In addition to its direct effects on the water itself, the irrigation with magnetized water shows higher productivity and a positive impact on plants growth (Maheshwari and Grewal, 2009) as well as on seed germination percentage (De Souza *et al.*, 2006) and roots development (Iqbal *et al.*, 2016).

In the current study, we will evaluate the effect of magnetization on some chemical characteristics of natural salt water with different ranges of salinity, then evaluate the productivity of those magnetized water to enhance seed germination.

Material and Methods

The magnetic Treatment Device (MTD) used for this experiment is made of stainless steel with a power of 13.5mT. The water must pass in the direction indicated previously by the manufacturer in order to guarantee its magnetization.
Three different waters with 3.02, 5.83 and 8.65 mS/cm of salinity were used during the experiment. All waters were brought from farms located in the agricultural zone of Menzel Chaker, Sfax, Tunisia.
The experiment took place in the laboratory of Environmental Engineering and EcoTechnology (GEET) at the National School of Engineers of Sfax, Sfax, Tunisia.
In germination test were used seeds of tomato (Rio grande), turnip (turnip guebsi) and corn (commun corn), all bought from a local supplier recognized by the ministry of agriculture and water resources of Tunisia. For each experiment, 100 seeds were used. In each petri dish, we put 3 layers of filter paper, 10 seeds than 5 ml of the water. Seeds were grown in the dark, at constant temperature (25°C) and humidity (100%) for 7 days, at the end of which the germination percentage and the length of roots were determined.
Electrical Conductivity and pH was measured according to the NF T 90-008.
*T*he analyses of the element Ca^{2+} and Mg^{2+} was laid out according to the NF EN ISO 7980. NF T90-005 and those of the Na^{+} and K^{+} were according to the NF T90-020.and the concentration determined by atomic absorption spectrometry.

Results and Discussion

After passing through the magnetic treatment device, we don't observe any significant change on the chemical characteristics of the water (Table 1) for the three ranges of salinity used. The exception concerns the pH and the electrical conductivity values. For all waters, pH value (Fig.1) shows a slight increase that is maintained for 24 hours after the treatment. Whereas, the electrical conductivity (Fig.2) decreased 9%, 2.5% and 1.7% for the magnetized waters in salinity W1, W2 and W3 respectively and the effect was permanent for the same time interval as indicated for the pH. We suggest that the magnetic field don't change the chemical characteristics of water, but work on the physical properties of the water and its molecules arrangement as it was explained by (Toledo et al., 2008).

Table 3. Chemical characteristics of the irrigation water. W1 (3.02mS/cm), W2 (5.83 mS/cm), W3 (8.65mS/cm); NM-non magnetized; M -magnetized.

	W1		W2		W3

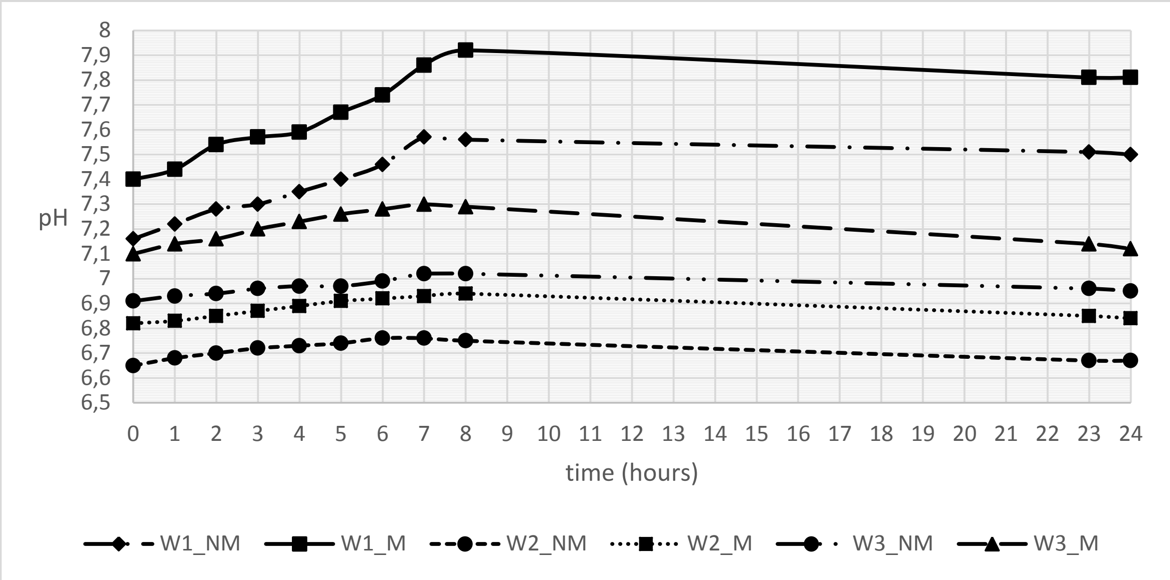

Figure 4. Effect of the magnetic treatment on the water pH

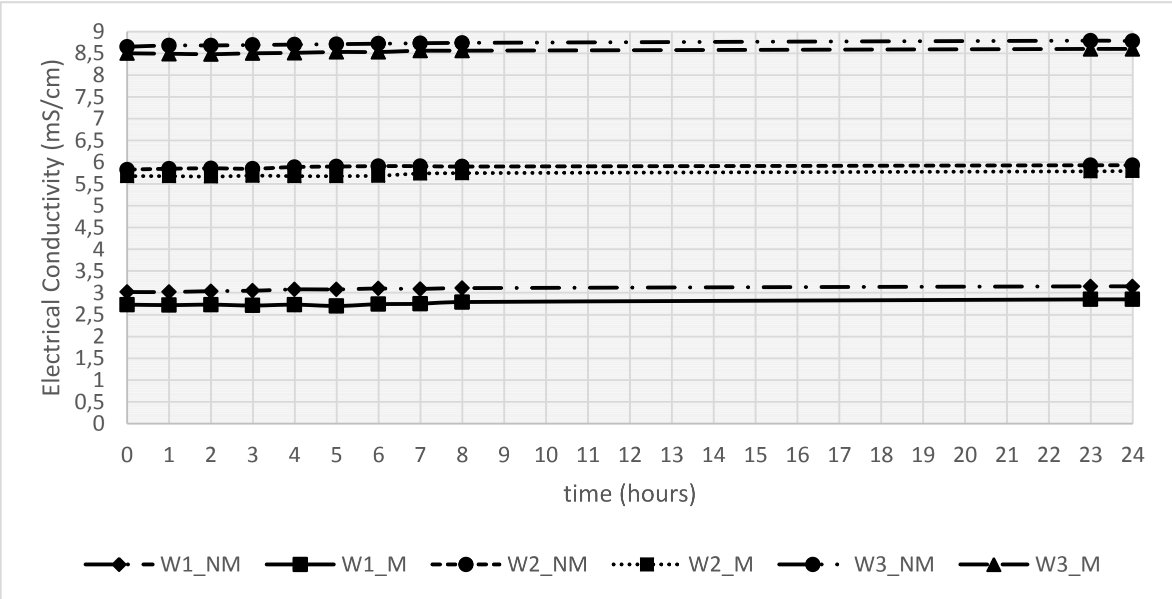

Figure 5. Effect of the magnetic treatment on the electrical conductivity of water

Germination

From Fig.3 is possible to see that salinity did not affect germination of turnip and corn and that magnetized water improved germination in both species. Germination of turnip seeds with magnetized water was increased by 11.6%, 5.7% and 7.1% for salinity W1, W2 and W3 respectively. Turnips are more salt tolerant at germination than at subsequent stages of growth. Francois (1984) found that salinity level of 11.6 dS/m had no effect on final germination percentage. Tomato and corn are moderately sensitive to salinity and tolerance to salt level exists among genotypes (Singh *et al.*, 2012). Tomato was the specie that presented lower values of germination with the salinity. However, for the same salinity level, the magnetization of the water caused increases of 15.1%, 16.7% and 17.9% in the germination percentage. Salinity did not affect germination of maize seeds and, as for the other two species, germination increased by 9.9%, 27.9% and 20.9%, respectively, in W1, W2 and W3 salinities with magnetized water.

