) 3.Taipei Veterans General Hospital(Taipei, Taiwan) 4.Tri-Service General Hospital(Taipei, Taiwan)*

Introduction A compliant tendon in repaired Achilles tendons has been observed within one year after surgical management (Wang et al., 2013). Whether this phenomenon affects fascicle behavior in the muscle, however, remains unclear. The aim of this study was to

measure the fascicle morphologies, including angle and curvature radius, of the medial gastrocnemius muscle in legs with and without a repaired Achilles, and to investigate the asymmetry between different force levels during a ramping isometric contraction. Methods Seven subjects with an Achilles tendon repair within the past 6 months were recruited. Bilateral ultrasonographic measurements were performed with each subject lay prone with ankles hanging over the edge of the bed and positioning at 90 degrees. During each test, subjects were asked to perform at least three repetitions of a five-second ramping plantarflexion to maximum voluntary isometric contraction (MVIC), e.g. 30, 60, and 90%, each of which was then followed by a five-second period of muscle relaxation. The fascicle angle and curvature radius were recorded at different contraction levels. The asymmetry index (AI) was calculated according to the following formula:  $AI = 1 - (\Delta_{\text{healthy}} / \Delta_{\text{repaired}})$ . A small absolute AI represented symmetric fascicle behaviors between the uninjured leg and the repaired leg. Results The AI of the fascicle angle decreased and neared zero as muscle force increased to 90% MVIC from 30% MVIC. The AI of the fascicle angle at 30% MVIC had a significantly higher value than the AI at 90% MVIC ( $p < 0.017$ ). There was a tendency for the AI of the fascicle curvature radius to increase from negative values to values close to zero as the muscle force increased from 30% MVIC ( $p > 0.017$ ). Discussion This study found that the level of symmetry between uninjured and repaired legs in terms of changes in muscle fascicle angles was greater during a vigorous contraction than during a contraction of mild intensity. We have previously argued that the differences in muscle fascicle behavior at different levels of muscle contraction may be contributed by a compliant tendon after surgical management (Wang et al., 2013). Insignificant results with regard to the AI of fascicle curvature may imply that changes in muscle hardness at different levels of muscle contraction are similar (Wang et al., 2009). Measuring the aponeurosis stiffness is suggested as a means of clarifying the mechanisms of symmetries of muscle fascicle behaviors between uninjured and repaired Achilles. References Wang HK, Wu YK, Lin KH, Shiang TY. (2009). *Man Ther*, 14(3), 264-269. Wang HK, Chiang H, Chen WS, Shih TT, Huang YC, Jiang CC. (2013). *Arch Phys Med Rehabil*, 94(8), 1590-1598.

### EFFECT OF STATIC STRETCHING ON SHOULDER RANGE OF MOTION AND PITCHING BIOMECHANICS IN UNIVERSITY STUDENT PITCHERS

Nakamura, M., Sakabe, T., Nakamura, Y., Hojo, T., Takeuchi, K., Tsukuda, F., Fujisawa, Y.  
*Doshisha University*

Introduction: Recently, there have been a growing number of pitching-related upper extremity injuries that require surgery because of an increase in participation volume (Olsen et al., 2006). Pitching-related upper extremity injuries often decrease the shoulder range of motion (ROM) and increase the shoulder joint loading; therefore, it is important to increase the shoulder ROM and decrease the shoulder joint loading. Clinically, static stretching (SS) is performed to increase the shoulder ROM, which is believed to decrease the shoulder joint loading. However, the effects of SS on pitching biomechanics are unclear. Purpose: The purpose of this study was to investigate the effect of SS on the shoulder ROM and pitching biomechanics in university student pitchers. Methods: Internal and external rotation ROM and three-dimensional pitching biomechanics (Mac3D System, Motion Analysis) were measured before (PRE) and after SS intervention (POST) in university student pitchers (age:  $19.2 \pm 0.6$  years). SS intervention comprised three types of SS intervention, with each type comprising three sets of 30 sec. The kinetic variables calculated were the peak shoulder joint moment and joint moment at maximum shoulder external rotation. Results and Discussion: There were significant increases in the internal and external rotation ROMs after SS (internal rotation: PRE:  $41.8 \pm 12.8$  degrees, POST:  $47.8 \pm 11.4$  degrees,  $p < 0.01$ ; external rotation: PRE:  $127.7 \pm 7.5$  degrees, POST:  $131.8 \pm 7.4$  degrees,  $p < 0.01$ ). However, there were no significant changes in the kinetic variables. Briefly, SS intervention effectively increased the shoulder internal and external rotation ROM; however, it did not decrease the joint loading during pitching. Because an increase in the shoulder joint loading is associated with a variety of pitching-related upper extremity injuries (Oyama et al., 2013), the results suggested that SS intervention could not decrease the risk of pitching-related upper extremity injuries. Effect of excessive contralateral trunk tilt on pitching biomechanics and performance in high school baseball pitchers. *Am J Sports Med*. 41(10):2430-2438, 2013.

### MOTOR IMAGERY COMBINED WITH ACTION OBSERVATION OF CHOPSTICK USE FACILITATES MOTOR CORTEX EXCITABILITY IN THE DOMINANT HEMISPHERE

Shimizu, S.1, Shibata, K.1,2, Suzuki, M.1, Watanabe, M.1, Kawaguchi, T.1, Yoshida, S.1, Fukuda, M.1, Matsunaga, A.1  
1: *Kitasato Univ. (Kanagawa, Japan)* 2: *Sagamihara Chuo Hosp. (Kanagawa, Japan)*

Introduction Motor imagery plays an important role in motor learning for patients with poststroke hemiparesis. A previous study suggested that primary motor cortex (M1) excitability during motor imagery (MI) with action observation (AO) increased more than during motor imagery alone (Wright et al., 2014). However, the involvement of non-dominant M1 during MI with AO has received little attention. The purpose of this study is to examine change in excitability in dominant and non-dominant M1 during kinesthetic MI with AO of movement of the right or left hand. The imagery task utilized in this study was chopstick use, as it is commonly used in rehabilitation. Methods Nine neurologically healthy right-handed male subjects participated in this study. The subjects performed under two conditions: (1) control where the subjects were instructed to look a fixation cross displayed on the computer screen and (2) MI+AO where the subjects were instructed to imagine performing an action depicted with the right or left hand in a video. Under MI+AO conditions, a video displayed on the computer screen showed the right and left hand respectively of a male subject using chopsticks to grab a small tomato. Single-pulse transcranial magnetic stimulation (TMS) was performed using a Magstim 200 stimulator (Magstim, Gwyneth, Dyfed). TMS delivered 1.2 times the resting motor threshold intensity. Under each condition, motor-evoked potentials (MEPs) were recorded from the first dorsal interosseous (FDI) muscles of the right hand and left hand, respectively. Two-way repeated-measures analysis of variance (ANOVA) was performed to compare differences in MEP amplitudes between condition (MI+AO by right hand, MI+AO by left hand, control) and hemisphere (dominant and non-dominant). Results Repeated-measures ANOVAs showed significant interaction between the MI+AO condition and hemisphere, a significant main effect of MI+AO condition ( $p < 0.01$ ), and a significant main effect of hemisphere ( $p < 0.01$ ). Post-hoc testing found a significant increase in MEP amplitude during MI+AO with the right or left hand in the left hemisphere compared to that during control ( $p < 0.01$ ,  $p < 0.01$ ), whereas there was no significant increase in the right hemisphere. Discussion The main findings of this study are that MI combined with AO using chopsticks with either hand facilitates the motor cortex in the dominant hemisphere, whereas no facilitation is shown in the non-dominant hemisphere. This finding has implications for the use of MI combined with AO in rehabilitation. References Wright DJ, Williams J, Holmes PS. (2014). *Front Hum Neurosci*. 27(8):951.

## EMG EVALUATION OF THREE ELASTIC BAND EXERCISES FOR BEDBOUND PATIENTS

Stensgaard, S.H.1, Dalager, T.1, Sjøgaard, K.1, Sjøgaard, G.1

1. University of Southern Denmark

**Introduction** Elderly medical patients who are being hospitalised in Denmark spend up to 17 hours a day in bed. Besides the risks for decreased balance, lung complications and bedsore, even few days of immobility induces a loss of muscle mass and muscle strength. Strength training is shown to counteract these effects. However, being hospitalised and newly operated limits the choice of suitable exercises and training equipment. Therefore, the aim of this study was to evaluate muscle activity during three elastic band exercises carried out in the hospital bed. **Methods** Seven healthy females (mean age 46, range 27-56 yrs, mean BMI 24, range 20-29) volunteered. Three elastic band strength exercises (shoulder extension, elbow extension and hip extension) using Thera-Band™, were evaluated. All exercises were performed while lying in bed with the elastic band fixed in the ceiling. Electromyography (EMG) was measured on 10 relevant muscles (5 upper body, 5 lower body muscles) with wireless MYON 320 (Myon AG Switzerland) and shown as mean peak and percentage of Maximum Voluntary Electrical activation (MVE) for each muscle. Individual 8 and 15 Repetition Maximum (RM) was pre-defined by a combination of elastic band resistance and length of the elastic band. Rate of perceived exertion (RPE) was measured by the Borg 10-point RPE scale. Results Shoulder extension primarily activated m. triceps brachii with a peak (mean (SD)) of 622.7  $\mu$ V ( $\pm$ 272.3) for 15RM, 616.2  $\mu$ V ( $\pm$ 224.5) for 8RM, and a relative muscle activation (mean (SD)) of 27.4% ( $\pm$ 2.3) MVE for 15RM and 29.4% ( $\pm$ 4.3) MVE for 8RM. Elbow extension primarily activated m. latissimus dorsi with a peak of 525.7  $\mu$ V ( $\pm$ 376.5) for 15RM, 466.8  $\mu$ V ( $\pm$ 329.5) for 8RM, and a relative muscle activation of 24.0% ( $\pm$ 4.0) MVE for 15RM and 25% ( $\pm$ 4.8) MVE for 8RM. The hip extension exercise primarily activated m. biceps femoris, with a peak of 337.2  $\mu$ V ( $\pm$ 170.3) for 15RM, 333.4  $\mu$ V ( $\pm$ 167.0) for 8RM, and a relative muscle activation being 25.5% ( $\pm$ 4.8) MVE for 15RM and 28% ( $\pm$ 6.7) MVE for 8RM. RPE for shoulder extension (Mean (SD)): 15RM = 8.3 ( $\pm$ 1.1), 8RM = 9 ( $\pm$ 0.8). Elbow extension: 15RM = 8.7 ( $\pm$ 1.0), 8RM = 8.7 ( $\pm$ 1.1). Hip extension: 15RM = 8.3 ( $\pm$ 1.0), 8RM = 8.3 ( $\pm$ 1.3). **Discussion** This is the first study using a fix-point in the ceiling for in-bed elastic band exercises. This, in combination with different levels of elastic band resistance and lengths makes an individual's adaptation to strength training feasible, even for bedbound patients. Furthermore the EMG and RPE measurements show that the three chosen exercises target different muscle groups. The study advocates using intensive strength training during a hospital stay. It is of great importance to look for new ways to facilitate a more optimal recovery period among elderly postoperative patients. Contact: sstensgaard@health.sdu.dk

## EFFECT OF FUNCTIONAL TRAINING ON PHYSICAL FITNESS AND GLYCEMIC CONTROL OF OLDER ADULTS WITH TYPE 2 DIABETES

Heubel, A.1, Gimenes, C.1, Carreira, T.C.1, Arca, E.A.1, Martinelli, B.1, Barrile, S.R.1

Sacred Heart University (USC)

**EFFECT OF FUNCTIONAL TRAINING ON PHYSICAL FITNESS AND GLYCEMIC CONTROL OF OLDER ADULTS WITH TYPE 2 DIABETES 1: USC (Bauru, Brazil)** **Introduction** Functional training (FT) is recommended to improve motor skills of older persons, but their effects in treatment of type 2 diabetes (T2D) are not certain. Therefore, this study aimed to verify the effect of a FT program on physical fitness and glycemic control of older adults with T2D. **Methods** Twenty-five diabetics aged >60 yr were randomly assigned in two groups: training (TG, n = 13) and control (CG, n = 12). A progressive FT was conducted for 16 wk, 3 d/wk and 70 min/d. Before and after training program, were performed physical tests (chair stand, arm curl, sit-and-reach, timed up and go (TUG) and 6-min walk test (6MWT)) and glycemic analysis (fasting plasma glucose [FPG] and glycated hemoglobin [HbA1c]). Data were analyzed using Student's t-test with 5% significance level. Results Training induced significant improvement in arm curl (P < 0.01), sit-and-reach (P < 0.01), TUG (P < 0.01), 6MWT (P = 0.05) and HbA1c (P = 0.05) in post compared to pre-training. Between two groups, only arm curl (P < 0.01) and sit-and-reach test (P = 0.01) showed statistical differences. No significant changes were observed in chair stand test and FPG. **Discussion** In our study, we found improvement in most physical tests, which justifies recommendation of American College of Sports Medicine, prescribing FT to improve and maintain physical function of older persons (Garber et al., 2011). Chair stand test was the only one which no improvement was observed. This finding may be related to fact that, in older persons, T2D is associated with reduced muscle strength and worse muscle quality in lower limbs (Volpato et al., 2012). So perhaps a specific increase in exercise loads was needed to improve strength of these muscle groups. In glycemic analysis, although it has not been observed changes in FPG, HbA1c showed a decrease (-0,28%) in TG. However, this decrease was lower than that reported in meta-analysis involving other types of training, such as aerobic (-0,73%) and resistance (-0,57%) (Umpierre et al., 2011). Finally, we conclude that FT program proposed in this study improved physical fitness and glycemic control of older adults with T2D. Also, we suggest the association of FT with other types of training, such as aerobic and resistance, aiming to maximize benefits, mainly in relation to glycemic control. **References** Garber CE, Blissmer B, Deschenes MR, Franklin BA, Lamonte MJ, Lee IM, Nieman DC, Swain DP. ## REASONS OF USING INDIVIDUAL OR GROUP FORMS OF REHABILITATION OF PEOPLE WITH SCOLIOSIS OF I-III DEGREES

Shklyarenko, A.1, Kovalenko, T.2, Pashkova, L.1, Ulyanov, D.2, Degtyarenko, Y.1, Tarasenko, D.1

1: Kuban State University branch in Slavyansk-on-Kuban; 2: Volgograd State University (Volgograd, Russia)

**Introduction** During the process of muscular activity the cosmetic changes of posture are very influenced by the anatomical and physiological features of spine. **Methods** The motions' number of 998 girls aged 8-16 years old with the scoliosis to 30o during the processes of flexion, extension, inclination and rotations both directions has been tested. **Results** The research has shown that 12% of the girls aged 8-9 years old with the scoliosis of I-II degrees have hypermobility below the normal in a lumbar part of spine (A-degree). 25% of girls have a level of hypermobility within the normal (B-degree). And 63% have the index of this parameter above the normal (C-degree). The surveyed people aged 15-16 years old have 62%, 27% and 11% of this parameter. 12-16 years old with the scoliosis of III degree have a hypermobility above the normal which dominates during the process of extension, 64% of the tested girls have shown this result. The opposite situation has been observed during the testing spine's mobility in the process of inclination forward at the sitting position. 78% of 8-9-years old girls, 66% of 9-10- years old girls and 72% aged 10-11 have had A-degree. Hypermobility has been noticed among 14% of girls aged 14-15 years old and among 21% - 15-16 years old. B-degree has been registered on average among 48% of adolescents aged 12 years. C-degree has been found among 29% and 34% of girls aged 14-15 and 15-16 years. Besides, during the research it has been noticed that

the mobility's rate in the process of flexion out of sitting position among 45% of the tested girls aged 12-16 years suffering of III-degree scoliosis exceeds 15 sm. The rotation's volume both sides over 90o (hypermobility is above normal) has been registered among 46% of 8-9 years old girls suffering of I-degree scoliosis. The number of adolescents with increased hypermobility was in average 3 times less. The largest number of tested people with the rotation to 70O (hypermobility is below normal) has been registered in the age of 12-13 years old (52%). Testing of the volume of body's flexion at the frontal surface has found that the number of girls with hypermobility is being reduced. In the process of evaluation the volume of body's flexion at the frontal surface in the group of the girls aged 12-16 years suffering of III-degree scoliosis it was found that 65% of tested has the limited amplitude of motions. Discussion The obtained information confirms that the volume of the spine's mobility at the various surfaces among children and adolescents with the different degree of scoliosis in the aged point of view essentially varies in the aspect of hypo- and hypermobility. We consider it efficient to use the group form of rehabilitation in the case of I-degree scoliosis and individual training with the combination of special exercises and massage in the case of II-III-degree of scoliosis. ### **EFFECTS OF PROPRIOCEPTION-BASED EXERCISE ON HEART RATE VARIABILITY AND SENSORY PROCESSING IN CHILDREN WITH ADHD**

Su, C.T.1, Lin, W.S.2, Yang, A.L.3

1: *Fu Jen Catholic University*, 2: *University of Taipei*, 3: *University of Taipei*

**Introduction** Attention deficit hyperactivity disorder (ADHD) is one of the most prevalent neurodevelopmental disorders in children, and studies examining nervous system on this population have been increasing. Problems of sensory processing and heart rate variability (HRV) in children with ADHD have been reported in some studies, which indicated the lower level of nervous function in children with ADHD. Furthermore, the effects of enhanced proprioceptive inputs on amelioration of nervous system problems have been assumed in sensory integration theory (Su and Parham, 2014). However, the effects of proprioception-based exercise on nervous system in children with ADHD have not been fully explored. Thus, the purposes of this study were to investigate the effects of proprioception-based exercise on sensory processing and heart rate variability (HRV) in children with ADHD. **Methods** We recruited 20 children diagnosed with ADHD. These children were assigned into the proprioception-based exercise group (ADHD-EX; aged 9.7±1.1 years old) and control group (ADHD-CON; aged 9.1±1.7 years old). No group differences existed in height, weight, and ages. Seven weeks of proprioception-based exercise intervention, including running and resistant exercise, was conducted in ADHD-EX group for 30-40 minutes per day, 5 days per week. Sensory processing and HRV were measured by Sensory Profile (SP) and Polar heart rate monitor with accompanying software respectively at the baseline and the end of the intervention. **Results** Before intervention, no significant differences on HRV and sensory processing were found between two groups. After seven weeks of proprioception-based exercise, the mean RR (ms) in the ADHD-EX group was significantly greater than the ADHD-CON group, and the mean heart rate (bpm) in the ADHD-EX group was significantly lower than the ADHD-CON group. Also, the scores on multiple sensory processing and vestibular processing were significantly higher in the ADHD-EX group than the ADHD-CON group. **Discussion** This study indicated that proprioception-based exercise could improve the performance of nervous system in children with ADHD as measured by sensory processing and HRV. Our results suggest that proprioception-based exercise could be an appropriate activity to accompany regular intervention for children with ADHD (Verret et al., 2012). **References** Su CT, Parham LD (2014). *Am J Occup Ther*, 68(5), 546-554. ### **INFLUENCES OF EXERCISE AND PROTOCATECHIC ACID INTERVENTION ON BLOOD PRESSURE AND ENDOTHELIAL FUNCTION IN POSTMENOPAUSAL HYPERTENSION**

Yang, A.L.1, Su, Y.F.1, Su, C.T.2

1: *University of Taipei*, 2: *Fu Jen Catholic University*

**Introduction** Hypertension is one of the common cardiovascular diseases in postmenopausal women. Exercise training has been known to exert cardio-protective effects in patients with cardiovascular disease. Moreover, evidences have indicated that protocatechic acid (PA), a simple phenolic acid, has antioxidant and anti-inflammatory effects, and could improve cardiovascular health. However, whether exercise training and PA intervention positively influence blood pressure and endothelial function in postmenopausal hypertension remains unclear. Therefore, the aim of this study was to investigate the influences of eight-week exercise training and PA intervention on blood pressure and endothelial function in postmenopausal hypertensive rats. **Methods** Sixteen-week-old female spontaneously hypertensive rats (SHR) were divided into three groups: the ovariectomy group (SHR-O), the ovariectomy with exercise training group (SHR-OT), and the ovariectomy with PA group (SHR-OP). Also, the normotensive Wistar-Kyoto (WKY) rat was used as the normal control group. The exercise training was conducted by treadmill at moderate intensity for 1 hour/day, 5 days/week, for 8 weeks in the SHR-OT group. The SHR-OP group was supplemented with PA solution (200 mg/kg/day) in the daily water consumption for 8 weeks. After the intervention, the systolic/diastolic blood pressure was measured and thoracic aortas were isolated for the evaluation of endothelial function (i.e., vasorelaxation). The endothelium-dependent (acetylcholine, ACh) and endothelium-independent (sodium nitroprusside, SNP) vasorelaxation was evaluated by the organ bath system. **Results** After eight-week intervention, we found that systolic blood pressure was significantly ( $p < 0.05$ ) decreased in the SHR-OT and SHR-OP groups compared with the SHR-O group. However, no significant changes were found for diastolic blood pressure among four groups. Moreover, either exercise training or PA intervention significantly ( $p < 0.05$ ) improved the ACh-induced vasorelaxation in the SHR-OT and SHR-OP groups compared with the SHR-O group. However, no significant difference was found in the SNP-induced vasorelaxation among four groups. **Discussion** Our results indicated that either exercise training or PA intervention could reduce systolic blood pressure and improve the endothelium-dependent vasorelaxation in postmenopausal hypertensive rats. It suggested that exercise and PA intervention would ameliorate parts of cardiovascular function in the population of postmenopausal hypertension. **References** Barton M, Meyer MR. ## EFFECTS OF DIFFERENT WARM-UP PROGRAMS ON FLEXIBILITY AND STRENGTH OF GASTROCNEMIUS MUSCLE

Takeuchi, K., Nakamura, M., Nishiguchi, S., Tsukuda, F., Hojo, T., Takemura, M., Miyakawa, S.

*Biwako seikei sport college*

**Introduction:** Warm-up programs comprise aerobic exercise, anaerobic exercise, and passive warm-up with heat modalities. Aerobic exercise promotes greater circulation compared with anaerobic exercise (Taylor et al., 1988). Passive warm-up raises the muscle temperature without muscle contractions (Sawyer et al., 2003). Therefore, it is possible that the effects of these warm-up programs are different; however, the differences are still unclear. **Purpose:** The aim of this study was to compare the effects of three different warm-up programs on the flexibility and strength of the gastrocnemius muscle. **Methods:** Fourteen healthy males (age:  $23.1 \pm 2.6$  years) performed three separate randomized conditions: (1) bike condition (10 min, 60 W), (2) hot condition (10 min, immersed their lower limb in 40°C water), and (3) MVC condition (10 min, five sets of 10 maximal voluntary contractions). The flexibility during passive ankle dorsiflexion and the muscle strength during an isometric contraction were measured prior to and following the warm-up. Muscle tendon unit (MTU) stiffness from 15 to 25 degrees of ankle dorsiflexion, ankle dorsiflexion range of motion (ROM), passive torque at ROM maximum, and peak torque during isometric contraction were measured using an isokinetic dynamometer. **Results:** In the bike condition, ROM ( $30.0 \pm 5.9 - 33.2 \pm 7.0$  degrees,  $p < 0.01$ ), passive torque at ROM maximum ( $28.6 \pm 7.1 - 33.7 \pm 8.0$  Nm,  $p < 0.01$ ), and peak torque ( $106.4 \pm 36 - 113.7 \pm 38.7$  Nm,  $p < 0.05$ ) increased; however, MTU stiffness was not different ( $0.56 \pm 0.33 - 0.48 \pm 0.11$  Nm/deg,  $p = 0.34$ ). In the hot condition, ROM ( $31.4 \pm 6.3 - 33.9 \pm 6.3$  degrees,  $p < 0.01$ ) and passive torque at ROM maximum ( $29.7 \pm 6.7 - 33.3 \pm 6.5$  Nm,  $p < 0.01$ ) increased; however, MTU stiffness ( $0.46 \pm 0.10 - 0.48 \pm 0.18$  Nm/deg,  $p = 0.62$ ) and peak torque ( $101.4 \pm 42.4 - 105.9 \pm 38.3$  Nm,  $p = 0.34$ ) were not different. In MVC condition, ROM ( $28.2 \pm 6.1 - 33.9 \pm 6.3$  degrees,  $p < 0.01$ ) and passive torque at ROM maximum ( $26.8 \pm 5.7 - 32.6 \pm 5.9$  Nm,  $p < 0.01$ ) increased; however, MTU stiffness ( $0.53 \pm 0.18 - 0.48 \pm 0.11$  Nm/deg,  $p = 0.88$ ) and peak torque ( $104.9 \pm 37.8 - 95.4 \pm 35.5$  Nm,  $p = 0.25$ ) were not different. **Conclusions:** The results indicated that all the warm-up programs increased ROM through an increase in tolerance. Aerobic exercise is better for the muscle strength. **References:** Taylor WF, et al. Cutaneous vascular responses to isometric handgrip exercise. *J Appl Physiol*, 66: 1586-1592, 1988. ## THE EFFECT OF COOLING ON MUSCLE WEAKNESS AND MUSCLE ATROPHY CAUSED BY DETRAINING

Endo, S., Kubota, A., Sakuraba, K.

*Juntendo University*

**Introduction** Two weeks of detraining produces 6.4% of muscle atrophy even after long term strength training. Thus, to maintain the training effect, preventing the muscle weakness and muscle atrophy caused by detraining would be valuable. Exposure to cold stimulus by cold water inhibits muscular atrophy. The purpose of this study was to investigate the effect of cooling by ice bag on muscle weakness and muscle atrophy caused by detraining. **Methods** Six healthy males ( $23.0 \pm 2.5$  y/o) performed elbow flexion resistance training three times per week for 6 weeks. After the 6 weeks training, the subjects were instructed to limit upper arm activity within their activity of daily living level during three weeks of detraining period. During the detraining period, one of the arms was cooled at inside of upper arm by an ice bag for 30min a day (ICE), and the other arms was control condition (CON). The measurements were elbow flexion torques at angular speeds of 60 and 120deg/s under concentric contraction (CC60, CC120) and isometric contraction (IM), cross-sectional area (CSA) and circumference of the upper arm. The measurements were done, at pre-training (PRE), post-training (POST), after the first week (D1), second week (D2) and third week (D3) of detraining. **Results** IM significantly increased after training in both conditions (CON:  $118.0 \pm 13.6\%$ , ICE:  $112.5 \pm 2.4\%$ ) ( $p < 0.05$ ). Significant decreases of IM in CON was observed at D2 ( $66.6 \pm 17.4\%$ ) compared to POST ( $78.8 \pm 24.8\%$ ) ( $p < 0.05$ ). Circumference significantly increased after training in both conditions (CON:  $102.1 \pm 1.0\%$ , ICE:  $101.4 \pm 0.7\%$ ) ( $p < 0.05$ ). Significant decreases of circumference in CON was observed at D3 ( $29.6 \pm 3.4\%$ ) compared to D2 ( $29.8 \pm 3.5\%$ ) ( $p < 0.05$ ). CSA significantly increased after training in both conditions (CON:  $108.5 \pm 3.3\%$ , ICE:  $107.9 \pm 2.2\%$ ) ( $p < 0.05$ ). CSA significantly decreased after the detraining in both conditions. However, there was no significant difference in all of measurements between CON and ICE. **Discussion** Elbow flexion resistance training three times per week for 6 weeks increased the muscle force, circumference and CSA of the upper arm. Only IM increased after the training. It may be because of the fact that the training was composed of isometric contraction. Even though increased the muscle force, circumference and CSA by the training decreased by the detraining. The values at D3 were higher than the values at PRE. Consequently, the training effects were maintained. On the other hand, there was no decrease in IM and circumference in ICE during detraining period. This result suggests the possibility that the cooling prevents muscle weakness and muscle atrophy; however, there was no significant difference between both conditions, therefore we consider that the effect of cooling was weak. **In conclusion**, the cooling for 30min a day shows possibility that the cooling prevents muscle weakness and muscle atrophy caused by detraining. ## EFFECTS OF LOW-INTENSITY PULSED ULTRASOUND EXPOSURE ON SKELETAL MUSCLE REGENERATION AFTER DAMAGE IN AGED MOUSE MODEL

Sakamoto, M., Nakamura, A., Shimose, R., Yona, M., Muro, M., Tadano, C.

*School of Allied Health Sciences, Kitasato University*

**INTRODUCTION** Skeletal muscle regeneration is markedly impaired with age. Because protein synthesis decreases with age, satellite cell (muscle stem cell) numbers and their proliferative potential also decrease with aging. Low-intensity pulsed ultrasound (LIPUS) is a therapeutic modality commonly used for enhancing tissue healing. Previous studies have demonstrated that LIPUS increases activated satellite cells and promotes muscle regeneration in injured muscles (Nagata K, et al. 2013). Therefore, we hypothesize that LIPUS may provide a beneficial effect in injured aged skeletal muscle. This study examined the effects of LIPUS exposure on the regenerative process in injured aged muscle using histological analysis. **METHODS** Ninety-week-old female ICR mice (N=5) were used in this study. To induce muscle injury, cardiotoxin was injected into both sides of the tibialis anterior (TA) muscle. LIPUS, which was initiated 24 hours after injury, was applied to the left TA muscles (LIPUS side). LIPUS was applied once a day under the following conditions: 10 min/day, frequency of 3 MHz, intensity of  $0.5\text{W}/\text{cm}^2$ , 50% duty cycle. The right TA muscles (control side) received a sham maneuver where only the transducer was moved. TA muscles were excised 7 days after injury. Frozen cross sections of excised TA muscles were made. Sections were stained using hematoxylin and eosin, and sections were reacted with anti-desmin antibody (a myogenic cell marker). The fiber cross sectional area (FCSA) of centrally nucleated muscle fibers was measured. **Results** were analyzed using the paired t-test with statistical significance set at  $p < 0.05$ . **RESULTS** The regenerating muscle fibers with central nuclei were observed in the injured area. Mononuclear cells had

infiltrated the interstitium in both the control side and LIPUS side. FCSA of regenerating fiber varied in size from small to large. The mean FCSA of the control and LIPUS side was  $519.6 \pm 178.9 \mu\text{m}^2$  and  $598.5 \pm 200.0 \mu\text{m}^2$ , respectively. There was no significant difference between the control side and the LIPUS side. Regarding the size distribution of FCSA, it tended to differ between the control side and LIPUS side. In the control side, the number of myofibers with FCSA  $< 200 \mu\text{m}^2$  was larger compared with the LIPUS side. DISCUSSION In this experiment, the mean of FCSA was similar in both the control side and LIPUS side. However, the number of smaller myofibers tended to increase on the control side compared with the LIPUS side. Thus, exposure with LIPUS seems to have a beneficial effect on injured aged muscle. REFERENCES Nagata K, et al. (2013). *Ann Biomed Eng* 41, 1095-1105.

## DO SESSIONS OF WHOLE-BODY CRYOSTIMULATION HAVE INFLUENCE ON RHEOLOGICAL PROPERTIES OF BLOOD IN HEALTHY MEN ?

Kepinska, M., Szygula, Z., Teleglow, A., Dabrowski, Z.

*University School of Physical Education in Krakow, al. Jana Pawla II 78, 31-571 Krakow, Poland*

**Introduction** The rheological properties of blood are very important for the proper functioning of the body. The present research of rheology is blood viscosity. Blood viscosity within the given shear stress depends on the value of hematocrit, plasma viscosity and the rheological properties of erythrocytes. The rheological properties of blood change in different situations, both physiological (physical exercise, the last trimester of pregnancy, the time of year) and pathological conditions, such as. inflammation or cardiovascular disease. **Objective** The aim of this study was to analyze the changes in rheological parameters of blood after 12 whole body cryotherapy (WBC) treatments. **Methods** The study was carried out on 8 healthy men aged  $22 \pm 2.1$  years old. The mean body height was  $175.5 \pm 3.16$  cm, body mass was  $70.4 \pm 10.3$  kg, BMI  $22.8 \pm 2.8$  kg/m<sup>2</sup>. To analyse the morphological, (hemoglobin, hematocrit, fibrynogen) and rheological properties (aggregation index, the amplitude and total extent of aggregation, the half time of the aggregation, deformability of RBC ) of blood, the blood was sampled immediately before the first treatment (control blood sample) and after 12 WBC treatments. Twelve WBC treatments (every second day, for 1 months) were performed in a special cryogenic chamber at the temperature of about  $-120^\circ\text{C}$  for 3 minutes in the Matopolskie Centrum Krioterapii in Krakow, Poland. **Results** After 12 WBC treatments there was not any changes in the rheological properties of blood. There was recorded a statistically significant decrease in hemoglobin but without changes in hematocrit. All results were within the physiological norms. **Conclusions** 1. WBC is the safe treatment for health people, does not cause changes in blood flow. 2. 12 sessions of whole body cryostimulation causes small changes in the blood parameters. 3. The results of this research should be validated in a larger study group. The project was financed from the funds of the National Science Centre in Krakow, Poland on the basis of a decision no. DEC-2012/05/N/NZ7/01107. Contact m.kepinska@tlen.pl

## Sociology

### RESEARCH ON THE ORDER OF TAE KWON DO : POPULARIZATION AND ATHLETICISM

Zhu, W.

*Guangdong Institute of Education*

From understanding the concept of sports order and its process including spontaneity, self-consciousness, heteronomy, autonomously, self-discipline to analyze the order of Tae Kwon Do as sport. This article aims to discover the fact that the order of Tae Kwon Do in the development of Popularization and Athleticism has its process as well as others sports . Tae Kwon Do can be developed Vigorously only follow this process and take advantage of its principle and requirement. The spontaneity and self-consciousness of Tae Kwon Do should be respected in its development of Popularization, while the heteronomy should be complied with its mightiness of Athleticism. The order of Tae Kwon Do would be run in the society after the unity of Popularization and Athleticism operation cause of autonomously and self-discipline be in motion.

### THE USE OF PERFORMANCE-ENHANCING SUBSTANCES AMONG MEDICAL STUDENTS OF A MIDDLE EASTERN UNIVERSITY

El Osta, L., Tarhini, H., Saadallah, N., El Osta, N.

*School of Medicine, Saint-Joseph University of Beirut*

**Introduction** The use of performance-enhancing substances (PESs) can be extremely dangerous. Multiple data among college students exist in the literature (Buckman et al., 2009; McCabe et al., 2007). However, it could be interesting to describe this phenomenon among medical students, future health promoters. The aim of this study was to determine the prevalence of PESs use and identify the factors associated with this behaviour among medical students of a Lebanese university. **Methods** A cross-sectional survey using an anonymous structured self-administered questionnaire was conducted between January and March 2013 among 579 students at a major Lebanese school of medicine. PESs users were defined as students who reported use of PESs (including prohibited substances and nutritional supplements) within the past year. **Results** A total of 505 valid responses were obtained (response rate: 87.2%). More than half of the respondents (58.6%) stated they participate in sports once or more per week, and 18 (3.6%) reported past-year use of a PES. There were statistically significant associations between the use of PESs and being male (-p-value=0.001), cigarette smoking (-p-value<0.0001), regular alcohol consumption (p-value=0.018), practicing sports more than once a week (-p-value=0.013), practicing strength (-p-value=0.032) and team sports (-p-value=0.019), participating in national (-p-value=0.018) and regional competitions (-p-value=0.010), and receiving an award following a sport competition (-p-value=0.014). Nutritional supplements and proteins were the most PESs used, followed by ephedrine and anabolic steroids. **Discussion** Fortunately, the use of PESs is not prevalent in our population despite the fact that the majority of participants are sporty. It is probably due to the future role of medical students as actors in the field of anti-doping activity. However, the PESs use by our students fits the standard profile of substance use (Buckman et al., 2009; McCabe et al., 2007) because it was associated with other risky behaviours such as smoking and alcohol consumption. It is also associated with frequent sport practices, which exposes the fact that PESs use is an important area of concern for athletes (Morente-Sánchez et al., 2013). Since our survey was conducted among medical students, more researches on the use of PESs in athletes (elite and amateur) are needed. The factors associated with PESs use may have important implications for future studies and preventive measures. **References** Buckman JF, Yusko DA, White HR, Pandina RJ. ## THE RELATIONSHIP BETWEEN CHILDREN'S OPTIMISTIC CHARACTERISTIC AND SPORT ENJOYMENT

You Yi, C., Wen Yi, W.

*University of Taipei, Taiwan*

**Introduction** Physical activities are beneficial to the development of body and mind in children. Therefore, it is important to discover relative factors that enhance youngsters to participate in physical activity. In particular, sport enjoyment is one indicator of long-term adherence to physical activity. Further, personality trait is considered as a crucial factor that may influence children's participation motivation of physical activity (Schneider & Graham, 2009). The purpose of this study was to investigate the relationship between children's optimistic personality and sport enjoyment. **Methods** One hundred and sixty-two 3rd grade to 6th grade elementary students (boy: 147, girl: 15, mean age: 10.12 ± years) who participated in after-school soccer and fitness programs were recruited to complete the Youth Life Orientation Scale and Physical Activity Enjoyment Scale. A Pearson's product moment correlation was used to analyse the data. **Results** Optimistic personality was found to positively relate to the four sub-scales of enjoyment, such as activity itself ( $r = .38$ ), social and life opportunities ( $r = .42$ ), praise and reward ( $r = .46$ ), and perceived competence ( $r = .38$ ). **Discussion** Individuals with optimistic characteristics tend to expect a positive result and keep a high level of confidence while facing challenges. Further, they are apt to stick to the enthusiasm and demonstrate persistence toward difficult events (Scanlan, Stein, & Ravizza, 1989). With such a positive psychological quality, an individual is relatively easy to feel positive emotions such as joy, happy, making new friends, competence and other sports enjoyment when participating in physical activity (Allen, Greenlees, & Jones, 2013). The finding suggests that physical education teachers or instructors are needed to pay attention to students' personality traits that may moderate the positive affect of participation in physical activity. **References** Allen, M. ## EXERCISE PASSION, PERCEIVED RISK, AND BENEFITS OF RECREATIONAL SCUBA DIVERS

Ya Ju, H., Hsien Jung, L.

