def __init__(self):

"""
 Main takeaways from our study.
 """

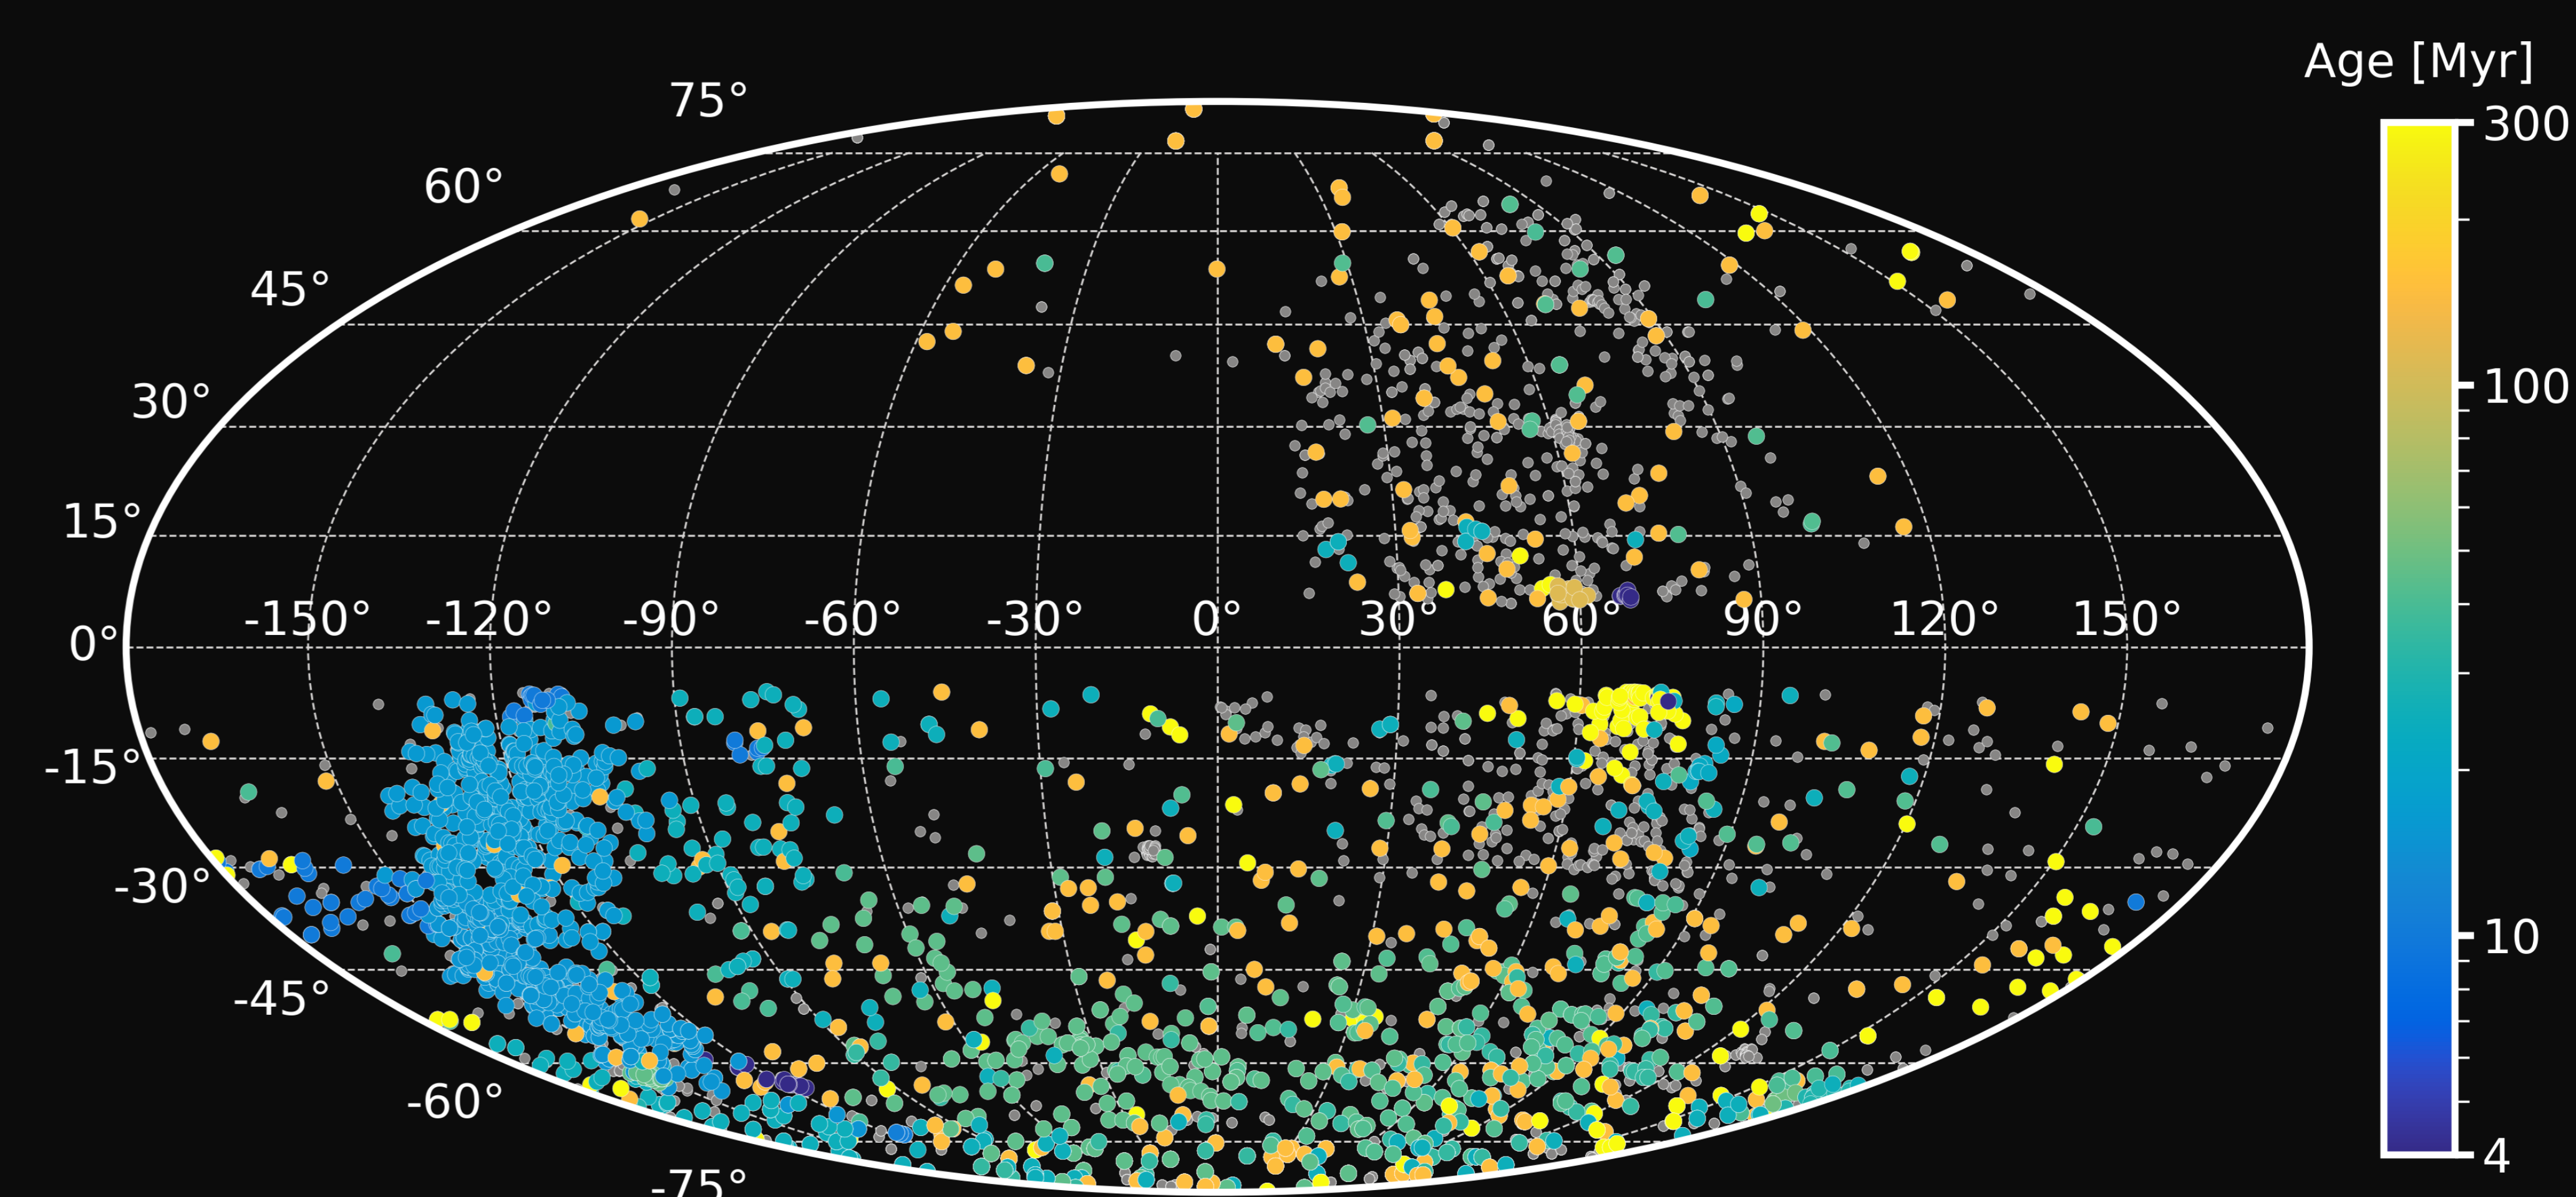

- M dwarfs have consistently high flare rates across the first 800 Myr, while hotter stars have fewer flares over time.
- M dwarfs with $T_{\text{eff}} < 3200$ K have the highest normalized energy flares in the sample.
- We find no dependence between flares and spot phase, suggesting a large, mostly uniform distribution of spots in longitude space.

def methods(self):**import banyan-sigma**

- Young stars were identified through a literature search. The Gaia kinematics were run through banyan-sigma to assign each star to a young moving group, open cluster, OB association, or star forming region.
- Our final sample included **3200 young stars** observed at 2-minute cadence in TESS Sectors 1-19.