	H2O (Ref. test)	W1 NM	W1 M	W2 NM	W2 M	W3 NM	W3 M
Tomato	62	53	61	48	56	39	46
Corn	62	71	78	68	87	67	81
Turnip	81	86	96	88	93	85	91

Figure 6. Effect of three levels of salinity (W1, W2, W3), non-magnetized (NM) and maganetized (M) water on seed germination of tomato, turnip and corn

Roots length

Length of root provides an important clue to the response of plants to salinity. Turnip was the specie that presented longer roots in all saline levels (Fig.4) and with increments of 10.5%, 4% and 5.6% with magnetized water. Growth of tomato roots was affected only in higher salinity (W3-8.65 mS/cm) while corn roots show a decrease in growth from W2 (5.63 mS/cm). In tomato, root length increased by 15.2%, 24.07% and 14.73% and in maize increased by 5.7%, 8.4% and 23.7%, respectively, in W1, W2 and W3 salinities with magnetized water.

	H2O Ref.Test	W1 NM	W1 M	W2 NM	W2 M	W3 NM	W3 M
Corn	55,21	57,04	60,3	41,52	44,99	30,55	37,78
Tomato	51,11	59,18	68,18	54,7	67,87	40,04	45,94
Turnip	61,84	61,62	68,09	87,63	91,16	71,28	75,29

Figure 4. Effect of three levels of salinity (W1, W2, W3), non-magnetized (NM) and maganetized (M) water on root length of tomato, turnip and corn

Conclusions

The results showed that after passing water samples through Magnetic Treatment Device, its pH presented a tend to increase, while the electrical conductivity decreased compared to normal water. Those magnetized salt waters overcome the deleterious effects of salinity and enhanced the germination percentage for the three chosen seeds as well as the length of root. Those results encourage us to conduct more research under greenhouse and in the farms. More investigations shall be done concerning the effect of magnetic field on the physical characteristics of water as well as in other physiological parameters.

Abstract

The aim of the study was to determine of some seed properties and the effect of sulfuric acid pretreatments on the seed coat thickness of *Crataegus microphylla* (C. Koch.), *C. monogyna* (Jacq.), *C. orientalis* (Palas. Ex. Bieb.), *C. pontica* (C. Koch) and *C. pseudoheterophylla* (Pojark.)) seeds. For this purpose, seed weight, size, moisture contents and coat thickness of seeds were considered as seed properties. Ripe fruits of the species were collected from wild plants growing in Artvin province (Turkey) in October 2016. Identification of seed properties and experiments were performed in May 2017. The seed coat thicknesses were measured from the thinnest and thickest part of the seeds. The seeds were kept in sulfuric acid for 1 - 5 hours to determine scarification rates. The diameters and lengths of the seeds were also measured before and after the acid pretreatment. As a result of the study, it was determined that seed properties of *Crataegus* species varied significantly and of acid pretreatment durations affected seed coat thicknesses at different rates. The seed coat thickness of the thinnest part of seed changed between 0.82 (*C. orientalis*) and 1.63 mm (*C. pseudoheterophylla*). Species with the largest seed diameter were *C. pontica* and *C. pseudoheterophylla* (5.81 and 6.56 mm, respectively) and the species with smallest diameter was *C. orientalis* (3.48 mm). While the seed diameters pretreated with one hour sulfuric acid scarified by 4.68%, seed diameters pretreated with five hours sulfuric acid scarified by 10.04%.The most affected seeds by acid scarification belong to *C. orientalis* and the least affected seeds belong to *C. pontica*. It has been also determined that even though *C. orientalis* have the lowest seed weight (8.88 g) and the least seed size (3.47-6.36 mm) among the hawthorn species, it is one of the species which has highest (8.98%) moisture content.

Key words: *Hawthorn seeds, seed weight, seed size, moisture content, coat thickness, sulfuric acid, scarification rate.*

Introduction

Hawthorn trees (*Crataegus* spp.) are tolerated to extreme edaphic and climatic conditions in which they grow. Because of this adaptation, hawthorn trees can be found in even the midst of steppe or high altitude pasture of mountains (Gultekin et al., 2005). In addition, they have important usage areas such as in medicine and pharmacology. Hawthorn trees also provide a major food source not only for humans but also for wildlife due to their nutritional value.

Despite their mentioned importance, seedling production efforts have not been successful because of the difficulties in germination of their seeds. Seed dormancies blocks the germination process despite the presence of favorable environmental conditions, and is one of the factors that negatively affect the growth of the greatest number of high-quality seedlings in the shortest amount of time (Yahyaoglu and Olmez, 2005).

Seed dormancies are classified as external, internal, secondary and combined inhibitors. External germination inhibitors, due to the seed coat, occurs when the seed coat limits or blocks the passage of water and gas (physical), the seed coat mechanically blocks the growth of the embryo (mechanical), or the presence of certain chemicals in the seed coat inhibit germination (chemical). Internal seed dormancy or embryonic seed dormancy occurs when there are inhibiting substances present in the embryo and in the nutritional tissue surrounding the embryo, resulting in an undeveloped embryo when the seed disintegrates or at the time it is picked (Bonner and Vozzo, 1987; Tilki 2005; Guner and Tilki 2009). The aforementioned seed dormancies vary among different varieties and seed sources or within seed sources of a given species as well as seed harvest time and among individuals (Wolf and Kamondo, 1993; Poulsen, 1996).

Warm or cold wet stratification is recommended to eliminate seed dormancy from fruit meat and endosperm. The most commonly used method is to fold the seeds in a humid, low temperature environment in a given period (Genc, M., 2005). Chemical scarification in sulfuric acid is recommended to prevent seed dormancy due to the seed coat.

Seed dormancy resulting from the water scarcity and gas movement through the thick and hard seed coat and the underdevelopment of the embryo (Hartmann et al., 1997; Gokturk and Yilmaz, 2015). As a result, stratification and sulfuric acid scarification methods need to be carried out together for an extended period to eliminate seed dormancy (Yahyaoglu et al., 2006). The length of the sulfuric acid pretreatment period varies due to differences in seed coat thickness among hawthorn species (Lasseigne and Blazich, 2003; St. John, 1982). For example while the species of *C. phaenopyrum* can germinate very easily due to its very thin seed coat (Brinkman, 1974; Dirr and Heuser 1987; Bir,1992; Lasseigne and Blazich, 2003), it is recommended that hawthorn species such as *C. monogyna*, *C. douglassii* with thick seed coats be treated with an acid scarificatioin process for periods ranging from 30 mins to 480 mins prior to other pretreatments (Dirr and Heuser, 1987; Lasseigne and Blazich, 2003).

Crataegus microphylla (C. Koch.), *C. monogyna* (Jacq.), *C. orientalis* (Palas. Ex. Bieb.), *C. pontica* (C. Koch) and *C. pseudoheterophylla* (Pojark.) species have natural distribution in Artvin (Turkey) region (Gokturk et al., 2006).

The objectives of this study are i) determination of some seed properties, ii) determination of sulfuric acid pretreatment effects on seed coat thickness of *Crataegus* species

Materials and methods

In this study, five *Crataegus* species naturally growing in Artvin region, located in the northeastern part of Turkey including *C. microphylla* (C. Koch.), *C. monogyna* (Jacq.), *C. orientalis* (Palas. Ex. Bieb.), *C. pontica* (C. Koch) and *C. pseudoheterophylla* (Pojark.) were sampled to obtain seeds and fruits. Ripe fruits of the species were collected from wild plants in October 2016. The seeds were separated from the fruit material, rinsed in tap water, dried in the shade, and stored at 4±1 ºC in plastic bags. Identification of seed properties and the experiments to determine the scarification rates of seed coat by sulfuric acid were performed at Artvin Coruh University Seed and Afforestation Laboratory in May 2017.