*University of Taipei*

**Introduction** The benefits of participation in leisure activity include relieving stress, enhancing life excitement, maintaining physical fitness, and promoting social relationships. Few studies have examined the influences of perceived leisure risk and exercise passion on leisure benefits of adventure leisure activities (Vallerand et al., 2003). The purpose of the study was to explore the relationships between exercise passion, perceived leisure risk, and leisure benefits in scuba diving participants. **Method** Two hundred scuba divers (age ranged from 20 to 60 years) were recruited to complete a battery of questionnaires regarding exercise passion, perceived leisure risk, and leisure benefits in a resting setting. Data obtained in this study were analyzed by correlated analyses and multiple regression analyses. **Results** Compared with the beginning divers, those who were certified divers indicated higher perceptions of diving risk and diving benefits. For the certified divers, harmonious and obsessive passion and perceived leisure risk could positively predict leisure benefits. For the beginning divers, harmonious passion and perceived leisure risk could positively predict leisure benefits, whereas obsessive passion was negatively related to leisure benefits. **Discussion** The certified divers revealed higher levels of harmonious passion, leisure risk and leisure benefits than the beginning divers. Similarly, previous research has showed that harmonious and obsessive passion of recreational tennis players positively correlated with long-term exercise adherence (Vallerand & Miquelon, 2007). Further, those participants who demonstrated a higher level of involvement in leisure were apt to perceive a larger amount of leisure benefits (Vallerand et al., 2003). For adventure leisure participants, they might consider activity-related risks as a part of adventures that would not reduce the interests or values of involvement in such activities (Dowling & Staelin, 1994). The findings indicate that individuals may perceive larger benefits in physiological, psychological, and social aspects when they gain greater knowledge of diving risk. Diving experience seems to be a moderator between exercise passion and leisure benefits. **References** Dowling, G. R., & Staelin, R. (1994). *Journal of Consumer Research*, 21(1), 119-134. ## THE INFLUENCES OF PSYCHOLOGICAL NEEDS AND EXPECTANCY VALUE ON LEARNING MOTIVATION IN PHYSICAL EDUCATION CLASS OF MIDDLE SCHOOL STUDENTS

Poyi, C., Wenyi, W., Chienchih, C., Juchu, L.

*University of Taipei*

**Introduction** A close relationship has been found between students' involvement in physical education and their learning motivation. Previous study showed that learning motivation of middle school student was effected by the levels of self-determination (Deci & Ryan, 2002). Further, based on the expectancy-value theory (Eccles et al., 1983), expectancies and values are assumed to influence directly performance, effort, and persistence. Fewer studies have simultaneously discussed the influences of self-determined motivation and expectancy values on learning motivation. The purpose of the study was to investigate whether students' psychological needs satisfaction and expectancy values may affect learning motivation in physical education class. **Methods** This study recruited 451 junior high school students (age = 14.21 years) as the participants from Taipei city. Participants completed the Basic Psychological Needs Scale, Learning Motivation in PE Scale, and the Sport Expectancy Value Scale. The data were processed by descriptive statistics and independent t-tests. **Results** The results indicated that the students with higher perceptions of relatedness, autonomy, and competence demonstrated higher learning motivation than those with lower perceptions of basic psychological needs. Besides, the students who reported higher task value exhibited higher learning motivation than those who reported lower task value. **Discussion** The findings indicated that basic psychological needs satisfaction and expectancy values could significantly influence students' learning motivation in PE. Perceived relatedness was the most important factor affecting learning motivation, which is presumably related to the needs of belonging and identity by peers in adolescents (Deci & Ryan, 2002). Consistent with the prediction of the expectancy-value theory (Eccles & Wigfield, 2002), a higher level of perceived task value would enhance intrinsic motivation in PE class. PE teachers and instructors might facilitate the learning motivation of students by satisfying their basic psychological needs and enhancing their value perceptions of participating in PE class. **References** Edward Deci, & Richard M. ### **A QUALITATIVE ANALYSIS OF THE OPINIONS OF ATHELETES, COACHES AND ANALYSTS ON THE PROVISION OF FEEDBACK IN ELITE AND SUB-ELITE SPORT.**

Davies, G.1, Hughes, M.D.2, Dancs, H.3

*1 UWIC, Cardiff, Wales, UK, University of West Hungary, University of West Hungary*

Introduction Qualitative research is classified as a broad interpretive or hermeneutic tradition in social science and the humanities (Taylor, 1979; Messer et al., 1988), such information seeks to understand the meaning of an experience to the participants in a specific setting (Thomas et al., 2005). Since the advances in technology aiding the reliability of feedback, a qualitative study has not been instigated to investigate the roles of the coach and opinions of the athletes with respect to feedback procedures. Limited research (Murray et al., 1998) has been conducted investigating the psychological states of athletes, but athlete opinions were omitted from the investigation. Methods By formulating three individual questionnaire and interview guides, athletes, coaches and analysts were enquired about feedback, in the event to confirm the value of performance analysis strategies and suggest any further quantitative techniques. Following a detailed pilot study, data were collected from 93 athletes and nine coaches and nine analysts. Results Results indicated that verbal instruction was the athletes most preferred method to receive feedback, in addition to all coaches predominately using this method. 98.91% of athletes find video feedback beneficial, with analysts insisting, that video feedback is the most effective way to convey a message to team/individual. Athletes addressed that statistical feedback alone does not hold the same significance as video instruction, yet when combined an effective feedback measure is produced. All coaches (100%) take advantage of time following performance, by providing feedback through verbal, statistical and video measures. Elite analysts, conduct analysis in-event or directly after, providing immediate feedback and allowing coaches to interpret results prior to presenting to athletes. This improving the quality of feedback, as an overload of information is not presented. Statistical, verbal and video feedback are used within a training environment, seizing the advantage of time available to transfer information. Discussion Results strongly confirmed the value of performance analysis techniques when only 5.00% of athletes did not find analysing their own performance in post-event beneficial. ### **Sport Management and law**

#### **DRAFTING A PROPOSED POLICY LEGISLATIVE WOMEN AND SPORT IN KUWAIT**

Ali, E.

*asic education college*

Witness sports movement great attention and sensation of the relationship correlation between sport, legislation, specifically between sport and legislative policy based on the principle of a stable legal emphasizes the correlation of law in all walks of human life, economic, political and sports as well, and some believe that the laws and legislation is not suitable for field sports, and it is far from sports practice However, within the framework of regulations for games such as football, basketball, volleyball, etc. and 00 but became the subject is important and vital for the management of sports and action sports practice and influential but also in production in many developed countries. The legislative policy is the goal of the legislation relevant to the promulgation and application of public policy senior, in varied Bmajaladtha in various aspects of political, social, economic, and enacted through legislation. Public policy is difficult to impose, and is applied through legislation is characterized by a set of legal rules from the application of these characteristics make the policy binding. Discipline is achieved for each game through legislation and laws as they are in compliance with international law of the game and the referees are judges who implement the law as it is an important component of the evolution of the sport movement. Sued the governance of a particular kind is issued judgments immediate and decisive as that at the same time, the executive authority of any decision he takes, and working on its implementation What we are dealing with in this context is to develop a vision of philosophy for the formulation of a proposed reality of women's sports in the State of Kuwait and that as part of work leadership and management in sports organizations where you need to participate in the formulation of public policy upon the parties to the first party of government decision-maker which is based on ensuring the safety of the implementation of decisions and the second community He is represented in this context (science and scientists) as an important basis to participate in the formulation and elaboration of this policy where adopt the experience of countries that apply the reform programs, all aspects of human life as this reform for Nokia moving right only if the voice of civil society, scientists heard through participation in the formulation of policy both in his speciality.

#### **COMPARE AND RELATIONSHIP BETWEEN ORGANIZATIONAL CULTURE AND HUMAN RESOURCE PRODUCTIVITY IN PHYSICAL EDUCATION ORGANIZATION OF THE ISLAMIC REPUBLIC OF IRAN FROM THE VIEWPOINTS OF MANAGERS AND EXPERTS**

Nakhaie, H.1, Mahdiyeh, M.2, Mosavi Gilani, S.R.3

*1and3: Faculty Member, Zahedan University of Medical Sciences (Zahedan, Iran), 2: M.Sc., Physical Education and Sports Sciences (Elam, Iran)*

Introduction Achieving productivity is one of the main goals of any organization. To achieve this goal, there is no other way except resorting to some kind of systematic, native, and practical perspectives. Methods From among 1600 general manager, based on Morgan sampling table, we chose 310 managers and experts from the Physical Education Organization of the Islamic Republic of Iran who is working across the country. Data were collected from three demographic questionnaires with eight questions, Robbins' organizational culture questionnaire with 30 questions, and productivity questionnaire with 26 questions. Then, the data were analyzed using descrip-

five statistics including measures such as frequency, mean, standard deviation and inferential statistical techniques in addition to tests such as Cronbach alpha test of Levin, the Kolmogorov-Smirnov test, t-test and u Mann-Whitney. Results The analysis of finding is shown that have meaning full relationship between organizational culture with efficiency of managers and experts. The relationship between individual's characteristic such as age, Education unseem with organizational culture and efficiency. But was seen the negative meaningful ( $P=0/021$ ,  $r=136$ ) relationship between information work with organizational culture and the positive meaningful ( $P<0/699$ ,  $r=0/023$ ) relationship with efficiency. Discussion Therefore, if there is a necessity to improve the elements of organizational culture, productivity of employees needs to be increased or vice versa. Since, in this study, most elements of organizational culture and productivity of employees were at average level, it is suggested to take appropriate measures to improve the current organizational culture in the Physical Education Organization of Iran. Such measures should include providing an appropriate and desirable environment for inventive and creative individuals along with awareness-raising through continuous on-job training by experts. In this way, it is hoped to improve organizational culture and have greater productivity in the future. References 1. Andreassi, J. K., Lawter, L., Brockerhoff, M., Rutigliano, P. J. (2014). ## Sport Statistics and Analyses

### RELATIONSHIP BETWEEN BALL SPEED OF SPIKE IN VOLLEYBALL AND TRUNK STRENGTH

Momoko, S., Rieko, K., Yoshisa, U.

*CHUKYO UNIVERSITY*

**PURPOSE :** The spike in volleyball is one of the effective ways to score. Increasing the spike speed increases chance to score. Yoshihara et al. (2009) reported, 1) plyometrics with exercise ball is the effective training to increase the spike speed, and 2) condition of increasing the spike speed is requires balance in the air and the fast start of arm and trunk motion. We conclude it requires measuring trunk strength, but Yoshihara et al. didn't reported. So, the purpose of this study is to identify relationship of the spike speed with trunk strength and with balance. **METHODS :** Research participants were 16 hitters of C university men's volleyball team, their height, weight, age, and volleyball career (average $\pm$ SD) were 1.80 $\pm$ 0.04 m, 73.3 $\pm$ 1 kg, 20.3 $\pm$ 0.9 years old, 9.6 $\pm$ 1.9 years. Measurements were the spike speed calculated by radar speed gun, strength of trunk flexion and extension by BIODEX, and throwing medicine ball test with 3kg and 5kg in following positions; standing, standing on knees, sitting on an exercise ball, and standing on balance discs. Correlation coefficient was calculated the spike speed and each measurement. Pearson's correlation coefficient was used ( $p<0.05$ ). **RESULTS :** In throwing medicine ball test, throwing distance performed on exercise ball and balance disc both with 3kg and 5kg were significantly correlated with the spike speed. Throwing distance in standing on the floor with 3kg was significantly correlated with spike speed. Throwing in knee-standing was not significantly correlated with the spike speed. In BIODEX measurement, trunk flexion strength was significantly correlated with the spike speed. **CONCLUSION:** Yoshihara et al. (2009) reported to increase the spike speed, the high performance of trunk in the air was needed. In this study, we found throwing performance on exercise ball and on balance disc related the spike speed. These positions are more unstable than standing on a floor. To increasing the performance under unstable conditions will enhance performance in the air, therefore, increase the high performance of the spike speed. Yoshimatsu et al. (2006) reported, in spike, swing is produced by trunk flexion and twist. We also found strength of trunk, especially flexion strength related the spike speed. Then the trunk performance in unstable condition and trunk flexion strength will increase the spike speed.

### REASONS FOR SPORTS PARTICIPATION AMONG JAPANESE HIGH SCHOOL STUDENTS: DIFFERENCES BETWEEN SPORTS CLUB MEMBERS AND NON-SPORTS CLUB MEMBERS

Aoyagi, O., Yaita, A., Choi, T., Han, N.

*Fukuoka University, Kyushu Kyoritu University and Jeju National University*

**Purpose** People play sports because they are fun (Sugihara, 2000). However, the structure of the joy felt while playing sports is complicated and not yet fully understood (Wada, 2000). This study aimed to investigate differences in the reasons for participating in sports among Japanese high school students who regularly participate in sports and those who do not. **Methods** A questionnaire survey was conducted of 738 high school students (386 sports club members and 352 non-sports club members) at two high schools in Japan. Questionnaire items were taken from Han et al.'s questionnaire on the motivation for participating in sports (2014), which was translated from Korean to Japanese. All questionnaire responses were rated on a 5-point Likert scale. Factor analysis was conducted and the factorial structure was extracted. For factor analysis, extracted factors with eigenvalues greater than 1.0 were rotated using Varimax orthogonal rotation. Factor scores were also computed with regression analysis. The students were categorized as either sports club members or non-sports club members and t-tests were conducted to compare the two groups. **Results** Three factors were extracted as a result of factor analysis. Since the first factor had significant factor loadings in items that effectively use the students' time to improve their motor skills or physical fitness, we interpreted this factor as the "improving physical fitness or motor skills" factor. The second factor was interpreted as the "showing off sports/exercise performance" factor because it had significant loadings in items relating to boasting about motor skills or exercise performance. We also found significant loadings in items for making friends or getting along with friends in the third factor, which we interpreted as the "sociability" factor. **Statistical comparison** of the three factor scores between sports club members and non-sports club members indicated that a significant difference was found in the first and third factors, and that sports club members had a positive opinion of sports. **Conclusion** Sports club members regularly played sports or exercised and sufficiently understood the effects of such activities, such as improved physical fitness or motor skills. Many non-sports club members played sports or exercised in their spare time because they did not have other activities to participate in. In addition, we found two factors related to motivation to participate in sports/exercise; individual factors and social factors. The former was the individual reasoning to improve individual abilities (e.g. physical fitness or motor skills), and the latter was the social reasoning to maintain or advance friendships. However, no sports club members played sports or exercised in order to show off their motor performance or skills.

## 5SD BODY BUILD CLASSIFICATION OF 13–15-YEAR-OLD MALE VOLLEYBALLERS FOR COMPARATIVE ASSESSMENT OF THEIR SPIKING PERFORMANCE DURING THE ESTONIAN CHAMPIONSHIPS IN 2014

Stamm, R., Stamm, M., Joao, P.V.

*Tallinn University*

**Introduction** We somatotyped 13–15-year-old volleyballers into a 5 SD height-weight classification according to concordance or discordance between their height and weight. As a number of earlier researchers have found that anthropometric characteristics influence the competition results in different sports, we tried to find if there is a relationship between body type and spiking efficiency. **Methods** The subjects of the study were 63 male volleyballers who participated in the Estonian Championship in 2014. During 28 matches, each boy's spiking performance was recorded by the computer program Game. Thirteen body measurements were taken: height, weight, suprasternal height, xiphoidal height; chest, waist, hip, wrist, upper thigh and lower leg circumferences, arm circumference flexed and tensed, and wrist breadth. We applied a classification that was based on the boys' mean height and weight and the respective standard deviations. The following classes were created: (1) small – small height and small weight; (2) medium – medium height and medium weight; (3) big – big height and big weight; (4) pycnomorphs – small height and big weight; (5) leptomorphs – big height and small weight. The boys were placed into the classes according to their individual heights and weights. The boys' spiking performance in the games of the whole tournament was assessed in the same 5 SD classes into which they had been systematized according to their anthropometric measurements. **Results** Statistical differences appeared between the classes of pycnomorphs and leptomorphs. Leptomorphs were statistically significantly better in the total numbers of spike, average number of spikes per game, total of number of successful spikes, average number of successful spikes per game. The total number of spikes for the class of leptomorphs was 77.6 and for pycnomorphs 21.2 on average. The classes of small, medium and large did not statistically differ from one another, but in all cases, the large class was better than the medium, and the medium class was better than the small class. The index of proficiency during spike was 0.25 in the large class, 0.14 in the medium class and 0.11 in the small class. **In conclusion**, the boys of the large class were the most successful. **Discussion** The 5 SD classification applied by us enabled us to systematize simultaneously the anthropometric variables and performance results. The classification has been acknowledged in C. Raschka's monograph *Sportantropologie* (2006) as an innovative Estonian system of sports and constitutional typology. **References** 1.Raschka C. *Sportantropologie*. Köln: Sportverlag Strauss, 2006, 219–220.

## INJURIES IN GERMAN CLUB SPORTS –EPIDEMIOLOGY AND FIELDS OF PREVENTION

Henke, T., Schulz, D.

*Ruhr-University Bochum, ARAG Sports Insurance Dusseldorf*

**Introduction:** Almost one out of four Germans is registered in a sports club. Nowadays, sport is acknowledged as an integral component of a healthy lifestyle. Numerous studies provide evidence of the benefits of sports on health. However, about 2 million sports injuries per year diminish the health benefits of sport. On the basis of epidemiological data of sports injuries in German sports club it is aimed to identify focal areas for the development and implementation of prevention measures. **Methods:** Continuous questionnaire-based injury monitoring on club sports injuries that have been reported to the respective sports insurance. Full survey among selected federal sports associations. **Results:** Since 1987 a database of more than 200,000 sports injuries has been established. 75% of the injuries are registered in football, handball, basketball and volleyball, although only 30% of all sports club members are organized in these sports. Ankle injuries have decreased from 30% to 19%, whereas the rate of knee injuries has increased slightly from 17% to 21%. Days of disability have dropped steadily since the 1990s, whereas inpatient hospital days have doubled from 5 to 10 days. The share of injuries that need surgery increased from 30% to 40%. Injuries to the knee, lower leg and upper arm have the highest surgery rate, indicating more serious injuries here. **Discussion:** The presented injury figures raise the question of how an active lifestyle can be promoted while reducing the 'side effects' of sport – i.e. sports injuries – to the lowest possible level. To maximize the reach of preventive measures, the focus should firstly be on sports with a large number of active participants and high absolute number of injuries, or a relevant level of serious or fatal injuries, leading to team ball sports are a major area of focus for injury prevention. Moreover, prevention measures should be tailored to those body regions that are most commonly and severely affected. While the prevention of ankle injuries seems to be headed in the right direction, especially the proportions of knee injuries and head injuries are increasing. Prevention programs need to be adjusted to trends e.g. team ball sports becoming more popular among women, who are more prone to severe knee injuries. The fact that "bad luck" or "a series of unfortunate events" are still frequently quoted as main causes for sports injuries shows how essential information on injury causation and the existence of effective prevention measures is. Preventive measures can be found in the four "fields of prevention": "Training measures and athletic preparation", "technical and political measures", "equipment and facilities" and "medical and non-medical support". thomas.henke@rub.de

## FACTORS OF SUCCESS IN A TRIATHLON MIXED RELAY WORLD CHAMPIONSHIP RACE

Pöller, S.

*Institute for Applied Training Science*

**Introduction** Recently, the triathlon competition system organised by the International Triathlon Union (ITU) has been modified and now consists of less standard distance and more sprint and super sprint races. In the 2014 ITU Mixed Relay World Championships in Hamburg all national teams consisted of four athletes (woman-man-woman-man). Each athlete had to race a super sprint triathlon of 300 m swimming, 6.600 m cycling and 1.600 m running. Until today, no mixed relay competition analysis has been published. The aim of the present analysis was to objectify performance and to identify the impact on the overall result. **Methods** 16 finishing teams were included into this study. To objectify performance, swimming and running distances were calculated using laser tracking (Laser 1200S, Nikon, Tokyo, Japan) and a measuring wheel (Rollfix Easy, BMI, Hersbruck, Germany), respectively. The length and power output of the bike leg was quantified using the German athletes' PowerMeters (SRM GmbH, Juelich, Germany). Official results were obtained from the online database of the ITU. Significant group differences between medallists (rank 1-3) and participants (rank 4-16) were detected using Mann-Whitney U-test. **Results** Swim velocities amounted to  $1.30 \pm 0.04$  m/s for females and  $1.44 \pm 0.05$  m/s for males. Female triathletes on third position were significantly faster in the medal winning teams ( $1.33 \pm 0.01$  m/s vs.  $1.28 \pm 0.04$  m/s;  $p < 0.05$ ). Females and males showed an average bike speed of  $37.3 \pm 0.9$  km/h resp.  $40.1 \pm 1.1$  km/h. Male medallists achieved significantly higher speeds than participants on the second and fourth position ( $41.3 \pm 0.2$  km/h vs.  $40.4 \pm 0.8$  km/h and  $41.2 \pm 0.4$  km/h vs.  $39.3 \pm 1.1$  km/h;  $p < 0.05$ ). Mean absolute and relative power output for position one, three and four in the German team were 211 W (4.2 W/kg), 209 W (4.1 W/kg) and 325 W (4.6 W/kg), respectively. Running speeds were  $4.91 \pm 0.17$  m/s for females and  $5.60 \pm 0.23$  m/s for males. Significant differ-

ences were found between male medallists and participants on the last leg ( $5.98 \pm 0.13$  m/s vs.  $5.57 \pm 0.26$  m/s;  $p < 0.01$ ). Discussion In comparison to individual triathlons, the swim and bike parts have an increased impact on the competition result. Swim velocities and power outputs were higher than in other analysed ITU World Triathlon Series sprint and standard distance races whereas running speeds were almost identical (unpublished data). Cycling has a higher influence as bike groups are smaller and the possibility for drafting is reduced. Because the mixed relay might be added to the program of the 2020 Olympic Games, there is an increasing need to understand the factors determining success in this event. ### WHAT DO RHYTHMIC GYMNASTICS JUDGES THINK ABOUT THEIR CODE OF POINTS?

Leandro, C.1,2, Ávila-Carvalho, L.3, Bobo-Arce, M.2, Sierra-Palmeiro, E.2

1:ULP (Porto, Portugal), 2:UDC (Coruña, Spain), 3:FADEUP (Porto, Portugal)

Introduction The Code of Points (COP) is an evaluation tool but that contribute also to the evolution of Rhythmic Gymnastics (RG) as sport. This tool is applied in competition by the judges giving them a very important role in this process. So it becomes very important to know the RG judges that apply this tool in the main competitions (the international level RG judges) and their opinion about de COP. The main role of this study was to characterize the international level judges and their perception of the objectivity level of their judgment in competitions. Methods 160 international RG judges answered a survey to collect the data. The survey was composed by 15 questions grouped in 2 categories: (1) personal information, education, professional experience and experience as judge, and (2) objectivity of evaluation in RG and proposals to change the COP.(FIG,2012) For the data analysis, non-parametric tests were used. Results The judges were  $43 \pm$  years old (min 22 - max 68 years old), 49% have a university degree, 87% are also coaches and all of them are judges for more than 2 Olympic cycles. For the judges, the Difficulty evaluation has more subjectivity for the difficulty elements of Mastery and Dance Steps and less subjectivity in the difficulty elements of Balance. Concerning the Execution, the judges found that the evaluation of the Artistic faults is the most subjective in this domain. Inside the Artistic faults the parameters Unity of the Composition and Relation between the music and the movements, were those who registered higher significant results for the subjectivity in the evaluation. Discussion This evidence might be related to the fact that the validating criteria for the elements are, probably not enough specific, what can cause some pliability in the evaluation, as well as some definitions such as refer Simões (2000) which states that any evaluation system should hold precise criteria for judging performance. The judges proposed changes in the COP regarding evaluation criteria of the following difficulty groups: Mastery, Dance Steps and DER. Also they found that changes must be done to make the Artistic faults, more precise. Finally the judges referred their wish to have some rule to avoid the repetition of the same difficulty elements on the routines with the different apparatus. This result can contribute to an improvement of the COP and in consequence to help in the development of this sport. References FIG. (2012). ### ANALYSIS OF INTERACTION BETWEEN OFFENSE AND DEFENCE TACTICS IN TEAM HANDBALL BY MEANS OF ARTIFICIAL NEURAL NETWORKS

Alsaied, S., Schrapf, N., Hassan, A., Tilp, M.

University of Graz, Austria, Mansoura University, Egypt

Introduction In team handball performance indicator analysis of single actions provides a general view about playing trends and can reveal valuable information about the strength and weak points of teams (Meletakos et al., 2011). However, the focus on single action analysis only gives restricted insight into tactics and does not take into account team interaction. Therefore, the aim of this study is to propose a method to analyze action sequences and team interaction in handball by means of artificial neural networks (ANN) to obtain a deeper understanding of the tactical performance. Methods Twelve games from the EHF EURO Men 18 in Hard (Austria) were captured by 8 cameras. Ground positions of offensive and defensive teams were determined with custom-made software. In total, 723 offensive actions and defensive situations were recorded. Subsequently, offensive and defensive data were analyzed separately with ANN software (Perl, 2002) to determine tactical patterns. Each neuron of the trained ANN represents a pattern of offensive or defensive actions, respectively. Neighboring neurons which are grouped to clusters represent similar offense or defense behavior. In a next step the related offensive and defensive behaviors were further analyzed. In order to compare the success of different defensive behaviors odds ratios were calculated. Results The ANN determined 25 offensive and 14 defensive clusters (i.e. behaviors). We observed that different defensive behaviors with different chances of success were used against specific offensive behaviors. As an example, nine different defensive behaviors were used against offensive behavior cluster #1. However, odd ratio analysis revealed that defensive behavior #3 was 2.8 times more successful than defensive behavior #5. On the other hand we observed that e.g. defensive behavior #1 was more successful (by 1.7 times) against offensive behavior #1 compared to offensive behavior #16. Discussion The results showed the applicability of ANN for identifying offense and defense patterns in team handball which could then be used for the analysis of interaction. Odds ratio analysis allowed estimating the chance of success of different defensive tactics against a specific offensive tactics and vice versa. The proposed method augments tactical analysis for coaches and can support them in the development of offensive and defensive tactics in game preparation. ### COUNTERATTACK IN TEAM HANDBALL: ANALYSIS AND COMPARISON OF WINNERS AND LOSERS OF EHF CHAMPIONS LEAGUE 2013/2014 FINALISTS

Musa, V.S., Menezes, R.P.

Universidade de São Paulo

Do not insert authors hereIntroduction Team sports, like handball, are divided in different phases (offensive, defensive and transitions) depending on the ball possession. The teams changes the way they play based on which stage they are, the game result or their strategies. During the offensive transition teams can use a strategy called counterattack to reach fastly the opponents goal and attack with their defense system unpositioned. The use of this strategy could determine significantly the game result and differentiate winners and losers of the game. Thus, coaches and their staffs can improve training sessions. The aim of this work were to investigate the counterattacks sequences of EHF Champions League 2013/2014 finals, to analyze the beginning, the end and the numerical ratio between the teams during the actions (comparing winner and losers). Methods Twelve matches of the EHF Champions League 2013/2014 finals, semi-finals

and quarter-finals were analyzed, through videos obtained of broadcasting public website. The counterattack sequences of these matches were analyzed and some variables proposed by Prudente et al. (2004) were quantified and adjusted. These adjustments led us to create a numerical ratio index, based on numeric differences between players of each team. After quantify this variables, winners (WG) and losers (LG) were compared to observe differences between these groups. Results In the beginning of the counterattacks, the reasons that most differentiate WG and LG was the goalkeepers saves (33% WG; 26% LG) and the output shots (11% WG; 6% LG). In the end of the counterattacks WG shows a better effectiveness in the counterattack actions (52,7%) than LG (47,8%). The numerical ratio shows that WG uses more frequently the counterattack strategy when they are in numerical inferiority, while LG uses it more when they are in numerical superiority. Discussion The comparison between WG and LG pointed out that WG had a better performance in goalkeepers effectiveness, output shots, counterattack effectiveness and more often use of counterattacks when they are in numerical inferiority than superiority. We conclude that those variables, including numerical inequalities, are important for a team which wants to use this strategy and they have to focus on this in their planning training sessions. ## QUANTITATIVE ASSESSMENT PROPOSAL OF FOOT ARCH DEVELOPMENT FOR EARLY CHILDHOOD

Ueda, K., Kokudo, S.

*Kobe University*

**Introduction** During the early childhood, child foot has covered by fixed fat pad which protected their foot from overloading until the skeletal system has adapted to the vertical load during stance and gait. The fat pad is absorbed and the longitudinal arch of the foot is said to continue to develop until the age of 6 years. The purpose of this study is to present a new quantitative assessment of foot arch development from the review of "child's foot arch assessment" articles. **Methods** A literature search of ScienceDirect and CiNii used the following keywords alone and in combination: "footprint" AND "child": "plantar" AND "evaluation". The term "foot development" was also used in combination with the above terms. The reference lists of relevant publications derived from the above electronic search were scanned. It was searched by one investigator for all years available up to February 2015, without language restriction. **Results and discussion** Main results that have been described in the collected literature were, as follows: the literatures of footprint assessment were 1,516 (English literatures were 1,450, Japanese literatures were 66). The visual assessment literatures(60) and the ratio of area assessment literatures(70) were target to review. In accordance with ligaments and skeletal is formed, the child's foot arch is formed from the middle. Instead of a medial gap caused by the longitudinal arch a characteristic fat pad can be found on the medial margin of the midfoot. However, it is not clear how evaluate such kind of the child's foot arch development even a large number of researches have been carried out research into the evaluation of footprint. It was seemed that the length and width information have some advantage because the area was able to calculate from length and width and visual assessment would be extend to distance. Therefore, proposal of a new quantitative assessment of child's foot arch development is as follows. **【1st stage】** Descriptive (D): medial longitudinal arch (MLA) is comes enter in from the inner tangent (IT). Quantitative (Q): Maximum width of IT-MLA **【2nd stage】** D: Medial gap (MG) caused by the development of MLA can be found on the center of the midfoot. Q: MG's width and length **【3rd stage】** D: MG expand to near MLA. Q: MG's width and length and Maximum width of IT-MLA **【4th stage】** D: MG reaches to MLA. Q: MLA-MG's width and length. **【5th stage】** D: outer longitudinal arch (OLA) comes enter in from outer tangent (OT) . Q: Maximum width of OT-OLA. Vertical distance from MG's width and length. **Conclusion** Child's foot arch is considered to be an important component of musculoskeletal assessment in clinical practice and research. However, many measurement approaches were not clear how evaluate the child's foot arch development process. Quantitative assessment of foot arch development for early childhood was developed in this study. This information should be helpful to evaluate the child's foot arch development forming process with regard to foot shape and function. Contact [allurekeiko@gmail.com](mailto:allurekeiko@gmail.com)

### RUNNING SPEED ESTIMATED FROM FOOT CONTACT TIME AND STRIDE FREQUENCY

de Ruiter, C.J., van Oeveren, B.T., Francke, A., Zijlstra, P., van Dieën, J.H.

*MOVE Research Institute Amsterdam, VU University Amsterdam, The Netherlands*

**Introduction** The global positioning system (GPS) is often used to monitor running speed. However, it cannot be used indoors and GPS functions less well when the signals are poorly received. Moreover, its accuracy declines when sharp turns or bends are made or rapid changes in speed occur. As an alternative, small inertial sensors are used to provide runners with estimates of their running speed. A few of these commercial devices have been validated, but only under laboratory conditions and the protocols and algorithms used to derive running speed from these sensors are proprietary and consequently unknown. However, it seems likely that either foot contact time (CT) and/or stride frequency (SF) are used to estimate running speed. Therefore, we investigated the validity and reliability of speed estimates from foot contact time (CT) and stride frequency (SF) during outdoor running on tarmac, thus under ecological conditions. **Methods** Participants signed written consent forms and the study was approved by the local ethics committee. CT and SF were measured with tri axial inertial sensors attached to the feet of 14 runners who varied in training background. They wore a Garmin Forerunner 620 sports watch with GPS function. First, the relationships between running speed with CT and with SF were established with participants running six 125m intervals at different speeds. These relationships were subsequently used to estimate speed during a 4km run. Stopwatch derived speed during the 4 km runs, measured for each of the 32 consecutive 125m intervals, was used as reference. The measurements were repeated on another day. **Results** Individual speed-CT relations, but not speed-SF relations, were strong ( $r^2 > 0.96$  for all trials) and consistent between days. During the 4km runs, errors (%) for SF, CT and GPS derived speed respectively were  $7.6 \pm 5.5$ ,  $2.7 \pm 1.3$  and  $1.6 \pm 0.2$  ( $P < 0.05$  between methods) while the correlation with stopwatch-speed, indicating how well small speed fluctuations were monitored during the 4 km runs, respectively were  $0.59 \pm 0.27$ ,  $0.89 \pm 0.08$  and  $0.82 \pm 0.11$  ( $P < 0.05$  between methods). **Discussion** Participants ran a straight course in an open area, which probably minimized the errors in the speed estimates for GPS. We noted that GPS became less ( $P < 0.05$ ) accurate around the turning point at 2 km. The present study was limited to running on flat terrain, but included various weather conditions. We noted that the speed-SF relation was affected by head or tailwinds, while the speed-CT was unaffected by wind. **Conclusion** Running speed estimates based on individual speed-CT relations, but not speed-SF relations, have acceptable accuracy during natural outdoor over ground running on flat terrain. ## Sports Medicine and Orthopedics

### THE TNF-ALPHA SYSTEM IS SUBSTANTIALLY INVOLVED IN MARKED MUSCLE OVERUSE

Renström, L., Forsgren, S.

*Anatomy Section, Department of Integrative Medical Biology, Umeå University, Sweden*

**Introduction** Muscle inflammation (myositis) and damage can occur in response to heavy exercise. The cytokine TNF $\alpha$  has marked effects in situations with inflammation, damage and tissue reorganization. However, there has been a lack of information concerning the TNF $\alpha$  system for muscle tissue when a muscle is subjected to marked overuse. We use an experimental rabbit model for which the triceps surae muscle is subjected to marked overuse and for which we have noted that TNF $\alpha$  is existing in the infiltrating white blood cells and in muscle fibers, both necrotic or regenerative muscle fibers (1,2). The expression pattern of TNF $\alpha$  receptors in overused muscle is unknown why this was examined in the present study. **Methods** An animal (rabbit) model leading to marked muscle overuse for the triceps surae muscle was used. This model has been used in previous studies evaluating the processes that occur in overused muscle (1,2). The soleus part of the triceps surae muscles was analyzed with immunohistochemistry. Antibodies against TNF receptor I and II (TNFRI and II) were utilized. **Results** A muscle inflammation (myositis) occurred within parts of the muscle specimens. That included presence of muscle fiber necrosis. TNFRI and TNFRII immunoreactions occurred for the infiltrating white blood cells, small vessels and in muscle fibers in myositis areas, some of which were necrotic fibers. Interestingly, immunoreactions for both types of receptors were also seen in nerve fascicles in the myositis areas. **Discussion** The present study, coupled with our previous studies (1,2), shows that the TNF $\alpha$  system to a large extent is involved in overexerting muscle. The two TNF receptors TNFRI and II were thus extensively expressed. That included expressions within the inflammatory cells, muscle fibers as well as nerve structures. The TNF $\alpha$  system therefore seems to be an important system in myositis processes that occur in response to marked muscle overuse. This is likely to be related to both regenerative and degenerative/necrotic processes. This is of relevance when considering the fact that muscle inflammation and damage are features that frequently are associated with heavy sport activities. **References** 1. Forsgren S et al. ### RELATIONSHIP BETWEEN LOWER EXTREMITY ALIGNMENT DURING SINGLE-LEG SQUAT TEST AND THE HIP MUSCLE STRENGTH

Omi, T.

*CHUKYO UNIVERSITY*

Dynamic alignment is an important role to evaluate dynamic movements in sports. Single-leg squat test (SLS) is considered as an effective evaluation approach of dynamic alignment in lower extremity. Poor functions of hip muscles cause a mal-alignment such as valgus knee posture during SLS. Then strengthening the hip muscles is effective to prevent the mal-alignment of lower extremity that may cause injuries. Previous study reported the hip muscle activity showed minimum value at the specific position during the SLS (knee flexion angle at 60deg). The purpose of this study was to investigate the relationship between the hip muscle strength at the position where hip muscle activity is low, and alignment of lower extremity in SLS. Twenty six males participated this study (19.8 $\pm$ 2.2yrs, 173.7 $\pm$ 16.3cm, 64.3 $\pm$ 13.3kg). Lower extremity alignment (Q-angle) and trunk motion during SLS were evaluated using 3D motion analysis method (Frame-DIAS). And isometric muscle strength of hip joint was evaluated by handheld dynamometer. In addition, we divided the subjects into two groups rating Q-angle in frontal plane as "decrease" or "increase" when the knee angle changed from 30° to 60° in sagittal plane in performing SLS. Then we compared "decrease" group with "increase" group in hip strength, Q-angle and trunk posture. There was significant correlation between the hip abduction strength and Q-angle ( $r=0.39$ ,  $p<0.05$ ). There was no significant difference between two groups in hip strength. But the "decrease" group tended to show larger lateral bent of the trunk to support side of SLS. In general, hip abduction muscles prevent the increase of Q-angle (knee valgus angle). However, this study showed a contradict result from anatomical principle. "Duchenne's sign" was showed in the "decrease" group as compensate movement of valgus knee posture. The result that was considered compensates movement as an inclination of trunk had an effect on alignment of lower extremity. In a word, to evaluate an alignment of lower extremity by only isometric hip abduction strength may be insufficient in evaluation of alignment. Therefore, when we evaluate alignments, we should consider factors such as inclination of trunk and sole of foot pressure.