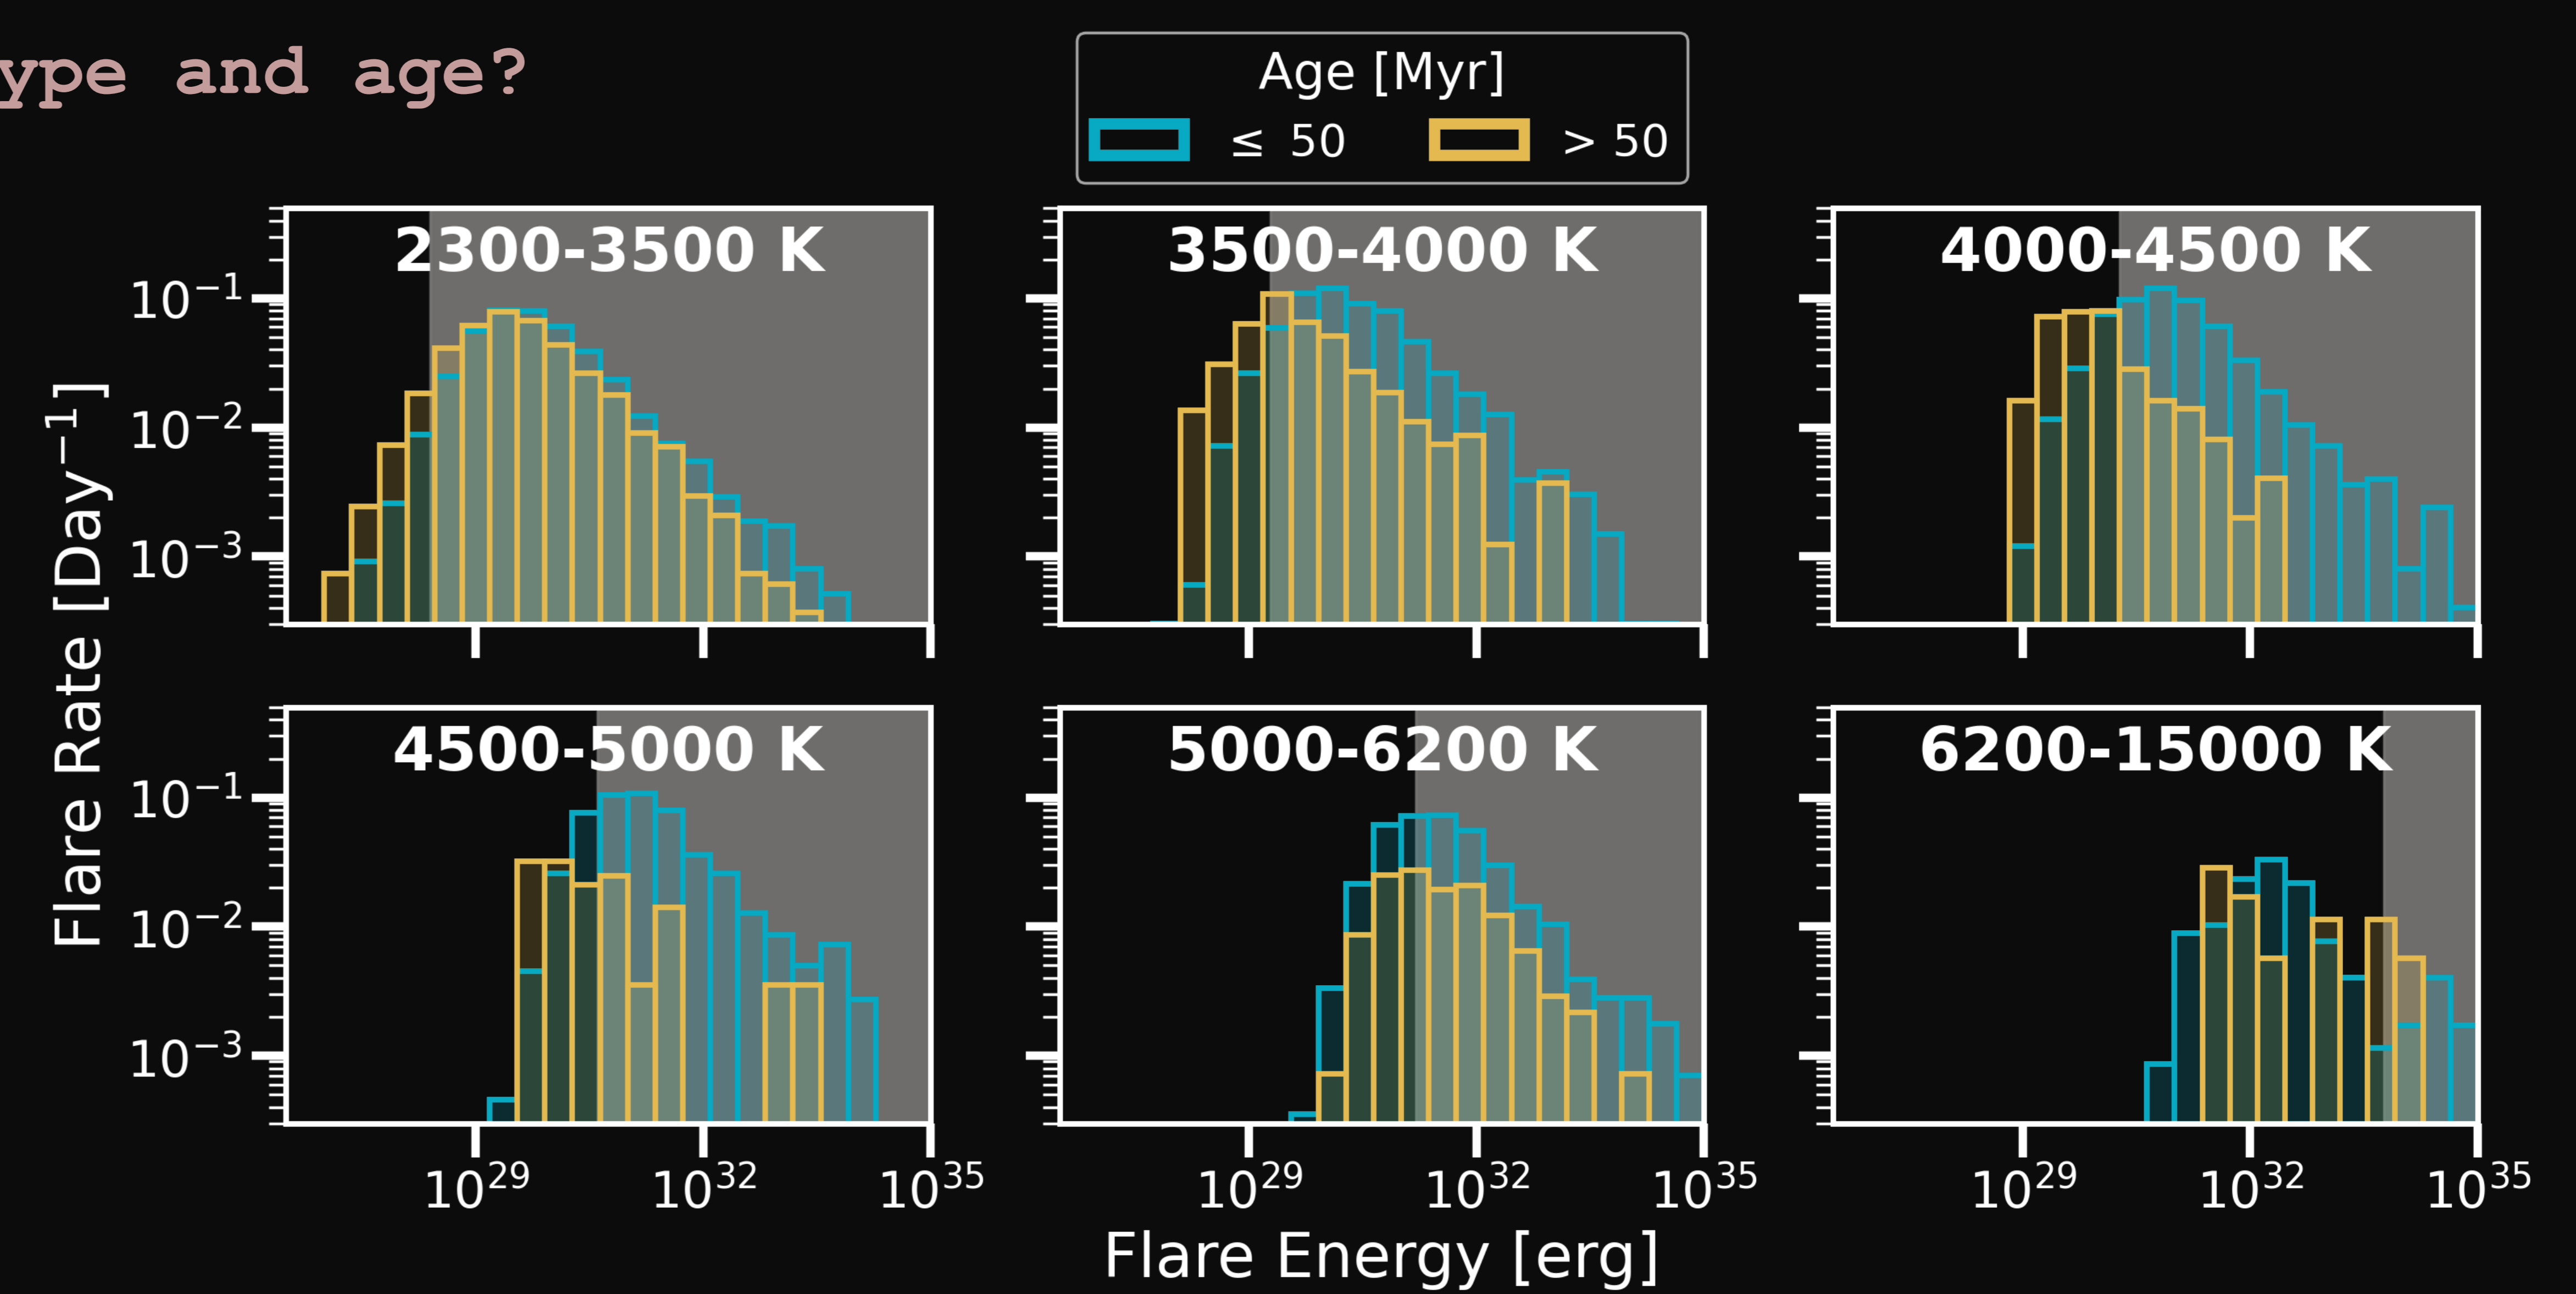

import tensorflow as tf

- To identify flares, we trained a convolutional neural network (CNN), **stella**, on the flare catalog from Gunther+2020.
- With **stella**, we are able to assign a probability that a given cadence is part of a flare. By assigning probabilities, which is traditionally not done in other flare detection techniques, we are able to say something truly statistical about flare rates.

**def flare-rates(self, bin_by='age'):**

"""
 What relationships do we find between flare rate and spectral type and age?
 """

- There is a noticeable drop-off in flare rate and energy as the star's temperature increases. M and late K type stars ($T_{\text{eff}} < 4000$ K) experience similar flare rates and energies across the entire age range of the sample.