Seed properties including diameter, length, seed weight (100 seeds), moisture content and coat thickness were measured. Digital caliper was used to measure diameter, length and coat thickness of seeds. In order to measure the seed thickness, seeds were pressed in a clamp and then seeds were filed with sandpaper by using honing machine until half of the seed length was reached. A hundred seeds per species were used in this process. After sandpapering process, it was observed that seed thickness was not uniform. Therefore, coat thickness was measured separately at points where the seed coat was the thickest and the thinnest. These measurements were recorded as thick and thin coat thickness.

By determining seeds weight, average weight of 8 samples ($\overline{X}$), each is consisting of 100-seed, was used (ISTA, 1993). 10 seeds with 4-replication were used to determine moisture content of seeds. Seed samples were placed in a dry oven and dried at 105°C for 24 hours

after which they were weighed and recorded. Moisture content was calculated after dry weights of the seeds were measured by the following formula:
MC = ((IW – DW) / IW) x 100, where MC is moisture content, IW is initial weight and DW is dry weight.
30 seeds with 4-replication per species were kept in sulfuric acid for 1 to 5 hours periods to determine the scarification rates. The diameter and the length of seeds were measured both prior to being placed in sulfuric acid and after being removed and rinsed with water. Seed diameter was measured in two directions perpendicular to each other and the average of these measurements was recorded as the diameter value. The following formulas were used to calculate scarification rates of seed diameter (Sd) and length (Sl):

SRD: $(Sd_b – (Sd_b\text{-}Sd_a))*100 / Sd_b$ SRL: $(Sl_b – (Sl_b\text{-}Sl_a))*100 / Sl_b$

where SRD is the scarification rate on seed diameter, SRL is the scarification rate on seed length, Sd_b and Sl_b are root diameter and length before being treated with sulfuric acid, and Sd_a and Sl_a are root diameter and length values after scarification in sulfuric acid.
One-way ANOVA was used to identify the interspecies differences in seed properties and the Duncan test was used to determine which species differed significantly. Multiple ANOVA was used to identify the effect of treatment period and species on scarification rates.

Results and discussion

It was observed significant differences (α <0.05) in the diameter, length, weight, moisture content and coat thickness of seeds among *Crataegus* species. *C. orientalis* had the smallest seed diameter and length as 3.48 mm and 6.37 mm respectively; and *C. pseudoheterophylla* had the largest seed diameter and length as 6.56 mm and 8.38 mm respectively (Table 1).
Interspecific differences in coat thickness found in this study are similar to those found by Lasseigne and Blazich (2003) and St. John (1982). Coat thickness varied not only among species but also within species. In this study, variability of seed coat thickness was observed even on the same seed. *C. orientalis* had the smallest coat thickness (0.82 mm) and *C. pontica* had the greatest coat thickness (1.63 mm) at the thinnest part of the seed coats. *C. orientalis* possessed the smallest seed weight (8.88 g) and the highest moisture content (8.98%) while having the thinnest coat thickness.

Table 1. Seed characteristics of the hawthorn species

Species	Diameter (mm)	Length (mm)	Seed weight (g/100 seeds)	Thin coat (mm)	Thick coat (mm)	Moisture content (%)
C. microphylla	4,87 b*	8,00 c	11,71 b	1,11 c	1,79 a	6,02 a
C. monogyna	5,35 c	7,78 b	13,79 c	1,00 b	2,30 c	8,57 b
C. orientalis	3,48 a	6,37 a	8,88 a	0,82 a	2,12 b	8,98 c
C. pontica	5,81 d	8,26 d	20,09 d	0,90 ab	2,96 e	9,03 c
C. pseudoheterophylla	6,56 e	8,38 d	22,21 e	1,63 d	2,74 d	6,12 a

*The letters in a given column indicate significant differences among species

It was observed that the scarification rates in both the diameter and the length of seeds increased in all species, as the duration in sulfuric acid increased (Figure 1, Table 2). Similar results were also obtained in species-level evaluations. Change in seed diameter due to scarification was the greatest in *C. orientalis* (8.67%) and the smallest in *C. pontica* (5.90%). Change in seed length due to scarification was the greatest in *C. microphylla*, 12.03% and the smallest in *C. pontica,*4.60% (Figure 2).

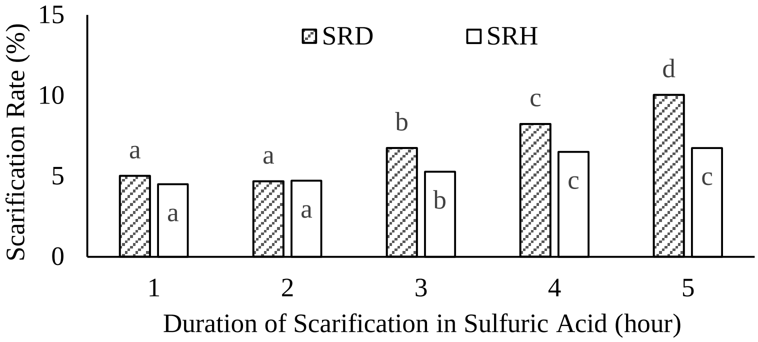

Figure 1. Scarification rates in seed diameter (SRD) and length (SRL) due to duration of scarification in sulfuric acid.

Table 2. Scarification rates in seed diameter and length among species due to duration of scarification in sulfuric acid.

Species	SRD/H (%)	Duration (Hour)									
		1		2		3		4		5	
C. microphylla	SRD	1,36	a*	4,45	b	2,09	a	10,55	c	11,13	c
	SRL	9,57	a	11,25	b	11,97	b	15,81	c	11,53	b
C. monogyna	SRD	6,09	a	6,73	ab	6,29	a	7,29	c	9,01	d
	SRL	6,18	ab	6,02	a	5,96	a	6,80	bc	7,24	c
C. orientalis	SRD	3,32	a	4,23	a	9,60	b	10,20	b	14,94	c
	SRL	3,19	a	4,44	b	5,06	c	5,79	d	6,08	d
C. pontica	SRD	5,29	b	3,57	a	3,83	a	7,92	c	8,62	c
	SRL	2,26	a	2,79	a	4,28	b	6,67	c	6,89	c
C. pseudoheterophylla	SRD	5,52	b	4,19	a	7,51	c	7,48	c	7,68	c
	SRL	5,11	a	5,39	a	5,01	a	5,51	a	6,44	b

*The letters in a given line indicate significant differences among

It was determined that *C. orientalis* had the greatest change in seed diameter due to scarification (8.67%) and the smallest change in seed length due to scarification despite being the species with the smallest thin coat thickness (0.82 mm). The high scarification rate observed in seed diameter of *C. orientalis* may be attributed to its high moisture content (8.98%). However, *C. pontica* had the smallest scarification rate observed both in seed length and diameter despite being the species with the highest moisture content (9.03%). Sulfuric acid may be negatively affecting germination by reacting with the moisture in seed coat and accessing the embryo. Indeed, Gokturk and Yilmaz (2015) and Baba (2017) found that sulfuric acid scarification employed to eliminate seed dormancy from seed coats negatively affected germination. Gokturk and Yilmaz (2015) could not detect germination when sulfuric acid scarification was used in *C. orientalis* and Baba (20117) observed better germination with ash solution treatment compared to sulfuric acid scarification in *C. orientalis* and *C. pontica* species.