### PREVALENCE AND CHARACTERISTICS OF OSTEOCHONDRITIS DISSECANS OF THE ELBOW AMONG ADOLESCENT BASEBALL PLAYERS

Hojo, T.1, Morihara, T.2, Kida, Y.2, Kotoura, Y.2, Tachiiri, H.2, Sukenari, T.2, Furukawa, R.2, Nakamura, M.1, Takeuchi, K.3, Iguchi, J.4, Fujisawa, Y.1, Kubo, T.2

*1: Doshisha University (Kyoto, Japan), 2: Kyoto Prefectural University of Medicine (Kyoto, Japan), 3: Biwako Seikei Sport College (Shiga, Japan), 4: Kyoto Gakuin University (Kyoto, Japan)*

**Introduction:** Osteochondritis dissecans of the elbow (OCD) is a condition that occurs in children and adolescents who participate in sports that place a large amount of stress on the humeral capitellum. Baseball, a popular sport in Japan, is one of the high risk sports which induces OCD. Many children start playing baseball during elementary school. Recently, medical check-ups for OCD in adolescent baseball players utilizing ultrasonography is becoming more popular. The prevalence and clinical characteristics of OCD among adolescent baseball players are unknown. The aim of this study was to investigate the frequency and clinical characteristics of OCD among adolescent baseball players. **Methods:** The subjects were 3310 young baseball players from 12 to 17 years (mean, 13.6 years) who participated in medical check-ups for OCD. The elbow of each subject's throwing arm was assessed using a questionnaire and ultrasonography. Subjects with abnormal results on ultrasonography were further examined through radiographic study. OCD lesions were classified into stages based on radiographic results. We compare the differences of demographic data between OCD players and non-OCD players. **Results:** OCD was detected in 101 (3.1%) of 3310 elbows by ultrasonogram. Eighty-seven of the 101 OCD players underwent further radiographic examination. Six of them (6.9%) were stage S (superficial stage), 17 (19.5%) were stage I (radiolucent stage), 32 (36.8%) were stage II (fragmentation stage), and 9 (10.3%) were stage III (loose body stage). An additional 9 (10.3%) players were stage IV (residual stage), and 14 (16.1%) were stage V (postoperative stage). There was no significant difference on the starting age of playing baseball ( $p = 0.094$ ).

Players with OCD had longer duration of competitive play ( $p < 0.001$ ). They also had present ( $p = 0.003$ ) and past elbow pain ( $p < 0.001$ ) compared to non-OCD players, however fifty five OCD players in stage S, I and II (before loose body stage) had no significant differences. Discussion: Players with OCD had longer baseball career but players in stage S, I and II do not have significant present elbow pain compared to non-OCD players. Medical check-ups of adolescent baseball players utilizing ultrasonography is useful for detecting OCD with no associated elbow pain. Contact: thoj@mail.doshisha.ac.jp

### **AGE DIFFERENCES IN DYNAMIC ALIGNMENT DURING SINGLE-LEGGED SQUATTING AND DROP LANDING IN FEMALE BASKETBALL PLAYERS**

Kagaya, Y.1, Kiba, K.2, Fujii, Y.2, Fujita, H.2

1: Showa University (Yokohama, Japan), 2: National Institute of Fitness and Sports in Kanoya (Kanoya, Japan)

**Introduction** Anterior cruciate ligament (ACL) injury occur by dynamic knee valgus during landing tasks. To identify athletes at a higher risk, we developed a two-dimensional (2D) screening test focused on hip abductor and rearfoot function (Kagaya et al., 2013). However, age differences in hip or rearfoot motion as a contributor to dynamic knee valgus remains unclear. This study aimed to determine how age differences contribute to hip or rearfoot motions. **Methods** One hundred-four female basketball players (31 junior high-school, 42 high-school and 31 college students) agreed to participate in this study. Participants were required to perform single-legged squatting and drop landing from a 30 cm box. This procedure was recorded using a 2D video camera in the front and the back. Knee-in distance (KID) was measured as the distance from hallux to the point where the line connecting the center of the patella and the anterior superior iliac spine (ASIS) intersects the floor. Hip-out distance (HOD) was measured as the distance from hallux to the projection of ASIS on the floor. Hip abductor function and rearfoot dynamic alignment was evaluated by a dynamic Trendelenburg test (DTT) and a dynamic heel-floor test (HFT), respectively. Additionally, we measured navicular height on sitting position and navicular drop. Results There was effect of age on DTT-positive during single-legged drop landing ( $p < 0.05$ ). Junior high school athletes were greater prevalence of DTT-positive than high school and college athletes. Additionally, they demonstrated smaller HOD values in single-legged squatting than older athletes ( $P < 0.01$ ). The navicular drop in high-school athletes was significantly smaller than in junior high-school and college athletes ( $p < 0.001$ ), however the navicular height was smaller in junior high-school athletes ( $p < 0.01$ ). **Discussion** Some researchers reported that the females in the late or post pubertal stage were greater dynamic knee valgus than in the early pubertal stage (Hewett et al., 2004, Yu et al., 2005). In our study, junior high-school athletes demonstrated smaller HOD values than older athletes, although KID values were not significant. Higher prevalence of DTT-positive in junior high-school athletes was suggested that the female athletes in early pubertal had not developed the hip abductor function. Player's age is an important consideration in ACL injury preventative conditioning. **References** Kagaya Y, et al. (2013). *J Sport Health Sci*, <http://dx.doi.org/10.1016/j.jshs.2013.08.002>, 1-6. ### **THE RELATIONSHIP BETWEEN MUSCLE LENGTH CHANGE AND MUSCLE ACTIVATION OF BACK MUSCLE DURING APPLIED ROMAN CHAIR STRENGTHENING**

Kang, K.K., Hu, C.Y., Ko, H.T., Chuang, W.C., Lin, H.T.

*Kaohsiung Medical University*

**Introduction** The Roman chair has been applied to train spinal muscle, however; there were very limited discussions on which postures is more efficient when doing back muscles strengthening (Dolan and Adams, 1993). The purpose of this study is to investigate the relationship between the muscle length change and its corresponding activation of back muscles when applied the Roman chair for muscle strengthening through ultrasound image and surface electromyography (EMG). Understanding the correlations of the contraction of back muscles and muscle length change during training is helpful to design a more efficiency training program. **Method** The "stiff-legged deadlifts" in Roman chair when doing back muscle strengthening was tested in this study. Three back muscles including upper back muscle (lower trapezius), lower back muscle (Erector Spinae) and lower trapezius were studied in this study. The results presentation was from one of the subject who is a graduate student without back muscles injury. The starting position of training was to keep back straight and bent the trunk slowly for 60 degrees. Using the ultrasound images, the length of three muscles could be identified, and surface EMG system (TrignoTM, USA) was used to detect the muscle activation from starting position to bent 60 degrees. The relationship between muscle length change and muscles activation of three testing back muscles were quantified. **Result** During "stiff-legged deadlifts" in Roman chair, the initial muscles length at starting position of the lower trapezius, middle erector spinae and lower erector spine were 2.47cm, 2.94cm and 2.94cm respectively, while at the bent forward 60 degrees, muscles length changed to 2.61cm, 3.17cm, 2.41cm. During bending, the largest muscle activation was lower erector spinae (average was 35 mV), following by the erector spinae (average was 23 mV), and the least was lower trapezius (average was 8mV). **Discussion** This research had found that the muscle length change and muscle activation of the trapezius and middle erector spinae during training had positive correlation. On the contrary, the muscle length change and muscle activation of lower erector spinae had negative correlation. Since the muscle length change represents its contraction type (concentric/eccentric), it is interpretable that all the muscle length change and muscle activation of back muscles have highly correlation. That is, all of three testing back muscles had contraction when applied this kind of training and reached its purpose. This study especially indicated that the lower erector spinae had the best training effect because it was eccentric contraction and had largest muscle activation. Through this kind of study, an efficient muscle strengthening training system could be established for back muscles training.

### **SLEEPING IN MODERATE HYPOXIA AT HOME FOR PREVENTION OF ACUTE MOUNTAIN SICKNESS : A PLACEBO-CONTROLLED, RANDOMIZED DOUBLE BLIND STUDY**

Dehnert, C., Böhm, A., Grigoriev, I., Menold, E., Bärtsch, P.

*Medbase Sports Medical Center, Zurich Switzerland; University Hospital, Medical Clinic, Internal Medicine VII, Sports Medicine, Heidelberg, Germany*

**Objective:** Acclimatization at natural altitude effectively prevents acute mountain sickness (AMS). It is, however, unknown whether prevention of AMS is also possible by only sleeping in normobaric hypoxia. **Methods:** In a placebo-controlled double-blind study 76 healthy unacclimatized male subjects, 18-50 years, slept for 14 consecutive nights at either FIO<sub>2</sub> of 14-15 % (average target altitude 3043 m; treatment group) or 20.9 % (control group). 5 days later AMS scores and incidence of AMS were assessed during a 20-hour exposure in normobaric hypoxia at FIO<sub>2</sub>=12 % (equivalent 4500 m). **Results:** Due to technical problems with the nitrogen generators target altitude

was not achieved in the tents and only 21 of 37 subjects slept at an average altitude considered sufficient for acclimatization (above 2200 m; average 2600 m). Therefore, in a subgroup-analysis these subjects were compared to the 21 subjects of the control group with the lowest sleeping altitude. This analysis showed a significantly lower AMS-C score (0.38 (95%-confidence-interval 0.21-0.54) vs. 1.10 (0.57-1.62),  $p=0.04$ ) and lower Lake Louise Score (3.1 (2.2-4.1) vs. 5.1 (3.6-6.6),  $p=0.07$ ) for the treatment-subgroup. The incidence of AMS defined as an AMS-C score  $>0.70$  was also significantly lower (14 vs. 52 %;  $p < 0.01$ ). Conclusion: Sleeping 14 consecutive nights in normobaric hypoxia (equivalent to 2600m) reduced symptoms and incidence of AMS 5 days later on exposure to 4500 m.

### MEDICAL EVALUATION OF MUSCULOSKELETAL DISORDERS IN STUDENTS USING THE "HEALTH NOTEBOOK"

Kamada, H., Miyakawa, S., Takeuchi, R., Tanaka, K., Tsukagoshi, Y., Yamazaki, M.

*University of Tsukuba*

Introduction In Japan, each school is required to conduct physician-performed medical examinations of all elementary and junior high school students. In addition, Japan's Ministry of Education, Culture, Sports, Science and Technology has decided to include a 'medical evaluation of the extremities' in these examinations, beginning in April 2016. Previous studies have estimated that the prevalence of musculoskeletal disorders is approximately 7%, and that the approach to musculoskeletal disorders are finally close-up. Since 2008, we have used the 'Health notebook' to screen for musculoskeletal disorders among elementary and junior high school students; we describe the findings below. Material and Methods We developed the 'Health notebook', which includes a musculoskeletal disorders check list, and began musculoskeletal screening in the elementary and junior high schools of Tsukuba city, Ibaraki Prefecture, during 2008. Orthopedic surgeons performed the screenings, and recorded their findings in this notebook, which the record can be stacked every year. We summarized the results from 1 school with 7 years of continuous medical screening data that was recording using the notebook. Results In 2014, musculoskeletal disorders were observed in 41.7% of the students, including symptoms of tightness in 35.0% of the students. We found that 3.1% of the students had severe symptoms that required secondary screening; these findings were consistent over the 7-year period. Discussion It is possible to perform examinations while comparing the findings to those in the previous year, which can help identify changes in students' musculoskeletal status over time. These records are likely a useful communication tool that can help the students, parents, teachers, and doctors better understand the student's health. Conclusion In sporadic screening, it is difficult to track the type and extent of the disorders that are associated with growth. If the 'Health notebook' is used effectively as a continuous evaluation tool, musculoskeletal disorders can be confirmed at an early stage during the students' growth period, thereby facilitating early and more effective treatment.

### FINGER PULLEY INJURIES. DIAGNOSIS AND CHARACTERIZATION WITH MR IMAGING AT 0,5T

Ramos-Álvarez, J.J., Del Castillo, F., Rodríguez Fabián, G., Jiménez-Herranz, E.

*Fac.Medicina.Universidad Complutense (Madrid), Fac.Ciencias de la Salud. Universidad Camilo José Cela (Madrid)*

INTRODUCTION: Pulley ruptures are an injury mainly in rock climbers(1), with report a 19% to 26% incidence in population surveys(2). Ruptures most commonly affect the A2 and A4 pulley(3). Pulley ruptures were rare among the general population but now is seen much more commonly in no specialized participants, and information regarding diagnosis and treatment can be limited(1). To determine the ability of MRI to depict finger pulley injuries in rock climbers and others sports and activities. To evaluate MRI in the diagnosis and characterization of lesions of the finger flexor A2 pulley and A4 pulley(4) in patients with clinically suspected pulley lesions. MATERIALS AND METHODS: Fourteen consecutive patients with clinically suspected lesions of the annular pulley system were included in this retrospective study. Ten rock climbers, two judokas, one metal worker and one hotel attendant were examined by using 0.5T MRI with T1-weighted, T2-weighted fat suppressed, and STIR sequences. The distance between the flexor tendon and phalanx was evaluated in forced flexion at the level of the A2 and A4 annular pulleys as an indicator of tendon bowstringing. The images were analyzed and pulley lesions characterized(5). RESULTS: In the 14 symptomatic fingers 14 pulleys were abnormal at MRI. Characterization of the different pulley lesion was possible. MRI depicted 11 complete A2 pulley ruptures(78,57%), 3 complete A4 ruptures(21,42%). Also MRI depicted 10 volar plate rupture(71,42%). Measurement of distance between the flexor tendon and phalanx was significantly different among patient subsets without pulley ruptures and those with complete, or complete combined pulley ruptures(1). A distance between the flexor tendon and phalanx greater than 5.0 mm was interpreted as positive for a complete pulley injury(2). The fourth(n=7) and the third(n=4) fingers are the most frequently injured. Also, fifth(n=2) and second(n=1) fingers were affected. CONCLUSION: MRI at 0.5T allows excellent depiction and direct visualization and characterization of A2 and A4 finger pulley injuries. BIBLIOGRAFÍA 1.Kubiak EN, Klugman JA, Bosco JA. ### EFFECTS OF EXERCISE MODES ON THE HEMODYNAMIC PARAMETERS DURING GXT

Kim, C., Kim, Y., Kim, H., Kang, D.

*Soonchunhyang University, Inje University Snaggy Paik Hospital, Korean National University of Education, Soonchunhyang University*

The aim of this study is to exam the effects of exercise modes on the systolic blood pressure and rate-pressure product during a gradually increasing exercise load from low to high intensity. For the purpose, fifteen apparently healthy adults performed the graded exercise tests on cycle ergometer and treadmill. During the low-to-maximal exercises, hemodynamic parameters including oxygen uptake, heart rate, systolic blood pressure and rate-pressure product were tested. As result, There was a significantly lower maximum VO2 on cycle ergometer than treadmill ( $p<0.01$ ). However, CE showed a higher maximum SBP at the all-out exercise load than TM ( $p<0.001$ ). During the low-to-maximal intensity increment, the slope of the HR with VO2 was the same as VO2 increased in times of the graded exercise test of CE and TM. The slope of increase on SBP accompanied by VO2 increase was significantly higher in CE than in TM ( $p<0.01$ ). In conclusion, the response of systolic pressure in cycle ergometer is stronger than in treadmill during the graded exercise test (GXT). Therefore, it was shown a possibility that exercise by cycle ergometer could induce a greater burden on workloads to cardiovascular system in humans than exercise by treadmill.

**EPIDEMIOLOGY OF INJURIES IN JAPANESE ELITE HANDBALL PLAYERS**

Imoto, K., Sakuma, K., Kainuma, K., Sakamoto, S., Okuwaki, T.

*Japanese Red Cross Kumamoto Hospital*

**Introduction** Handball is a contact sport and hence has a high frequency of injury (Engebretsen et al., 2013). However, injury in Japanese elite handball players has not been well documented. The purpose of this study was to investigate the pattern of injury in Japanese elite handball players using the data from past medical checks. **Methods** We analysed the medical check data of the Japanese national handball team that has performed at the Japan Institute of Sports Sciences since 2002. Medical checks were conducted 6 times for men and 7 times for women from 2002 to 2014. There were 75 male players (144 players in multi-year) and 62 female players (126 players in multi-year), averaging 24 players and 18 players, respectively. We prepared a problem list for each player, which was classified as Active (requiring medical treatment and detailed checking), Follow (requiring follow-up) and Inactive (healed status and closed case). We analysed the injury patterns of Japanese elite handball player from the problem lists. **Results** The number of male and female players with Active cases averaged 3.8 (16%) and 3.7 (19%), respectively, at each medical check. Moreover, there were 4.5 Active male cases and 4.6 Active female cases; some players had multiple Active cases. The sum of players having Active and Follow cases was 18.7 (78%) in males and 14.3 (79%) in females. The knee (24% and 34%, respectively) in males and females was the most commonly injured anatomical location, followed by the ankle (20% and 23%, respectively), shoulder (16% and 13%, respectively) and lumbar region (16% and 12%, respectively). The most common injury in each anatomical location in males and females was to the anterior cruciate ligament in the knee, sprain/instability in the ankle and rotator cuff injury in the shoulder, at each medical check. **Discussion** We researched the injury pattern of Japanese elite handball players from past medical checks. Injury to the knees, ankles and shoulders were common in both sexes. Injuries in these locations greatly influenced handball players' performance; hence, preventive measures to prevent potential injuries in these locations are needed. Moreover, to link the injury data with the development of preventive methods, it is necessary to implement regular surveys and for systematic surveillance studies, including items such as recording absence from sport and standardizing the criteria for problem determination. **References** Engebretsen, L., Soligard, T., Steffen, K., Alonso, J. **PREVALENCE OF RISK FACTORS FOR SHOULDER INJURIES IN COLLEGIATE HANDBALL PLAYERS DURING PRESEASON SCREENING**

Ogaki, R.1, Kuwahara, K.1, Oda, K.1, Murakami, K.1, Yamaguchi, T.1, Takahashi, Y.1, Shirahata, K.1, Suzuki, N.1, Takemura, M.2, Miyakawa, S.2

*1: Sendai University, 2: University of Tsukuba*

**Introduction** Shoulder injuries are among the frequently encountered injuries in handball (Olsen et al. 2006). The aim of this study was to evaluate the prevalence of intrinsic risk factors for shoulder injury in collegiate handball players during preseason screening. **Methods** 20 collegiate handball players (male, 15; female, 5; age,  $19.2 \pm 0.7$  years; height,  $169.1 \pm 6.6$  cm; body mass,  $65.4 \pm 8.9$  kg; handball experience,  $6.3 \pm 2.0$  years) participated in the study. All players received a preseason screening that included basic demographics, history of injuries, and physical findings in throwing arm. We collected data on history of injury, range of motion [ROM], isometric muscle strength, joint instability, and special tests for the rotator cuff. A goniometer was used to measure shoulder passive ROM of internal rotation [IR], external rotation [ER], horizontal flexion [HF] and horizontal extension [HE]. A handheld dynamometer was used for measurement of isometric muscle strength during shoulder IR and ER. Player with a history of injuries, or those who with an anterior joint instability, or those who result in the positive special tests, were classified as shoulder injury risk [SIR] group. Other players were classified as healthy [H] group. **Results** 9 players (45%) were classified into SIR group as a result of medical screening. The following data shows the number of positive result of each risk factor; history of injury, 6; anterior joint instability, 3; empty can test, 3; full can test, 4; hawkins kennedy test, 6; neer test, 1. ER ROM was significantly lower in SIR group ( $90.6 \pm 9.8$  degrees) compared with H group ( $100.5 \pm 9.2$  degrees) ( $p < 0.05$ ; effect size, 1.05). HE ROM was significantly lower in SIR group ( $23.3 \pm 10.0$  degrees) compared with H group ( $30.9 \pm 5.1$  degrees) ( $p < 0.05$ ; effect size, 0.99). IR muscle strength was significantly lower in SIR group ( $2.27 \pm 0.5$  N/body mass) compared with H group ( $2.80 \pm 0.4$  N/body mass) ( $p < 0.05$ ; effect size, 1.10). ER muscle strength was significantly lower in SIR group ( $2.56 \pm 0.4$  N/body mass) compared with H group ( $3.31 \pm 0.7$  N/body mass) ( $p < 0.05$ ; effect size, 1.29). **Discussion** The intrinsic risk factor of shoulder injuries were found in many collegiate handball players during preseason screening. Players with risk factors had lower ROM and muscle strength in their throwing arm. This is consistent with previous study in other athlete (Ogaki et al. 2014). Decreasing the shoulder ER ROM and muscle strength was reported risk factors for shoulder injuries among elite male handball players (Clarsen et al. 2014). Improvement of the ROM and/or muscle strength in preseason might therefore help to prevent shoulder injuries among handball players. **References** Clarsen B, Bahr R, Andersson SH, Munk R, Myklebust G. **INJURIES IN AN ELITE FEMALE SOCCER TEAM FROM THE SPANISH FIRST DIVISION: AN 11-SEASON PROSPECTIVE STUDY**

Larruskain, J.1, Odriozola, A.1, Celorrio, D.2, Aznar, J.M.2, Lekue, J.A.3, Gil, S.M.1

*1: University of the Basque Country (UPV/EHU), 2: BAIGENE, 3: Athletic Club Bilbao*

**INTRODUCTION:** The first step in soccer injury prevention is to assess injury epidemiology. However, elite female soccer players, particularly those from southern European countries, have been scarcely investigated. Thus, the aim of this study was to describe the occurrence of injuries in an elite female soccer team from the Spanish first division. **METHODS:** Athletic Club Bilbao's elite female team was prospectively followed for 11 seasons from 2003 to 2014 (63 total players, mean $\pm$ SD,  $21.9 \pm 1.6$  players per season,  $24.3 \pm 4.7$  years old). Time-loss injuries were diagnosed and recorded by the team's medical staff. **RESULTS:** A total of 278 injuries were recorded, 52.7% during training and 46.9% during matches. Recurrent injuries accounted for 19.8% of all injuries. 74.8% of injuries occurred in non-contact situations, and there was a similar amount of traumatic (48.4%) and overuse (51.6%) injuries. 89.2% of injuries affected the lower limbs, with the thigh (30.2%), ankle (18.0%) and knee (16.2%) being the most common locations, and muscle (47.1%) and articular (36.7%) injuries being the most common types. Conversely, only 4 cases of pubalgia and no concussions were recorded. On average, there were  $13.7 \pm 3.4$  ( $62.7 \pm 14.9$ ) players injured per season, with each player sustaining  $1.2 \pm 1.3$  injuries and losing 36.4 days (median 7.9). There were  $25.3 \pm 8.4$  injuries per season, specifically,  $4.5 \pm 2.4$  quadriceps strains,  $2.8 \pm 1.8$  ankle lateral ligament sprains,  $2.5 \pm 1.2$  hamstring strains,

2.3±1.3 adductor strains, and 1.0±0.6 anterior cruciate ligament ruptures. Most injuries were of moderate severity (41%, 8-28 days lost). Knee injuries accounted for 52% of total days lost (150.6 days lost per injury, median 33), and were more severe than muscle strains (17.4 days lost, median 12,  $P=0.02$ ) and ankle sprains (18.6 days lost, median 11,  $P=0.03$ ). The number of injuries, especially quadriceps strains, was higher during the pre-season ( $P<0.01$ ). DISCUSSION: Contrary to previous reports in elite female soccer players, where ankle, knee and hamstring injuries were predominant (Hagglund et al 2009), quadriceps strains were the most common injury in this team. The high percentage of overuse injuries and the lack of concussions are also noteworthy. Further research is required to explain these findings. The lack of exposure data is the main limitation. Based on these results, prevention strategies should target thigh muscle strains, ankle sprains, and most important, severe knee injuries. REFERENCES: Hagglund M, Walden M, Ekstrand J (2009). ### THE INFLUENCE OF EXERCISE SPEED IN MUSCULAR STRENGTH EXERCISE, ON THE RATING OF PERCEIVED EXERCISE, VITAL SIGN, AND STRESS BIOMARKER RESPONSE

Kudo, H., Hasegawa, H.

*Mejiro University*

**Introduction** The low-intensity resistance exercise with slow and tonic movement (LST) is a one of the effective method on the muscular strength exercise. (Tanimoto M. & Ishii N., 2006 ) The salivary amylase has been known as one of the stress biomarker (Yamaguchi, 2007) The purpose of this study was to compare with the RPE, vital signs, and saliva amylase activation between LST and the low loaded resistance exercise with normal speed (LN). **Methods** This study comprised 29 healthy male volunteers (LST:15, LN:14). All volunteers performed knee extension exercise (8times×3sets) with 30%1RM load at each exercise speed (LST : con/ecc = 3sec/3sec, LN : con/ecc = 1sec/1sec). The RPE, blood pressure, and heart rate were measured immediately after each sets of exercise. The salivary amylase activation was measured at time of pre-exercise, immediately after 3rd set, and 30 minutes after exercise. The salivary amylase activation after exercise was quantitated by the amount of change from pre-ex value. **Result** The salivary amylase activation of LST and LN had mean amount of change of 20.9+/-24.2KU/L and 6.5+/-2.5.2KU/L respectively, before exercise. Although there were no statistically significant different between LST and LN, the salivary amylase activation in LST was much increase than LN. The RPE of LST showed a high value from LN significantly. In both groups after each set, the blood pressure and heart rate had not changed remarkably from pre-exercise value. **Discussion** In blood pressure and heart rate, these results suggested the LST could be a promising exercise method in the rehabilitation for circulated disease and elderly. However it was necessary to pay attention to RPE and a stress. **Reference** Tanimoto M, Ishii N: Journal of Applied Physiol 100: 1150-1157, 2006. Yamaguchi M. (2007). ### DROPOUT RATE OF ITALIAN RANGER TRAINEES: WHO IS THE ENEMY?

Colosio, A., Fontana, Y.F., Pogliaghi, S.

*University of Verona, Department of Neurological and Movement Sciences*

In the Italian Army, a specific process selects the highest calibre soldiers to be enrolled in the successive highly demanding, 2-years Rangers Training Program. Yet, preliminary statistics indicate a dropout (DO) rate of 50%. The most critical phase is the first 6 months of the program, the so-called OBOS course, when roughly 63% of the total DO occurs. **PURPOSE:** This pilot observational study was aimed at determining the causes of DO during the OBOS and identifying possible predictor characteristics, with the final aim to prevent DO by optimising selection strategies and training practices. **METHODS:** In a total of 103 male recruits (26±2 yrs) we monitored DO date and cause (clustered in Personal P, Technical T, and Medical M) and measured anthropometric (body mass; stature; plicometry) and functional characteristics (pull-ups; dips; push-ups; sit-ups; 2km run). The possible association of specific anthropometric or functional parameters with DO was evaluated by unpaired t-test between the successful vs DO groups. **RESULTS:** The body weight, stature, fat mass and the results of the functional tests are similar to those reported in the literature for special forces trainees in Europe (1, 2). 42 recruits (41% of the total) abandoned the program during the OBOS phase. The main cause of DO was voluntary withdraw for personal reasons (60% of total dropouts); 30% of the recruits were excluded from the program for medical reasons; 10% of the recruits were excluded for technical reasons (e.g. discipline issues, fail of technical exams or physical requirements). Significant differences between successful and DO groups were detected in % body fat (11±3 vs 13±3) and the number of pull-ups (12±3 vs 11±4). **CONCLUSIONS:** Ours are the first available data on Italian Army Ranger trainees. The DO group was characterised by increased body % fat and reduced upper body strength compared to the successful group. Data would suggest targeting individual motivation, self-efficacy and resilience upon admittance to the program as potential factors affecting DO. Furthermore, optimal physical preparation practices (including gradual overload and injury prevention strategies) and optimal medical treatment could potentially reduce DO for medical and technical reasons. **REFERENCES** 1. ### INJURY IN JAPANESE FEMALE UNIVERSITY JUDO ATHLETES

Saho, Y.1, Asahiyama, K.1, Sato, Y.1, Sanomura, M.1, Yamamoto, A.1, Tateishi, T.2

*1: Teikyo University, 2: The Doai Memorial Hospital*

**Introduction** Judo is a martial art. A lot of injuries occur during Judo not only slight injuries like contusion but also severe injuries like catastrophic head and neck injuries. Epidemiology of judo injury is limited, especially in Japanese judo athletes. To prevent injuries, it is necessary to investigate the epidemiology of Judo injuries. The purpose of this study was to investigate the frequency and characteristic of injuries in Japanese female university Judo athletes. **Methods** Medical records of a Japanese female university Judo club (numbers of athlete: 35, age: 18-22 y) collected by an orthopedic surgeon were analyzed retrospectively in 2013 seasons (from April 2013 to March 2014). **Diagnosis**, injured body part, type of injury and injured body side were extracted. Percentage of injured athlete was calculated. **Results** One-hundred and twenty-seven injuries occurred in 2013 seasons. Thirty-one out of 35 players (89%) sustained an injury. Incidence of injury was 3.61 (injury/player/year). Two injuries required surgery; lateral meniscus injury and cervical disc herniation. The most common injured part was knee joint (20%), followed by neck (11%) and elbow joint (9%). Six head injuries occurred (5%). Almost half of all injuries were to lower extremities (47%) and 28 % to upper extremities. The most common type of injuries was sprain (21%), followed by muscle spasm (15%), ligament injury (13%) and contusion (9%). As a severe head injury, 4 concussions occurred in a year. Eight ligament

injuries occurred in the knee; 5 medial collateral ligament injuries, 2 posterior cruciate ligament injuries and 1 lateral collateral ligament injuries. Discussion Head injuries sometimes link to catastrophic injury. Kamitani et al. reported that 90% of head injuries occurred in athletes younger than 20 years of age. In this study, 5 of 6 head injuries and 3 of 4 concussion occurred in athletes younger than 20 years of age. These results revealed that young athletes may be more vulnerable to severe head injuries. The present study provide a injury frequency in female university judo athletes. These results are helpful for identifying the risk factor and mechanism of judo injury and developing effective Judo-related injury prevention program. References Kamitani T, Nimura Y, Nagahiro S, Miyazaki S, Tomatsu T. (2013). *AJSM*, 41, 1915-1921.

### IMPAIRMENTS OF MOTOR PERFORMANCE AFTER TREATMENT FOR PEDIATRIC BONE TUMORS

Kesting, S.

*University Hospital of Muenster*

**Introduction** After treatment for pediatric bone tumors patients are at high risk of developing physical limitations due to severe surgical interventions (Abded et al. 2010). These consequences persist lifelong (Hoffman et al. 2013) and may also result in impairments of motor performance. Motor performance has not yet been sufficiently investigated in this patient group although it could negatively affect physical activity and the participation in sports in early aftercare. Therefore this study aimed at assessing motor performance in pediatric bone tumor patients. **Methods** The MOON-test was used to determine motor performance within 24 months post-treatment (Götte/Kesting et al. 2013). This instrument enables quantitative data collection even in patients with severe physical impairments and allows comparison with age- and gender-matched reference values. **Results** Data of 21 patients (m=13) aged 15.2±2.1 years (median: 15 years, range: 10-19 years) were collected 9.4±7.4 months post-treatment (median: 6 months, range: 2-24 months). Severe impairments ( $P<0.001$ ) were identified in reaction (91% scored below reference values), flexibility (81% scored below reference values), eye-hand coordination (62% scored below reference values) and muscular explosive strength (89% scored below reference values). The strength endurance of the legs was reduced in 43% of the patients. However, in hand grip strength >33% and in static balance >52% of the patients showed better results compared to the reference values. **Follow-up duration, body mass index and tumor localization** apparently affected motor performance. **Discussion** These findings provide valuable objective information about impairments of motor performance in a group of pediatric bone tumor patients within 24 months post-treatment and highlight the need for interventions to improve motor performance. Well documented reduced physical activity (Winter et al. 2009) might on the one hand be associated with these results, and on the other hand be negatively influenced by these physical limitations. Therefore, the results should be used to individually advise and support patients to engage in suitable physical and sports activities and improve sports promotion already during acute treatment. **References** Abded R, Grimer R. ### CO-PREVALENCE OF CERVICAL INTERVERTEBRAL DISK DEGENERATION AND BURNER SYNDROME IN COLLEGIATE-LEVEL AMERICAN FOOTBALL PLAYERS

Hakkaku, T., Nakazato, K., Kouzaki, K., Maeda, S., Hiranuma, K.

*Nippon Sport Science University*

**Introduction** American football is a high-energy collision sport that places players at risk for cervical spine injuries. Notably, burner syndrome is frequently induced in players during practices or games. This syndrome occasionally demonstrates a prolonged recovery period, and may lead to a prolonged loss of practice or game time (Meyer et al 1994). Cervical intervertebral disk degeneration (IDD) is another frequent injury in collision sports. However, IDD has not been clearly demonstrated to occur in American football players with a history of burner syndrome. Therefore, this study investigated the occurrence of IDD in collegiate-level American football players with histories of burner syndrome. **Methods** Forty-nine, male, collegiate-level American football players participated in this study (age, 20.0 ± 1.1 years; athletic experience 3.8 ± 2.3 years; height, 172.3 ± 4.8 cm; weight, 83.1 ± 12.2 kg; means ± SD). Burner syndrome was defined as numbness and burning pain from the neck to the hand. Magnetic resonance imaging (MRI) was used to obtain T2-weighted images of cervical regions. Each MRI was assessed, by orthopedists, according to the Pfirrmann classification. IDD severity classification was based on the Pfirrmann (I–V) classification (Pfirrmann CW et al 2001); grade III or higher classifications were defined as representing IDD. The co-incidence of burner syndrome and IDD was statistically analyzed using the chi-square test ( $p < 0.05$ , IBM SPSS statistics 22.0). **Results** Burner syndrome was diagnosed in 19 athletes (39%), and IDD was observed in 22 athletes (45%). Among those with IDD, 13 athletes (59%) also suffered burner syndrome. In the 27 athletes without IDD, only 9 (41%) suffered from burner syndrome. The incidence of IDD was significantly higher in the burner syndrome group ( $p < 0.01$ ). **Discussion** A higher IDD occurrence was observed in athletes suffering from burner syndrome than in those who did not have burner syndrome. Since IDD is accompanied by intervertebral foramina stenosis (Levitiz et al 1997), we believe that the surrounding tissues, such as the cervical nerve root, were deformed. Also, because burner syndrome is accompanied with nerve symptoms, such as numbness and pain, IDD-deformed nerves might be easily damaged by external stress. Although our study design was cross-sectional, we suppose that the preexistence of IDD might be a risk factor for burner syndrome. **In conclusion**, cervical IDD shows a high prevalence in collegiate-level American football players with burner syndrome. **References** Levitiz CL, Reilly PJ, Torg JS. *Am J Sports Med* 25; 73-76, 1997 Meyer SA, Schulte KR, Callaghan JJ, et al. *Am J Sports Med* 22; 158-166, 1994 Pfirrmann CW, Metzdorf A, Zanetti M, Hodler J, Boss N. *Spine* 2001; 26: 1873-1878 Contact [14m0019@nittai.ac.jp]

### RIGHT VENTRICULAR LONGITUDINAL FUNCTION DETERMINES EXERCISE CAPACITY IN TENNIS PLAYERS

Nogami, Y., Tomoto, T., Sugawara, J., Maeda, S., Aonuma, K.

*Shonan Institute of Technology*

**Introduction** Exercise training induces the change of left ventricular (LV) functional in athlete. The pump function of right ventricular (RV) ejected same volume as the LV stroke volume (Voelkel et al 2006), so, it is a important to evaluate RV function in athlete. However, to evaluate RV function by 2D echocardiography is difficult due to complicated structures. Previous study reported the relationship between LV function and exercise capacity, it is still unclear whether the change of RV function influence exercise capacity in athlete. Therefore, the purpose of this study was to evaluate whether RV function affected exercise capacity in high intensity endurance trained athletes. **Methods** Eight men well-trained tennis players were enrolled in this study. All subjects underwent a cardiopulmonary exercise testing (CPX) using cycle ergometer. RV and LV function was measured by ultrasound echocardiography at rest. Systolic RV and LV longitudinal func-

tion were assessed by tricuspid and mitral annular velocity in systole (S') with tissue Doppler imaging. Additionally, systolic global longitudinal strain (GLS) was measured with 2D speckle tracking imaging, and peak oxygen uptake (peakVO<sub>2</sub>) was assessed as an index of exercise capacity. Results Mean peakVO<sub>2</sub> was 51.0±2.7 ml/kg/min. Relationship between peakVO<sub>2</sub> and RV GLS was significant ( $r=0.74$ ,  $p=0.03$ ), and S' at tricuspid was significant trend observed ( $r=-0.68$ ,  $p=0.06$ ). In addition, peakVO<sub>2</sub> was slightly correlated to LV indices, LV GLS ( $r=0.69$ ,  $p=0.06$ ) and S' ( $r=-0.67$ ,  $p=0.07$ ). Discussion GLS generally decline with aging. In this study, RV function at rest was smaller particularly in athletes with high exercise capacity. Moreover, in the present study, athletes with high aerobic ability tend to be lower RV longitudinal function at rest. Consequently, RV longitudinal function in systole may be more effective than LV longitudinal function to determine the exercise capacity in athlete. References Norbert F. Voelkel, Robert A. Quaife, Leslie A. Leinwand, Robyn J. Barst, et al. (2006). *Circulation*, 114, 1883-1891.

### PHYSICAL CHARACTERISTICS AND THROWING PERFORMANCE OF YOUTH BASEBALL PITCHERS WITH AND WITHOUT A HISTORY OF MEDIAL ELBOW PAIN

Tsai, Y.S., Tsai, S.C., Juang, L.G., Wu, B.R.