- The high-energy flare tail extends out to 10^{35} ergs and is most noticeable for $t_{\text{age}} < 50$ Myr.
- $T_{\text{eff}} > 6200$ K corresponds to the Kraft break and thus a change in internal structure, which may be the cause of such a lack of flares.

The gray shaded region corresponds to the energies at which we expect to be able to detect flares on all stars in that sub-panel.

def rotation-periods(self, relationship=None):

"""
 What relationship do we find between flares and rotation period?
 """

- We were able to measure rotation periods (P_{rot}) for 1500 stars.
- Plotting as a function of Gaia color, we see a noticeable decrease in flare rate at $B_p - R_p = 2$ (which corresponds to $T_{\text{eff}} = 4000$ K).
- Most stars with $B_p - R_p > 2$ do not exhibit any flares, while the cooler stars show a variety of flare rates across all rotation periods.
- There is an artificially induced break at $P_{\text{rot}} > 12$ days, as the result of our rotation period metrics.

"""
 What relationship do we find between flares and spot phase?
 """

- We were able to measure rotation periods (P_{rot}) for 1500 stars.
- There is no preference for where flares occur with respect to phase. Here a phase = 0 is the peak of the rotation modulation (i.e. the less spotted hemisphere).
- These results are consistent with Doyle+(2018, 2019, & 2020).
- These are also consistent with high (> 80%) spot coverages, as seen in Gully-Santiago+2017.
- The result presented here is the largest sample of young stars for which such an analysis has been completed.