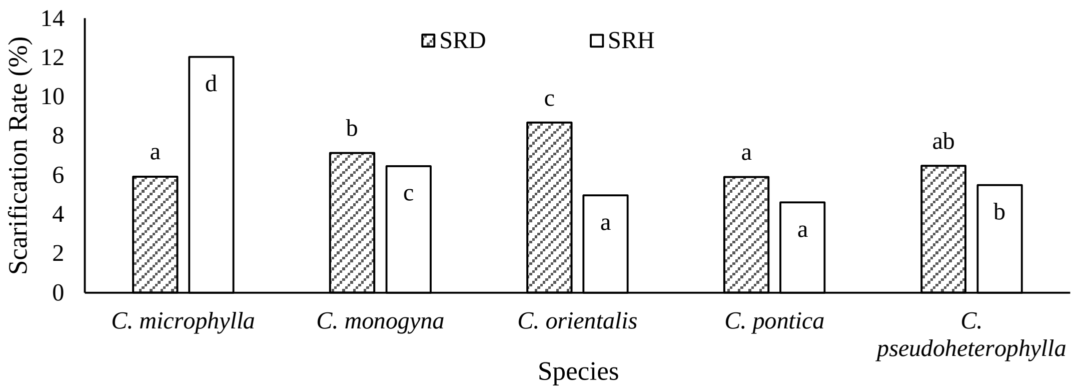

Figure 2. Distribution of scarification rates (measured as changes in seed diameter and length) among species following scarification in sulfuric acid. (Letters denote significant differences among species for SRD and SRL, respectively).

Conclusions and Recommendations

Interspecific differences in terms of seed characteristics and an increase in scarification rate in seed coat with the increase in duration of scarification in sulfuric acid is an expected phenomenon. However, it is especially important to know the differences in seed characteristics and the proportional values of the scarification resulting from varying durations of sulfuric acid scarification and how they differ among species in evaluation of germination studies. The results show that there are significant differences among species in terms of seed characteristics. *C. orientalis* is the species, which has the smallest seed diameter and length and *C. pseudoheterophylla* is the species with the greatest seed diameter and length. *C. orientalis* and *C. pontica* have the smallest thin coat thickness while they have the greatest moisture content.

Scarification rate measured both as change in seed diameter and length increases as the duration of scarification in sulfuric acid increases. The scarification rate associated with seed diameter is greater compared to seed length. *C. orientalis* has the greatest and *C. pontica* has the smallest change in in seed diameter among species. Change in seed length is the smallest in *C. pontica* and *C. orientalis* and the greatest in *C. microphylla*.

The duration of sulfuric acid scarification should be decided based on the coat thickness and moisture content to prevent damage to the seed given the effect of sulfuric acid on the seed. Possible negative effects of long duration sulfuric acid scarification are particularly problematic for species with thin coat thickness and high moisture content.

THE EFFECTS OF SOME SUMMER PRUNING AND HUMIC SUBSTANCE APPLICATIONS ON THE NUTRITIONAL VALUE OF ALPHONSE LAVALLÉE GRAPE CULTIVAR

Aydın AKIN

Selçuk University, Faculty of Agriculture, Department Horticulture, Konya, TURKEY
*Corresponding Author: aakin@selcuk.edu.tr

Abstract

Viticulture is an important agricultural branch in Turkey. Grape is the most grown fruit species in Turkey. The study was conducted Alphonse Lavallée grape variety (*Vitis vinifera* L.) grown on grafted 1103 Paulsen rootstock in Turkey in 2016. In the study, It was investigated effects of Control (C), 1/3 Cluster Tip Reduction (1/3 CTR), Shoot Tip Reduction (STR), Humic Substance Application (HS), 1/3 CTR+STR, 1/3 CTR+HS, STR+HS, 1/3 CTR+STR+HS applications on nutritive values. According to results; the maximum dry matter content 87.64 g/100 g with HS, 87.76 g/100 g with 1/3 CTR+HS, 87.78 with STR+HS and 87.67 with 1/3 CTR+STR+HS applications; the maximum crude protein 3.38 g/100 g with HS and 3.40 g/100 g with STR+HS applications; the maximum crude cellulose 4.46 g/100 g with HS application; the maximum total sugar content 64.64 g/100 g with STR and 64.64 g/100 g with HS applications were obtained. No statistically significant difference was found in terms of crude ash content.

Keywords: *Alphonse Lavallée grape cultivar, 1/3 cluster tip reduction, shoot tip reduction, TKI-humas application, nutritive values.*

Introduction

Turkey is among the most important viticulture countries in the world. Viticulture is a source of livelihood for a significant number of producers. It was produced 74 million tons from 7 million hectares in the World (Anonymous 2017). 4.000.000 tons grape from 435.227 hectares was produced vineyard in Turkey (Anonymous 2016). Humic acid in nutrition of the plants plays an important role directly and indirectly (Lobartini et al. 1997). In the full bloom period of humic acid application, berry weight, titratable acidity and maturity index values of Italy grape cultivar increased significantly (Ferrara and Brunetti 2010). Reducing cluster number application in Amasya and Cardinal grape cultivars decreased the amount of titratable acid and fresh grape yield per vine, while it increased maturity index value (Dardeniz and Kısmalı 2002). 1/3 Cluster Reduction + Humic Substance application was increased grape yield, berry weight values of Horoz Karası grape variety. 1/3 Cluster Reduction application was increased grape yield and maturity index values of Gök grape variety (Akın 2011a). The highest grape yield was obtained in 1/3 cluster tip reduction + herbagreen in Müşküle table grape variety (Akın 2011b). The highest fresh grape yield with 5.48 kg/vine was obtained with HA application in Kabarcık (*Vitis vinifera* L.) grape cultivar (Akın and Alağöz 2016).
İlter and Altındişli (2007) was reported that 100 g of raisins contained 275 kcal, 2.7 g protein, 0.4 g oil, 69.4 mg carbohydrate, 64 mg Ca, 2.2 mg Fe, 86 mg P, 1060 mg K, 19 mg Na, 12 µg carotene, 0.70 µg vitamin E, 0.25 mg vitamin B6, 0.05 mg Riboflavin, 0.8 mg Niacin, 27 µg Folate, 4.8 µg Biotin. Altındişli (2003) was put forward that raisin is accepted as a high-calorie and quick source of energy; it attracts attention with its sustainable energy content and positive effects on health. Raisin is a very good source of inulin. İlter and Altındişli (2007)

was reported that there can be 3.63 grams of inulin in 100 grams; with its prebiotic characteristic, it has positive effects on cholesterol, immunity and intestinal health and digestible fiber has positive effects on intestines and digestion. Raisins are valued for their medicinal and nutraceutical properties. They are widely used and are popular as a good source of potassium, magnesium and fiber (Dev *et al*., 2008). Raisins eliminate bad breath and they are good for lung diseases, bad mood, forgetfulness, anemia, liver vulnerability and hoarseness. A lot of grapes should be eaten to get rid of leprosy (Subaşı and Bostan, 2011). Nutritional values of raisin gained by drying Gök grape variety in the sun and in the shade are compared. According to the data collected, in the grapes dried in the sun, the amount of dry matter, crude ash, crude oil, crude fiber, total sugar, phosphorus, and magnesium, and in those dried in the shade the amount of crude protein, sodium, selenium were found to be relatively high in the statistical sense. The differences between these two drying methods in terms of potassium, calcium, iron, zinc, copper and boron and energy values were found to be statistically insignificant (Akın et al. 2011).
The purpose of this study was to identify the effects on the nutritional value of some summer pruning and humic substance applications of Alphonse Lavallée grape cultivar.