*University of Taipei*

**Introduction** Medial elbow pain (MEP) is common in youth baseball pitchers. Body height and weight have been reported to be associated with MEP due to players with better body figure get more chances to pitch. However, the relationships between physical characteristics and MEP in this age have not been fully understood. The purpose of the study was to investigate the differences in physical characteristics (body composition and elbow soft tissue structures) and throwing performance between youth baseball pitchers with and without a history of MEP. One year follow up study was also conducted to evaluate the effects of growing up on physical characteristics and their relationships with throwing performance. **Methods** Twenty-eight elementary school pitchers (EP group) (10 injured and 18 non-injured with similar ball speed of 24.5 m/s) and 36 junior high school pitchers (JP group) (21 injured and 15 non-injured with similar ball speed of 30 m/s) participated in this study. Body composition was scanned by a dual-energy X-ray absorptiometry. Tendons and ligaments around the elbow were examined by a musculoskeletal ultrasound. Throwing movement was analyzed using an optical motion analysis system integrated with a telemetry electromyographic system. Ball speed was recorded with a sports radar gun. All tests were conducted again one year after the first test. **Results** In the JP group, the injured pitchers had more body fat than the non-injured pitchers (24.3% vs. 17.6%). In the EP group, the injured pitchers demonstrated less elbow flexion angle (91.4° vs. 104.4°) when the shoulder reached its maximal external rotation angle; the injured pitchers also demonstrated less peak muscle activities of pronator teres during cocking phase (131.8% vs. 224.0% MVC) and acceleration phase (181.8% vs. 278.0% MVC). Follow up study showed that the major changes in body composition for all pitchers were increments of bone mineral content (BMC) (2.2 vs. 2.5 kg) and lean muscle mass (LMM) (43.2 vs. 48.7 kg). The amount of BMC ( $r=0.75$ ) and LMM ( $r=0.73$ ) had positive relationships with ball speed. The size of elbow soft tissues were increased. The injured soft tissues around the elbow recovered well without irregular alignment in the injured players. **Discussion** Growing up may increase BMC and LMM in youth baseball pitchers. These changes may contribute to their ball speed. However, greater amount of body fat may be associated with MEP that need to be careful. Less elbow flexion angle during the cocking phase with less peak muscle activities of pronator teres may also be associated with MEP. Strengthening of elbow muscles should be emphasized for injury prevention. Soft tissue injuries can be well recovered during this age that need to be taking good care of. ### THE ASSOCIATION BETWEEN GENERALIZED JOINT HYPERMOBILITY AND SHOULDER MOBILITY IN YOUNG, COMPETITIVE SWIMMERS

Junge, T.

*University of Southern Denmark*

**Introduction** Shoulder overuse injuries frequently occur among competitive swimmers (Wanivenhaus et al, 2012), however, the aetiology of shoulder dysfunction remains unclear (Zemek et al., 1995). Increased shoulder mobility as well as Generalised Joint Hypermobility (GJH), are both suggested being predisposing risk factors for shoulder injuries (Pink et al., 2000, Zemek et al., 1995). An association between GJH and shoulder mobility among young, competitive swimmers has not been studied. The aim of this study was firstly to evaluate the association between GJH and horizontal shoulder abduction (HSA) in young, competitive swimmers, and secondly to describe reference values for HSA among this group. **Methods** In total, 92 pain-free competitive swimmers (age 10-15 years) participated. GJH was evaluated by the Beighton test (BT) a 0-9 scoring system. GJH was classified at cut points  $\geq 5/9$ ,  $\geq 6/9$  and  $\geq 7/9$ . Shoulder mobility was measured as HSA using an inclinometer in a standardized protocol format. A multiple regression analysis was used to reveal associations between GJH and horizontal shoulder abduction, adjusted for sex and age. **Results** Overall, significant associations between GJH and HSA were found. An increase in the BT score was positively associated with an increase of HSA, seen as an increased HSA of 3.9 degrees at BT cut point  $\geq 5/9$ , 5.7 degrees at BT cut point  $\geq 6/7$  and 7.9 degrees at BT cut point  $\geq 7/9$ . Normative values for HSA ranged from 40 to 52 degrees, with a trend towards decreasing HSA by increasing age. **Conclusion** In this study, a significant association was observed between GJH and HSA, as the horizontal shoulder abduction increased with increasing BT scores. The predictive validity of GJH and HSA with respect to shoulder injuries must be assessed in future studies. **References** Pink, M.M., Tibone, J.E. ### THE EFFECT OF ACUTE MODERATE INTENSITY EXERCISE ON LAND AND THAT IN WARM WATER ON ARTERIAL STIFFNESS IN ELDERLY SUBJECTS

Nogami, J.

*Teikyo Heisei University*

**Introduction** Age-associated change in the structure and function of arteries might increase the risk of cardiovascular disease. It has been reported that aerobic exercise decreased arterial stiffness in young humans (Kingwell, et al., 1997, Naka et al., 2003, Heffernan et al., 2007). However, it is still unclear the effect of moderate intensity exercise in warm water on arterial stiffness in elderly compared to the moderate intensity exercise on land. Therefore, the purpose of this study was to investigate the effect of 38°C water exercise on arterial stiffness in elderly subjects. **Method** Six healthy elderly subjects performed a 15min of cycling exercise with 50% peak VO<sub>2</sub> on land and

that in 38°C water. Arterial Compliance,  $\beta$  stiffness index, Brachial and Carotid blood pressure, heart rate (HR), and rectal temperature (T<sub>rec</sub>) were measured at baseline, 30min, and 60min after the exercise. T<sub>rec</sub> were continuously measured from baseline to 60min after exercise. All measurements were performed in a quiet and air conditioned room at the same time of the day in the morning. Results T<sub>rec</sub> significantly maintain the elevation after the warm water exercise ( $P < 0.0167$ ). HR slightly increased, and significantly increased at 30min after the warm water exercise ( $P < 0.0167$ ). The arterial compliance was significantly increased, and  $\beta$  stiffness index was significantly decreased at 30min after the warm water exercise. Brachial and Carotid arterial blood pressure also significantly decreased at 30min and 60min after the exercise ( $P < 0.0167$ ), whereas there were no significant changes in the exercise on land. Conclusion The present study showed that arterial stiffness significantly decreased after acute 38°C water exercise. On the contrary, there were no changes after exercise on land in elderly subjects. Although the underlying mechanism is unknown, the results in the present study may suggest that 38°C water moderate intensity exercise may induce decrease in arterial stiffness in elderly.

## RELATIONSHIP BETWEEN SPRINT PERFORMANCE AND MORPHOLOGY OF HIP EXTENSORS

Tokutake, G., Kuramochi, R., Murata, Y.

*Chukyo University*

Running is the essential element of sports performance. Especially, the running ability affects directly to sprint race of track and field. Gluteus maxims muscle (GM) and hamstring muscles have been regarded as an important role on hip extension and sprint performance. Morphology of hamstrings has been measured by a lot of studies, although morphology of GM has been measured rarely because of the difficulty and uncertainty of measuring methods. In addition, researches are limited that examined relationships between morphology of hip extensors and sprint performance. The aim of this research is to examine relationships between function and morphology of hip extensors and sprint performance. Seventeen Japanese male subjects (height 174.7±9.3cm, weight 66.1±13.1kg, age 20.1±2.1yrs) participated in this study. They were sprint athletes in track and field team at university. Muscle thickness was measured by ultrasonic diagnostic equipment on GM and biceps femoris long head (BF). We examined muscle thickness, ratio of muscle thickness BF/GM (ratio BF/GM), and right and left differences of each ratio BF/GM. We measured the single leg triple hop test (SLTH-test) for an index of hip extension power. Three subjects were excluded because of lower extremity injury. Official record of 100m sprint was used for evaluating sprint performance. Right and left differences of ratio GM/BF was significantly relevant to sprint performance ( $r = **$ ,  $p < 0.05$ ). However, muscle thickness and ratio BF/GM were irrelevant to sprint performance. Record of SLTH-test was irrelevant to sprint performance. But right and left differences of SLTH-test showed a tendency to relevant to sprint performance. In this study, we examined the morphology of GM. GM had been regarded as an important role in sprint performance. But GM morphology had no relevance to sprint performance in this study. Higher performance athletes showed larger differences between right ratio BF/GM and left ratio BF/GM. This indicated that hip extensors of higher performance athletes were forced asymmetry load. On the other hand, though it had no significant differences, right and left differences of SLTH-test had a tendency to relevant to sprint performance. These results show that muscle imbalance does not always lead muscle dysfunction.

## EFFECT OF SLEEP QUALITY ON COGNITIVE FUNCTIONS DURING EXERCISE IN HEALTHY YOUNG MEN

Nakamura, Y., Choi, Y., Akazawa, N., Park, I., Kawana, F., Satoh, M., Tokuyama, K., Maeda, S.

*University of Tsukuba*

Introduction Sleep plays an important role in recovery from fatigue, memory, skill acquirement and so on. Total or partial sleep deprivation induces reduction in many performances, such as physical or psychological performance. The sleep deprivation has also been associated with cognitive function. Thus, quantity of sleep is needed for keeping these performances and/or functions. On the other hand, quality of sleep also may affect in physical or psychological performance and cognitive function. However, it is not unclear the effect of sleep quality on cognitive function. This study examined the effect of acute reduction of sleep quality on cognitive function during exercise. Methods Eight healthy young men performed cognitive tasks by use of the reaction time and the interference in stroop task during exercise on a cycle ergometer at 30%HRreserve for 8 min following 2 sleep conditions (exposure of bright light for 3h and control). Results and Discussion In Polysomnography (PSG) analysis, sleep latency was significantly increased in bright light condition. In Oguri-Shirakawa-Azumi sleep inventory MA version (OSA-MA) test, the score for refreshing was significantly lower in bright light condition than control condition. These results suggest that the quality of sleep may be decreased by exposure of bright light before sleep. There was no significant difference in reaction time in stroop task during exercise between control condition and bright light condition. Latter part of interference in stroop task during exercise significantly increased in bright light condition. These results suggest that cognitive function, such as sustenance of attention, during exercise was decreased by exposure of bright light before sleep. Conclusion In conclusion, cognitive functions during exercise were decreased by reduction of sleep quality in healthy young men.

## THE EFFECT OF DEHYDRATION ON AIRWAY INFLAMMATION IN JUDOISTS

Tomoko, I.I., Koichi, W.2

*University of Tsukuba*

Introduction Athletes, who are endurance training in outdoor area sports such as marathon and cross country skiers, is known that they have a high incidence of exercise induced asthma (EIA) and exercise-induced bronchospasm (EIB). However it is not completely clear that what conditions induce EIA and EIB. Judo competitions are organized according to weight class, so some judoists rapidly reduce body weight (RWL) before competition. Athletes use a variety of methods to achieve RWL under limitation of liquid ingestion and energy intake; those limitations may occur to dehydration and may affect airway inflammation, because dehydration may cause reduction of the mucus secretion in upper respiratory mucous membrane. We tested the hypothesis that serum blood osmotic pressure, which show dehydration biomarker, affects airway inflammation in judoists that reduce their body weight. Purpose The purpose of this study is to examine that dehydration affect airway inflammation in judoists. Methods Total number of 24 men college judoists took part in this study. The subjects were investigated twice: before 2weeks (baseline) and the day before game day (post). Judoists were measured their body weight, and collected serum blood to evaluate osmotic pressure that is index of dehydration. Fraction of exhaled nitric oxide (FeNO), which is index of airway inflammations, was measured by a portable NIOX MINO. Results Serum osmotic pressure was significantly increased [baseline 290.7±3.3, post 294±3.8mOsm/L]. FeNO was higher than normal level (53.2±24.3ppb) in 11 judoists. The others judoists had not airway inflammation at baseline (13.0±5.3 ppb). FeNO didn't significantly change in judoists with or without airway inflammation (Pre 31.4±26.2, Post 33.0±25.5ppb). Rate of osmotic pressure change didn't significantly associate with rate of FeNO change.

On the other hand, FeNO increased with change of more than 1.7% osmotic pressure. Discussion There was not correction between change of serum osmotic pressure and FeNO. Many risk factors, that are allergen and air pollution, may affect FeNO in addition to dehydration. However, increase of more than 1.7% osmotic pressure induced airway inflammation. Large dehydration may induce higher airway inflammation in judoists. Conclusion Dehydration with increase of osmotic pressure might induce airway inflammation in judo athletes. References Anderson, S. D., & Daviskas, E. (2000). The mechanism of exercise-induced asthma is ... The Journal of Allergy and Clinical Immunology, 106(3), 453-9.

### WHAT IS THE BEST SQUAT AND DEADLIFT TECHNIQUE?

Berglund, L., Falk, J., Eliasson, K., Aasa, U.

*Department of Community Medicine and Rehabilitation*

**Introduction** Resistance training is becoming increasingly popular for use in both sports as well as rehabilitation. The barbell back squat and deadlift are two fundamental exercises in most strength and conditioning programs. There are, however, no evidence based guidelines regarding the optimal technical performance of these exercises. Therefore, the aim of this pilot study was to investigate if there exist a preferred technical execution of the squat and deadlift exercises among health care professionals and resistance training practitioners. **Methods** An online questionnaire was created where participants were prompted to arrange eight pictures depicting variations of technical executions of the barbell back squat and deadlift exercises in order of preference in respect to both injury prevention as well as performance. To determine the most preferred execution median, mode and proportions were analysed. Qualitative comments justifying the preference of execution was also collected. Results In total, 19 participants answered the questionnaire; 3 physical therapists, 1 physician, 5 personal trainers and 10 weightlifters/powerlifters/crossfit lifters. The analysis showed that the most preferred back squat and deadlift techniques were shown in the respective pictures representing a traditional powerlifting technique. For the back squat 44 % of the participants chose the powerlifting squat as the best technique and for the deadlift, 56 % chose the conventional powerlifting deadlift technique. The qualitative comments as well as the descriptive analysis showed that the least preferred execution of both the back squat and the deadlift was a technical execution with a flexed or hyperextended lumbar spine and/or valgus position of the knees. **Discussion** The results of this study provides preliminary data of a technical execution of the back squat and deadlift exercises that health care professionals and resistance training practitioners in Sweden prefer. For the back squat, a neutral spinal position and a neutral hip, knee and foot alignment was preferred. The most preferred squat technique was the powerlifting style squat which incorporates a low bar placement on the shoulders and a hip-dominant movement which puts the torso at an angle between vertical and horizontal. As for the deadlift exercise, an execution promoting a neutral spinal position was preferred. The most preferred deadlift technique was the powerlifting style deadlift, depicted with a stance of about shoulder width and hips higher than the knees in the starting position. The most concerning methodological limitation in this study is the limited sample included in the study. This is however expected for a pilot study. Moreover, the participants also reported that the online questionnaire with pictures was demanding and would have benefitted by including short films instead of pictures. Further studies of optimal technique in the barbell back squat and deadlift exercises are warranted. Contact Lars.berglund@umu.se

### EFFECTS OF FUNCTIONAL ANKLE INSTABILITY ON COLLEGIATE FEMALE FOOTBALL PLAYERS' PERFORMANCES

Oda, K.1,2, Ogaki, R.1, Murakami, K.1, Yamaguchi, T.1, Takahashi, Y.1, Kurosawa, T.1, Kanamori, A.2, Miyakawa, S.2

*1:Sendai University 2:University of Tsukuba*

**Introduction** Football is played worldwide by more than 265 million players, of whom 26 million are female players.(Astrid et al., 2007). 17-20% of all injuries are sprains in soccer players (Ekstrand et al., 1990). Ankle sprains cause functional instability in a large proportion of cases. However, no studies have examined a link between functional ankle instability and physical performances. The purpose of this study was to investigate the relationship between functional ankle instability and collegiate female football players' performance. **Methods** 16 collegiate female football players (mean age= 19.7±1.4 years, mean height=159.8±7.6cm, mean weight=56.7±6.1kg) participated in this study. Ankle instability was defined as functional instability based on the Karlsson score. The players were categorized as either having ankle instability (5 injured subjects) or control group (11 uninjured subjects). All subjects underwent performance tests (Yo-Yo Intermittent Recovery test, 20m Sprint, Shuttle run (10m×5), Arrowhead Agility test, One leg vertical jump, Figure 8 hop and Side hopping) . Results A significant relationship was found among the functional ankle instability index, Figure 8 hop (control group:9.2±0.6 sec, injured subjects:9.9±0.9sec, P≤0.05) and Side hop (control group:7.6±0.8sec, injured subjects:6.9±0.5sec, P≤0.02). No relationship was revealed between the functional ankle instability index and other performance tests. A significant relationship was found between the functional ankle instability index and Figure 8 hop (control group: 9.2±0.6 sec, injured subjects:9.9±0.9sec, P≤0.05), and also found between the functional ankle instability index and Side hop (control group:7.6±0.8sec, injured subjects:6.9±0.5sec, P≤0.02). No relationship was revealed in the other performance tests. **Discussion** Figure 8 hop seems to force a rotational stress on the ankle joint and lower leg (Carrie et al., 2005). Side hop test did not reveal a relationship with functional ankle instability. It is hypothesized that functional ankle instability affects the movement to the front direction more than the movement to the side direction. Acquisition of this movement is considered to be a measure of the recovery condition for athletes with functional ankle instability References Junge A, Dvorak J. (2007). ### THE INFLUENCE OF MODERATE INTENSITY EXERCISE IN WATER ON ARTERIAL STIFFNESS DURING RECOVERY PERIOD

Matsui, T.1, Saito, T.2, Murata, M.4, Yoshioka, A.3, Watanabe, Y.4, Yoshida, N.4, Wada, T.4, Tamari, Y.4, Onodera, S.2

*1: Otemon Gakuin University, 2: Kawasaki University of Medical Welfare, 3: Okayama University, 4: Graduate School, Kawasaki University of Medical Welfare*

**Introduction** It is well known that physical exercise affects arterial stiffness. Moderate intensity aerobic exercise on land leads to a transient decrease in arterial stiffness (Hefferman et al., 2007; Nogami et al., 2011). However, there have been few studies on the effects of exercise in water on arterial stiffness. Therefore, we investigated the effects of acute moderate intensity exercise in water on arterial stiffness. **Methods** Seven healthy males (age: 27.4 +/- 10.6 years, height: 172 +/- 6.2 cm, weight: 68.1 +/- 6.7 kg; mean +/- SD) participated in this study as the subjects. They separately completed both 10-min walking in water (WW trial; at a swimming pool, about 110 cm deep, 30 degrees C) at a pace of 75 steps/min (velocity: 46.9 m/min) and that on land (WL trial; at the poolside) at a pace of 150 steps/min (velocity: 93.8 m/min). These trials were followed by 15min recovery period on land. The brachial-ankle pulse wave velocity

(baPWV) and blood pressure were measured at rest, immediately after the exercise, at 10min postexercise, and at 15min postexercise while supine. These data were obtained in both trials on a makeshift bed placed at the poolside. The heart rate (HR) was measured in the same postexercise period and also during the exercise. Results and Discussion The baPWV of WW trial significantly decreased at 10 and 15min postexercise compared to the resting value (rest: 1,232 +/- 91, 10min: 1,123 +/- 111, 15min: 1,151 +/- 132 cm/sec;  $P < 0.05$ ). In addition, there was a significant difference between WW trial and WL trial at 10min postexercise (WW: 1,123 +/- 111, WL: 1,219 +/- 129 cm/sec;  $P < 0.05$ ). At 10min postexercise of WW trial, a significantly lower ankle diastolic blood pressure was observed compared to the resting value and that of WL (rest: 75 +/- 8, WW: 69 +/- 7, WL: 73 +/- 6 cm/sec). The HR during exercise was significantly higher in WW than WL trial (at the end of exercise, WW: 132 +/- 12, WL: 120 +/- 9 bpm). Although there is some difference in exercise intensity based on HR, it was considered that moderate intensity exercise in water elicited a distention of peripheral arteries during the recovery period compared to exercise on land. Therefore, it is suggested that this type of short-time exercise in water could be effective in lowering arterial stiffness (by baPWV), at least temporarily. References Hefferman et al. (2007). *Int J Sports Med.* 28, 197-203. Nogami J et al. (2011). *Jpn J Phys Fitness Sports Med*, 60(3), 269-277. Contact Takeshi Matsui (t-matsui@haruka.otemon.ac.jp)

## Training and Testing

### ORTHOCLINOSTATIC TEST AS A METHOD OF FITNESS LEVEL ASSESSMENT IN ATHLETES

Tarbeeva, A., Tarbeeva, N., Zakharova, A.

*Ural Federal University*

**Introduction** Achieving high sport result demands the verge of human physical abilities. But the way to the peak of sport career is long and unpredictable. The aim of the study was to determine the effects of different fitness level athlete organism adaptation in environment and to physical activity. Methods 20 athletes (12 females and 8 males, cross country skiers) aged from 10 to 20 with different fitness levels were undergoing an active orthoclinostatic test (supine position 1 during 3 min– standing during 3 min–supine position 2 during 3 min). During the test the hemodynamic monitoring with MARG 10-01 'Microlux' based on impedance cardiography provided us the data of electrocardiogram, automatically registered by beat-to-beat record. Heart rate (HR) and correlation rhythmogram (set of points which have coordinates defined by two adjacent cardiointervals values RRI and RRI+1) were under consideration. Results HR dynamics in orthoclinostatic test was 65-86-70 for novice with 1 or 2 years of sport experiences, 63-80-63 with 3 years of sport experiences, intermediate trainees had 58-70-55 while advanced athletes were close to 48-62-45. The correlation rhythmogram in supine position 2 changed from "cloud" to "dot" through "dense cloud" according to age of sport experience. Discussion Correlation rhythmogram method is used in different body position with special attention for the transient periods as it allows estimating participation of parasympathetic and sympathetic systems in HR regulation and also speed and quality of this regulation. Comparison of organism reactions while active orthoclinostatic tests revealed that athletes with 1 or 2 years of sport experience demonstrate the strong reaction of HR while transient into standing position. After returning to supine position 2 HR of novices in sport was higher than in initial supine position 1. Positive changes in adaptation as a rule appear in the end of the third year of sport trainings: HR in supine position 2 (HR3) tended to HR1. Athletes (4-7 years of sport experience) have adequate adaptation reaction in orthoclinostatic test similar to reaction on physical workload: the HR rise is moderate. Advanced athletes have professional sports reaction in orthoclinostatic test: HR3 is even lower than HR1. Correlation rhythmogram specifies HR reaction in orthoclinostatic test: the longer the experience in sport, the less R-R intervals dispersion at rest and transient ("cloud") and the shorter is the period of HR getting stabilized. Thus, according to athlete organism orthoclinostatic test reaction indicators (HR changing and "cloud" sizes in correlation rhythmogram) one can judge about the fitness level of young sportsmen and adjust the physical workload in correspondence to athletes' physiological readiness to train hard. ### INDIVIDUALIZATION OF TRAINING PROCESS OF CROSS-COUNTRY SKIERS OF 12-14 YEARS

Tarbeeva, N., Tarbeeva, A., Zakharova, A.

*Ural Federal University*

**Introduction** During training process planning of children of 12-14 years it is necessary to consider uniformity and irregularity of organism physiological development in pre-puberty and puberty period. It is recommended to start going in for cross-country skiing at the age of 9-10 years. So at the age of 12-14 years there is a period of initial sport specialization (the beginning of specific training). Modern cross-country skiing is a very physically-demanding sport, requiring unique combination of endurance and strength. The purpose of the research was to suggest an informative and available testing method for diagnosis of cardiovascular and muscular systems development in order to individualize training process of cross-country skiers 12-14 years old. Methods Incremental test was held without preliminary warm-up on a treadmill which design allows to adjust running speed up to 26 km/h. Initial speed was 4 km/h. Each 2 minutes the speed of running was increased gradually (step by step) by 2 km/h. Physical work was performed to the full. Heart rate monitoring with GPS (Forunner 310XT) was used during the test and 5 minutes after it for recovery recording. Young cross-country skiers, 12-14 years old, with 1-2 years of sport experience took part in the experimental testing several times a year. Results According to HR-curves during the incremental test all athletes were divided into 3 groups: with muscle development prevalence (athletes with high HR during low intensity running), cardio development prevalence (athletes whose HR at the highest speed was lower than 180 bpm) and balanced muscle-heart development. Discussion Athletes with muscle development prevalence need to choose an aerobic orientation of training process. It is recommended to increase a number of low intensive (HR= 120±10 bpm) aerobic trainings and use HR monitoring during trainings in order not to exaggerate HR limits especially at long duration workouts. Athletes with well developed cardiovascular system should pay more attention to low and high intensity specific strength trainings. When forming training groups it is necessary to take into account a biological level of human organism development and individualize the physical workload in correspondence with athlete' physiological readiness to train in cross-country skiing. ### PHYSIOLOGICAL DEMANDS OF AMATEUR MIXED MARTIAL ART FIGHTING

Petersen, C., Lindsay, A., Walter, S., Carr, S.

*University of Canterbury*

**Purpose:** To quantify in-competition physiological loads of amateur mixed martial art (MMA) fighting. **Methods:** Ten male amateur MMA fighters (Age: 27.3 ± 3.3 y; Mass: 79.5 ± 0.5 kg; Height: 1.77 ± 0.04 m) training 9 ± 4 hours per week (strength 1 ± 1 h; aerobic 7.5 ± 3.5 h; anaerobic 0.1 ± 0.2 h), were filmed during 3 x 5min competitive rounds. Notational analysis was performed on the video-recordings from

the referee head-mounted camera (Go Pro, USA). This quantified standing punches including elbows thrown, kicks (including knees) attempted and respective percentage of each landed, furthermore accumulated time standing, clinching (standing grappling) and grappling (grappling and wrestling on the ground) were calculated. Heart rate (Polar, Finland) was measured during the post-round 1-min rest period, while the fighters perceived exertion (RPE) and earlobe sampled blood lactate (Lactate Pro, Arkray, Japan) were taken immediately post fight. Results: Similar heart rates were recorded ( $176 \pm 7$ ,  $175 \pm 14$ ,  $177 \pm 11$  beats.min) after each of the three rounds respectively; with the peak heart rate at  $92 \pm 6\%$  of age predicted maximum. The post bout blood lactate (taken within 3 minutes)  $12.0 \pm 2.8$  m.mol.L<sup>-1</sup> and RPE  $16 \pm 1$  a.u. values are in agreement with those found after competition ( $10.2 - 20.7$  m.mol and  $13-19$ , respectively) by Amtmann et al, 2003. While  $39 \pm 18$  punches were thrown per round, only  $20 \pm 11$  or  $47 \pm 20\%$  of these were landed. In comparison,  $11 \pm 7$  kicks were attempted, with a similar  $48 \pm 20\%$  ( $5 \pm 5$ ) of these striking the opponent. The fight time spent standing, clinching and grappling was  $38.5 \pm 17.6$ ,  $21.2 \pm 11.5$  and  $40.3 \pm 23.1\%$ , respectively. Conclusions: The proportionally higher amount of time spent fighting while standing and grappling on the floor indicates a higher priority training need for these components of fighting technique. This research may help develop training protocols that produce similar lactate and RPE responses to those found in athletes competing in amateur MMA. References: Ammann JA, Ammann KA, and Spath WK. Lactate and rate of perceived exertion response of athletes training for and competing in mixed martial arts event. *J Strength Cond Res* 22: 645-647, 2003

### EFFECT OF DETRAINING ON PHYSICAL FUNCTION AND EXECUTIVE FUNCTION AMONG ACTIVE ELDERLY

Cordellat, A., Roldan, A., Olagüe, M.A., Blasco-Lafarga, C.

*University of Valencia, Spain*

Introduction Moving from sedentary to active way of life may help to delay Age-related cognitive impairment (Sherder et al., 2014), even more if Physical Activity (PA) implies a special emphasis on cognitive stimuli (Rebok, 2007). Multicomponent, enriched-environment, programs are usually prescribed among elderly (Cadore et al. 2014), expecting that the effects of PA on executive function will be later transferred to Daily Life Activities (DLA). On the other hand, if the PA programs reach a minimum of ten sessions, cognitive gains are expected to last from three to six months (Kelly et al., 2014), but relying on the type and doses of exercise, the detraining period which follows can be very deleterious, especially in this population. Yazigi & Armada-da-Silva (2008) concluded that physical function impairment due to detraining was bigger the older the population, but little is known about detraining and cognitive impairment. Objectives The present study aims to analyze the negative effects of detraining in a group of active Elderly, comparing Functional Capacity and Executive Function. Elderly were tested at the end of nine-month of a multicomponent and cognitive functional-training program, and 4 months later. Methods 16 women and 2 men ( $71.26 \pm 5.19$  years) completed the Stroop Test, the Time Up&Go Test (TUG) and the Six Minutes Walk Test (6MWT). T-test for related samples were conducted (Student and Wilcoxon) and the percentage of the differences was also considered. Results Detraining leads to a significant impairment only in Body composition and Physical Function ( $p < 0.05$ ): an increase in Weight ( $3.94\%$ ) and Fat Mass ( $11.30\%$ ), and a worsening in time (TUG:  $4.22\%$ ) and distance (6MWT:  $-3.78\%$ ), with no significant impairment on Executive Function. Discussion Similarly to Kelly et al. (2014), our results confirm that cognitive capacities in healthy elderly remain for a period of time, but not the physical fitness. One of the main aims of exercise training would be to keep physical fitness since it is a key factor in the maintenance of Executive Function (Yogev-Soligman, 2008) and ADL. ### CONSTRUCT VALIDITY OF THE PHYSICAL ACTIVITY QUESTIONNAIRE FOR ADOLESCENTS : MAXIMAL OXYGEN UPTAKE CRITERION.

Benítez-Porres, J., Dorado-Guzmán, M., Barrera-Expósito, J., Correas Gomez, L., Alvero-Cruz, J.R., Carnero, E.A.

*University of Málaga*

Introduction: The Physical Activity Questionnaire for adolescents (PAQ-A) is a cost-effective tool to assess physical activity (PA) patterns during adolescence and it has been widely used in research and field settings. Convergent validity of PAQ-A has been confirmed in several countries (Bervoets et al., 2014; Janz, Lutuchy, Wenthe, & Levy, 2008; Martinez-Gomez et al., 2009). However, the construct validity has often been overlooked. Therefore, the aim of this study was to analyze the construct validity of PAQ-A, using maximal oxygen uptake as criterion. Methods: One hundred and seventy-eight ( $n=99$  boys,  $n=79$  girls) adolescents ( $14.2 \pm 1.9$  years,  $21.1 \pm 4.1$  BMI) participated in this study. A PA score was estimated by PAQ-A and additionally a sport history was recorded. BMI, waist circumference (WC) and fat mass percent (FMP) were assessed by anthropometric measurements as adiposity markers. Aerobic fitness (VO<sub>2</sub>Max) was assessed by a progressive continuous test (Chester Step Test). Associations between PA-score and criteria were analyzed by Spearman correlations; a one-way ANOVA was conducted to detect differences between each item level from the PAQ-A; independent sample t tests were used to compare values between boys and girls, and athletes and non-athletes. Results: The results showed moderate significant positive correlations between VO<sub>2</sub>Max and the PAQ-C for total score ( $\rho = 0.28$ ,  $P < 0.01$ ) and items 5, 6, 7 and 8 ( $\rho = 0.24$ ;  $\rho = 0.25$ ;  $\rho = 0.22$ ;  $\rho = 0.25$ , all  $P < 0.05$ ; respectively). Adolescents who were enrolled in competitive and organized sport practice had higher scores on the questionnaire (2.8 vs 2.5 average score) as well as higher VO<sub>2</sub>Max values (37.4 vs 34.2 ml/kg/min). Discussion: Our data confirm the PAQ-A had acceptable construct validity when using VO<sub>2</sub>Max as criterion. Moreover, our results suggest that information from some items could be more related with some health markers than others. ## PREDICTORS OF MOTOR COORDINATION PERFORMANCE IN PREPUBERTAL CHILDREN

Luz, L.1, Valente-dos-Santos, J.2, Macedo-do-Carmo, B.1, Duarte, J.2, Padez, C.3, Seabra, A.4, Coelho-e-Silva, M.2

(1)IACAPS, Federal University of Alagoas, Arapiraca, Brazil; (2)CIDAF, University of Coimbra, Portugal; (3)CIAS, University of Coimbra, Portugal; (4)CIAFEL, University of Porto, Portugal.

**INTRODUCTION** Motor development is apparently related to involvement in physical activities and sport participation and it is believed that motor coordination is directly associated with motivation for physical activity (Rivilis et al., 2011). The aim of this study was to examine the association of anthropometric and maturation predictors on motor coordination performance in prepubertal children. **METHODS** The sample included 128 children (males: n=61; females: n=67) aged 8.0-8.9 years. The battery comprised stature (S), body mass (BM), sitting height (SH), waist circumference (WC) and measurements needed to estimate fat mass (FM), fat-free mass (FFM) and to percentage of predict mature stature (%PMS). Body mass index (BMI) was calculated. The Körperkoordinationstest für Kinder (KTK) was also used. Initially, descriptive analysis and Kolmogorov-Smirnov were performed. Sex differences were reported by 'd' of Cohen and interpreted as recommended by Hopkins et al. (2009). Multiple linear regression (backward method) was used to estimate the relative contributions of anthropometric and maturation predictors to variation in KTK test by sex. **RESULTS** Comparisons between sexes were significant for maturation (males: 74.7%; females: 80.5%) and among anthropometric variables, sex differences were uniquely significant for FFM (males: 23.4Kg; females: 21.5Kg). Among the KTK battery, sex differences was trivial for two items: walking backward (d=0.16) and moving sideways (d=0.02); and small for the other two tests: jumping sideways (d=0.20) and hopping for height (d=0.44). The predictor variables explained 29% of the variance in the KTK for males (BMI and WC were the selected predictors in the model, positive and negative, respectively) and 23% for females (S and BMI as significant negative predictors, SH as significant positive predictor). **DISCUSSION** Interpretation of sex differences needs to be considered in the context of growth, maturation and the familial and ecological predictors principles may be central in studies devoted to sex differences in the transition from childhood to pubertal years.

## TRUNK MUSCLES ACTIVITIES DURING FREESTYLE SWIMMING STROKE

Iizuka, S.1, Imai, A.2, Kaneoka, K.2

1: GRADUATE SCHOOL OF SPORT SCIENCES, WASEDA UNIVERSITY, 2: FACULTY OF SPORTS SCIENCES, WASEDA UNIVERSITY

**Introduction** In recent years, trunk stability has been thought to be important in swimming performance. In fact, a lot of training for improvement of the trunk stability is taken in. However, the trunk muscle activities during swimming have not been determined yet. If the timing of the trunk muscle activity is clarified, a more effective trunk training can be offered. Therefore, the purpose of this study was to observe the trunk muscle activities during freestyle swimming. **Methods** The subjects included in this study were seven male college elite competitive swimmers. Sixteen EMG signals were obtained using disposable surface electrodes and two trunk muscles activities were analyzed in this study. Pairs of electrodes were positioned onto the internal oblique (IO) and external oblique muscle (EO) on the right side of subjects, in the direction of the muscle fibers. All of the subjects were required to perform freestyle swimming at a moderate speed to approximately 15 m from the swimming pool wall. The stroke cycle was divided into 10 equal time intervals and EMG activities during each interval were normalized compared to the peak signal value which is estimated as 100 percentage. **Results** The muscle activities of the IO and EO were maximized (IO:57.3%, EO: 59.5%) at approximately 50% of the stroke cycle when an ipsilateral hand passed the deepest position. **Discussion** This might be the first research which measured the EMG of trunk muscles during swimming. We analyzed the muscle activation period mainly in this study, and revealed that the peak of the IO and EO activities were observed when a hand passed the deepest position. During the freestyle strokes, hand drawing speed might be maximized at the middle phase of pull-through motion and the propulsion power to the swimmer's body might be maximized. If the trunk stability is insufficient, propulsion power might not be sufficiently transmitted to the body, so we think that the elite swimmers activate their trunk muscles at that period in order to swim faster. **Conclusion** During the freestyle swimming strokes, the activities of the IO and EO muscles peaked at the middle phase of pull-through motion.

## EFFECTS OF ECCENTRIC STRENGTH TRAINING IN RUNNING ECONOMY OF RECREATIONAL ENDURANCE RUNNERS

Festa, L.1, Tarperi, C.1, La Torre, A.2, Schena, F.1

1. University of Verona, 2. University of Milan

**Introduction** Several studies showed the effects of combined strength and endurance training on endurance performance and running economy (RE). However, few studies investigated specifically the effects of eccentric strength training. Aim of this research was to measure variation of RE after a combined eccentric strength-endurance training versus low or high intensity endurance training programs. **Methods** Twenty-nine well trained recreational runners (average age 35-55y; V'O<sub>2</sub>max around 50 ml/min/kg) were randomized in 3 training programs: combined eccentric strength-endurance (EST), low intensity endurance (LIT), high intensity training (HIT). Each group performed 8-week of training, 3 times a week; training volume (time x intensity) was accurately equalized among the groups. Reference Velocity (RV) as the medium speed between the first and the second ventilatory threshold was used to identify individual training intensity. RV ranged 95-140% for HIT and 70-105% for LIT and EST groups respectively. EST group, in addition to LIT program, performed once a week, 4 sets of 7 repetitions of Yo-Yo Leg Press (Yo-Yo Technology Stockholm Sweden). Before and after training each runner underwent metabolic measurements (Cosmed Quark, Italy) on a treadmill for determination of V'O<sub>2</sub>max and RE at three submax steady state speeds. Lower Limb Free Fat Mass (LLFFM) were measured by DXA (Holometric, USA) and leg-press 1RM (Technogym, Italy). Data were analysed by two way ANOVA and significance level was set at p<0.05. **Results** The combined endurance and strength training (EST group) produced significant improvements in RE (pre 4.5±0.3 J/m, post 4.3±0.4 J/m (p ≤ .05) and 1RM leg press (pre 143.8±35.8 kg, post 162.4±37.3kg (p ≤ .05) while no change in RE was found in HIT (pre: 4.6±0.3, post 4.6±0.4 J/m-l) and in LIT (pre: 4.2±0.5, post 4.2±0.3). V'O<sub>2</sub>max and LLFFM. Did not show significant modification in any groups. **Discussion** The data from the present study show a significant increase of muscle strength with associated reduction of RE in EST group with no concomitant changes in the V'O<sub>2</sub>max and in the lower limb muscle mass. These adaptations seem to indicate that short duration eccentric training (one bout/week for about 20min) produces changes in structural muscle characteristics (fibers, architecture) and intra and inter muscular coordination allowing a reduction in RE in well trained recreational runners without any reduction in aerobic power. ## THE RELATIONSHIP OF SHOULDER MAXIMAL EXTERNAL ROTATION RANGE OF MOTION ON BALL-THROWING SPEED IN YOUTH BASEBALL PITCHERS

van Dis, F.1, Hoozemans, M.J.M.1, Veeger, H.E.J.1,2, van der Graaff, E.1

(1)VU University Amsterdam; (2)Delft University of Technology

**Introduction** To pitch a baseball high rotational forces are needed. Repetitive pitching at high velocities leads to adaptations in the shoulder complex of the throwing arm. Several authors have documented that the throwing shoulder in overhead-athletes exhibits significantly more external rotation and significantly reduced internal rotation when compared to the non-throwing shoulder or to non-overhead-throwing athletes (Ellenbecker et al., 2002; Savers et al., 2014; Wilk et al. 2011). A lot of research into this subject has been done in relation to injuries. The purpose of this study was to see if there is a relation between maximal external rotation of the throwing arm and throwing velocity. **Methods** As a part of a larger study maximal external rotation range of motion of the throwing shoulder was measured using a digital inclinometer in a group of 61 Dutch male youth baseball pitchers. All participants were members of the six talent academies of the Dutch baseball federation and were playing in the Aspirant and Junior Elite League. Throwing velocity was measured using a radar gun and the average of ten subsequent throws was calculated. Measurements were taken in October at the end of the game season. Linear regression analyses were performed to explore the relation between maximal external rotation of the throwing arm and throwing velocity. **Results** The throwing velocity of this group of young pitchers was on average 67.6 (SD 6.2) miles per hour (mph) with a range of 54-80 mph. The average maximal degree of external rotation of their throwing arm was 116.1 (SD 19.8) degrees with a range of 44-169 degrees. Linear regression analysis showed that maximal external rotation was not significantly associated with throwing velocity (regression coefficient 0.008 mph/degree, 95% confidence interval [-0.073, 0.090]). Adding the age groups to the regression model did not change this finding substantially (regression coefficient 0.013 mph/degree, 95% confidence interval [-0.053, 0.078]). However, this final model showed that junior pitchers on average throw 7.6 mph (95% confidence interval [5.0, 10.2]) faster than aspirants. **Conclusion** The amount of maximal external rotation was not significantly related to the throwing velocity of youth baseball pitchers. **References** - Ellenbecker T.S., Roetert E.P., Baillie D.S., Davies G.J., Brown S.W. ## THE DIAGNOSTICS OF ED ELEMENTS IN COMPETITIVE SPORT

Ozimek, M.1, Szmatlan-Gabrys, U.1, Gabrys, T.2, Stanula, A.3

1: AWF (Cracow, Poland), 2: PWSZ (Oswiecim, Poland), 3: AWF (Katowice, Poland)

**Introduction** The verification of effectiveness and accuracy of used methods and their practical use in managing training and sports contests is a key element of training process management (Gabrys and Kosmol 2000, Neuman et al. 2005, Ozimek 2007, Zemkova 2008). The aim of this papers is to present the selected elements of diagnostics in competitive sport with special attention to the determination raining indicators in selected areas of motor preparation of team members of Polish volleyball of men. **Methods** The research included 9 members of Polish volleyball of men premier league (PlusLiga). The programme of the research was as follows: Warm-up. Psychomotorics on a large field (before and after effort) – a test evaluating reaction and orientation speed performed by legs on a field of 3 meters (a square; Fitro Agility Check). Evaluation of lower limbs (before and after effort) – tests: SQUAD JUMP, CMJ – Counter movement jump with and without backswing and DROP JUMP. Aerobic capacity – BIP TEST – every 3 min. increase in load and biochemical examination (K4b2 Cosmed; BIOSEN C-line). **Results** The results point to a direct aim of conducted research and determine the effect on the controlled indicators on the effectiveness of training, comparisons between participants, evaluation of oxygen consumption, determination of the kinetics of oxygen deficit and oxygen debt as well as determination of the level of lactate at different moments of effort. The results of this research provide direct information on the state of preparation and its possibilities related to the conducted control of training effects. **Discussion** Numerous questions related to success and failure of a sportsperson can be answered by a sports training diagnostician. What is more, comprehensive and systematic diagnostics supports both the work of a player and a trainer (Neuman et al. 2005, Ozimek, 2007). The scope of training control and its effect should include a wide range of observations. Their most important elements include: biochemical supervision, physiological supervision of anaerobic and aerobic capacity in laboratory conditions as well as conditions specific to a particular sports discipline, physical fitness and specialist preparation regarding power, force, speed, speed and strength endurance as well as the analysis of a sports training conducted in a training series (Gabrys and Kosmol 2000, Zemkova 2008). **References** Gabrys T., Kosmol A. /red./ (2000). ## NEUROMUSCULAR AND CARDIOVASCULAR ADAPTATIONS IN RESPONSE TO A HIGH INTENSITY INTERVAL POWER TRAINING.

Marquez, G., Ruiz, R., Vera-Ibáñez, A., Romero-Arenas, S.

Catholic University of Murcia

**Introduction:** The aim of the present study was to examine the effects of a high-intensity interval power training (Power-HIIT) of 6 weeks on the aerobic and power performance. **Methods:** For this purpose, 29 healthy participants were recruited and randomly distributed in three different groups. One group performed traditional power training (TPT; n=10), the second group performed Power Training organized as a HIIT (PHT; n=10) and the third one serve as a control group (CG; n=9). During the power training sessions, subjects performed the following exercises: Bench Press, Rebound Jump, High Pull and all-out cycle-ergometer. In both training protocols, subjects were instructed to perform the exercises during 10 seconds at the maximal velocity using the optimal load for each exercise. The amount of work load (set and session volume, and velocity) and local muscular rest period (90 sec) were equated, however, the time between exercises was different (PHT: 15 sec.; TPT: 90 sec.). The training protocols differed in the organization of the exercises. Power-HIIT training was performed in a circuit training fashion and traditional one in a vertical way. In order to know the effects in the aerobic performance, maximal aerobic speed (MAS) was measured. In order to identify the effects on the power performance subjects performed a Wingate test, a counter-movement jump test (CMJ) and a power load curve in Bench press. A two way RM-ANOVA (time -pre vs. post- and group -PHT vs. TPT vs. CG- as factors) were used to test the effect of the different power training protocols. **Results:** The main results showed that after both power training protocols subjects increased significantly ( $p < 0.05$ ) the power production during the Wingate Test, the height and power reached during the CMJ and the peak power produced during the power-load curve. However, when analyzing the MAS only the PHT

group improved significantly ( $P < 0.05$ ). Discussion: Present results are in line with those findings that have previously demonstrated concurrent improvements in both aerobic and force parameters using heavy resistance circuit training (Romero-Arenas et al., 2013). Conclusion: Therefore, the current study shown that power-HIT is a time-efficient method to improve both aerobic and power performance. References: Romero-Arenas, S., Blazevich, A. J., Martínez-Pascual, M., Pérez-Gómez, J., Luque, A. J., López-Román, F. J., & Alcaraz, P. E. (2013). Effects of high-resistance circuit training in an elderly population. *Experimental gerontology*, 48(3), 334-340.

### EFFECTS OF A STRENGTH TRAINING SESSION ON RECOVERY AFTER AN EXERCISE-INDUCED MUSCLE DAMAGE: A RANDOMISED CROSS OVER STUDY

Abaidia, A.1,3, Delecroix, B.1,3, Leduc, C.2, Lamblin, J.3, Baquet, G.1, Dupont, G.1,3

1: University Lille Nord de France (Lille, France), 2: UPJV (Amiens, France), 3: Lille FC (Lille, France)

**Introduction** In football, many eccentric actions are performed and lead to muscle damages. When two matches per week are played, the recovery period between these matches may be too short to fully recover. In this context, the ability to accelerate the return to the initial level of performance is major. Several hormones, such as growth hormone and testosterone play a major role in muscle regeneration (Goldspink, 2005; Schoenfeld, 2010). As some strength training session induces an increase of these hormones (Kraemer et al., 1990; Simao et al., 2013), this study was designed to analyse the effects of a strength training session after an exercise inducing muscle damage on the recovery kinetics. It was hypothesised that the strength training session improves the recovery kinetics. **Methods** In a randomised crossover design, subjects performed, at two separate occasions (control versus experimental conditions) on a one-leg exercise (dominant in one condition and non-dominant in the other condition), 5 sets of 15 eccentric contractions on the knee flexors. After this exercise-induced muscle damage, the subjects were allocated to the control condition (passive recovery) or the experimental condition, which consisted in performing an upper-body strength session. Creatine kinase, hamstring strength and muscle soreness were assessed immediately, 20h, 24h and 48h after exercise-induced muscle damage. **Results** Concentric strength at 120°.s-1, eccentric strength at 120°.s-1, isometric strength at 60° and muscular soreness was largely reduced ( $p < 0.001$ ;  $ES = 1.28$  to  $3.25$ ) at 20h, 24h and 48h after exercise-induced muscle damage. However, no difference was observed in the two conditions (control versus experimental;  $p > 0.05$ ,  $ES = 0.03$  to  $0.4$ ). **Discussion** The results failed to confirm the hypothesis, as no difference was found between the two conditions. The upper-body strength session, performed after exercise-induced muscle damage, does not accelerate the recovery process, but does not delay the recovery kinetics. **References** Goldspink G (2005). *Physiology*, 20, 232-238 Kraemer WJ, Marchitelli L, Gordon SE, Harman E, Dziados JE, Mello R, Frykman P, McCurry D, Fleck SJ (1990). *J Appl Physiol*, 69(4), 1442-50. ### RELATIONSHIPS BETWEEN DIFFERENT PHYSICAL FACTORS IN MALE SOCCER PLAYERS

Kristoffersen, M.1, Nilsen, A.K.1, Iversen, V.1, Røksund, O.D.2, Mæland, S.2, Engeseth, M.S.2, Bogen, B.E.2, Wisnes, A.3, Monsen, G.4, Instebø, A.4, Tønnesen, E.3, Gundersen, H.1

1,2Bergen University College, Bergen, Norway, 3The Norwegian Olympic committee, ASK Brann, Bergen, Norway

**Introduction:** In addition to technical and tactical skills, modern soccer players need to evolve physical capacities to succeed on high level. Soccer game analyses have shown that both sprinting abilities and endurance are important success factors. Other studies have shown a relationship between speed and leg-strength, and between balance and change of direction speed. The aim of this study was to investigate relationships between linear speed, change of direction speed, aerobic and anaerobic endurance, strength, power, flexibility and balance in male soccer players. **Method:** Eighty-two male soccer players (age:  $20 \pm 4$  years; weight:  $75\text{kg} \pm 9$ ; height:  $181\text{cm} \pm 6$ ; body fat:  $10.4 \pm 3.1\%$ ) from first, second and third level in the Norwegian league system participated in the study. All tests were performed during two following days. At day 1 all players performed 40 meter linear sprint (time measurements at 10, 20, 30 and 40 meters), 30m change of direction sprint and repeated sprint (8 x 20 meters, starting every 30 seconds). All running tests were performed at an indoor running track, and the times were measured using timing system (Brower, USA). In addition all players performed a 90 seconds anaerobic endurance jump test and a countermovement jump tests using a force plate (Kistler, Switzerland), at both legs and at single-legs. Moreover, all players performed a 5 repetition maximum (RM) squat test, a 1 RM bench press test, followed by a test of maximal repetitions of chins and in brutal bench. At day 2 all players underwent body composition analyses (InBody 720, Biospace), spirometry (Vyntus CPX, Jaeger, Germany) and maximal oxygen consumption test (Jaeger Oxycon Pro in mixing chamber mode, Jaeger, Germany). In addition hip, knee, ankle and hamstring flexibility and balance were tested. NB! All analyzes will be completed in late March. Results and discussion will be forwarded when the analyzes are done. ### PHYSICAL CHARACTERISTICS AND GAME RELATED STATISTICS OF ELITE ADOLESCENT FEMALE BASKETBALL PLAYERS

Fort-Vanmeerhaeghe, A., De Blas, X., Latinjak, A., Montalvo, A., Unnithan, V.

School of Health and Sport Sciences (EUSES) (Salt, Spain)/Blanquerna Faculty of Psychology, Education Sciences and Sport (FPCEE) (Barcelona, Spain)

**Introduction** Optimal performance in basketball is highly complex because it requires a combination of technical and tactical abilities and a high degree of physical fitness (Ben Abdelkrim et al., 2010; Ziv & Lidor, 2009). The main aim of this study was to evaluate the relationship between physical fitness and game-related performances in young elite basketball players. **Methods** Twenty-three young, female, elite Spanish basketball players (age:  $16.2 \pm 1.2$  years, mass:  $71.6 \pm 10.9$  kg, stature:  $1.82 \pm 0.07$  m) participated in the study. The average physical fitness performance scores of the pre and post – season testing were used as the representative values for subsequent analyses: aerobic power (yo-yo intermittent test), speed (¼ basketball sprint test), agility (T-test), anaerobic capacity (line drill), repeated sprint ability (10 x 30 m), strength (leg and bench press) and power (jumping and throwing abilities). Anthropometric variables were also measured. To evaluate game performance, statistical data of games played and minutes, points, rebounds, assists, steals and blocks per game were identified during every competitive match of one season and the data were averaged. **Results** Only two game-related performance variables correlated significantly ( $p < 0.05$ ) with physical fitness test performance. Assists per game correlated with: vertical jump ( $r = 0.44$ ), speed ( $r = 0.65$ ), agility ( $r = 0.70$ ), anaerobic power ( $r = 0.68$ ), repeated sprint ability (mean and best) ( $r = 0.62$  and  $r = 0.64$ , respectively) and aerobic power ( $r = 0.66$ ). Steals per game correlated significantly with: speed ( $r = 0.48$ ), agility ( $r = 0.48$ ), anaerobic power ( $r = 0.51$ ), repeated sprint ability (best) ( $r = 0.47$ ) and aerobic power ( $r = 0.56$ ). **Discussion** Our results suggest that superior aerobic and anaerobic power, speed and agility and jump capacity are related to some key game-related performance measures. There is a scarcity of

research available investigating the relationship between game-related performance and physical fitness capacity in basketball players. To the best of our knowledge, there is one similar study in the literature. McGill et al. (2012) showed that standing broad jump and lane agility time were significantly correlated with some game-related performance measures (e.g. minutes, assists, rebounds) in male basketball players. Our finding indicates that it may be of interest to identify and develop physical fitness characteristics that are associated with some game-related statistics in order to improve game success. #### **A FOUR WEEK ANALYSIS OF RECOVERY STATUS IN KOSOVAN YOUTH SOCCER PLAYERS**

Gjaka, M.1, Tschan, H.2, Francioni, F.M.1, Tessitore, A.1

1: *University of Rome*

The trend to increase training loads has to be counterbalanced by proper recovery strategies (Tessitore et al 2007, 2008). This fact requires the awareness of how external training loads can affect the recovery status of athletes. Therefore, this study aimed to investigate the recovery status of young soccer players during four weeks of in-season, characterized by training sessions and two weekly match conditions (one match (W1match) and two matches (W2 match) per week, respectively). Hence, in order to examine differences between the two conditions, if any, the players' recovery was measured before each training and match. Thus, 22 Kosovan soccer players belonging to the "2 korriku" (Pristina, Kosovo) youth team (age:  $14.5 \pm 0.30$  yrs, height:  $174 \pm 7.93$  cm, weight:  $60.1 \pm 7.95$  kg) participated in this study. Consequently, individual recovery data were collected during 12 training sessions and before six matches by means of a modified TQR questionnaire (based on 10 point scale), which was translated in Albanian language to facilitate the players' comprehension. In addition, a training log was administered for each training session, in order to collect information regarding the loads imposed to the players. Surprisingly, no significant differences were found in players' recovery status ( $p = 0.63$ ) between W1match and W2match conditions ( $6.50 \pm 0.91$ , and  $6.19 \pm 1.01$ , respectively). Moreover, general results of the current study showed that players' recovery was rather similar (slightly higher) compared with results provided by Brink et al. (2010a & 2010b). Furthermore, according to the individual scores gathered by the questionnaires submitted before each game, our players felt a recovered status, testified by their answers which scored at least a point of 7 ("very good recovery") or above. Additionally, in the light of findings of the current study, it can be speculated that players were strictly following the guidelines received by their coach about how to manage eating, sleeping, drinking and resting after training sessions and matches. Finally, training log results demonstrated that a complete exclusion of strength and conditioning was implemented as a coach's strategy during the weeks scheduled with two matches, in order to avoid high physical stress during the last training period before the play-off phase competition. #### **ROWING ERGOMETER 30 MINUTES ALL-OUT TEST AS A PREDICTION OF THE VENTILATORY TRESHOLD**

Mladen, M.1, Suk, S.2

1: *KIFST (Split, Croatia)*, 2: *HVS (Zagreb, Croatia)*

Introduction For the purpose of properly dosing the training load in rowing sports, the value of the ventilatory threshold (VT) and maximal oxygen consumption are most often used. Laboratory measurements of functional abilities, with which specifically measured values of these characteristics are obtained, are not available to everyone, due to both financial reasons and lack of facilities. Therefore, the aim of this study is to find the relation of intensity of ventilatory threshold obtained in the laboratory to the average split time achieved on the 30 minutes all-out test. Methods The analysis was performed on a group comprised of 44 rowers of the Croatian national team. Measurement of  $VO_{2max}$  was done in a laboratory and the ventilatory threshold was derived from this. The same rowers performed the standardized 30 minutes all-out test on the rowing ergometer. In addition to the total distance travelled, the average split time was recorded. Both tests were carried out within a time period of two weeks. Descriptive analysis, t-test and regression were processed using the statistical package Statistica 11. Results The values of the intensity of work on the ventilatory threshold are shown by the 500 meters split time (VT split), which also shows the average intensity during performance of the 30 minutes all-out test. Work intensity of the 30 minutes all-out test was  $1:44.8 \pm 4.0$  (mean  $\pm$  standard deviation), while the VT was reached on values of  $1:45.2 \pm 4.7$ . Evaluation of equality of arithmetic means of the two groups gave the t-value = 0.44;  $p = 0.66$ . Regression analysis indicated a statistically significant correlation between these two parameters ( $r = 0.8002$ ;  $p = 0.0000$ ) and formed the regression equation  $VT_{split} = 7.3296 + 0.934 * X$ . Discussion The results indicate that there is no statistically significant difference between the data measured by the two tests. The statistically significant and high correlation indicates that a large part of the variability of the ventilatory threshold can be explained by the result of the 30 minutes all-out test. That leads us to the conclusion that the average split time on the 30 minutes all-out has a high prediction, and that the regression equation can be used with very small risk for approximating the ventilatory threshold. #### **RELIABILITY OF SIDE-HOP LIMB IMBALANCE RATIO**

Mirkov, D.M.1, Knezevic, O.M.2, Dakic, M.1, Djuric, S.1, Stankovic, A.1

1: *University of Belgrade Faculty of Sport and Physical Education, Serbia*; 2: *University of Belgrade Institute for Medical Research, Serbia*

Introduction Although Side-hop test (SHT) has been commonly used to evaluate functional performance after lower limb injuries (Itoh et al. 1998; Docherty et al. 2005), some important metric characteristics have not been evaluated yet. Therefore, the primary aim of the study was to determine the number of measurements (i.e., sessions/trials) necessary to obtain a stable limb imbalance ratio assessed through limb symmetry index (LSI). The secondary aim was to examine the absolute and relative reliability of LSI. Methods Fifteen subjects performed 3 trials of SHT (jumping 20 times from side-to-side over two lines set 30 cm apart), within 6 sessions separated with 2 days of rest each. LSI was calculated as a percentage ratio of the nondominant and dominant limb score. Within-within ANOVA was used to investigate the within and between day differences in LSI. Absolute within and between day reliability was evaluated with the intraclass correlation coefficients (ICC), while absolute reliability was assessed through the standard error of measurement (SEM), presented as percent of the mean value. SEM was further used to determine minimal detectable changes (MDC) for LSI. Results There was no difference in LSI both

within day ( $F=0.92$ ;  $p=0.48$ ) and across the sessions ( $F=0.15$ ;  $p=0.86$ ). Although relative reliability (both between and within day) was generally moderate (ICC ranged from 0.36 to 0.74), the absolute reliability was exceptionally high (all SEM below 5%), while within day MDC ranged from 10.2-18.2%. Between-day MDC was 9.1%. Discussion The comparison across the sessions revealed that LSI was stable both across the days and between sessions, suggesting that SHT could be routinely used without previous familiarization sessions. It also appears that LSI could have the property of low relative and high absolute reliability, suggesting that LSI as a measure of imbalance ratio should be used and interpreted with caution. Future studies should examine possible strategies designed to increase the reliability of LSI and compare it across different populations to ascertain the clinical application of LSI obtained from SHT. ### **A RELATIONSHIP BETWEEN SINGLE LEG TASKS AND SIDESTEP CUTTING IN MALE RUGBY PLAYERS -LATERAL HOP AND HOP-AND-SIDESTEP-**

Ito, W., Kagaya, Y., Kawahara, T.

*National Institute of Fitness and Sports in Kanoya*

**Introduction** Many non-contact anterior cruciate ligament (ACL) injuries occur during sidestep cutting in rugby players. Knee valgus moment is viewed as an important predictor of non-contact ACL injury risk. Screening tests for the risk of non-contact ACL injuries tend to focus on knee valgus moment and angle during landing tasks on both legs. But the injuries are predominantly distributed to a single leg in sidestep cutting. We required simple and easy clinical screening tests based on single leg tasks. The purpose of this study was to investigate whether there is a relationship between lateral hop, hop-and-sidestep, drop vertical jump (DVJ) and sidestep cutting in male rugby players. **Methods** Seven male rugby players (23.7±1.5 years, 170.4±3.4 cm, 75.3±7.5 kg) participated in this study. Lateral hop and hop-and-sidestep were included in single leg tasks. Lateral hop was defined as single leg hop toward the same side of the standing leg. Hop-and-sidestep was defined as single leg hop forward, landing with the same leg, and cutting to the opposite direction of the standing leg. Participants performed lateral hop, hop-and-sidestep, DVJ and sidestep cutting tasks. A three dimensional motion analysis system featuring ground reaction force was used to determine kinematics and kinetics of both legs (7 right legs, 7 left legs). Peak knee valgus angle and moment during tasks were calculated. Peak knee valgus moment was normalized to weight. **Results** There was no significant difference in peak knee valgus angle between tasks. Peak knee valgus moment in sidestep cutting (1.3±0.5 Nm/kg) was greater than in DVJ (0.5±0.2 Nm/kg) and lateral hop (0.4±0.3 Nm/kg). There was no significant difference in peak knee valgus moment between hop-and-sidestep and sidestep cutting. Strong correlation was found in peak knee valgus moment between DVJ and sidestep cutting ( $r=0.64$ ,  $P<0.05$ ), lateral hop and sidestep cutting ( $r=0.89$ ,  $P<0.01$ ), and hop-and-sidestep and sidestep cutting ( $r=0.76$ ,  $P<0.01$ ). **Discussion** The results suggest that there are relationships between lateral hop and sidestep cutting, and also hop-and-sidestep and sidestep cutting in knee valgus moment. We believe lateral hop and hop-and-sidestep are simple and easy clinical screening tests based on single leg tasks. Contact E-mail: wtr0804@hotmail.co.jp

### **RELATIONSHIP BETWEEN THE JUDO FITNESS TEST AND LOWER SKELETAL MUSCLE POWER AMONG JAPANESE FEMALE JUDO PLAYERS**

Okawa, M., Yazaki, R., Ide, Y., Sakurai, T.

*International Budo University*

**Introduction** Judo is the martial art fathered by Jigoro Kano in 1882. He is called to 'the fatherhood of the judo' or 'the fatherhood of the Japanese physical education' in Japan. It was adopted formally at the Tokyo Olympic games in 1964 (men's only, the women's event was introduced at the Olympics in 1988). The Japanese judo is traditional well-known sports in the world. There are divided into seven classes weight divisions system (under 48kg, 48-52kg, 52-57kg, 57-63kg, 63-70kg, 70-78kg, and over 78kg), and it is 4 minutes for women's competition. Judo is the sport that throws an opponent at restriction time. Competitive judo can be described as a combative, high intensity sport in which the athlete attempts to throw the opponent onto partner back or to control partner during groundwork fight. It is necessary specific techniques and tactical skills with the support of good physical fitness. It was based on special qualities, and was contrived "the special judo fitness test" by Sterkowicz (1995), which test executor throws partners using the ippon-seoi-nage technique, as many times as possible. And then when the seoi-nage is performed, Mori et al (2011) are explaining necessity of the thigh muscles strength and power. The purpose of this study was to examine mutual relation measured by the special judo fitness test (SJFT) (Emerson et al, 2009; Franchini et al, 1998; Patrik et al, 2012; Sterkowicz, 1995) with blood lactate and heart rate and lower extremity muscular power by 30-s wingate anaerobic test (WAnT) (Bar-Or O, 1987). **Methods** Japanese female judo players were applied in this study obtained their parents' informed consent. SJFT and WAnT on mechanically braked cycle ergometer were used for evaluation. **Results & Discussion** Franchini et al shared Brazilian judo players with 3 categories (juvenile, junior, and senior) by the age and compared the SJFT. When it will be analyzed, neither the each SJFT item, nor blood lactate and heart rate were confirmed by the difference between three groups (Okawa et al, 2015, unpublished). A relation between the SJFT and the lower muscle power in the Japanese female judo players is announced. **References** Bar-Or O (1987). *Sports Med*, 4(6), 381-394. ### **RESEARCH ON PHYSICAL FITNESS CHARACTERISTICS OF TENNIS PLAYERS**

Umebayashi, K.

*Osaka University of Health and Sport Sciences*

In order to achieve top-level results in major matches domestically and abroad, continuous practice and building of physical fitness from the junior period is required. However, there is very little research into the correlation between playing ability and physical fitness. And so the purpose of this research was to examine items testing physical fitness which is beneficial to exercise and training and contribute to improving player ability in the future. The subjects were 98 boys and girls aged 9 to 22 whose game of specialization is tennis (61 boys, 37 girls). The measurement items measuring general physical fitness were standing long jump, long seat type body antelexion, sit-ups,

medicine ball throwing, and 3-minute shuttle stamina. Furthermore, as items measuring tennis-specific physical fitness, measurement items were 10m run, 505-agility test, pro-agility test, hexagon jump, and one-leg standing long jump. Analyzing the correlation between age and each measurement item of physical fitness showed a strong correlation with general physical fitness measurement items, but the correlation with tennis-specific physical fitness measurement items was weak or in some cases non-existent. Furthermore, players who showed high values in the tennis-specific physical fitness measurement items were also superior in playing ability. These facts suggest that these tennis-specific physical fitness measurement items may have the potential to measure physical fitness factors required in tennis players from a young age

### INDIVIDUAL HAEMOGLOBIN MASS RESPONSE TO ALTITUDE TRAINING AT 1800 M IN ELITE ENDURANCE ATHLETES

Troesch, S., Hauser, A., Steiner, T., Gruenenfelder, A., Heyer, L., Gojanovic, B., Wehrlin, J.P.

*Swiss Federal Institute of Sport Magglingen*

**Introduction** Given the interindividual variability of haemoglobin mass (Hbmass) -responses to altitude training (Friedmann et al., 2005), one can speculate that despite the insignificant mean increase of Hbmass after altitude training at < 2000 m (Pottgiesser et al., 2009), there can be athletes with a substantial increase of their Hbmass even at < 2000 m. However, the assessment of individual Hbmass-responses is challenging, as adaptations can be concealed by measurement error. Using error-reducing duplicate measures of Hbmass, we aimed to identify individuals with an increase of Hbmass after 20 days of classical altitude training at 1800 m. **Methods** By a novel method combining two optimised CO-rebreathing procedures within hours (Naef et al., in press), Hbmass of seven male elite endurance athletes (all in the top eight of the Swiss national ranking in their disciplines) was assessed in duplicate before (T0) and after (T1) a three-week control period as well as after (T2) a subsequent 20-day classical altitude training period at 1800 m. **Results** Mean Hbmass at T0, T1 and T2 was  $936 \pm 38$ ,  $945 \pm 24$  and  $961 \pm 51$  g, respectively. The effect of the altitude stay on mean Hbmass was trivial in relation to the smallest worthwhile change of Hbmass (2%). Individual responsiveness was  $\pm 1.5\%$  from the mean effect. The 95% confidence limits for individual Hbmass changes ( $\pm 5.0\%$ ) were exceeded by two athletes. **Conclusion** We conclude that no mean increase of Hbmass can be expected after a three-week stay at 1800 m but that some individuals significantly increase their Hbmass nonetheless. Therefore, we recommend to elite athletes 1) to enhance the chance of an individual Hbmass benefit by completing their altitude training at > 1800 m and 2) to analyse their individual Hbmass-response to an altitude stay using duplicate measures pre and post altitude. **References** Friedmann, B., Frese, F., Menold, E., Kauper, F., Jost, J., & Bartsch, P. ### DIFFERENCES IN TRUNK TWIST MOTION USING LONG OR HEAVY BATS WITH EQUAL MOMENTS OF INERTIA

Takahashi, K.1, Yamada, K.2, Kariyama, Y.1, Hayashi, R.1, Yoshida, T.1, Zushi, A.1, Zushi, K.1

*1: UNIVERSITY OF TSUKUBA (JAPAN), 2: JISHUKAN SENIOR HIGH SCHOOL (JAPAN)*

**Introduction** Increasing bat head velocity is an important way to improve hitting performance in baseball. Using a training bat with altered length or mass is one such method. These bats alter the moment of inertia (MOI). Previous studies have investigated training effects of using weighted bats (Sergo, 1993); however, none have investigated the characteristics in hitting motions using long bats or evaluated differences in hitting motions when players use bats with the equal MOI but different length and mass. This study aimed to investigate differences in hitting motions to focus on trunk twist, which is important in increasing bat head velocity (Fleisig et al., 2013), using training bats with equal MOI but different length and mass. **Methods** Eleven male collegiate baseball players participated in this study (age  $19.09 \pm 1.04$  years, height  $1.75 \pm 0.05$  m, mass  $72.45 \pm 8.12$  kg, mean  $\pm$  SD). All subjects performed tee batting with maximal effort. Four long bats (LB) and four weight bats (WB) were manufactured based on a normal bat (NB 0.84 m, 0.9 kg). LB and WB were manufactured to have the equal MOI (Spurr et al., 2014). The three-dimensional co-ordinates of nine reflective markers fixed on the body and bat were collected by the Vicon system (250 Hz). The swing motions was analysed from take-off of the stride leg to ball impact. The angular displacement of trunk twist and upper trunk and pelvic rotations were investigated in the transverse plane. **Results and Discussion** No significant differences in angular displacement of trunk twist and upper trunk and pelvic rotations were seen while using LB and WB. However, the angular displacement of trunk twist tended to be larger with increasing MOI using LB. Subjects were divided into two groups based on the mean value of angular displacement of trunk twist using NB: a large displacement group and a small displacement group. Participants in the small displacement group demonstrated larger differences in angular displacement of trunk twist using LB with the highest MOI when compared with NB. In the small displacement group, using NB, the pelvic and shoulder rotations started almost simultaneously. However, when the same subjects used LB with the highest MOI, pelvic rotation started before shoulder rotation. Thus, LB may contribute to improved trunk twist motion in players who cannot get a proper trunk twist with NB. **References** Sergo C, Boatwright D. (1993). *J Strength Cond Res*, 7(2), 115-117. ### THE SOMATOTYPE OF AFRICAN SPORTSMEN

Mimouni, N., Bensaiibi, Y., Abdelmalek, M., Zaki, S.

*ES/STS*

**Introduction** The knowledge of sportsmen somatotypes is of great importance for many researchers in sport and physical education (Malina, 1982; Wilmore, 1983; Heyters, 1986; Crankcase, 1990; Heyward, on 1999). During these last decades, several researchers were interested in the estimation of the composition and in the physical structure of sportsmen and proposed several equations. In front of this multitude of formulae estimating the same parameter, our choice concerned to determine the somatotype of our sample. The main of this study is the determination of the somatotypes of African sportsmen and to use the typology as parameter of control of the training plans. **Method** The study concerned athletes of the African national teams, who participated in the IXth African Games organized in Algiers. Anthropometric measures were taken during the African Games. We used an anthropometric suitcase of the type GPM (Siber Hegner firm) for all the measures. We determined the various somatotypes by using the software «Somatotype» conceived by Kagi Systems firm. **Results** The estimation of the somatotype gives an overview onto the physical composition and the structure of the high-level sportsmen. This overview can be used as parameter of control for training and allows rectifying errors of the planning. It thus seems

necessary to verify the good choice of a method of training from the variation between two main components: endomorphy and mesomorphy, to consider the level of preparation of an athlete. Conclusion Studies on somatotypes are still necessary to improve the evaluation of the physical composition. It is thus essential to determine our own anthropometric profiles of African somatotypes not to take any more in reference the data stemming from other populations. References CARTER JEL, Heath BH. ## A METHODOLOGY FOR A TEAM PERFORMANCE SCORING SYSTEM FOR RUGBY UNION

Burt, E.1, Hughes, M.D.2, Dancs, H.3

*University of Middlesex, University of West Hungary, University of West Hungary*

Introduction Studies of complex team sports, such as rugby union, that have assessed performance using a simple analysis of frequency data have struggled to identify a consistent statistically significant link between team performance indicators and match outcome (Vaz et al. 2011; Hughes et al., 2012). Methods This proof-of-concept study outlines a methodology that transforms standard notational analysis inputs into a qualitative assessment using a simple weighted algorithm for every action variable. From this, key highlights in individual matches can be automatically identified. Thirty nine home and away matches played by a single RFU National League 3 team in the 2011/12 season (n=26), and International matches played in 2011/2012 season (n=13) were coded and used to develop the system. Results Intra-operator reliability was tested on two matches from each population group, achieving an acceptable (<5%) difference across categories. The system was deemed to be valid as it correctly calculated 92% of National 3 and 82% of International match outcomes (excluding draws) and successfully identified key passages of play, for example 72.6% of tries at National 3 and 86.8% of tries at International level above the 80th percentile of key incidents despite try scoring events accounting for 17.62%  $\pm$  0.12% of system points awarded for National 3 games and 10.19%  $\pm$  0.10% of system points in International games. Discussion It is recommended that further research and development is required to improve the robustness of this system and the underlying academic assumptions. References Hughes, M., Hughes, M. ## TRAINING INTENSITY DISTRIBUTION IN YOUNG TENNIS PLAYERS

Gomes, R.V.1, Moreira, A.1, Capitani, C.2, Aoki, M.S.1

*1: University of São Paulo (São Paulo, Brazil), 2: University of Campinas (Limeira, Brazil)*

Introduction The aim of this study was to describe the distribution of training intensity in a group of elite young tennis players during both preseason and the beginning of their competitive season, based on the session rating of perceived exertion (session-RPE) and heart rate methods. Methods Twelve professional tennis players (age: 18.5  $\pm$  0.4 years; height: 178.0  $\pm$  4.0 cm; body mass: 72.4  $\pm$  6.0 kg) participated in this study. HR and session-RPE were collected in 407 tennis training sessions (including 23 simulated matches) and 17 official matches, during the first 7 weeks of the competitive season. From week 1 to week 5, no official or simulated matches were performed. During the last 2 weeks (week 6 and week 7), simulated and official matches took place. Training intensity distribution was quantified from heart rate using pre-defined HR and session RPE zones (HR: Zone 1 = <70%HRMAX; Zone 2 = >70-85% HRMAX; Zone 3 = > 85% HRMAX and session RPE: Zone 1 = <4; Zone 2 = >4-7; Zone 3 = > 7). Results All individual correlations between the session RPE method and the HR-based method were significant ( $r = 0.58 - 0.89$ ;  $p < 0.01$ ). The correlation coefficients between methods during on court tennis training sessions, simulated and official matches were  $r = 0.74$ ,  $r = 0.57$  and  $r = 0.99$ , respectively. The total training time spent in the heart rate zone 1 (52.00%) and zone 2 (37.10%) was greater than the time spent in zone 3 (10.90%) during the training period ( $p < 0.05$ ). Similarly, the total training time spent in the session RPE zone 1 (42.00%) and zone 2 (47.50%) was also greater than the time in zone 3 (10.50%) ( $p < 0.05$ ). Discussion The data of the present study demonstrated that these young tennis players train in a low to moderate intensity zone, and therefore under the intensity performed in the official matches. Additionally, the current data indicated that young tennis players adopt a polarized training intensity distribution. [email: aoki.ms@usp.br]

## AGREEMENT BETWEEN DIFFERENT APPROACHES OF A SLED TOWING SPRINT TEST

Pantoja, P., Carvalho, A., Berriel, G., Ribas, L., Peyré-Tartaruga, L.