Materials and Methods

This study was conducted in the viticulture of Selçuk University in Konya, Turkey in 2016. Alphonse Lavallée grape cultivar is evaluated as table grape and grafted 1103 Paulsen rootstock. Yield and development is a good standard grape variety, matures in the middle of the season, big and long cluster, big and round berry, black-blue colour and suitable for short pruning.
Experimental design; 1) Control (C), 2) 1/3 Cluster Tip Reduction (1/3 CTR), 3) Shoot Tip Reduction (STR), 4) Humic Substance (HS), 5) 1/3 CTR+STR, 6) 1/3 STR+HS, 7) STR+HS, 8) 1/3 CTR+STR+HS.
Effects on nutritive values of this application in the cultivar Alphonse Lavallée grape were determined. This study were used 63 vines of Alphonse Lavallée grape variety. The maturing grapes were harvested and the necessary measurement and analysis procedures were carried out according to the following criteria.
1/3 Cluster Tip Reduction (1/3 CTR): The 1/3 cluster tip reduction (berry thinning) was applied by cutting the tips of the cluster at the point of one third of the cluster length, while the 1/3 cluster reduction of all clusters outside the control in the berry set period was conducted.
Shoot Tip Reduction (STR): From 40 to 45 cm long and 10 cm from the ends of the shoots located on the cluster part is amputated.
TKI-Humas Composition: TKI-Humas; leonardit produced from low-quality lignite, containing 12% humic and fulvic acid is a liquid natural organic soil conditioner (Gezgin 2013). Total Organic Matter: 5%; Humic Acid + Fulvic Acid: 12%; Water Soluble Potassium Oxide (K_2O-3%), PH: 11-13.
Implementation of TKI-Humas on Soil: 333 ml TKI-Humas/5 lt water for each vine was applied. Applications were made in the evening near the cool hours.
1. TKI-Humas was applied to soil before bud burst,
2. TKI-Humas was applied to soil before blooming.

Fresh grapes taken from Alphonse Lavallée grape cultivar vineyards that belonged to farmers were dried at three intervals with 10 kilograms each in the sun. Samples from the raisins were taken for analyses which were done immediately.
Dry matter analysis: The tare of the dry mass container, which is put into desiccator after being kept in a drying-oven of Binder brand at 105 °C for an hour, is taken. (a) 2-2.5 grams of

mashed dried grape is placed in the container (b) it is kept at 105 °C in drying cabinet for 8 hours and taken to desiccator. It is weighed after it cools down. (c) By using the formula dry mass= c-a x 100/sample amount, dry mass was calculated. Results were given as g/100 g.

Crude protein analysis: Kjeldahl apparatus of Behr brand was used for the analysis. The apparatus is switched on and left for 15 minutes to make it ready. 1-1.5 g mashed raisin sample is weighed and put into Kjeldahl tube; 1 gram catalyzer is added in it and 20 ml dense H_2SO_4 is added. It is kept in the incineration unit until it becomes light yellow or green. 80 ml 3-percent boric acid is put into an erlenmayer with a capacity of 300 ml; 2-3 drops of methyl rot is added; the color changes into pink. The Kjeldahl tube with burned sample, and the erlenmayer with boric acid are placed in the distillation unit. 100 ml pure water is poured into the tube, 33-percent 100 ml NaOH added. Te ammonia formed in the tube is retained by boric acid. The color changes into yellow; then, by using N/7 H2SO4, titration is carried out until the color changes into pink. The results are given as g/100 g.

Crude ash analysis: Burning the organic parts of the sample at 550 ^oC and considering the remaining parts as crude ash. The tare of the ash container, which was placed into desiccator after being kept for an hour, was taken (a) 1-1.5 g sample is weighed and put into it (b) the sample is kept in the ash furnace of Proderm brand at 550 ^oC for 6-8 hours, and it is taken to desiccator. It is weighed after it cools down (c) Dry matter is calculated by using the formula dry matter= (c-a) x 100/the amount of sample. The results are given as g/100 g.

Crude cellulose (fiber) analysis: According to Van Soest et al. (1991), cellulose analysis apparatus of Velp brand was used to carry out analysis. The results are given as g/100 g.

Total sugar analysis: 50 grams of grapes from the samples brought to the laboratory were kept in the drying cabinet for five days until it reached its constant zero humidity. 25 grams of grapes taken from the samples were mashed and 50 ml of water at 90 °C was poured into it. After it was blended in a mixer with heater for 4 hours at 45 °C, it was mashed and filtered through filter paper. The value was determined by taking several drops of filtered matter and reading it with the help of hand-size refractometer apparatus (Atago RX 7000 Alpha) at 20 °C. The results are given as g/100 g.

The research was planned in a completely randomized block design as a simple factorial experiment, and variance analyses and multiple comparison tests were done by JMP statistical package program (version 7.0; SAS Institute, Cary, NC, USA).

Results and discussion

Dry matter, crude protein, crude ash, crude fiber and total sugar were affected differently from applications. The results of nutritional value analyses were given in Table 1.

Table 1. Nutritional values of Alphonse Lavallée raisin (g/100 g)

Applications	Dry matter	Crude protein	Crude ash	Crude fiber	Total sugar
Control	86.64 b	3.33 ab	4.75	4.41 ab	64.59 ab
1/3 CTR	86.63 b	3.34 ab	4.73	4.40 abc	64.54 ab

LSD 5%	0.96	0.13	N.S.	0.13	0.18

N.S.: No significant

According to findings, dry matter content of the raisin was found to be statistically significant (Tab. 1). The maximum dry matter content was determined 87.64 g/100 g with HS, 87.67 g/100 g with 1/3 CTR+STR+HS, 87.76 g/100 g with 1/3 CTR+HS and 87.78 g/100 g with STR+HS applications. The minimum dry matter content was found 86.47 g/100 g with 1/3 CTR+STR, 86.63 g/100 g with 1/3 CTR and 86.64 g/100 g with C applications. In the smilar studies, 83.68 g/100 g dry matter in Ekşi Kara raisin and 83.31 g/100 g dry matter in Kara Dimrit raisin (Akın et al. 2011) were found.

Crude protein content was statistically significant (Tab. 1). The maximum crude protein content was determined 3.38 g/100 g with HS and 3.40 g/100 g with STR+HS applications. The minimum crude protein content was found 3.23 g/100 g with 1/3 CTR+STR and 3.24 g/100 g with 1/3 CTR+HS applications. In the smilar studies, Crude protein content was 2.89 g/100 g in Kara Dimrit raisin and 2.31 g/100 g in Ekşi Kara raisin (Akın et al. 2011). 2.7 g/100 g was determined in Sultani Seedless raisin (İlter and Altındişli 2007).

Crude fiber content was found to be statistically significant (Tab. 1). The maximum crude fiber content was determined 4.46 g/100 g with HS application. The minimum crude fiber content was found 4.28 g/100 g with STR application. In the similar studies, 2 g/100 g crude fiber was reported in Sultani Seedless raisin (İlter and Altındişli 2007). 18.42 g/100 g crude fiber in Kara Dimrit raisin and 14.92 g/100 g in Ekşi Kara raisin was determined (Akın et al. 2011).

Total sugar contents were found to be statistically significant (Tab. 1). The maximum total sugar content was determined 64.65 g/100 g with STR and 64.65 g/100 g with HS applications. The minimum total sugar content was found 64.45 g/100 g with STR+HS application. In similar studies, it was determined 69.4 g/100 g total sugar in Sultani Seedless (İlter and Altındişli 2007). 73.60 g/100 g total sugar content in Kara Dimrit raisin and 74.51 g/100 g in Ekşi Kara raisin was determined (Akın et al. 2011).

As a result, Alphonse Lavallée raisin has a important food source in terms of dry matter, crude protein, crude cellulose and total sugar content. It is played an important role for more conscious consumer with determining of the nutritional values of Alphonse Lavallée raisin. Crude ash content was not effected statistically from applications. It can be advise to increase dry matter content with HS, with 1/3 CTR+HS, with STR+HS and with 1/3 CTR+STR+HS applications; to crude protein content with HS and with STR+HS applications; to crude cellulose content with HS application; to total sugar content with STR and with HS applications.