*Federal University of Rio Grande do Sul*

Introduction A critical examination on key elements and fundamental features of training methods is crucial in order to achieve more consistent results. The execution of running tests with loads demands application of a proper rest interval, which will allow the achievement of maximal performance. Hence, this study aimed to analyze the agreement between a running protocol performed with different loads, with a determined rest interval, and a protocol in which the running tests with different loads were performed in different days. Methods Eleven athletes practicing sprint running participated in this study. One protocol included sprints of 50 m, in four distinct situations: without a sled; towing a sled with a load corresponding to 20% of body mass (including the sled weight); 30% and 40%. The order of the running tests was randomized and a rest interval of 15 min separated each test. After about two weeks, the athletes performed each running test, with each load, in separate days. Time was measured with an automatic timing system, including the watch and timing gates for start and finish (Freelap SA, Fleurier, Switzerland). Bland Altman testing was applied using the software Analyse-it 2.3, with a level of significance of 0.05. Results An agreement between protocols was found for running without sled and for sled towing with a load corresponding to 20% of body mass, showing a bias of 0.039 and -0.032, respectively, without significant difference. In contrast, for loads corresponding to 30% and 40% of body mass, an agreement was not assumed, because bias was greater and distant from zero (-0.303 and -0.496, respectively), with significant difference for 30% load. Discussion The lack of agreement observed for greater loads may be associated with the reduced time performed by the athletes during running in separate days. Probably, when running with 30% and 40%, in randomized order with tests involving 20% and without sled, with 15 min rest interval, athletes were under the effect of

fatigue, which possibly was not present during testing in separate days. This effect can be ascribed to a fatigue on stretch-shortening cycle (Komi, 2000) and/or due to intrinsic local/muscular mechanisms (e.g. myofibrillar  $Ca^{2+}$  sensitivity, Allen et al., 2007). This may have caused the difference in running time between protocols. In conclusion, for running without a sled or towing a sled with load of 20% of body mass, there is an agreement between tests performed separately and those performed at the same day, with 15 min rest interval, in contrast to what was observed for loads corresponding to 30% and 40% of body mass. ### RELATIONSHIP BETWEEN TOE TOUCH JUMP ABILITY AND PHYSICAL FACTORS IN CHEERLEADERS

Rieko, K., Maya, T.

*Chukyo University*

Jump is one of the important elements of competitive cheerleading. It is the only technique that everyone in the team performs at the same time. Toe touch jump with the leg straddled parallel to the frontal plane is the most common technique. The evaluating criteria of toe touch jump are not only the height of jump but also the degree of legs. Therefore, physical skills for performing toe touch jump can be many factors. Moreover, the skills and physical factors of toe touch jump remain nucleated, and there seems only few guideline of coaching. Therefore, the purpose of this study is to clarify relationship between toe touch jump ability and physical factors in cheerleader. Sixteen female cheerleaders participated in this study ( $158 \pm 5.8$  cm,  $53.5 \pm 5.6$  kg,  $19.5 \pm 1.37$  yrs). Body composition, vertical jump, repetition maximum of parallel squat and functional movement screen (Gray Cook 2010) were measured. As an indicator of the flexibility the passive leg angle (PROM) was measured when participants performed the maximum angle of leg holding by hand while standing on the other leg. The maximum and minimum angle of the leg (AROM) were measured after participants held leg for 6 seconds without hands while standing as an index of muscle strength. To evaluate the jump skill, we recorded toe touch jump in frontal and sagittal plane and calculated the leg angle of each participant's toe touch jump. Significant positive correlation between the leg angle of the toe touch jump and vertical jump ( $r=0.569$ ), maximum AROM of the left leg ( $r=0.597$ ), minimum AROM of the left leg ( $r=0.543$ ) were observed ( $p < 0.05$ ). There was no correlation between the toe touch jump performance and the other physical factors. To perform better toe touch jump, one has to have a better jump ability. Those who jump higher can have longer time in the air, therefore have time to perform large leg angle. While positive correlation between leg angle of toe touch jump and AROM was observed, PROM wasn't. Therefore, to develop the skills of toe touch jump, the jumping ability and muscle strength of the hip and trunk that enables one to bring legs up in the air are necessary.

### HEART RATE RESPONSES TO TRAINING AND TESTING IN POSTPUBESCENT FEMALE VOLLEYBALL PLAYERS: THE EFFECT OF MATURITY

Kostoulas, I.1, Tasiopoulos, I.1, Padulo, J.2, Busko, K.3, Afonso, J.4, Torres-Luque, G.5, Nikolaidis, P.T.1

1: *Hellenic Army Academy (Athens, Greece)*, 2: *University e-Campus (Novedrate, Italy)*, 3: *Institute of Sport (Warsaw, Poland)*, 4: *University of Porto (Portugal)*, 5: *University of Jaen (Spain)*

Introduction Although physiological characteristics have been well studied in female volleyball players (e.g. Nikolaidis et al., 2015a,b; Nikolaidis et al., 2014; Nikolaidis et al., 2012), less information about the physiological impact (e.g. heart rate, HR) of maximal and submaximal exercises either on field or laboratory is available. Moreover, the effect of maturity on this impact has not been studied so far. Therefore, the aim of the present study was to examine the effect of maturity, assessed as difference between chronological age and age at peak height velocity, on HR responses to maximal and submaximal laboratory and field exercises. Methods Twenty-eight postpubescent female volleyball players participated in the present study (age 13.8 (0.6) yrs, body mass 62.5 (8.2) kg and height 1.73 (0.05) m; mean (standard deviation)). They were divided into two groups with regards to their maturation: less matured (LM) and more matured (MM). In laboratory, HR was recorded during 5 min rest, physical working capacity in heart rate 170 bpm, 3 min step test, 30 s Bosco test and Wingate anaerobic test (WAnT) were performed. In field, a 70 min training session (consisted by three parts: warm-up, 1x1 drills and team drills) was monitored and 20 m shuttle run endurance test was performed. Results There was significant difference between LM and MM groups over HR responses (%HR reserve, %HRR) to exercise training ( $F(2,21)=6.08$ ,  $p=0.008$ ,  $\eta^2=0.37$ ). There was a main effect of part session of exercise program on HR responses with the highest intensity recorded in 1x1 drills (~75%HRR) and the lowest in team drills (~60%HRR in LM and ~65%HRR in MM). There was also a moderate effect of maturity on HR during cycling against 90 W and in the WAnT, and small effect on HR during cycling against 60 W, in the end of the step test, Bosco test and running endurance test, where the highest scores were recorded in LM. Conclusions Based on the findings of the present study, it was concluded that maturity exerted an effect of small to moderate magnitude on HR responses in a laboratory setting and this should be taken into account by coaches and trainers when evaluating physiological characteristics. ### ACUTE EFFECTS OF LOW-INTENSITY RESISTANCE TRAINING WITH SLOW MOVEMENT IN SWIMMING: A PILOT STUDY

Scurati, R., Formenti, D., Rossi, A., Invernizzi, P.L., Michielon, G.

*University of Milan*

Introduction Low-intensity resistance training with slow movement and tonic force generation (LST) has been recently proposed as effective for strength improvement (Tanimoto et al., 2009). Transferability of the effects of dry-land strength training on swimming performance is still debated and questioned (Aspenes et al., 2012). Nevertheless, this pilot study aimed to assess whether LST and slow strip set resistance training (SSS) might affect front crawl swimming, while specific in-water adaptations were not performed. Methods Eight male swimmers were randomly assigned to LST or SSS dry-land resistance training. Participants trained for 6 weeks, 3 times per week, by one set until to complete exhaustion of: i) LST: push-ups, 5s down + 5s up; ii) SSS: knee push-ups, 5s down + 5s up, further decreasing the load by changing the angle at the knee (120-90-60 degrees) just before exhaustion, at each angle. During the training, participants were asked to reduce their swimming sessions. The muscular strength of the upper limbs (nr. of push-ups in 30s, PU30) and the velocity in the central 10m ( $v_{10}$ ), the stroke rate (SR), the stroke length (SL) and the Efficiency Index ( $EI = v_{10} * SL$ ) during a 25m all-out front crawl bout were measured, before and after training. Mixed two-way ANOVA was applied to assess differences between pre- and post-training, and between groups. Results Pre- and post-training significantly differed, while no intercepts were found between LST and SSS, in each parameter. PU30 and SR increased by 5% ( $p=0.022$ ) and 4% ( $p=0.049$ ),  $v_{10}$  and EI decreased by 5% ( $p=0.011$ ) and 6% ( $p=0.043$ ), respective-

ly. Discussion Six weeks of dry-land LST and SSS are confirmed to equally improve the muscular strength of the upper limbs (Alberti et al., 2013). However, the swimming performance did not reflect improvement in muscular strength, which has been obtained by dry-land strength training. The significant decline of swimming performance and stroke parameters might be due to troubles in the readjustment of the motor patterns, consequently to changes induced by muscular strength gain (Aspenes et al., 2012). SR and EI variations would confirm this assumption. Furthermore, LST and SSS would not be satisfactorily specific for and transferable to swimming performance. Altogether, the contribution of LST and SSS to training for swimmers should be fully clarified, also in association with in-water specific practice. ## THE DIFFERENTIAL LEARNING APPROACH IN STRENGTH TRAINING

Hegen, P., Polywka, G., Schöllhorn, W.I.

*Johannes Gutenberg University of Mainz (Germany)*

Introduction The methods of classical strength training have not changed a lot in the past few years. The training recommendations in Europe and in the US are very similar and still mainly rely on Zatsiorsky (1972) and Kusnezow (1975). In all methods deviations from prescribed exercises (fluctuations) are completely neglected. Fluctuations are exploited in the differential learning (DL) approach, which shows positive effects for motor learning in sports and physical therapy (Schöllhorn, Beckmann, Davids, 2010). The aim of this study is to investigate whether the DL approach is practicable in strength training (Squat). Methods 24 healthy and physically active men ( $25.5 \pm 2.5$  years) were tested for their one repetition maximum (1RM) in the squat and in the performance of Countermovement Jump (CMJ), Squat Jump (SJ) and Drop Jump (DJ) before and after two types of training interventions with two training sessions per week. A classical training group (CG) trained with a weight of 60 to 97.5% of the 1RM according to the principles of hypertrophy, strength and power and the realizable repetitions. A DL group (DG) trained with only approximately 60% of the 1RM with an overall identical load in comparison to the CG. In difference to the DG the fluctuations of movement executions were held up as much as possible between every repetition and every set. Results For the 1RM in the squat the within-subjects effect time is highly significant and the observed effect size is very high (F1, 22 = 128.0,  $p = .000$ ;  $\eta^2 = .853$ ). For the within-subjects effect of interaction time and group (F1, 22 = .672;  $p = .421$ ;  $\eta^2 = .03$ ) as well as for the between-subject effect group (F1, 22 = .088,  $p = .769$ ;  $\eta^2 = .004$ ) the results are not significant. Significant results can be observed for all three jump-tests with respect to the factor time with a high effect size (CMJ: F1, 22 = 59.037,  $p = .000$ ;  $\eta^2 = .729$ ; SJ: F1, 22 = 48.850,  $p = .689$ ;  $\eta^2 = .689$ ; DJ: F1, 22 = 52.825,  $p = .000$ ;  $\eta^2 = .706$ ). A significant result with a medium effect size for interaction of time and group can only be detected at the CMJ (F1, 22 = 5.308,  $p = .031$ ;  $\eta^2 = .194$ ). All other results are not significantly. Discussion Both groups can noticeably increase their performance in the 1RM. It is remarkable that the DG can realize this increase with a lower intensity of training load. Both groups enhance their jumping heights in the post-test. Only in the CMJ a greater improvement of the CG is observed. The results encourage for further research towards more variations in strength training. ## DEVELOPMENT OF AEROBIC WORK CAPACITIES ON YO-YO INTERMITTENT RECOVERY TESTS IN AGED FROM 13 TO 22 YEARS OLD JAPANESE MALE SOCCER PLAYERS.

Teshima, T., Hosoda, M., Tsunoda, N.

*Kokushikan University*

Purpose The purpose of this study was to clarify development of aerobic work capacities on Yo-Yo intermittent recovery test in Japanese male soccer players. Methods This study was participated in 185 male soccer players aged from 13 to 22 years old. Subjects were classified into 8 chronological age group (12G, 13G, 14G, 15G, 16G, 17G, 18G, 19G and 20G). Subjects were performed Yo-Yo intermittent recovery test level 1 (Yo-Yo IR1) and level 2 (Yo-Yo IR2) (Bangsbo, J. and Mohr, M., 2012). Comparison of age group difference was analyzed by one-way ANOVA with Bonferroni-Dunn multiple comparisons post hoc test. Regression analysis was used double logarithmic graph in relationship between body height and Yo-Yo IR1 and Yo-Yo IR2. Intermittent work capacity index (IWCI: YoYo IR2 / YoYo IR1) was calculated in all the subjects. Results Running distance of Yo-Yo IR1 was obtained significantly difference between 14G ( $845.0 \pm 373.8$ m) and 15G ( $1556.7 \pm 409.7$ m), 17G ( $1666.7 \pm 402.6$ m) and 19G ( $2902.5 \pm 473.5$ m). And also, running distance of Yo-Yo IR2 was obtained significantly differences between 14G ( $192.5 \pm 51.2$ m) and 15G ( $435.6 \pm 167.3$ m), 17G ( $417.8 \pm 165.9$ m) and 19G ( $1320.0 \pm 350.1$ m). CV of Yo-Yo IR1 distance were decreased due to chronological age. However, CV of Yo-Yo IR2 distance was not changed among the all age groups. Yo-Yo IR1 was significantly correlated to the Yo-Yo IR2 in all the subjects ( $r=0.902$ ,  $p<0.05$ ). In the relationship between body height and Yo-Yo IR1 and Yo-Yo IR2, running distances were increased at the 167.0 and 166.3 cm, respectively. There were significantly increased from 17G to 19G in IWCI. Discussion Yo-Yo IR1 and Yo-Yo IR2 were developed from 14 to 15 years old in male soccer players. Running distance of Yo-Yo IR1 and Yo-Yo IR2 were increased at the about 167 cm. Therefore, Physical growth was effected on aerobic work capacity. But also, Rate of high intensity intermittent performance (Yo-Yo IR2) were improved during post adolescence. From these findings, it seems that using Yo-Yo intermittent recovery test must be considered for physical growth in male adolescent soccer players. References Bangsbo, J., Mohr, M. (2012), *Fitness testing in football*. Contact teshima@kokushikan.ac.jp

## THE AGREEMENT BETWEEN LACTATE MINIMUM POWER AND 3 MINUTE ALL-OUT CRITICAL POWER

Sharpe, G., Johnson, M.A., Hughes, Z.

*Nottingham Trent University*

Sport scientists have long sought a test which accurately predicts maximal lactate steady state (MLSS). Whether the 3 min all-out test for determining critical power (3minCP) meets this brief remains contentious [1,2]. The aim of this study was to test the agreement between 3minCP and lactate minimum power which has previously been shown to provide an excellent estimate of MLSS [2]. Nine recreationally active males of diverse training status (age: 27 (10) years; body mass: 78 (11) kg; height: 181 (7) cm) initially performed a validated lactate minimum cycling test [2] comprising three consecutive phases: (I) lactate elevation phase comprising maximal, incremental exercise ( $30W \cdot \text{min}^{-1}$  ramp); (II) 8 min recovery phase at 60 watts (W); and (III) an incremental phase comprising five consecutive 4 min stages at 45, 50, 55, 60 and 65% of peak power achieved during phase (I). Lactate minimum power was defined as the nadir of a 2nd order polynomial function (identified by differentiation) fitting the blood lactate concentration (measured at the end of each stage) vs. power data.

Participants completed two 3 min all-out tests. The first test served as familiarization and data were not included in subsequent analyses. The 3 min all-out test resistance was set using the linear mode of the Lode Excalibur Sport cycle ergometer to allow the attainment of a power output halfway between peak oxygen uptake and the gas exchange threshold (determined during phase I of the lactate minimum test) on reaching the preferred cadence (linear factor = power/ cadence<sup>2</sup>). Feedback of elapsed time was not provided to prevent pacing, however participants were given strong verbal encouragement throughout and were instructed to maintain their highest possible cadence throughout the 3 minutes. The 3minCP was defined as the average power achieved during the final 30 seconds of the test. All tests were separated by at least 48 h. Lactate minimum power (182 [55]W, min: 99W, max: 259W) was lower ( $p < 0.05$ ) than 3minCP (253 [80]W, min: 145W, max: 374W). The difference between lactate minimum power and 3minCP correlated positively ( $p < 0.05$ ) with lactate minimum power. Several participants tolerated the 3minCP test poorly, reporting symptoms of nausea and lightheadedness after completing the test. These findings agree closely with a previous report [3] that 3minCP overestimates MLSS by around 50-80W with agreement becoming worse at higher powers. These findings suggest that the lactate minimum test is better tolerated and provides a much closer estimate of MLSS within a single laboratory visit. ### COMPUTERIZED DEVICE FOR TESTING AND TRAINING OF SHOULDER GIRDLE MUSCLES FOR FITNESS AND REHABILITATION CENTERS

Vinogradova, O., Borovik, A., Prilutsky, D., Kuzmin, I., Fadin, V.

*Institute for Biomedical Problems RAS*

Fitness training includes programs for both aerobic and strength training adapted to subject's current functional capacities. Development of shoulder girdle contractile characteristics is important: 1) for increasing aerobic capacities of elite athletes in skiing, swimming etc., 2) for fitness training as arm muscles are usually less trained than leg muscles; 3) in rehabilitation as working of arm muscles induces greater shifts in cardio-vascular and respiratory systems than leg muscles; 4) for patients with damaged mobility of lower extremities because usage of training machines for arms is the only accessible method of training for them. The aim of our study was to design a "training and gauge" device for aerobic and strength training and testing of arm muscles for fitness and rehab centers. The device is to set profile of load changes, follow the reproduction of load by subject and physiological changes in his organism. The device consists of power block, controller, external sensors and tablet computer with specialized software. The load in power block originates from braking of rotating metal fly wheel in the magnetic field. The resistance force depends on rotation speed, therefore the load is close to isokinetic. The software allows to measure the parameters of load and provides user interface for different regimes of training and testing. The user may design testing protocol, save it in graphical form. During training the previous training protocol will be loaded, the user may edit it, or choose the protocol suggested by software according to the results of last testing. Usage of tablet computer permits to monitor current values of load parameters and physiological indices in graphical form, therefore to control load and physiological state of the subject during training or testing. Data base allows to keep training diary. Various external sensors for measuring heart rate, muscle force, angles and angular velocities, EMG, tissue oxygenation etc. may be plugged in. It is of special importance in functional diagnostics. The work was supported by the Ministry of Education and Science of Russian Federation (subvention No 14.604.21.0029)

### PRIOR UPPER BODY RESISTANCE EXERCISE IMPAIRS SUBSEQUENT INTERMITTENT RUNNING PERFORMANCE

Johnson, M.A., Coultman, J.P., Sharpe, G.R.

*Nottingham Trent University*

Concurrent resistance and endurance training using the same muscle groups is often prescribed to improve sports performance and physical fitness. However, prior resistance exercise may limit the ability to perform subsequent endurance exercise training if insufficient recovery is provided [1]. Although this may, in part, be attributed to the same muscle groups being engaged in the strength and endurance exercise training, it is also possible that endurance exercise tolerance (e.g. running) is limited by prior resistance exercise using different muscle groups (e.g. upper body) due to an increase in the perception of effort. This study thus examined the effects of prior upper body resistance exercise on subsequent intermittent running performance. Ten male 1st team university rugby players (age: 22 (1) years; body mass: 87 (9) kg; height: 181 (5) cm) performed 1RM assessment for four upper body resistance exercises: bench press, seated row, seated military press, and seated latissimus dorsi pull-down. Thereafter, participants performed 2 Yo-Yo intermittent recovery level 1 tests (YYIR1) separated by 1 wk. Tests were randomised and performed with (UB-RUN) or without (RUN) prior upper body resistance exercise. Prior resistance exercise comprised 5 sets of 12 repetitions at 60% 1RM for each of the four exercises described above. Sets and exercises were separated by 1 min rest intervals. Resistance exercise was followed by 6 min rest before the start of the YYIR1. Heart rate (HR), capillary blood lactate concentration ([La]B), and rating of perceived exertion (RPE) were measured at rest, after upper body resistance exercise (UB-RUN) or an equivalent period of rest (RUN), and upon completion of the YYIR1. Running distance during the YYIR1 was 37% lower in UB-RUN (812 (300) m) compared with RUN (1286 (282) m) ( $P < 0.01$ ). After upper body exercise (UB-RUN) or an equivalent period of rest (RUN) [La]B (UB-RUN vs. RUN: 13.2 (3.1) vs. 1.3 (0.2) mmol/L), HR (147 (14) vs. 64 (8) bpm) and RPE (18.1 (0.9) vs. 6.0 (0.0)) were higher in UB-RUN compared with RUN ( $P < 0.01$ ). Upon completion of the YYIR1 [La]B (15.1 (3.6) vs. 10.5 (2.2) mmol/L) and RPE (19.9 (0.3) vs. 18.8 (1.0)) were higher ( $P < 0.01$ ), whereas HR was lower (178 (9) vs. 188 (7) bpm) ( $P < 0.05$ ), in UB-RUN compared with RUN. In summary, prior upper body resistance exercise impaired subsequent intermittent running exercise performance. The reduced ability to perform endurance exercise due to prior resistance exercise is thus not dependent on the same primary muscle groups being used in both training modalities and may be related to an accelerated increase in the perception of effort. These findings may have implications for the design and efficacy of concurrent resistance and endurance training programmes. [1] Robineau et al. *J Strength Cond Res*. In Press

### SUBJECTIVE COACH ASSESSMENT OF BIOLOGICAL MATURATION IN ELITE YOUTH SOCCER

Romann, M., Fuchslocher, J.

*Swiss Federal Institute of Sport Magglingen*

Introduction Biological maturation (BM) of young athletes is implicit in models of talent identification, selection, and development. In several elite team sports proportionally more players were detected who are advanced (early) in BM and proportionally fewer players who are delayed (late) in BM (Malina, et al. 2012). The aims of the present study were twofold: firstly, to assess the biological maturation of elite under-15 (U-15) soccer players and secondly, to determine if coaches are able to classify BM of soccer players compared to a categorization by X-ray. Method Subjects: 119 male Swiss soccer players (age: 14.0±0.3 years; weight: 53.0±8.7 kg; height: 164.9±8.4 cm) of the U-

15 national team. Measurements: X-rays of the left wrist-hand were performed to evaluate BM. Bone age assessment was calculated blinded by a trained observer according to the reference method of Tanner & Whitehouse (1975). Players were classified as late, on time (normal) or early maturing on the basis of the difference between skeletal age (SA) and chronological age (CA). On time was defined as an SA within 1.0 year of CA. Early maturing was defined as an SA in advance of CA by more than 1.0 year. Late maturing was defined as an SA younger than CA by more than 1.0 year. Additionally three coaches observed the players during a training session and did a visual subjective assessment applying the same maturity categories (late, normal, early developed). Statistics: Cohen unweighted kappa coefficients were calculated to evaluate the concordance of maturity classifications using IBM SPSS. The level of significance was set at  $p < 0.05$ . Results The players had a mean SA of  $13.9 \pm 1.1$  years (range: 11.7 – 16.4) measured by X-ray. In comparison to chronological age players were advanced by  $0.1 \pm 1.1$ . 25 players were rated as late developed, 70 players as normal developed and 24 players as early developed. The visual subjective assessments of coaches showed moderate agreement ( $k = 0.48$ ) with the x-ray profiles. Assessments were identical in 88 of the 119 (74%) occasions. Discussion In contrast to previous research Swiss elite U-15 soccer players were not accelerated in SA (Malina, et al. 2012). The coaches of elite youth teams were able to demonstrate a good “feel” for assessing BM compared to the classifications using X-ray. Therefore subjective assessment of BM might be a useful and practicable tool in talent identification of youth soccer players. In the same manner subjective assessment of BM might be helpful for the purpose of designing training programs. References Malina, R. M., Silva, M. J. C. E., Figueiredo, A. ## THE ASSOCIATION BETWEEN MUSCLE POWER, AEROBIC CAPACITY AND SWIM TIME PERFORMANCE IN YOUNG, COMPETITIVE SWIMMERS

Henriksen, P.

*University College Lillebaelt*

Introduction Swim time performance is affected by physiological factors such as muscle strength and power of the upper and lower extremities as well as aerobic capacity (Smith et al., 2002). The association between these factors and swim time performance may plausibly identify some of the determinants for performance enhancement in swimming (Smith et al., 2002). In order to detail the individual training programme, reference values are needed. The aims of this study were firstly to determine the association between muscle strength and power, aerobic capacity and 100 m freestyle time (FT) in young, competitive swimmers, and secondly to determine reference values for these physiological factors. Methods In total, 119 competitive swimmers aged 11-15 years were assessed with Grip Strength (GS), Vertical Jump (VJ) and an intermittent running test to estimate maximal oxygen uptake, the Andersen Test (AT). Swim time performance, expressed as 100m FT, was obtained from a national database for Danish swimmers. A multiple linear regression model was used to determine the association between GS, VJ, AT and 100m FT, adjusted by sex, age, height and weight. Results A negative association was found between GS ( $p = 0.002$ ), VJ ( $p = 0.01$ ) and 100 m FT for both boys and girls, seen as an increase of one kg in GS improving the swim time by 0.3 sec and similarly, an increase of one cm in VJ improving the 100 m FT by 0.3 sec. For the AT, a negative association with 100 m FT ( $p = 0.001$ ) was also found, indicating that an increase in running distance by 10 m increased the swim time performance with 0.3 sec. An increase of 3.6 sec in swim time performance was seen with increasing age ( $p = 0.001$ ). Reference values differed between sex and ages, with boys performing better than girls in all tests, and with increasing values by increasing age. Conclusion Muscle strength and power tests for upper and lower extremities, expressed as GS and VJ, were found to be significantly and negatively associated with 100 m FT in the current study. Also, increasing aerobic capacity was found to improve swim time performance. These simple and low-cost tests, including data on reference values for each test, may be considered in order to improve dry-land training prescription, thereby supporting the enhancing swimming performance in young, competitive swimmers. ## THE ANALYSIS OF GLENO-HUMERAL RHYTHM AFTER REPETITIVE THROWING BY 3D DIGITIZER

Otsudo, T.1, Fukuta, Y.2, Akasaka, K.1, Sawada, Y.2, Okubo, Y.2

*1: Saitama Medical University Graduate school of Medicine (Moroyama, Japan), 2: Saitama Medical University (Moroyama, Japan)*

Introduction Fatigue associated with repetitive throwing can lead to scapular malposition among pitchers and overhead athletes (Pellegrini A, et al., 2013). In case of measuring the position of scapular, 3D electromagnetic tracking system is available in previous studies. However, this apparatus has some limitations that it can only apply under free metal environment (Rosa DP, et al., 2013) and analyze less than 120° of humeral elevation (Karduna AR, et al., 2001). Meanwhile, 3D digitizer is a useful device in terms of measuring three dimensional coordinate accurately in a short period (Boldt F, et al., 2009; Keibaetse M, et al., 1999). The aim of this study was to analyze gleno-humeral rhythm after repetitive throwing by 3D digitizer. Methods Six healthy males (age:  $21 \pm 0.89$  years old, height:  $174.03 \pm 9.23$  cm, weight:  $65.68 \pm 9.67$  kg) were participated in this study. We measured their bilateral scapular position at 0°, 30°, 60°, 90°, 120°, 150° of humeral elevation before 60 repetitive throwing and five consecutive days starting on the day of throwing by 3D digitizer (Microscribe® G2X, Revware Inc., USA and Rhinoceros ver.5.0, Robert McNeel & Associates, USA). Dominant side of scapular position including (1) Upward - Downward rotation, (2) Internal - External rotation, (3) Anterior - Posterior tilting, (4) Flexion - Extension, (5) Elevation - Depression were compared with non - dominant side at each humeral elevation. Results In our pilot study, reliability of 3D digitizer showed that ICC(2.1), 95%CI, and SEM were 0.8~0.74, 0.96~0.51, and 0.47~0.13 [mm], respectively. Dominant side of scapular position has been significantly changed downward rotation ( $\Delta 10.84 \pm 3.45^\circ$ ) at 120° of humeral elevation and also extension ( $\Delta 7.23 \pm 2.35^\circ$ ) at 60° of humeral elevation after 1 day, exclusively ( $p < 0.05$ ). Discussion Previous study showed that less posterior tilting (up to 90° of elevation), external rotation (up to 120° of elevation), and upward rotation (up to 60° of elevation) were observed significantly in the early to middle phases of humeral elevation with shoulder muscle fatigue (Tsai NT, et al., 2003). Our results indicated that less upward rotation of scapular was also occurred at 120° of humeral elevation after repetitive throwing. Thickness of subcutaneous tissue would be influenced when the scapular position was calculated by 3D digitizer. This work has been supported by JSPS KAKENHI Scientific Research (C) Number 25350775. ## INFLUENCE OF A NEW RE-BREATHING DEVICE ON PHYSIOLOGICAL STRAIN DURING MODERATE EXERCISE IN FIRE-FIGHTERS AND TRAINED SUBJECTS

Müller, A.

*University of Graz*

Introduction Life and health of firefighters during action is substantially dependent on a proper oxygen supply and they are required to use a self-contained breathing apparatus for respiratory protection when engaged in a variety of firefighting duties. The device provides crucial respiratory support and protection (Coca et al. 2011). Even at moderate physical demands rate of air consumption in these tasks will deplete the air supply within a short period of time (Williams-Bell et al. 2010) and re-breathing devices may extend the duration. The aim of this study was therefore to evaluate the influence of a new re-breathing device on physiological strain during moderate exercise. Method 22 male trained subjects and firefighters ( $29.0 \pm 9.2$  yrs,  $72.4 \pm 8.6$  kg) performed a standard incremental cycle ergometer exercise to determine the first (LTP1) and the second (LTP2) lactate turn point for subsequent exercise prescription. Some days later subjects performed three blocks (10 min) of constant load exercise at mid-point between LTP1 and LTP2 interspersed by 9 min of passive recovery in a randomized order in warm-up (WU), breathing ambient air (A) or re-breathing (RB) every second breath of exhaled air through a CO<sub>2</sub> filter applying a mechanic valve system. Heart rate (HR) was measured continuously and blood lactate concentration (La) was measured at the start of exercise and every min throughout exercise. Gas exchange data were measured applying two systems for inhaled and exhaled air. Results Power output at LTP1, LTP2 and Pmax were  $97.1 \pm 25.1$  W,  $208.7 \pm 35.1$  W and  $300.2 \pm 45.5$  W, respectively. Oxygen content in RB was 18.2% equivalent to 1100 m altitude. HR (A:  $142.8 \pm 10.6$  b.min<sup>-1</sup>; RB:  $144.5 \pm 11.3$  b.min<sup>-1</sup>) during moderate exercise was significant different between A and RB but not for La (A:  $1.89 \pm 0.76$  mmol.l<sup>-1</sup>;  $1.95 \pm 0.78$  mmol.l<sup>-1</sup>) although these differences are not physiologically relevant. Conclusion Re-breathing exhaled air with reduced oxygen content does not increase physiological strain at moderate task specific exercise intensity in firefighters under laboratory conditions. However, real situation simulations are needed to evaluate the system while wearing full protective gear and the breathing device. ## ACUTE EFFECT OF A CROSSFIT WORKOUT ON PATELLA, ACHILLES AND PLANTARIS TENDON THICKNESS

Fisker, F., Kildegaard, S., Thygesen, M., Grosen, K., Pfeiffer-Jensen, M.

*Aarhus University Hospital*

Introduction CrossFit is a strength and conditioning program built around constantly varied functional movements performed at high intensity in order to create a well-rounded athlete. Tendons are highly adaptive to load change, however little is known about their acute response to the strenuous and explosive physical exercise involved in CrossFit. The aim of this study was to investigate the immediate effect of a lower extremity CrossFit workout on patella, achilles, and plantaris tendon thickness. Methods A convenience sample of 34 healthy adults (26.5% females), who were regularly active in CrossFit, participated in this study. Female participants had a mean age of 28 (SD 10) years; weight 61 (6) kg; and height 166 (7) cm. Male participants had a mean age of 28 (SD 8) years; weight 79 (11) kg; and height 181 (7) cm. Sonograms (Hitachi Nobulus, 18 mHz probe) of the patella, achilles, and plantaris tendons were acquired perpendicular to the point of maximum tendon width according standardized settings and acquisition protocol. When, tendon thickness was measured at the thickest point of the tendons, the distance from the nearest bony point was also identified to be sure that the pre- and post-exercise sonograms were acquired at exactly the same point of the tendon. Following pre-exercise sonograms, participants completed a lower extremity CrossFit workout consisting of five rounds of 5 weighted back squats 50/30 kg; 10 box jumps (jumping onto and down from a 60/50 inch box), and 15 double unders (two rotations of a jump rope per jump). Sonograms were repeated immediately following completion of the CrossFit exercises. Results Paired-samples t-tests were conducted to compare tendon thickness before and after the CrossFit workout. Significant differences were observed in patella tendon thickness before ( $M=4.5$ ,  $SD=0.6$ ) and after ( $M=5.0$ ,  $SD=0.7$ ) workout,  $p<0.0001$ ; and in achilles tendon thickness before ( $M=4.4$ ,  $SD=0.4$ ) and after ( $M=4.5$ ,  $SD=0.5$ ) workout,  $p=0.01$ . There was not a significant difference in plantaris thickness before ( $M=3.4$ ,  $SD=0.5$ ) and after ( $M=3.4$ ,  $SD=0.5$ ) workout,  $p=0.97$ . Discussion These results suggest that a lower extremity CrossFit workout has an immediate impact on tendon thickness. Specifically, our results suggest that the thickness of the patella and achilles tendons increases after strenuous and explosive physical exercise of the lower extremities. This study adds to our understanding of the acute response of the patella, achilles, and plantaris tendons to high intensity lower body exercise. \*Contact filip-fisker@hotmail.com

## EFFECTS OF TWO DIFFERENT LOAD CARRIAGE EXERCISES ON PHYSIOLOGICAL RESPONSES IN SOLDIERS

Terho, A.1, Vaara, J.1, Kyröläinen, H.1,2

*1) National Defence University, Helsinki, Finland 2) University of Jyväskylä, Jyväskylä, Finland*

Introduction Load carriage ability is one of the most important physical capabilities for an infantry soldier. Modern soldiers are often well-equipped while the weight of load carriage depends on specific occupational tasks. Therefore, it is important to study the physiological responses induced by load carriage. The purpose was to examine metabolic changes in soldiers during a simulated road march with two different loads (29 kg and 45 kg). Methods Eight male soldiers participated in the study (age  $20 \pm 1$  yrs., height  $1.80 \pm 0.10$  m, body mass  $77.9 \pm 12.3$  kg, BMI  $23.9 \pm 2.4$ ,  $VO_{2max}$   $51.8 \pm 4.2$  ml·kg<sup>-1</sup>·min<sup>-1</sup>). Maximal oxygen consumption was determined one week before the first load carriage test, while maximal strength, muscular endurance and body composition a day before the first load carriage test. Between the two tests there were 48 h rest period. The load carriage tests were conducted on a treadmill. The first 45-min of the test was performed at the speed of 4 km·h<sup>-1</sup> and inclination of 1.0 deg. Thereafter, the angle and speed was increased by having their highest values of 12 deg and 6 km·h<sup>-1</sup>. Oxygen consumption ( $VO_2$ ), ventilation (VE), heart rate (HR), rating of perceived exertion (RPE) and blood lactate (La) were measured during the trials. Results Submaximal VE and HR were higher with the heavier load compared to the lighter load ( $p<0.05$ ). Time to exhaustion correlated with absolute maximum  $VO_2$  (ml·min<sup>-1</sup>), (29kg:  $r=0.80$   $p\leq 0.05$ , 45kg:  $r=0.92$   $p\leq 0.05$ ) but not with relative maximum  $VO_2$  (ml·kg<sup>-1</sup>·min<sup>-1</sup>). Maximal bench press results also correlated with both of the loads (29kg:  $r=0.75$   $p\leq 0.05$ , 45kg  $r=0.81$   $p\leq 0.05$ ). Maximal  $VO_2$  and maximal bench press were the only two factors from the pre-load carriage physical fitness tests that were associated with time to exhaustion in the two load carriage tests. Body weight and fat free mass correlated positively only with the heavier load ( $r=0.72$   $p\leq 0.05$ ), ( $r=0.74$   $p\leq 0.05$ ) and standing long jump with the lighter load ( $r=0.80$ ,  $p\leq 0.05$ ). A regression analysis revealed that height and bench press explained the variance of the load carriage test performance by 79% ( $p<0.01$ ). Discussion The

results of this investigation may indicate that upper body strength is a vital characteristic for carrying heavy loads. In addition, maximal aerobic capacity is important while operating near maximal effort with an additional load. Moreover, the load carriage performance of heavier soldiers may not be as hampered as that of lighter soldiers. The present results may suggest that strength training, especially for the upper body, and endurance training are beneficial for soldiers in order for them to sustain carrying of heavy loads. ### DIFFERENCES IN HEART RATE AT FIRST AND SECOND LACTATE TURN POINT IN TREADMILL RUNNING AND ERGOMETER CYCLING IN MAN

Wallner, D.1, Buchegger, M.1, Simi, H.1, Hofmann, P.2

(1) FH JOANNEUM Univ. Appl. Sci., Austria; (2) Univ. of Graz, Austria

**Introduction:** Based on a three-phase two turn point model, heart rate (HR) at the first (LTP1) and second lactate turn points (LTP2) represent reference markers for exercise prescription (Hofmann & Tschakert 2011). Very often HR recommendations from one type of ergometry are applied to various kinds of exercises (Röcker et al., 2003). Recently, we found a distinct difference and a highly individual variation in HR comparing running and cycling in woman (Wallner et al., 2014). The aim of this study was to analyse the HR at LTP1 and LTP2 in treadmill running and ergometer cycling tests in man. **Method:** 15 male students (21.1±2.0 years, 77.9±13.3 kg) performed two incremental tests within one week in randomized order. One test was performed as a running test (RT) on the treadmill and the other one as cycling test (CT) on a cycle ergometer. After 3 minutes of warm up at 2.0 m/s (RT) and 40 Watt (CT) workloads were increased every minute by 0.2 m/s (RT) and 20 Watt (CR), respectively to attain maximal power output within the same time frame. HR was measured continuously and blood lactate concentration (La) was measured at rest and after every load step. LTP1 and LTP2 were determined in both tests according to Hofmann & Tschakert (2011). **Results:** Mean workloads at LTP1, LTP2 and at termination of the test (MAX) were 2.65±0.20 m/s (60.8±4.0% vMAX), 3.35±0.38 m/s (78.9±2.8% vMAX) and 4.26±0.55 m/s in RT and 109.2±18.1 W (39.9±4.4% PMAX), 194.9±30.6 W (71.0±3.3% PMAX) and 273.3±32.7 W in CT, respectively. La at LTP1 (2.13±0.07 mmol/l vs. 1.37±0.32 mmol/l) was sig. higher in RT (p<0.01), but not at LTP2 (4.31±1.28 mmol/l vs. 3.98±0.82 mmol/l) and MAX (11.19±3.39 mmol/l vs. 10.93±2.52 mmol/l). HR in RT was significantly higher at LTP1, LTP2 and MAX (p<0.01) with a decreasing mean difference (169.4±9.0 min<sup>-1</sup> vs. 132.1±13.0 min<sup>-1</sup>, 187.2±6.7 min<sup>-1</sup> vs. 168.8±13.1 min<sup>-1</sup> and 199.2±7.3 min<sup>-1</sup> vs. 192.2±8.7 min<sup>-1</sup>). %HRmax at LTP1 (84.6±4.5% vs. 68.6±5.0%) and LTP2 (93.0±1.5% vs. 87.7±4.0%) were sign higher in RT (p<0.01). **Conclusion:** A distinct difference and a highly individual variation in HR were found between running and cycling in man. A main finding was, that %HRmax at LTP1 and LTP2 were significantly higher in RT. Beside the well-known fact that sport specific tests are essential for a reliable HR based exercise prescription %HRmax markers are limited and the use of turn point concepts are recommended. **References:** Röcker et al. (2003) *Int J Sports Med* 24 (3), 173-178 Hofmann & Tschakert (2011) Article ID 209302. doi:10.4061/2011/209302 Wallner et al. (2014) 19th Annual Congress of the ECSS (p. 718). SportTools, Cologne

### THE EFFECTS OF INCREMENTAL JUMP STEPS ON TAKE-OFF LEG JOINT KINETICS IN BOUNDING

Kariyama, Y., Hayashi, R., Yoshida, T., Takahashi, K., Zushi, A., Zushi, K.

University of Tsukuba

**Introduction** Bounding exercises (single-leg jumps for the horizontal direction) are often used for power output improvements in plyometric training. Several studies have investigated the kinematics and kinetics in terms of bounding (Mero and Komi, 1989), but very few studies have studied the joint kinetics (Kariyama and Zushi, 2014). Moreover, no study has investigated the joint kinetics of the effect of an incremental jump step on the take-off leg in bounding from a standing position. The purpose of this study is to clarify the effect of an incremental jump step on the take-off leg during bounding. **Methods** Participants included in this study were track and field jumpers (n = 11 males; age, 20.27 ± 1.35 years; height, 177.59 ± 6.04 cm; mass, 69.82 ± 4.92 kg). Participants performed bounding from a standing position and attempted to cover the longest distance by performing seven forward alternating single-leg jumps in a series. The 1st, 3rd and 5th steps in bounding were analyzed. In order to strike the force plate at each step, start position was adjusted between each trial. Three-dimensional coordinates of 47 retro-reflective markers fixed on the body were collected by the Vicon T20 system (250 Hz); ground reaction forces were measured using force platform (1,000 Hz). Joint torque and joint power of the take-off leg were calculated using inverse dynamics. **Results and Discussion** Analysis of the sagittal plane movements revealed that ankle plantar flexion torque and knee extension torque and power increased on the take-off leg; hip extension torque and power did not. These results indicate that ankle and knee joint kinetics are more important for increasing bounding at high horizontal velocity. The hip internal torque and power exerted on the take-off leg increased, but the effect size was small. Conversely, the hip abduction torque and power increased. Additionally, the patterns of hip abduction torque and power were similar to those of the vertical and lateral ground reaction forces. Hip abduction torque and power may play an important role at high horizontal velocity by resisting the impact force (ground reaction force) and maintaining the lateral balance during bounding (Kariyama and Zushi, 2013). These results suggest that although hip abductors are more important for horizontal high-speed take-off (5th step), they may also be important for low-speed take-off (1st and 3rd steps). **References** Mero A, Komi PV. ### TECHNIQUE AND ARTISTRY IN ELITE RHYTHMIC GYMNASTS: THEIR ASSOCIATION WITH PHYSICAL FITNESS PARAMETERS

Donti, O., Bogdanis, G.C., Kritikou, M., Donti, A., Theodorakou, K.

Faculty of Physical Education and Sport Science, University of Athens

**Introduction** Technical execution and artistry are the primary components of rhythmic gymnasts' evaluation (Rhythmic Gymnastics Code of Points, 2013-16). Although, overall performance improves with enhanced physical capacities (Hume et al., 1998) there is a need to precisely define performance components and the physical abilities that are more important in every stage of athletic development. The aim of this study was to examine the particular association between selected physical fitness parameters, technical execution and artistry in elite rhythmic gymnasts. **Methods** Eleven rhythmic gymnasts (aged 14.77±0.41 years, training experience 8±1 years) all members of the Greek national team, participated in this study. Technical execution was determined by deductions for faults in elements technique. Artistic performance score, in deductions, was the sum of the sub-scores of unity, relation between movements and music, use of space and body expression. Technical execution and artistry were evaluated by one international judge according to the International Gymnas-

tics Federation Code of Points (2013-16). The gymnasts underwent a series of physical fitness tests, (body composition, active and passive flexibility, muscular power and endurance and agility). Stepwise multiple regression analyses examined the strength of the association between technical execution and artistry scores, and physical fitness parameters. Results Multiple regression analysis indicated that sideways leg extension, hamstrings flexibility, agility, and one leg counter movement jump, accounted for 82.7% of the variance in technical deductions (adjusted  $R^2=0.827$ ,  $F=12.911$ ,  $p=.004$ ). Sideways leg extension, hamstrings flexibility, agility and one leg counter movement jump accounted for 59,3% of the variance in artistry score (adjusted  $R^2=0.593$ ,  $F= 4.648$   $p=.047$ ). Discussion It is concluded that hip joint flexibility, agility, and lower limb muscular power account for a large part of the variance of technical execution and artistry score. Although artistry is considered a matter of personal style, the results of this study highlight the importance of strength and conditioning programs for artistic competence and indicate that artistry and technique are interrelated aspects of performance in elite rhythmic gymnasts. ### INFLUENCES OF FASCICLE LENGTH DURING ISOMETRIC TRAINING ON IMPROVEMENT OF MUSCLE STRENGTH

Tanaka, H., Ikezoe, T., Umehara, J., Nakamura, M., Umegaki, H., Kobayashi, T., Nishishita, S., Fujita, K., Araki, K., Ichihashi, N.

Kyoto University

Introduction It is previously shown that effect of isometric training on muscle strength is greater at the angle where the training was performed (Kitai et al, 1989). On the other hand, there is a supersonic imaging study showing that the fascicle length (FL) during isometric contraction changes depending on both joint angle and exerted torque. Therefore, there is a need to re-examine the effect of isometric training whether the effect truly depends on joint angle or on FL. We hypothesized that by performing isometric contraction with low intensity which causes minor change in FL during contraction, we may find change in muscle strength in the angle where the FL is similar to that during training rather than in angle similar to that during training. Methods Twenty four healthy women ( $21.8 \pm 1.5$  years) participated in this study. The subjects were divided into 3 groups (training at slack position (SP), training at extension position (EP) and control groups). Plantar-flexion (PF) strength of isometric maximal voluntary contraction (MVC) and FL of gastrocnemius were measured before (Pre) and after (Post) training. MVC were measured at six positions with the ankle joint angle from  $20^\circ$  dorsiflexion (DF) to  $30^\circ$  PF at every  $10^\circ$ . FL was also measured at the six ankle positions using B-mode ultrasound in three conditions: at rest, 30%MVC and MVC, respectively. Resistance training on PF with intensity of 30%MVC was performed 3 days per week for 4 weeks with 3 sets of 20 repetitions of 3-seconds isometric contraction. The ankle joint angle during the training was placed at  $20^\circ$  PF in SP and at  $10^\circ$  DF in EP, respectively. Split-plot ANOVA using two factors (time [Pre and Post] and group [SP, EP and control]) was used to analyze interaction effects in MVC at each angle. When a significant interaction was observed, paired t-test was used as a post hoc test to determine the differences in MVC between Pre and Post at each group. Results and Discussion Split-plot ANOVA indicated a significant interaction in MVC at only  $0^\circ$  and  $10^\circ$  PF. Post hoc test showed that both MVC at  $0^\circ$  and  $10^\circ$  PF significantly increased after resistance training in SP group. There were no differences in MVC between Pre and Post in EP and control groups. FL in SP group were  $3.1 \pm 0.5$ cm,  $3.3 \pm 1.2$ cm,  $2.8 \pm 0.7$ cm and  $2.5 \pm 0.4$ cm during training and in measurements during MVC at  $0^\circ$ ,  $10^\circ$  and  $20^\circ$  PF. These results supports our hypothesis that the effect of isometric training is found at the same FL rather than the same angle as in the training. Reference 1.Kitai TA, Sale DG. Specificity of joint angle in isometric training. Eur J Appl Physiol Occup Physiol. 1989;58(7):744-8. Contact tanaka.hiroki.27w@st.kyoto-u.ac.jp

### THE CORRECTION OF CYCLISTS' TRAINING LOAD PARAMETERS IN THE FIRST WEEK OF THEIR STAY AT ALTITUDE

Gabrys, T.1,2, Szmatlan-Gabrys, U.1,2, Galinski, M.2, Stanula, A.3

1State School of Higher Education in Oświęcim 2Russia Cycling Federation, Russia

Introduction. The methodology of a training which uses hypoxia in accordance with the LH-TH (live high – train high) and LH-TLH (live high - train low and high) model is well-defined (Stray-Gundersen, Levine 2008). Special attention has been paid to conditioning of the effect of a 2-3 week stay at altitude combined with various combinations of training loads. (Friedmann-Bette2008) However, the issue of selection of training loads in one week stay in the conditions of hypoxia has not been described in literature. The aim of this investigation was to determine a correction algorithm for the level of training load and heart rate in cyclists during one week training conducted at the altitude of 2000 – 2200 m above sea level. The participants of the study were MTB cyclists XCO Nationals Teams Russia and Poland (women n=8, 24,3/2.5year, 50,2/2.7kg, 159,1/6.1cm; men n=8 21,2/1.2year, 65,5/4.5kg, 176/3.5cm). After arriving at the altitude of 2250 m in the first and second day the participants did a graded incremental exercise test (GXTs) at the altitude of 2250 m and 1350 m. The GXTs test was executed on Cyclus 2 (RBM, Germany) ergometer. The first step was 1Wx1-1 b.m., which was increased by 0,5 Wxkg-1 b.m. every three minutes. In the last 30 seconds of each exercise, a grade of 20  $\mu$ l of arterialized blood was taken to sign LA (Biosen S-line, EKF, Germany). In the course of effort  $VO_2$ , VE,  $VCO_2$  was measured by means of K4b2 analyser. The heart rate monitor Polar V650 (Polar Finland) was measured HR during GXTs. The power was subordinated to aerobic threshold (LT), Farell et al.(1979), anaerobic threshold (AT) (Powers et al.1983) and  $VO_2$ max. Results. A comparative analysis of  $VO_2$ max, LT and AT of power has indicated a varied direction of changes with the increase of hypoxia. Power on LT:  $P \downarrow$ ,  $VO_2 \uparrow$ ,  $VE \leftrightarrow$ ,  $HR \leftrightarrow$ ,  $O_2HR \uparrow$ . Power on AT:  $P \leftrightarrow$ ;  $VO_2 \uparrow$ ;  $VE \uparrow$ ;  $HR \uparrow$ ;  $O_2HR \uparrow$  and max. power:  $P \downarrow$ ;  $VO_2 \uparrow$ ;  $VE \uparrow$ ;  $HR \uparrow$ ;  $O_2HR \uparrow$ . Regression equations and coefficient of determination: LT have been determined for power (intensity indicator) - LT:  $y = 1,0266x - 3,8352$   $R^2 = 0,844$ , AT:  $y = 1,0014x - 4,0523$   $R^2 = 0,956$  and max:  $y = 0,8764x + 13,024$   $R^2 = 0,9315$ . Conclusion. The character of changes of physiological indicators at the level of LT, AT and  $VO_2$  max power shows that in all cases changes in power are closely related to each other. Low value of the coefficient of determination for HR:LT:  $R^2 = 0,1891$ ; AT:  $R^2 = 0,1663$  |  $VO_2$ max:  $R^2 = 0,5131$ ) means that HR is not a good indicator of regulation of physical effort intensity in the first week of stay at altitude. ### TIME MOTION ANALYSIS OF CADET TAEKWONDO ATHLETES IN RELATION TO THE WEIGHT CATEGORY

Menescardi, C.1, Estevan, I.2, Falco, C.3, Capranica, L.4, Tessitore, A.4

1: UCV (Valencia, Spain), 2: UV (Valencia, Spain), 3: UiB (Bergen, Norway), 4: University of Rome Foro Italico (Rome, Italy)

Introduction The relationship between fighting and non-fighting phases during Taekwondo bouts has been used to characterize physical demands of this Olympic sport (Santos et al., 2011; Tornello et al., 2013). In the literature (Santos et al., 2011) elite athletes competing in the heavy categories carried out longer non-fighting phases and shorter fighting phases with respect to those competing in the lighter cate-

gories. In considering that youth athletes compete at international level and the possible influence of the weight on the results, the aim of this research was to analyze the time activity phases of male cadet taekwondo athletes in relation to their weight category. Method Twenty-two bouts (semifinals and finals) of the 1st World Cadet Championship were analyzed according to the time activity phases proposed by Tornello et al. (2013): non-fighting (NF), fighting (F) and stoppage (S) phases. A one-way ANOVA with the weight category (light-LW, middle-MW, and heavy-HW) as a factor was applied to test differences in activity phases. Pairwise post hoc comparisons were carried out with Bonferroni adjustments. Partial eta-square was used to evaluate effect size (ES) for significant differences ( $p < 0.05$ ). Results Despite athletes competing in the heavy category showed longer (F [827,2] = 17.383;  $p = 0.01$ ; ES = 0.4) NF phases (3.7±2.9 s) with respect to their counterparts competing in the light (3.0±1.6 s) and middle (2.7±1.7 s) ones, no effect emerged for F (LW: 2.85±2.42, MW: 2.53±1.72, and HW: 2.48±1.88) and S (LW: 9.34±20.04, MW: 12.13±27.94, and HW: 11.47± 26.74) phases. Discussion The present findings indicate that youth athletes with high body mass could require longer NF phases to recover between fighting (Santos et al., 2011), suggesting that this difference could be due to the higher body mass of heavy competitors who spend more energy and need more rest time with respect to lighter competitors. Therefore, coaches should consider appropriate to structure simulated training allowing longer resting time periods for heavy athletes. References Santos VG, Franchini E, Lima-Silva AE. ### ACUTE NEUROMUSCULAR FATIGUE INDUCED BY REPEATED DIRECTION CHANGES DOES NOT INFLUENCE FREE THROW ACCURACY IN AMATEUR BASKETBALL PLAYERS

Feroli, D.1,2, Carlomagno, D.2, Connolly, D.2, Tornaghi, M.2, La Torre, A.1, Rampinini, E.2

1 Department of Biomedical Science for Health, Università degli Studi di Milano, Milan, Italy; 2 Human Performance Lab, Mapei Sport, Olgiate Olona, Italy.

Introduction Performance in basketball is determined by a combination of physical and technical aspects (Ziv and Lidor, 2009). It has been recently demonstrated that free throw (FT) accuracy can be negatively influenced by exercise intensity (HR ~80% HRmax) preceding FTs (Padulo et al., 2014). However, the acute effect of lower limb neuromuscular fatigue on FT accuracy has yet to be investigated. The aim of this study was to determine the acute effect of neuromuscular fatigue induced by a basketball specific exercise, repeated changes of direction (COD), on FT accuracy. Methods Twenty-one amateur basketball players (age: 26.2±8.1 yrs, height: 185±10 cm, weight: 81.6±13.8 kg) were randomly assigned to exercise (EG) or control group (CG). All players performed 4 series of FT with the aim of scoring as many FT as possible in a 10-sec period. The four series of FT were separated by 30-s of rest for CG and 30-s of repeated COD for EG. COD exercise comprised of 180° turns performed repeatedly on a 7 m course following pre-determined acoustic signals. The COD exercise increased in intensity following each series of FT. All subjects performed countermovement jumps (CMJ) on a Force plate (Quattro Jump, Kistler, Switzerland) prior to the first (PRE), and following the last (POST), series of FT. Results The CMJ performance was reduced only in EG (time x group interaction:  $p=0.001$ ,  $p=0.009$  and  $p=0.023$  for height, peak power and peak force respectively). In EG the CMJ indices were significantly reduced from PRE to POST measures (height: 45.5±4.2 vs 41.6±4.1 cm; peak power: 51.5±5.7 vs 47.8±5.6 W/kg; Peak Force: 2132±370 vs 2002±287 N, all  $p<0.05$ ). No differences in CMJ capacity were observed in CG. The number of FT shots taken increased significantly between PRE and the following three series of FT in both groups ( $p=0.024$ ) without any significant difference between them ( $p=0.467$ ). However, the number of successful FT was unvaried across FT tests as well as between groups ( $p=0.743$  and  $p=0.179$  respectively). Discussion Acute lower limb neuromuscular fatigue induced by COD exercise was not found to significantly impact upon FT accuracy in amateur basketball players. Future studies should further investigate the effect of fatigue induced by basketball specific exercises on FT accuracy and how exercise intensity can influence technical ability. ### COMPARISON METHODS FOR CALCULATING ANAEROBIC LACTATE THRESHOLDS IN MIXED MARTIAL ARTS COMPETITORS

Szmatlan-Gabryś, U.1, Gabryś, T.2, Stanula, A.3, Garnys, M.4

1University of Physical Education in Krakow, Jan Dlugosz University in Czestochowa, Institute of Physical Education, Tourism and Physiotherapy, Poland,

Introduction. Fighting and training in MMA require comprehensive physical preparation utilizing aerobic and anaerobic metabolic changes that determine athlete's special endurance. (Lenetsky, Harris 2012) The study aimed to determine the differences between VAT values calculated with analysing curve concentration blood lactate (LA) such as methods LTloglog (Beaver et al. 1985), LTvisual (Lundberg et al. 1986), LTΔ1 (Coyle et al. 1984), LT4.0 (Heck et al. 1985), LTD-max (Cheng et al. 1992). Methods. In investigation participated competitors MMA (n=22), age 27.5(2)years, height 179(3)cm, body mass 83.1(5.8)kg, VO2max 56.9 (5.4) ml·kg<sup>-1</sup>·min<sup>-1</sup>, length of training experience 8.6(1.8) years). The athletes were in preparation period before competition. The incremental exercise test was executed on the treadmill Saturn (HP Cosmos, Germany). The 1-st speed was 8 km h<sup>-1</sup> and increased every 3 minutes by 2 km h<sup>-1</sup>. In last 30 the seconds of every exercise grade was taken 20 µl of arterialized blood to the sign LA (Biosen S-line, EKF, Germany). Exercise intensity (VAT) at the lactate anaerobic threshold were determined using software (Newell et al. 2007). Results. VAT values obtained from all methods applied to analyse the blood lactate curve were statistically significantly correlated. Four moderate correlations were found between the values obtained from LTvisual – LT4 (0.65,  $p<0.01$ ), LTvisual – LTΔ1 (0.52,  $p<0.05$ ), LTloglog – LTΔ1 (0.69,  $p<0.001$ ), and LTΔ1 – LTD-max (0.64,  $p<0.001$ ). Highly correlated results were obtained from LTvisual – LTloglog (0.74,  $p<0.001$ ), LTvisual – LTD-max (0.87,  $p<0.001$ ), LTloglog – LT4.0 (0.76,  $p<0.001$ ), LTloglog – LTD-max (0.75  $p<0.001$ ), and LTΔ1 – LTD-max (0.80  $p<0.001$ ). A very high correlation was found to exist between VAT values generated by LT4.0 and LTΔ1 (0.91,  $p<0.001$ ). Regression equations for determining running velocities at the lactate anaerobic threshold calculable with LT4.0 using the results of LTVisual, LTloglog, LTΔ1, and LTD-max ( $y=9.54+0.381*LTvisual$ , SEE .873;  $y = 10.6 + 0.357*LTloglog$ . SEE .761;  $y = 5.49 + 0.714*LT \Delta 1$ , SEE .566;  $y = 5.84 + 0.669*LTD-max$ , SEE .674. Conclusion. Differences between VAT values obtained from each method described herein suggest that special attention should be given to the individualization of training. The proposed regression equations are able to convert the results as produced by each of the methods used to calculate the lactate anaerobic threshold to make them comparable with the result of the LT4.0 method. This approach allows training intensity to be programmed according to the same criterion. References: Newell et. al. *J.Sports Sci*;2007;25(12):1403-1409. ### THE RELATIONSHIP BETWEEN EXERCISE OF INTENSITY AND BLOOD LACTATE CONCENTRATION IN RUNNING FINESSES WITH CONTACT AND WITHOUT CONTACT.

Yao, N., Itaka, T., Nishimura, K., Koakutsu, A., Hasegawa, N., Machida, S., Kimura, H.

*Tokai University*

**Introduction** All Players require various kind of fitness in open-skill sports, such as soccer, basketball, handball and rugby football. Collision in the game spends a lot of energy and requires particular fitness for players. Coaches have to design effective training sessions or similar situations for games. Because collision sports such as rugby football consist of running and contact performance in the game, players must possess the same physical activities. However, running fitness training has been done for enhancing their fitness. The purpose of this study was to reveal the relationship between exercise of intensity and blood lactate concentration in running fitnesses with contact and without contact. **Methods** The participants were 8 rugby union players, (4 FWs and 4 BKs; mean±S.D. age, 20.4±0.69 years). Participants competed in two fitness test, 400m run, and 180m run with 4 contacts of tackle and wrestling (approximately 20seconds). Heart rate was measured to investigate intensity of exercise (at rest, after test immediately, after 3mins and 7mins). Blood lactate concentration (at rest, after 3mins and 7mins) was measured to investigate the ability of anaerobic exercise. **Results** The results showed that blood lactate concentration for running fitness test with contact were higher than without contact after 3mins ( $p<.01$ ), whereas HR for running with contact is significantly lower than without contact ( $p<.01$ ), however the exercise periods were almost same (61.8s for non-contact and 61.7s for with contact). **Discussion** The results indicated that running with contact could improve their anaerobic capacity more than running without contact. Because FWs player don't have enough running ability, it is hard to reach anaerobic threshold. Contact performance such as tackle and wrestle is more likely to generate high power for FWs, whereas BKs players are not as strong in contact than FWs. Some players do not have enough contact skill in high intensity training, so it will be difficult to improve high power fitness accurately. This study suggests that coaches should consider abilities and skill level of players for fitness training with contact.

### DISSOCIATED TIME COURSE OF NEUROMUSCULAR RECOVERY BETWEEN SINGLE AND MULTI-JOINT EXERCISES IN HIGHLY RESISTANCE TRAINED MEN

Soares, S.

*University of Brasilia*

**Introduction** Reduction of muscle strength for several hours or days (i.e., 8 to 96 hours) after training is primarily associated with muscle damage (Nosaka & Newton, 2002; Nosaka et al., 2005; Roth et al., 1999). However, no study has investigated the muscle damage and the time course of peak torque (PT) and muscle activation responses after multi- and single-joint exercises of the elbow flexors in highly resistance trained subjects. Thus, the purpose of this study was to compare the time course of muscle activation and peak torque after exercise-induced muscle damage performed with multi- and single-joint exercises. **Methods** Eleven resistance trained males ( $24.5 \pm 5.5$  years;  $175.1 \pm 5.0$  cm; mass:  $81.8 \pm 9.1$  kg) performed, in a counterbalanced order, 8 sets of 10 unilateral repetition maximum (RM) of multi-joint (i.e. seated row) and single-joint (i.e. biceps preacher curl) exercises using the contralateral arm. Rest intervals were 120 seconds between sets and 10 minutes between exercises. Isometric peak torque (PT) of the elbow flexors, and the surface electromyography (sEMG) of the biceps brachii were collected at baseline (PRE), 10 minutes, 24, 48, 72 and 96 hours after each exercise protocol. Comparison between different exercise protocols was performed using two-way repeated measures ANOVA (2 protocols x 6 time-points). **Results** For PT, there was significant interaction between exercise protocols. PT decrease was greater ( $P<0.05$ ) 10 min after single-joint (26.8%) when compared to multi-joint (15.1%). In addition, PT was less (8.4%) than baseline at 24 hours after the single-joint exercise ( $P<0.01$ ), whereas peak torque returned to baseline levels at 24 hours after the multi-joint exercise. For root mean square (RMS), there was no significant interaction between exercise protocols. However, there were significant main effects for time-points (10 minutes < PRE, 24h, 48h, 72h and 96h,  $P<0.05$ ). **Discussion** Our results showed that the muscle activation was not different between protocols although isometric PT was recovered at 24h after exercise only for the multi-joint. In addition, for the same level of muscle activation, torque production at 10 minutes after multi-joint exercise was greater than single-joint exercise protocol. Thus, our results suggest greater muscular efficiency after exercise-induced muscle damage performed with multi-joint when compared to single-joint exercise. **References** Nosaka K and Newton M. ### AGREEMENT BETWEEN VMAX29 AND THE NEW BREATH-BY-BREATH RESPIRATORY SYSTEM VYNTUS CPX DURING MAXIMAL INCREMENTAL EXERCISE

Carlomagno, D.1, Bosio, A.1, Morelli, A.1, Tornaghi, M.1, Induni, M.1, Rampinini, E.1

*Mapei Sport (Olgiate Olona, Italy)*

**Introduction** Automated metabolic gas analysis systems are widespread devices in exercise physiology (Macfarlane, 2001). As a good practice, a brand new device should be tested for validity and reliability and being in good agreement with previous, well known and validated devices. Aim of this study was to compare respiratory data collected using a validated VMAX29 system and a Vyntus CPX. **Methods** Ten subjects performed a maximal incremental exercise test ( $25 \text{ W}\cdot\text{min}^{-1}$ ) on a cycle ergometer while respiratory data were simultaneously collected and analyzed using two different devices (VMAX29 and Vyntus CPX). The agreement between the two systems in regards to  $\text{VO}_2$ ,  $\text{VCO}_2$  and  $\text{VE}$  during the whole test and at exhaustion were investigated through the Intraclass Correlation Coefficient (ICC), coefficient of variation (CV) and Bland and Altman plot (Bland and Altman, 1986). Differences for values at exhaustion were tested by paired t-test. **Results** During the whole maximal incremental exercise, ICC values for  $\text{VO}_2$  (0.997),  $\text{VCO}_2$  (0.996) and  $\text{VE}$  (0.997) were very high. The typical variation between the two systems, expressed as a CV, was low for all the parameters (1.9% for  $\text{VO}_2$ , 2.4% for  $\text{VCO}_2$ , and 2.0% for  $\text{VE}$ ). Good agreement was confirmed using the Bland and Altman plots: mean bias  $\text{VO}_2$   $-92 \pm 105 \text{ ml}\cdot\text{min}^{-1}$  (limits of agreement  $-298$  and  $105$ ),  $\text{VCO}_2$   $63 \pm 106 \text{ ml}\cdot\text{min}^{-1}$  (limits of agreement  $-145$  and  $271$ ) and  $\text{VE}$   $-1 \pm 2 \text{ L}\cdot\text{min}^{-1}$  (limits of agreement  $-5$  and  $3$ ). At exhaustion, no significant differences were detected between the two systems for  $\text{VO}_2$  ( $p=0.241$ ),  $\text{VCO}_2$  ( $p=0.793$ ) and  $\text{VE}$  ( $p=0.291$ ), nevertheless slightly lower ICCs (0.929, 0.974 and 0.936 for  $\text{VO}_2$ ,  $\text{VCO}_2$  and  $\text{VE}$  respectively) and higher CVs (3.4%, 3.6%, 2.8% for  $\text{VO}_2$ ,  $\text{VCO}_2$  and  $\text{VE}$  respectively) were detected. Bland and Altman plots confirmed these tendencies at exhaustion: mean bias  $\text{VO}_2$   $-97 \pm 242 \text{ ml}\cdot\text{min}^{-1}$  (limits of agreement  $-571$  and  $378$ ),  $\text{VCO}_2$   $24 \pm 275 \text{ ml}\cdot\text{min}^{-1}$  (limits of agreement  $-516$  and  $564$ ) and  $\text{VE}$   $-2 \pm 5 \text{ L}\cdot\text{min}^{-1}$  (limits of agreement  $-12$  and  $9$ ). **Discussion** The results of this study showed an overall good agreement between the Vyntus CPX and the widespread VMAX29. The new Vyntus CPX and the VMAX29 gave very similar values for  $\text{VE}$  while, albeit very small,  $\text{VO}_2$  was inclined to be higher and  $\text{VCO}_2$  lower for the Vyntus CPX. In spite of different hardware,  $\text{O}_2$  analysers (paramagnetic for VMAX and fuel cell for

Vyntus) and ventilator transducer (mass flow meter for VMAX29 and turbine for Vyntus), the two devices might be used interchangeably without compromising the consistency of the results. ### SHUTTER GLASSES AS A TRAINING TOOL IN TENNIS – CHANGES IN EYE-HAND COORDINATION ACCORDING TO FREQUENCY AND DUTY RATIO

Jendrusch, G.

*Ruhr-Universität Bochum, Faculty of Sports Science*

**Introduction** Shutter glasses seem to be a tool for training visual functions in the context of sports vision training to increase movement coordination. Several studies discussed effects and non-effects of training with shutter glasses e.g. within coincidence anticipation (Smith & Mitroff, 2012; Reichow et al., 2010), motion cognition or short-time memory (Appelbaum et al., 2011 and 2012). No investigation, however, justifies training and strobe settings yet. Based on the necessity of an adequate load dosage to allow training effects, the present study intends to assess which strobe settings lead to a significant decrease of target hit precision in tennis. **Methods** With a total number of 22 tennis players (18m, 4f, mean age=23.6, SD=+/-2.7 years) the target hit precision (precision of eye-hand (bat) coordination) was conducted. The tennis players had to return the balls played to them by a ball machine (25 balls for each test) using the forehand volley and to make direct hits to a "bull's eye" (high scores stand for a high target hit precision). The results with different (randomized) conditions (strobe rates level 2=5.3 Hz, level 5=2.3 Hz, level 8=1.0 Hz; duty ratio level 2=89 ms, level 5=343 ms, level 8=912 ms) of currently used shutter glasses (Nike Vapor Strobe) and without the glasses have been compared. Results High level tennis players reached better target hit precision scores "without the glasses" compared to lower level tennis players by trend (75.0+/-16.4 vs. 64.9+/-17.4; 2p>0.05). By increasing level (lower frequency and higher duty ratio) the tennis specific target hit precision scores decreases significantly ("without the glasses"=70.0+/-17.3, level 2=54.5+/-15.9, level 5=41.7+/-22.7, level 8=44.5+/-24.3; p<0.001). The scores with the shutter glasses (at levels 2, 5 and 8) were all significantly less than "without the glasses" (2p<0.001). The variability of the target point (coefficient of variation) increased playing with the shutter glasses ("without glasses"=24.8 %, level 2=29.1 %, level 5=54.4 %, level 8=54.7 %). **Discussion** Lower frequency and higher duty ratio lead to increasing perceptual stress for the eye-hand (bat) coordination in a tennis specific situation. No discrete levels for changes in performance were found. The levels 5-8 seem to be adequate demands to develop a tennis specific training program with shutter glasses. However, efficiency of such a (future) sport specific training program has to be analyzed first before establishing shutter glasses as an effective training method. **References** Appelbaum LG, Cain MS, Schroeder JE, Darling EF, Mitroff SR (2012). *Atten Percep Psychophys*, 74(8), 1681-1691. ### A STUDY OF HYPOXIC EXPOSURE AND TRAINING ON HAEMATOLOGICAL VARIABLES, PP, VO2MAX

Yoon, J.

*Korea National Sport University*

**Hypoxic exposure and training** in this study was to investigate the hypothesis that the various models 'live and/or sleep high: train low(LHTL)' by way of 4 weeks in elite level tennis players. Sixteen well-trained tennis players were divided into two groups: SITH(sprint intermittent hypoxic, n=8) and CON(control, n=8). SITH group were exposed to normobaric hypoxic chamber at fixed altitude (normobaric hypoxic chamber; b-cat, SIEMENS, Netherlands). The experimental group which SITH (SIT with hypoxic) from 2,500m to 4,000m performed the graded elevation every 500 m increased by the week five times a day, two times four weeks treated to a SIT (sprint interval training) and three hours of exposure in hypoxic chamber (simulated normobaric hypoxic). The CON (control) was conducted same period and methods without exposure to hypoxia that a SIT at sea level Each interval training session was performed in a laboratory on the treadmill(Quak b2, Italy) and bicycle ergometer(Excaliber, Lode) in normoxic or hypoxic conditions for the each group, respectively. The each group performed warm-up and cool-down plus recovery from each interval in hypoxic conditions. All blood variables were observed and this examination was conducted per week. As a results, the haematological variables were Hb and Hct compared Pre with the treatment at the end of 4,000 m has been shown to significantly increased in both groups respectively(p<.05, p<.01; vs. Pre). Aerobic exercise capacity related variables that Time was SITH has been shown to significantly increased at 4,000 m(p <.05; vs. Pre). Also, VO2max was SITH has been showed increased in the same period a tendency(p=.072). Anaerobic exercise capacity related variables that PPI(W) was both groups increased significantly at 4,000 m(p <.05; vs. Pre), and PP (W / kg) was CON group has been showed increased in the same altitude a tendency, whereas SITH group has been showed increased at 3,500 m and 4,000 m respectively(p<.05; vs. Pre). Therefore, this study, unlike previous studies with similar positive results as a follow-up study will be contribute to the attainment of a higher value.

### INTERDAILY VARIATIONS AND ACCURACY OF MEASUREMENT OF BODY COMPOSITION USING BIA ANALYZERS IN ATHLETES

Kutac, P.

*University of Ostrava*

**Introduction** Body composition is often used in the diagnostics of athletes. However, diagnostics often use repeated measurements performed in greater time intervals and therefore the mere knowledge of the error of measurement found on the basis of immediately repeated measurements is insufficient. The aim of the study is to analyze the changes in the body composition parameters measured during a workweek and to determine the size of the error of measurement. **Methods** The research group included 48 students of physical education (21.42±1.38 years) engaged in sports at the performance or professional level. The measurements took place every day during the workweek. The participants did not perform any organized physical activity during the week. The measurement was performed using the Nutriguard-MS multi-frequency analyzer (DataInput, Germany) and the Tanita-418 MA monofrequency analyzer (Tanita, Japan). To evaluate the differences of the means, we used the repeated measures (ANOVA). To assess objective significance, we used Eta-squared. To express the size of the error of measurement in the weekly analysis, we used the typical error of measurement (TE) (Hopkins, 2000). The parameters measured were body mass (BM), body fat (BF), total body water (TBW) and fat free mass (FFM). Results BF (%), kg) and TBW (%) measured by Tanita showed a statistically significant difference in measurements on Monday and Friday. Practical significance was not confirmed in any of the parameters. The TE values calculated for the parameters measured by Nutriguard were as follows: BM 0.44 kg, FFM 0.88 kg, BF 0.81 kg and 1.09%, TBW 0.64 kg and 0.80%. The TE values measured by Tanita were: BM 0.44 kg, FFM 0.86 kg, BF

0.68 kg and 0.90%, TBW 0.63 kg and 0.66%. Discussion The TE values we found are higher than the values stated in immediately consecutive repeated measurements (Macfarlane, 2007). This difference is given by the timing relationship that we chose for our study. The size of TE grows with the increasing interval of repeated measurements (Vicente-Rodríguez et al., 2012). However, the found TE values show very little fluctuation during the week. When interpreting the results of repeated measurements in diagnostics, we recommend using only the values that exceed the level of the typical error of measurement. References Hopkins WG. (2000). ### KAATSU TRAINING MODIFIES THE MEAN AND MAXIMUM BLOOD FLOW VELOCITY IN HEALTHY SUBJECTS

Puggina, E.F., Ferreira Neto, J.H., Castro, F.M.P., Oliveira, L.P., Alves, G.F., Tourinho Filho, H., Guirro, E.C.O.

*University of São Paulo*

**INTRODUCTION** Strength training with vascular occlusion (KAATSU training), has been investigated with the purpose of increasing muscle mass and strength of practitioners of strength training (Sato, 2005). Despite a growing number of studies, there are still many doubts about the method, especially related to influence of muscle strength in the bloodstream. The objectives of this study were to investigate the effects of KAATSU training on muscle strength and arterial circulation. **METHODS** Eleven male individuals physically active aging  $20.72 \pm 2.05$  years underwent to an eight-week training protocol (strength training with vascular occlusion on knee extension and elbow flexion) with 20% of maximum voluntary contraction. Muscle strength was assessed (Kg) using the Brzycki (1993) equation in three times of the training program and arterial blood flow velocity (cm/s) and systolic blood pressure (SBP) were recorded by using Doppler (Nicolet Versalab®) at the beginning and end of the protocol. Data were analyzed using the software GraphPad Instat® and PRISM® 6 (La Jolla, USA), using descriptive statistics, Shapiro-Wilk test, ANOVA for repeated measures and Tukey-Kramer to detect differences ( $p \leq 0.05$ ). **RESULTS** Results revealed no differences in SBP of upper and lower limbs in the beginning and at the end of the experimental protocol. However, increases of strength in both lower limbs, right ( $p < 0.02$ ) and left ( $p < 0.01$ ) comparing the pre and post training and increases in maximum ( $p < 0.0001$ ) and mean blood flow velocity ( $p < 0.03$ ) were found for both arms. **DISCUSSION** There were no differences in SBP of upper and lower limbs, indicating that strength training with vascular occlusion does not alter SBP. These results corroborate the findings of Polito et al. (2003), which concluded that the intensity of strength training can influence the duration and the magnitude of the load hypotensive effect. Where sessions with intensity around 70% of 1RM, would promote reductions of SBP, while sessions with low-medium intensity 40-50% of 1RM, would provide a less sensitive reductions of SBP, but this study was carried without the use of vascular occlusion. Nevertheless, differences in strength and maximum and mean blood flow velocity were found for the upper limbs. **REFERENCES** Brzycki M. ### CAN THE "TWO-STEP TEST" EVALUATE PHYSICAL CAPACITY?