DETERMINATION THE EFFECTS OF NITROGEN DOSES ON HAY YIELD AND QUALITY CHARACTERISTICS OF SOME OAT CULTIVARS/LINES

Celal BAYRAM*, İlknur AYAN

Ondokuz Mayis University, Agricultural Faculty, Department of Agronomy, Samsun, Turkey
*Corresponding author: byrm.celal@gmail.com

Abstract

In order to healthy ruminant feeding, they must eat high quality forage and at least half of feed should consist of forage. Though oat commonly use food and feed in the world, our country main usage area of oat is feeding as forage and kernel. The climatic characteristics of Samsun are very suitable for oat requirements. The aim of this study is to determine the effects of 5 different doses of nitrogen, on hay yield and mineral matter content of 2 oat varieties and 1 oat cultivars/lines. The experiment was established according to split plots design with 3 replicates in 11 November 2016. Harvest was made when oat become dough stage. During harvest 500 g sample was taken for each plot and dried in an oven at 60 ^{o}C temperature until constant weight. Then these samples grounded and analysed protein, ADF, NDF and mineral contents. The effect of applied nitrogen doses on hay yield was very significant and dry hay yield changed between 5589.68 – 20237.69 kgha^{-1}. The highest leaf ratio was determined to Line 38 (37.55%). Results obtained for Ca concentration in this study were more than these recommended values. Mg concentration of genotypes were ranged from 0.07% to 0.13%. This study showed that N doses had great effect on hay yield, crude protein, ADF and NDF content of oat cultivars and line. N15 and/or N20 doses can be recommended in similar ecological conditions regarding the genotype.

Keywords: *Oat, nitrogen dose, hay yield; mineral content*

Introduction

In order to healthy ruminant feeding, they must eat high quality forage and at least half of feed should consist of forage. Small grain cereal forage are greatly adjusted highly multi-purpose forages used for pasture, green chop, silage and hay (Fohner, 2002). Though oat commonly use food and feed in the world, our country main usage area of oat is feeding as forage and kernel. Climatic conditions of Samsun province is very suitable for oat. The proof of this fact that there are a huge variation of local oat population or ecotypes in Samsun (Kün, 1983). Oat (Avena sativa L.) is used extensively as feed for livestock because of its high quality as well as its high-forage yield (Moreira, 1989; Zhang et al., 1998). Oat would be very important crop in this region because of its really good adaptation, higher yield, nutritious and palatable for ruminants (Aydin *et al*., 2010). Oat can be grown as a catch crop from October to May without any time limitation for summer main crops. Yield potential and response of nitrogen fertilizer of oat is higher than the other cool season cereals. Additionally, it is possible to obtain high quality silage from oat forage (Hartman, 2000; Frazer and Mc Cartney, 2004). The aim of this study is to determine the effects of 5 different doses of nitrogen, on hay yield and mineral matter content of 2 oat varieties and 1 oat cultivars/lines.

Materials and methods

This study was conducted to determine the effects of 5 N doses (0, 5, 10, 15 and 20 kg da^{-1}) on hay yield and mineral contents of 2 oat cultivars (Kahraman and Faikbey) and 1 oat lines in Agricultural Research Center of Ondokuz Mayis University. In experiment oat seeded with 20 cm row spacing and each plot was consist of 6 rows. Consider soil sample analysis, 8 kg/da P_2O_5 was applied the whole experiment area. The half of N doses were applied with seeding, the other part was given when the plants started active growing in spring. Experiment was not irrigated. The experiment was established according to split plots design with 3 replicates in 11 November 2016. Maturity at harvest was determined using Zadoks's scale (Zadok et al., 1974). Harvest was done at late milk dough (Zadok scale 77). During harvest 500 g sample was taken for each plot and dried in an oven at 60 ^oC temperature until constant weight. Then these samples grounded and analysed protein, ADF, NDF and mineral contents. Analyses of grinded samples were performed in Foss NIRSystems (Hoy *et al*., 2002) Model 6500 Win ISI II v1.5 device by using IC-0904FE calibration program. Resultant data were subjected to statistical analyses according to split plot design. Differences in means were tested with Duncan's multiple range test.

Results and discussion

Significant differences were determined amongst the genotypes and N doses in the point of hay yield. While the highest hay yield was obtained from Faikbey cultivar (14271 kg ha^{-1}) as an average of N doses, two others genotypes were in the same statistical group. Regard the mean of genotypes, the highest hay yield was determined to N20, N15 and N10 doses (14248, 13821 and 13214 kg ha^{-1}, respectively). The lowest hay yield was 6426 kg ha^{-1}, obtained from N0 dose (Table 1). In previous studies carried out similar ecological conditions, oat hay yields were ranged between 12.1 – 12.9 t ha^{-1} (Aydın *et al*., 2010; Mut *et al.*, 2006).
The responses of genotypes to N doses were different. While hay yield of the cultivar Faikbey linearly increased parallel to N dose increase, hay yields of the other genotypes increased until N15 dose and then decreased (Table 1 and Figure 1). The highest leaf ratio was determined to Line 38 (37.55%). Even though leaf ratios slightly increased parallel to N dose increase, there were not significant differences (Table 1).
Protein content is an important feed factor, with high quality feed having high protein content. The chemical composition and nutritive value of green plant material can give useful information about the forage quality (Kjos, 1990). In terms of protein concentration there were no differences amongst the genotypes, but differences amongst the N doses were significant. Though increasing N doses increased protein content of genotypes, only N20 dose was in different and the highest group (Table 1). The results were consistent with the findings of Ericson *et al.* (1977), Kim *et al*. (2006) and Aydın *et al*.(2010).
Plant cell walls, containing a digestible and an indigestible fraction are an important element fixing forage quality. ADF (acid detergent fiber) and full denomination NDF contents in forages. Important quality characteristics for forages are the concentrations of ADF and NDF (Caballero *et al.,* 1995; Assefa and Ledin, 2001). In this experiment while differences amongst the genotypes were significant, there were no differences amongst the N doses considering the ADF and NDF values. The highest ADF and NDF ratios were obtained from Faikbey cultivar (34.1 and 56.83%, respectively) (Table 1). The effects of N doses on ADF and NDF ratios did not exactly unveil, because the whole plants harvested the same growing stage (Zadok Scale 77). The results were consistent with the findings of Kim *et al.* (2006) and Aydın *et al.(*2010).

*There was not significant differences amongst to figure shown the same letter in the same line or column ($P<0.05$)

There were significant differences amongst cultivars/line regarding their mineral content. The effects of N doses on mineral concentration of genotypes were found not to be significant. Differences in Ca contents were significant between cultivars/line. While the highest Ca ratio

determined in Faikbey cultivar (0.45%), there were no differences Kahraman cultivar and Line 38 (0.39 and 0.38%, respectively). Even if could not found statistical differences, in general, increasing N doses increased Ca concentration. Tajeda *et al.* (1985) reported that forage crops should contain at least 0.3% of Ca for ruminants. The American National Research Council (NRC, 1984) recommended that forage crops should contain 3.1 g kg Ca concentration for beef cattle. Results obtained for Ca concentration in this study were more than these recommended values (Table 1).
Differences in K contents of cultivars/line were significant. The highest K concentration was determined in Line 38 and Kahraman cultivar (respectively 2.14 and 2.0%). These results were higher than suggested values of 0.85% by Tajeda *et al*. (1985). But high K concentration may cause Mg deficiency (Loreda *et al*., 1986).