Masafumi, N., Shogo, T., Shiori, H., Takuma, S., Shuro, K., Wataru, I., Koichiro, A., Jun, I., Hideo, M.

*Keio University School of Medicine*

**Background & Objective:** Elderly people often suffer dysfunction of musculoskeletal system. Several tests to examine the dysfunction have been proposed. The "two-step test" is one of those, which is to measure the sum length of two steps when asked to walk with maximum strides. The aim of this study is to investigate whether the "two-step test" can evaluate physical capacity including muscle strength, standing balance, and suppleness of the lower limbs, which are the main factors for dysfunction of musculoskeletal system. **Materials & Methods:** One hundred subjects (52 males and 48 females) were involved in this study. Average age was  $51 \pm 11$  years, and average BMI was  $27.8 \pm 6.6$  kg/m<sup>2</sup>. After the "two-step test" was carried out, following five additional tests to evaluate physical capacity were performed: 1) grip strength, 2) quadriceps strength, 3) 30-sec. chair-stand test (CS30), 4) one leg stand test with open eyes, 5) finger-floor distance (FFD). CS30 is a test to count the number of times to repeat standing-up from and sitting-down on a fixed chair within 30 seconds. In 18 out of the 100 subjects, 24-hour physical activity was also monitored using portable accelerometer. The data were standardized by age, sex, body height and BMI, and the correlation between the results of "two-step test" and those of above mentioned physical tests were analyzed. **Results:** The average sum length of two steps (results of the "two-step test") was  $1.51 \pm 0.14$  (divided by body height, in order to standardize the data). Significant positive correlations were observed between the results of "two-step test" and those of all the physical tests ( $p < 0.05$ ); grip strength, quadriceps strength, CS30, one leg stand with open eyes, and FFD. A positive correlation was also observed between the results of "two-step test" and intensity of physical activity in the 18 subjects who monitored 24-hour physical activity ( $p < 0.05$ ). **Conclusion:** This study suggests that the "two-step test" is a simple and useful method to evaluate patient's physical capacity, and has a possibility to become a standard test in the "hurry-scurry" daily medical practice.

### VIBRATION TRAINING IN INDOOR BOULDERING: EFFECTS ON STRENGTH AND ENDURANCE.

Medernach, J., Kleinöder, H., Lötzerich, H.

*German Sport University Cologne*

**INTRODUCTION:** Indoor bouldering (IB) consists of low height climbing sequences with grip strength and endurance as key factors. Despite the increasing popularity and competitiveness, limited research has been conducted on sport-specific training methods. Therefore, the aim of this study was to investigate the use of fingerboards in the presence (VB) and absence (FB) of vibration stimulation to increase grip strength (GS) and climbing time to exhaustion (CTE). **METHODS:** Thirty-four male boulderers ( $25 \pm 4$  y;  $1.78 \pm 0.1$  m;  $70 \pm 5$  kg;  $6 \pm 2$  yrs climbing; 7b Fb mean ability) were randomly allocated to a 4-week VB (n=11), FB (n=11), or IB (n=12) training regimen with three sessions of 150 min per week. VB and FB involved finger hangs on a Transgression fingerboard (GER), fixed at head height on a vibration plate (Power Plate Classic; 2 mm amplitude; 40 Hz frequency) for vibration stimulation in VB. IB involved bouldering at individual ability level. Pre- and posttests with a 48 h rest prior data collection involved body weight (BW), perceived physical state (PEPS), handheld dynamometry to assess GS, and the repeated ascent until exhaustion of a 4 m high bouldering route with 10 bolt-on holds to determine CTE. **RESULTS:** GS increased significantly ( $p < .001$ ) in VB (+7.3%) and FB (+5.0%), but not in IB (+2.6%;  $p = .109$ ). Significant greater GS increases were found

in VB compared to IB ( $p = .045$ ) with, however, no significant ( $p = .656$ ) differences between VB and FB. CTE increased significantly in VB (+31.3%;  $p < .001$ ), but not in FB (+10%;  $p = .288$ ) and IB (+6.6%;  $p = .298$ ). No significant ( $p > .05$ ) changes in BW and PEPS were observed between the pre- and posttests and the training groups. **DISCUSSION:** Our findings indicate that VB and FB are highly effective in increasing GS. Both involve isolated grip positions that are worked maximally to the point of muscle failure, making GS gains to occur in a relatively short period of time. In contrast, IB involves multiple grip sizes and shapes, so the isolation of single grip positions cannot occur to the same extent as with VB and FB. Moreover, our results suggest that VB is highly effective in increasing CTE. The different findings between VB and FB may be explained by the additional vibration stimulus in VB, whereas the limited number of climbing moves may explain the insignificant findings in IB. **REFERENCES:** La Torre A, Crespi D, Serpiello FR, Merati G (2009). ### NEW BIOELECTRICAL IMPEDANCE ANALYSIS EQUATIONS FOR AMERICAN ADOLESCENT ATHLETES

Roberts Jr, J.

*Edinboro University of PA*

**Introduction** Bioelectrical impedance analysis (BIA) is a widely used commercial method of predicting body fat composition in the United States. It is convenient, easy to administer and widely accepted by the public. However, there are known errors associated with the use of BIA. Therefore, the purpose of this study was to develop a new set of gender-specific equations for predicting body composition in adolescent athletes using BIA. **Methods** Fifty-one American student athletes (25 males [age =17.36±1.15yrs] and 26 females [age=17.54±1.56yrs]) ages 14 through 19 underwent the experimental procedures. Using the Athletic IQ (AIQ) scale and stadiometer (Canton, MA USA), height and body mass were determined. The AIQ BC-100 was used to determine impedance, phase angle, resistance and reactance. Participants performed this test while hydrated (specific gravity under 1.025) and arms kept parallel to the ground. Percent body fat using hydrostatic weighing was used as the criterion. Body density was determined by using the average of the three heaviest underwater weights. Results Body mass Index (BMI) and impedance were significant predictors in each gender-specific equation. Age was a significant contributor to the female equation but not the male equation. Phase angle, resistance and reactance were not significant contributors in the development of either equation. Male equation: Body fat % = -68.48+1.81(BMI) +.066(Impedance)  $r=0.79$ ,  $r^2=0.63$ ,  $p<0.001$  SEE 4.37 Female equation: Body fat % = -4.33+1.3(BMI)-.68(AGE) +.013(Impedance)  $r=0.81$ ,  $r^2=0.66$ ,  $p<0.001$  SEE 3.40 **Discussion** Early research by Jackson et al. 1988 noted a high reliability between BIA, skinfold and hydrostatic weighing for body composition. More recently in a review of the literature of 50 published studies, it was cited that BIA is a practical method to estimate body fat percentage in children and adolescents but validity and measurement error concerns are still present (Talma et al., 2013). This study successfully generated new gender-specific BIA prediction equations for body composition in American adolescent athletes using hydrostatic weighing as the criterion. **References** Jackson A, Pollock M, Graves J, Mahar M. ### COMPARISON OF ENERGY EXPENDITURE AND HEART RATE ACCORDING TO SELF-SELECTED, SELF-PERCEIVED AND CONTROL WITH PERSONAL TRAINER DURING AEROBIC EXERCISE

Lee, H.

*SANGMYUNG UNIVERSITY*

**Introduction** The higher walking speed self-selected and the greater  $VO_2$  that lead to a greater energy cost (Kleverton Krinski, et al., 2012). Self-paced exercise may improve adherence to exercise programs among overweight and obese adults (Williams, D.M., et al., 2014). And imposing a speed that is just higher than what overweight women would have selected led to a significant decline in reported pleasure (P, Ekkekakis, et al., 2006). But, enforced constant paced exercise presents a significantly greater physiological challenge than self-paced exercise (Lander, P. J., et al., 2009). The purpose of this study was to compare on energy expenditure and heart rate according to the exercise ways of self-selected, self-perceived THR and exercise with personal trainer during bicycle aerobic exercise for 30 minutes. **Methods** 6 male college students (23±1.0year, 174±1.4cm, 70±5.2kg, 17.7±3.36%BF) participated voluntarily on this experiment. They were to engage in a 30-min bout of bicycle aerobic exercise (5min: warm-up, 20min: main exercise, 5min: cool down). All participants measured their heart rate reserved (HRR). And then figured target heart rate (THR) with their respective %70HRmax respectively. They performed (self-selected: SS, self-perceived THR: SP and control with the personal trainer: CPT) in the same amount of time, repeatedly. Subjects were measured energy expenditure (EE) and mean heart rate (mHR) at the point of warm-up, main exercise, and cool down. We analyzed it using independent t-test with SPSS/PC ver.18.00. Statistical significance was defined as  $p<.05$ . Results In the main exercise section, EE and mHR in CPT method was markedly higher than SS and SP. It showed significant difference ( $p<.001$ ). Meanwhile, in the whole 30-min exercise, mHR in CPT way was the highest. It demonstrated a statistically noticeable difference ( $p<.001$ ). **Conclusion** On the basis of these results, we have to be assisted with personal trainer, when exercising. Self-paced exercise may improve adherence to exercise programs among overweight and obese adults (Williams, D.M., et al., 2014). But normal person showed the different results in this study. These findings indicate that the exercise using the optimal THR under the personal trainer is expected to be more efficient than self-selected, and self-perceived exercise method. **References** Lander P. ### ACTIVE AND PASSIVE FLEXIBILITY OF THE LOWER LIMBS IN RHYTHMIC GYMNASTICS ATHLETES IN DIFFERENT COMPETITIVE LEVELS

Ávila-Carvalho, L., Santos, A., Lebre, E.

*Porto University, Sports Faculty*

**Introduction** Flexibility is considered one of the main characteristics requested by the practice of Rhythmic Gymnastics (RG). According to Lisitskaya (1995) without an adequate level of flexibility, is difficult to improve the technique, educate the expressivity and the lightness of

the movements. According to Nuñez (2005) the flexibility is the capacity that permits to perform movements with high performance level in gymnastics. A gymnast shows restricted and limited movements, when she has insufficient mobility in the joints. Therefore, the aim of this study was to study the level of Active and Passive Flexibility in Lower Limbs (LL) of Portuguese national level gymnasts when compared to international level gymnasts. Sample For this study we studied in total 30 RG gymnasts with  $13,73 \pm 0,17$  years old. Methods The evaluation was done using the flexibility Test Battery for LL (FIG, 2010) that includes the evaluation of seven specific movements in RG, executed by both lower limbs: preferred lower limb (PLL) and the not preferred (NPLL). The gymnasts were filmed for each proposed element for later appreciation in a scale of five levels (0-4). The data was treat using Parametric tests (T Test) and Nonparametric (Mann-Whitney Test). To compare the data from the same gymnast we used the Nonparametric test-Wilcoxon Test for paired samples. Results and conclusions The passive flexibility with the PLL, in the international level registered higher results than the national level in 75% of the tests. For the active flexibility ewe registered better results in the international level gymnasts, but only in 33,3% of the tests. Concerning the seven flexibility tests performed, we concluded the results for the both national and international levels were similar results. When compared the flexibility levels between the PLL and NPLL results shown that 86,7% of the Portuguese junior gymnasts presented flexibility differences between the LL equal or superior to 15%. ### RHABDOMYOLYSIS AFTER PERFORMING BLOOD-FLOW RESTRICTION TRAINING: A CASE REPORT

Shogo, T.1, Kei, T.2, Yukio, S.2, Koichiro, A.1, Hideo, M.1

1: Keio university hospital (Tokyo, Japan), 2: Kitasato Institute Hospital (Tokyo, Japan)

Introduction: Low intensity blood-flow restriction (BFR) training is routinely performed in Japan. Numerous studies using BFR training have shown muscle hypertrophy to occur with a training intensity as low as 20% one repetition maximum (1RM) [Loenneke JP et al. 2012]. However, little is known about the most effective BFR training protocol regarding exercise intensity and occlusion pressure and occlusion duration [Pope ZK et al. 2013]. Although many complications such as subcutaneous hemorrhage or temporary numbness caused by BFR training have been reported [Gualano B et al. 2010], to our knowledge, there are only a few reports about serious complications after performing BFR training. This is the case of a patient presenting with severe rhabdomyolysis on the next day after performing BFR training. Case Description: The patient is a 30-year-old Japanese obese male who has no significant past medical history. He performed squats (3 sets of 20 reps) with his leg muscle BFR under the instruction of a trainer for the first time. No further information about exercise intensity or occlusion pressure was available. On the next day, he was admitted to our hospital with complaints of severe muscle pain of his upper and lower extremities, high fever and pharyngeal pain. He was diagnosed with acute rhabdomyolysis, with serum creatine phosphokinase (CPK) of 56,475 U/l and urine myoglobin of >3000 ng/ml, accompanied by acute tonsillitis, with a white blood cell of 7,390 and CRP of 10.43 mg/dl. Excessive muscular workout with BFR and bacterial infection was suspected to contribute to the onset of rhabdomyolysis. He was treated with rapid and aggressive infusion of intravenous fluids and antibacterial drug, and CPK decreased without presenting acute renal failure after having reached to up to 89,824 U/l on the 2nd hospital day. Discussion: It has been reported that there are secondary factors that can exacerbate exercise muscle damage such as dehydration, existing bacterial or viral infections, heat stress and nutritional supplement and drug use [Springer BL et al. 2003]. Our case shows that BFR training in an inappropriate way is at risk for leading serious complications such as rhabdomyolysis, especially when accompanied by deconditioning. ### A NEW ASSESSMENT METHOD USING A COMBINATION OF JOINT KINETICS AND PERFORMANCE VARIABLES DURING THE REBOUND JUMP TEST

Zushi, A., Kariyama, Y., Yoshida, T., Hayashi, R., Takahashi, K., Zushi, K.

Univ. of Tsukuba

Introduction In sprint running and ball sports, measuring the stretch-shortening cycle (SSC) performance of the lower leg is necessary. Drop jump and rebound jump (RJ) tests are mostly used to test SSC performance (Bobbert, 1990; Zushi et al., 1993), although performance variables, such as contact time, jumping height and rebound jump index (RJ index; Zushi et al., 1993), are also used, which result from interactions between the muscle groups and three lower limb joints. Thus, if a new measurement system is developed that measures and calculates the mechanical variables of the three lower limb joints (torque, power and work) in real time with the performance variables, athletes' SSC performance can be diagnosed with more accuracy and detail. This study proposed a new assessment method that combines joint kinetics and performance variables in the RJ test. Methods The RJ test was performed by 27 male jumpers. Three-dimensional coordinates of 12 retro-reflective markers fixed on each subject's body were collected using a Vicon T20 system operating at 250 Hz. Ground reaction forces were obtained with a force platform at 1000 Hz. The Quick Motion Analysis System, which automatically calculates and presents the above-mentioned data immediately after the RJ test, was jointly developed with DKH Inc. in Japan and used to measure joint torque, power and work of the three lower limb joints. Results and Discussion The correlation coefficient between IAAF scores (jump events performance used by the IAAF Scoring Tables of Athletics) and RJ index had a marginally significant, while a significantly positive correlation was noted between IAAF scores and jumping height. Thus, our findings indicate that jumpers' specialized muscle strength and power exertions can be evaluated by RJ test. We examined the correlation between IAAF score and mechanical variables of the three lower limb joints. Significant correlation coefficients were noted between IAAF score and negative ankle joint work and between IAAF score and positive hip joint work. Therefore, high-performance jumpers were characterized by a significantly large amount of work in the ankle and hip joints on the RJ test. We also examined the correlations between the functions of the three lower limb joints; for relative work (calculated as the ratio of work for each joint relative to the total sum of work for the three lower limb joints), significant negative correlation coefficients were found in the ankle and knee joints and in the ankle and hip joints. This showed a relationship in work between the three lower limb joints, but the work by the three lower limb joints are in a conflicting relationship. Thus, we used a new assessment system to evaluate torque, power, work and relative work that may be a useful tool for assessing muscle strength and power. References Bobbert MF. (1990). *Sports Medicine*, 9, 7-22. Zushi K, Takamatsu K, Koto, T. (1993). *Japan J Phys Educ Hlth Sport Sci*, 38, 265-278.

## THE ANALYSIS FOR THE RELATIONSHIP BETWEEN BONE FORMATION AND PHYSICAL AND PERFORMANCE CHARACTERISTICS OF JAPANESE COLLEGIATE AMERICAN FOOTBALL PLAYERS

Iguchi, J.I., Hojo, T.2, Fujisawa, Y.2

1:Kyoto Gakuen University(Kyoto, Japan), 2 Doshisha University (Kyoto, Japan)

**Introduction** Although there have been many studies for athletes focusing on muscular strength and physical and/or performance characteristics (e.g., lean body mass), as far as we know, little studies have been conducted on the relationship between bone formation and those characteristics described above. One of the main reason why there has been a lack of such study is that there are the difficulties in measuring the index of bone (e.g., bone mineral density) such as exposure to radiation or time-consuming process, etc. In order to solve those problems, the LD-100 system (Oyo Electronics, Kyoto, Japan), which is a fast, non-invasive ultrasonic instrument using the ultrasonic parameters on the basis of fast and slow waves at the distal radius of non-dominant hand, has been newly developed. Thus, our aim of this study was to examine how the indexes of bone were related to the performances and physical characteristics of the collegiate American football players using a superior ultrasonic bone densitometry system. **Methods** Fifty-six collegiate American football players (age=20.5±1.2 years) were recruited for the current study. The subjects were divided into 2 groups according to their positions: skill positions, linemen. The LD-100 system was performed for each subject to obtain the parameters of bone: trabecular bone density (TBD, mg/cm<sup>3</sup>), the attenuation of waves (dB), radius thickness (mm), cortical thickness (CoTh, mm), elastic modulus of trabecular bone (EMTb, GPa) and modulus of section (mm<sup>3</sup>). As for physical and performance indexes of the subjects, we collected body weight (kg), height (cm), body fat (%), lean body mass (LBM, kg), bench press/squat /high clean (kg and relative to body weight), vertical jump height (cm) and power(kg · s<sup>-1</sup>). As the reference data, we referred to the data collected by Sai et al. (2010). **Results** We found that power and body fat were positively correlated with TBD for all ( $p < 0.05$ ). Regarding skill position players, high clean relative to body weight was negatively correlated with EMTb and squat was positively correlated with CoTh and TBD ( $p < 0.05$ ), although those parameters for linemen were not correlated. **Discussion** Although many previous studies have confirmed a positive relationship between muscular strength and bone density, we found that power was positively correlated with TBD. This may imply that Olympic lifting such as high clean emphasizing power is better than power lifting in order to increase bone density. Reference Sai et al. (2010). Osteoporos Int, 21(10), 1781-90. ## A COMPARISON OF MUSCLE FATIGUE BETWEEN MAXIMAL AND SUBMAXIMAL STRENGTH GAINS DURING THE BENCH PRESS IN MEN

Seo, S.W., Jeon, H.S., Song, S.H., Lee, H.S.

Dankook University

**Introduction** The bench press is one of the most popular exercises used in strength training for the upper body (Roland van den Tillaar & Gertjan Ettema, 2013). In the case of submaximal strength gain, the optimal number of repetitions to perform under same loading conditions to achieve certain training goals has not been established (Luis sanchez-medina & Juan jose Gonzalez-badillo, 2011). Moreover, the role of resistance training to maximal and submaximal to optimize strength and power gains is unclear (Izquierdo et al., 2006). The study aim was to investigate a comparison of muscle fatigue between maximal and submaximal strength gains during the bench press in men. It was hypothesized that maximal voluntary contraction (%MVC) would similar gains between maximal and submaximal strength gains during the bench press, but median frequency (MDF) would increase in maximal compared with submaximal exercise. **Methods** Employing a randomized, counterbalanced crossover design, 12 men were asked to perform maximal repetitions and submaximal repetitions (concentric: 1-s, eccentric: 1-s, 2-s/repetition) to failure with a load of 85% of 1RM for the bench press, with a 3-minute recovery between the sets (Sakamoto A. & Sinclair P. J., 2012; Baechle & Earle, 2008). Each subject was tested for the number of repetitions and sets, total work, and 1-RM in bench press. Surface EMG was recorded from the pectoralis major, deltoid anterior, and triceps brachii for maximal voluntary contraction (%MVC) and median frequency (MDF). **Results** The changes in number of repetitions and sets and total work were significantly higher ( $p < 0.05$ , respectively) in the submaximal repetitions as compared with the maximal repetitions performed during the bench press. The changes in %MVC were not significantly different between maximal and submaximal strength gains, but the changes in MDF were significantly smaller ( $p < 0.05$ , respectively) in the maximal repetitions as compared with the submaximal repetitions selected muscles during the bench press. **Discussion** Our study showed that a smaller muscle fatigue in submaximal repetitions, despite higher in total work and a similar in muscle activity were observed. It seems that these changes lead to the remarkable increased volume or intensity for improving maximum force and muscle power. References Roland van den Tillaar and Gertjan Ettema. (2013). ## THE EFFECTS OF FIVE WEEKS OF HIGH-INTENSITY INTERVAL TRAINING ON PHYSIOLOGICAL INDICES IN FEMALE FUTSAL PLAYERS: A COMPARISON BETWEEN TWO MODELS

Guglielmo, L.G.A., Arins, F.B., de Lucas, R.D., Carminatti, L.J.

Federal University of Santa Catarina

**Introduction** The purpose of this study was to compare the effects of two models of the high-intensity interval training (HIIT) performed during five weeks, on physiological indices in elite futsal players. **Methods** Sixteen female futsal players (divided in two groups) performed the Futsal Intermittent Endurance Test (FIET) to determine the peak velocity (PVFIET). The laboratory tests were performed on a motorized treadmill and consisted of a submaximal protocol to obtain the running economy (RE). And an incremental test was performed to determine the maximum oxygen consumption (VO<sub>2</sub>max), peak velocity (PVTR) and velocity at lactate threshold (vLT). The training models (implemented twice a week during five weeks) were designed from shuttle running intervals and consisted of four sets of 4-minute bouts with 4-minutes of rest intervals between sets. The main difference between the two models was the timing of the intervals, one being performed by 7.5s of running and 7.5s of resting (HIIT7.5x7.5), and the other by 15s of running and 15s of resting (HIIT15x15). In the HIIT7.5x7.5 model, the athletes performed 17x7.5s shuttle runs (with a direction change every 3.75s) and the HIIT15x15 model consisted of 9x15s (with a direction change every 3.75s). The intensity used for the HIIT7.5x7.5 was 86-91 %PVFIET and for the HIIT15x15 was 83-88 %PVFIET. The ANOVA mixed model with post hoc Bonferroni was used for comparing ( $p \leq 0.05$ ). The effect size (ES) was also calculated to

analyze the magnitude of the improvements. Results The PVFIET increased significantly from  $14.7 \pm 0.8$  to  $15.7 \pm 0.7$  km/h for HIIT7.5x7.5 (ES=1.58) and from  $14.9 \pm 1.0$  to  $16.1 \pm 1.2$  km/h for HIIT15x15 (ES=1.2). The PVTR increased from  $14.0 \pm 1.2$  to  $14.4 \pm 0.8$  km/h for HIIT7.5x7.5 ( $p=0.05$ ; ES=0.9) and from  $13.6 \pm 1.5$  to  $14.5 \pm 1.3$  km/h for HIIT15x15 ( $p \leq 0.01$ ; ES=1.9). The vLT was enhanced from  $10.1 \pm 0.6$  to  $11.6 \pm 0.7$  km/h for HIIT7.5x7.5 (ES=3.2) and from  $10.0 \pm 0.5$  to  $11.5 \pm 1.0$  km/h for HIIT15x15 (ES=2.1). The RE showed no significant improvement for both models, but showed an ES= 0.7 for HIIT15x15. Discussion The present study used two models of HIIT performed in shuttle running derived from FIET. The main hypothesis was that the model with more changes of direction (i.e. HIIT15x15) could trigger greater improvements in aerobic fitness. In conclusion, the completion of 10 training sessions in both HIIT models elicits similar improvements in aerobic fitness in female futsal athletes. References Almarwaey OA, Jones AM, Tolfrey K. ### **A STUDY TO ASSESS THE EFFECT OF THE PREVENT INJURY, ENHANCE PERFORMANCE PROGRAMME ON LOWER EXTREMITY INJURY INCIDENCE AND NEUROMUSCULAR FUNCTIONAL OUTCOMES IN GAELIC GAMES**

Lodge, C., Schlingermann, B., Rankin, P.

*Institute of Technology Carlow*

Introduction: Gaelic football and hurling are two highly popular field games in Ireland. A study conducted across inter county GAA football teams over 4 consecutive seasons revealed that 76% of the injuries recorded were lower extremity injuries, which suggests that lower extremity injuries predominate in the body(1). These injuries can have player, team and institutional impacts and may be resultant of the physical demands of the games. Murphy et al (2012) have shown it is possible to record injury data consistently with the GAA and stated that quantifying the incidence of injury is the first step of injury prevention. The goals of the PEP, as developed by Mandelbaum(2), were to avoid vulnerable positions, enhance flexibility, enhance strength, optimise plyometrics and address proprioception and sport specific agilities. Results showed there was a 74% reduction in ACL injuries after 2 years. No such injury prevention techniques have been researched and published by the GAA to date, therefore this study will investigate the effects of the PEP on injury incidence in Gaelic games. Methodology: Over 140 male players were recruited from the GAA teams of the Institutes of Technology Carlow (ITC) and Waterford (WIT). Pre-testing (at the start of the season) and post-testing (at the end of the season) involved two objective screening tests to assess pre and post intervention neuromuscular function. Practical workshops, with ongoing liaison, were executed with coaches and trainers involved with ITC and WIT on the implementation of the programme. A traditional PEP was created for WIT and a dynamic PEP for ITC. The existing GAA database was accessed and utilised to monitor player injuries. Semi-structured interviews with involved health care professionals, coaches and the players were conducted to gain an insight into the practicalities of the programme. Results: It is envisaged that this study will show the effects of the PEP on lower extremity injury incidence and neuromuscular function. The semi-structured interviews will provide insights into the practicalities of a structured warm up. Preliminary results are expected in April 2015. Discussion: The findings of this study will contribute to the continued development of the best practice guidelines in lower extremity injury prevention in the GAA. References: 1.Mandelbaum,B. ### **TEST-RETEST RELIABILITY OF THE WINGATE 6 AND 30 SECOND TESTS IN MALES AND FEMALES**

Phillips, S.M.1, Kavaliauskas, M.2

1: *University of Edinburgh*, 2: *Abertay University*

Introduction To accurately quantify the influence of an intervention, it is important to know the typical variance in test performance. Current data on the performance reliability of cycle sprinting suggests that reliability data from one sprint duration should not be applied to sprints of different durations, and that reliability data generated from males should not be applied to females. However, the performance reliability of the same group of males and females performing the 6 and 30 sec Wingate anaerobic tests has not been evaluated. This study assessed the performance reliability of the 6 and 30 sec Wingate tests in males and females. Methods Participants completed four trials each comprising of a single 6 sec cycle sprint against 7.5% body mass resistance, a 15 min seated recovery, and a single 30 sec cycle sprint against the same resistance. Peak power output (PPO) and mean power output (MPO) were calculated for each sprint. Participants consumed a light meal at least 2 h before testing, and refrained from strenuous exercise for at least 24 h before each trial. Within-participants, trials were completed at the same time of day. Results For both sprints, there was no significant difference in PPO or MPO between any pairs of trials for either gender. For males, PPO in both sprints demonstrated ICCs  $\geq 0.91$  and CVs  $\leq 3.9\%$  in all between-trials pairwise comparisons. For MPO, ICCs  $\geq 0.89$  and CVs  $\leq 2.9\%$  were found in all comparisons. For females, PPO demonstrated ICCs  $\geq 0.87$  and CVs  $\leq 6.5\%$  in all comparisons. Random variation in MPO in the 6 sec sprints fluctuated between comparisons. For the 30 sec sprint, MPO was more stable, with ICCs  $\geq 0.93$  and CVs  $\leq 5.0\%$  in all comparisons. Females improved PPO reliability across the trials for both sprints, whereas males were more consistent across trials. Females showed more variability in 6 sec MPO compared to males, but both genders produced consistent 30 sec MPO. Discussion The consistent PPO and MPO of the males in both sprints conflicts with previous research suggesting the requirement for at least one familiarisation trial (Barfield et al., 2002; Mendez-Villanueva et al., 2007). The progressive improvement in reliability for 6 and 30 sec PPO in females indicates that at least one familiarisation trial may be required, supporting the suggestion that females are less reliable than males (Hopkins et al., 2001). The greater reliability of females in the 30 sec vs. 6 sec sprint may reflect the greater number of pedal revolutions cancelling out fluctuations in force and cadence in individual revolutions (Hopkins et al., 2001). ### **SMALL-SIDED GAMES AND THE ASSESSMENT OF INTERNAL LOAD IN YOUNG SOCCER PLAYERS**

Sannicandro, I.1,2, Rosa, A.R.1, Mazzone, F.2, Cofano, G.1,2

1*University of Foggia*; 2*Strength and Conditioning Coach*

Introduction Small-sided games (SSG) are football training drills in the form of games played in a reduced space, involving fewer players and a shorter playing time. Many studies have analysed the different types of SSG in soccer training (Halouani et al., 2014); however, until now, no research has monitored the internal load (% max. heart rate [%HRmax] and % mean heart rate [%HRmean]) resulting from the 3vs3 format played in the "cage" mode, a training drill devised by a professional Italian football coach in 1991. The "cage" consists of a

playing areas delimited along its perimeters and above the pitch by a metal grid that prevents the ball from exiting the pitch and the game from stopping. The present study aims to evaluate and compare the cardiac responses recorded in players during 3vs3G and 8vs8G; and to investigate the correlation between VO<sub>2</sub>max and HR recorded during the different phases of a 3vs3G and at rest. Methods VO<sub>2</sub>max was assessed in 16 young soccer players (m±sd: age:13±0.1 years, height 155.5±8.6 cm, weight 45.4±10.1 kg) using the Leger test (Léger and Bocher, 1980) 72h after a 8x8G (2x25', 5' rest) and 72h after a 3x3G (4x3', 2' rest). HR was monitored during the SSG using a heart rate telemetry system (Polar, Kempele, Finland). Results The mean VO<sub>2</sub>max for the study group was 54.23±3.89 ml/kg/min. For the 3vs3G vs. 8x8G comparisons, %HRmean and %HRmax were: 88±2.7 vs. 77±3.8% and 94.6±1.5 vs. 88.6±2.9%, respectively. Both differences were significant (p<0.0005). A significant correlation emerged between the values of VO<sub>2</sub>max and HR recorded during the first (r=-0.843, N=16, p<0.01) and second minute of recovery (r=-0.579, N=16, p<0.05) in the first series, and in the first minute (r=-0.680, N=16, p<0.05) of the second series. Discussion The HR values recorded during the two SSG formats are coherent with those of other studies showing that higher performance intensity is associated with formats involving fewer players (Rampinini et al.,2007). The indirect correlations between the values of VO<sub>2</sub>max and HR during the recovery phases lead us to hypothesise that even young soccer players with higher levels of VO<sub>2</sub>max are able to recover better after intense exercise, as indicated in the literature (Borresen and Lambert, 2008). ## PHYSICAL STRENGTH AND MOTOR SKILLS CHANGE IN PARENTS AND CHILDREN PHYSICAL EXERCISE PROGRAM

Nadamoto, M., Nakamura, H., Nakatani, T., Terada, K.

*Educational Laboratory*

Introduction In recent years, declines in physical strength and athletic ability of children have become a social issue. To improve the physical fitness, parents and children should work together in young youth and make it as custom. This study aimed to examine the effect of 12-weeks physical activity program comprised class and home-based both once a week. Methods Participants are kindergartners from 4 to 6 years old and their parents. The subjects installed the intervention group (n=20 both children and parents) and the control group (n=30 both children and parents). The measuring evaluation items were Bone density, Ground reaction force, Reaction time, Functional reach test, Stepping test (10sec), Standing jump test, Catching the ball test and Throwing the ball test. We collected and analyzed data from participants who completed pre-and post-tests. Results There were significant group x time interaction of Reaction time and Stepping test (10sec) by the parents. Significant time effects were observed in the following tests: Stepping test (10sec) and Catching the ball test. Conclusion These results suggest the effect of parents and children physical exercises may be slightly enhanced by intervention with agility of parents and motor skill of children. References Epstein, Leonard H., Wing, Rena R., Koeske, Randi., Valoski, Alice(1984)Effects of diet plus exercise on weight change in parents and children. *Journal of Consulting and Clinical Psychology*, 52(3), 429-437. ## INFLUENCE OF TRAINING LEVEL ON NOCTURNAL HEART RATE VARIABILITY OF HEALTHY YOUNG STUDENTS

Kanoh, K., Satomi, J.

*Chuo University, Ritumeikan University*

For athletes who repeat intense training, it is extremely important to retain the function of parasympathetic nerves, to take good rest and to recover well. Purpose: Main purpose of this study was to examine the suitable indices of Heart rate variability (HRV) to prevent over-training and to evaluate athlete's daily condition. We also examine the autonomic function in healthy students with and without a habit of physical training. Methods: The Autonomic Nervous activity entering the heart was analyzed in following conditions. 1)HRV for 5 minutes direct after awaking was measured in long-distance runners at different training periods. 2)Nocturnal HRV was measured in 4 Lacrosse players at different training periods. In addition, 10 healthy students without a habit of physical training were also participated in this experiment. In both 1) 2), Polar analysis program was used to calculate the the heart beat fluctuation. 3)Nocturnal HRV of 2 male soccer players were repeatedly measured 10 times/year at different training sessions using Acti HR4. Results and Conclusion: Having exercise custom or not did not bring significant difference to sleeping parasympathetic nerve activity of young healthy students. HR and HRV Indices, such as %HF, SD1 (= Cross sectional distribution of R-R scatter diagram), reflected athlete's mental and physical condition during stressful training period to some extent. But further research is needed to establish a theory and methodology.

## CHANGING THE PARAMETERS OF VARIABILITY OF THE CARDIORESPIRATORY SYSTEM UNDER THE INFLUENCE OF THE TRAINING LOAD

Romanchuk, A.P.1, Guziy, O.V.2, Petrov, E.P.1, Braslavsky, I.A.3, Perevoshchikov, Y.A.4

1: SUNPU (Odessa, Ukraine), 2: LSUPC (Lviv, Ukraine), 3: ONMU (Odessa, Ukraine), 4: NU OLA (Odessa, Ukraine)

Introduction The adequacy of physical activity in terms of the training process often associated with the assessment of the response of heart rate and metabolic parameters with the calculation of individual indicators oxygen provided in response to exercise. At the same time, other informative criteria associated with the use of instrumental methods are rarely used because of the impossibility of their use in the process of training. Methods To solve this problem, we used express, noninvasive method spiroarteriocardiorhythmography (SACR), which allows simultaneous recording of ECG parameters in I leads, systolic and diastolic blood pressure (photo plethysmographic method) for each heartbeat and spirography and calculating indices of heart rate variability (HRV) systolic (SBPV) and diastolic (DBPV) blood pressure variability and spontaneous breathing variability (SBV) according to two-minute registrations. In previous studies, when examining qualified athletes we have obtained centile distribution of HRV, SBPV, DBPV and SB dormant within 0-5%, 5-25%, 25-75%, 75-95% and 95-100%, which are valued as a marked reduction, moderate decrease, the normal, a moderate increase and pronounced increase in, respectively (Romanchuk A.P.,2014). Results Were examined 32 qualified male athlete involved in water polo at the age of 20,6 ± 3,0 years. The study was conducted using Sacra before and during the first 5 minutes after your workout. It is shown that under the influence of the training load HRV significantly reduced - there is marked reduction of TP (ms2) in 54.8% of cases, VLF (ms2) in 29% of cases, LF (ms2) in 25.8% of cases, HF (ms2) 58%, and a moderate decrease TP (ms2) in 25.8% of cases, VLF (ms2) in 41.9% of cases, LF (ms2) in 32.3% of cases. The ratio of LF/HF is increased moderately in 48.4% of cases. Indicators SBPV and DBPV tend to increase - moderately and pronounced increase TSBP (mm hg.2) and TRDBP (mm hg.2) in 42.0% of cases each, VLF5BP (mm hg.2) in 61.3% of cases, LFSBP (mm hg.2) in 45.2% of cases, the ratio LF/HFDBP in 64.5% of cases. HFDBP (mm hg.2) moderately and pronounced decreases in 48.4% of

cases. Insignificantly changed under the influence of physical activity VLFDBP (mm hg.2), LFDBP (mm hg.2), HFSBP (mm hg.2). Characteristic changes were indicators SB - moderate increase and pronounced increase in TPSB (l/min2) in 71.0% of cases, VLFSB (l / min2) and LFSB (l / min2) in 48.4% of cases, HFSB (l / min2) in 61.3% of cases. Discussion Noteworthy changes dissociation indicators and VLFSBP, VLFDBP, LFSBP and LFDBP, HFSBP and HFDBP that can be used as the basis of differentiation level of functional state of cardiorespiratory system of athletes in the training process.