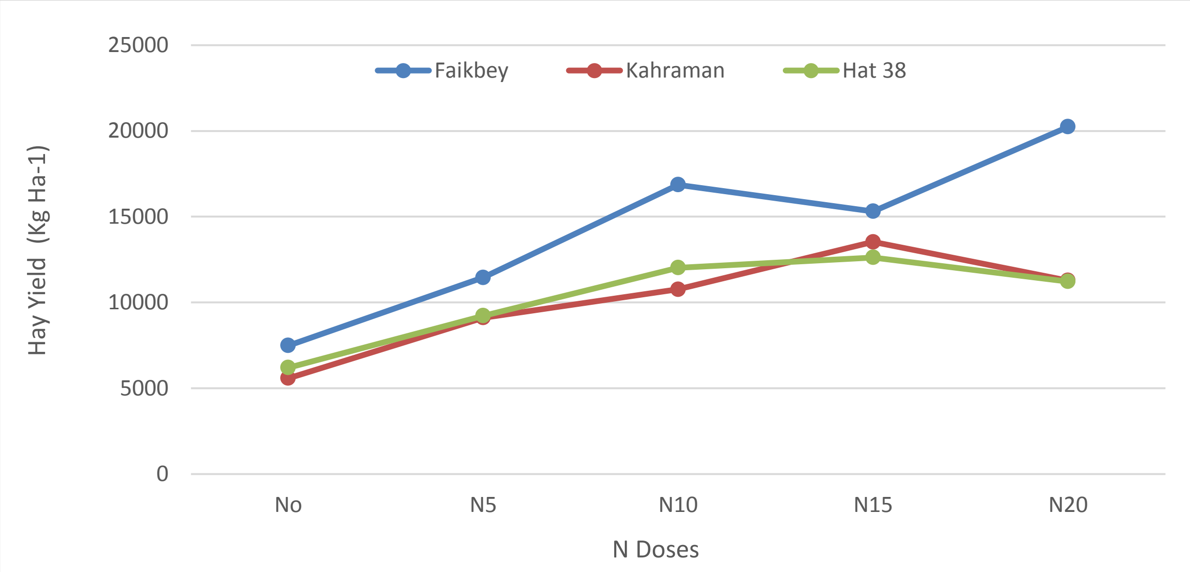

Figure 1. Hay yields of oat genotypes according to N doses

Mg content was higher in Kahraman cultivar and Line 38 than in Faikbey cultivar and this difference was statistically significant. Mg concentration of genotypes were ranged from 0.07% to 0.13% (Table 1). Mg concentrations for forage crops are recommended as 0.2% for ruminants by Tajeda *et al*. (1985) and 1 g kg for beef cattle by the NRC (1984). Grass tetany or hypomagnesemic tetany in cattle is caused by an imbalance of K, Ca and Mg in the diet. Mineral imbalances, deficiencies or excess and low bio-availability of essential minerals result in negative economic impacts when animal performance and health are compromised (Van Soest, 1982). Magnesium deficiency may lead to a reduction in weight gain, milk production and conception rate (Stuedemann *et al.*, 1983). P contents of genotypes were altered between 0.29% and 0.35%. While the highest P concentration was determined in Kahraman cultivar (0.34%), the lowest one obtained from Faikbey cultivar (0.29%) (Table 1). Results obtained for P concentration in this study were adequate for ruminants (National Research Council, 2001).

Conclusion

This study showed that N doses had great effect on hay yield, crude protein, ADF and NDF content of oat cultivars and line. N15 and/or N20 doses can be recommended in similar ecological conditions regarding the genotype. But, to clear the recommendation this type study should carry out at least 2 year.

Abstract

This study was carried out to determine relationships between physiological characteristics and yield of some maize varieties. The research was laid out as randomized complete block design with four replications in 2015 maize growing season. Six grain maize varieties which have different properties (PR31D24, Kalipso, 70MAY82, Suerto, P1921, DKC6724) were used as material. According to the obtained results, there were significant differences among varieties in terms of pre-flowering, flowering, post-flowering period's chlorophyll contents (SPAD readings), leaf area index (LAI) and stomatal conductance. The P1921 variety had highest yield by 15181.0 kg ha^{-1}. The correlation analysis showed that there were significant and positive correlations among grain yield and flowering period's chlorophyll content. It was determined that there were interrelations between physiological and morphological parameters and these interrelations affects grain yield; in addition, the results indicated that chlorophyll content can be used as selection criteria in maize breeding programs.

Key words: *Adaptation, physiology, maize, quality, yield*

Introduction

Maize is annual plant that belongs to *Poaceae* family. Its grain contains 70% starch, 20% protein, 5% oil, 2% sugar, 2% ash, vitamin A and pentosanes. Maize not only used for human and animal foods but also it used in industrial area as raw material for producing alcohol, oil, semolina *etc*. In the World's cereals production it takes place on the top with 183 million hectares planting area, 1.021 million tons production and 50.2 kg ha^{-1} average yield (Anonymous, 2014).

Maize must be produced as sufficient amounts and quality for meeting the needs of agricultural industries. The main researches must be focused on selecting suitable varieties for ecological conditions and resistant to the environmental factors, using quality seeds and generalizing planting hybrid seeds for increasing production. High temperature, water deficiency, freezing, pollution, drought and salt stress may decrease yield by negatively effects physiological structure of plant. Environmental factors such as drought, heat temperature *etc.* the most yield limiting in the maize. It was reported that at flowering stages occurring drought stress leads to yield decreasing (Chimenti *et al*., 2006; Saini and Westgage, 2000). Therefore, for increasing yield and quality determining the physiological basis of resistance of environmental factors is most important research areas. The results of such researches will help to develop new varieties in breeding programs.

The significant improvement has been made in yield potential by plant breeding. The successful of breeding depend on association between breeder and plant physiologists (Jackson *et al.,* 1996). The recent researches indicated that physiological parameters such as stomatal conductance, photosynthesis rate, cell membrane thermostability, plant canopy temperature and chlorophyll content can be used as selection criteria for yield (Fisher *et al.*, 1998; Amthor, 2001; Bavec and Bavec, 2001; Reynolds *et al.*, 2001; Soltani and Galeshi, 2002; Koç *et al*., 2003; Yıldırım *et al*. 2009).

At early development stages, if leaf area index is changed the leaf photosynthesis rate can be increased by increasing daily light used by plant and this cause high yielding (Lopez-Castaneda and Richards, 1994; Hafid *et al*., 1998). Plant photosynthesis and biomass production is closely related with ability of taking light by leaves (Muchow *et al*., 1990). Determination of leaf area where transpiration and production taken place is significant in terms of yield (Saeed and El-Nadi, 1998). Plant canopy temperature which associated with photosynthesis, stomatal conductance, water transmission etc. is significant selection criterion (Rashid *et al*., 1999). Chlorophyll content and canopy temperature is important criteria for developing high content and cooler ability varieties (Babar *et al*., 2006).

This study was carried out to determine relationships between physiological characteristics and yield of some maize varieties.

Material and Methods

The experiment was carried out at the GAP International Agricultural Research and Training Center's experimental area during 2015 growing seasons in Diyarbakir, Turkey.

In the study 6 maize varieties were used as material. The experiment was laid out as randomized complete block design (RCBD) with four replications. Each plot consisted of four rows of 5 m length, between and within the row spacing were 0.70 m and 0.20 m respectively. Seeds were planted with combine drilling machine on 27th April, 2015 and all plots were treated with 20-20-0 composite fertilizer to provide 100 kg ha^{-1} N and 100 kg ha^{-1} P_2O_5. Just before the flowering, 100 kg ha^{-1} N was applied as ammonium nitrate to the trial as an additional N source. Experimental plots were irrigated for the first time as sprinkler irrigation, the other irrigation was realized as furrow irrigation and repeated nine times at ten to twelve-days interval. Plots were harvested by hand and the harvests from the middle two rows of the plots were weighed and calculated for grain yield. The harvest was done on 29th of September. Statistical analysis were performed using JMP 5.0.1 statistical software (http://www.jmp.com) and the means were grouped with LSD $_{(0.05)}$ test. In the study chlorophyll content (SPAD values), leaf area index, stomatal conductance, plant canopy temperature and grain yield were observed.

Chlorophyll content (SPAD values): Observation was taken from randomly selected ten plants between 11^{00}a.m - 15^{00}p.m. at three different growing stage as pre-flowering, flowering and post-flowering by Minolta SPAD 502 chlorophyll meter.

Leaf area index (LAI): The observation was taken from each plots by LAI-2200 (LI-COR) Plant canopy analyzer.

Canopy Temperature: The observation was taken from each plots between 11^{00}a.m - 15^{00}p.m. by portable infrared thermometer (DT-8811H) according to methods of Reynolds et al, 2001.

Stomatal conductance: Observation was taken from randomly selected ten plants between 11^{00}a.m - 15^{00}p.m. by leaf porometer (Model SC-1).

Results and Discussion

The analysis of variance of the investigated characteristics and the findings from the maize varieties are presented in Table 1 and Table 2.
The differences between varieties with respect to chlorophyll content were highly significant in terms of pre-flowering and flowering periods ($p<0.01$), the difference for post-flowering period was significant at ($p<0.01$) level (Table 1).

Table 1. Mean of Chlorophyll Content

Variety	Chlorophyll Content (SPAD)		
	Pre Flowering Chlorophyll Content (SPAD values)	Flowering Chlorophyll Content (SPAD values)	Post Flowering Chlorophyll Content (SPAD values)
PR31D24	45.05 b	49.70 c	51.03 c
SUERTO	39.45 d	49.30 c	53.05 bc
70MAY82	43.65 bc	53.38bc	56.05 ab
KALİPSO	50.88 a	55.95ab	57.80 a
P1921	47.13ab	58.08 a	56.25 ab
DKC6724	40.65 cd	52.53bc	53.45 bc
MEAN	44.47	53.15	54.60
$LSD_{(0,05)}$	3.9^{**}	4.20^{**}	4.22^{*}
CV(%)	5.82	5.24	5.13

* The difference between the averages indicated by the same letter does not matter at 0.05
** The difference between the averages indicated by the same letter does not matter at 0.01

From Table 1, it can be seen that the means of pre flowering period's chlorophyll contents changed from 39.45 to 50.88; Kalipso variety had highest chlorophyll content (50.88), while Suerto variety had lowest (39.45). The means of pre flowering chlorophyll contents was 44.47. Previous researchers found that significant differences in terms of pre flowering chlorophyll contents Akarken and Taş (2014), Erdal (2014).
The means of flowering period's chlorophyll contents changed from 49.30 to 58.08; P.1921 variety had highest chlorophyll content (58.08), while Suerto variety had lowest (49.30). The means of flowering chlorophyll contents was 53.15. P.1921 and Kalipso varieties had highest values and shared the same statistical group (Table 1). The results of the study in terms of flowering period's chlorophyll content was coincide with that of Akarken and Taş (2014), Erdal (2014). In terms of post-flowering chlorophyll contents, the means changed from 51.03 to 57.80; Kalipso variety had the highest value (57.80), while PR31D24 variety had the lowest value (51.03). The means of varieties were 54.60. KALİPSO, P.1921 and 70MAY82 varieties had highest values and shared the same statistical groups. The significant differences at post-flowering period were reported by Akarken and Taş (2014), Erdal (2014), Reynolds *et al*., (1994).
When comparing the three periods, the results showed that chlorophyll content increased from pre flowering periods to post flowering periods for all varieties except P.1921. The highest values were obtained from post-flowering period, only P.1921 variety showed high value at flowering period. The correlation analysis showed that there were significant and positive correlations among grain yield and flowering period's chlorophyll content. This result coincide with results of Karademir *et al*.,(2009) who reported that direct positive effect of chlorophyll content on yield.
From Table 2 it can be seen that the means of leaf area index changed from 1.77 to 3.35; 70 MAY 82 variety had highest chlorophyll content (3.35), while Suerto variety had lowest (1.77). The means of leaf area index was 2.32. 70MAY82 and PR31D24 varieties had highest

leaf area index values and shared the same statistical group. These results coincide with the results of Karademir *et al*., (2012), Elings, 2000; Koca and Turgut 2012; Gitelson *et al*., (2003), Traore *et al*., (2000) who reported positive relation between LAI and yield.

In terms of plant canopy temperature the means changed from 38.95 to 42.48; P.1921 variety had highest plant canopy temperature (42.48), while 70 MAY 82 variety had lowest (38.95). This findings coincide with previous studies. Reynold *et al*., (1994) reported that there was positive relation between yield and low plant canopy temperature; Karademir *et al*.,(2012) reported that negative correlation between yield and canopy temperature.

From Table 2 it can be seen that the means of stomatal conductance changed from 66.29 to 107.43, Suerto variety had highest stomatal conductance (107.43), while Kalipso variety had lowest (66.29). The means of stomatal conductance was 85.17. Suerto and P.1921 varieties had highest stomatal conductance and shared the same statistical group. In crops decreasing stomatal conductance by closuring stoma is important for protection against to drought stress (Chaves *et al*., 2009; Arve *et al*., 2011; Erdal, 2014). The results of this study is coincide with that of Erdal (2014) who reported that existence significant differences between genotypes, but not with those of Reynolds *et al*., (1994) who found positive relation between stomatal conductance and yield. This situation may stemmed from growing varieties in different environment.

Table 2. Mean of Leaf Area Index (LAI), Plant Canopy Temperature, Stomatal Conductance and Yield

Variety	Leaf Area Index (LAI)	Plant Canopy Temperature (ºC)	Stomatal Conductance (mmol/m^2sn)	Yield (kg ha^{-1})
PR31D24	2.63 ab	40.25	90.36 ab	1375.1.6
SUERTO	2.02 b	40.80	107.43 a	12326.1
70MAY82	3.35 a	38.95	72.75 bc	13488.1
KALİPSO	1.77 b	40.65	66.29 c	14451.1
P1921	1.87 b	42.48	102.64 a	15181.0
DKC6724	2.28 b	39.85	70.54 bc	14621.9
MEAN	2.32	40.50	85.17	13969.9
$LSD_{(0,05)}$	0.93*	ns	23.74**	ns
CV(%)	26.69	5.68	16.78	12.34

* The difference between the averages indicated by the same letter does not matter at 0.05

** The difference between the averages indicated by the same letter does not matter at 0.01

From Table 2 it can be seen that the means of grain yield changed from 12326.1 to 15181.0 kg ha^{-1}, P.1921 variety had highest grain yield (15181.0 kg ha^{-1}), while Suerto variety had lowest (12326.1 kg ha^{-1}). The means of grain yield was 13969.9 kg ha^{-1}. P.1921, KALİPSO and DKC6724 varieties had highest grain yield. These results are coincide with those of Howell *et al*., (1996), Atakul *et al*., (2014), Kılınç *et al*., (2014), but the results of this research were higher than of Mankong (2000). This situation may stemmed from growing different varieties in different environment.

Conclusion

The results of the study showed that leaf chlorophyll content, leaf area index and plant canopy temperature characteristics can be used as selection criterion in breeding programs. Because generally the varieties have high physiological values showed higher yields and these results confirmed by previous researchers who reported that physiological parameters significant for yield. In terms of varieties P.1921, DKC6724 and KALİPSO varieties were promising varieties fort that region.

Abstract

The European chestnut (*Castanea sativa* Miller) is a native species of Turkey that grows in the coastal Black Sea, Marmara and Aegean regions and has a great economic importance. Insect pests cause significant economic yield losses in the chestnut. This study was carried out in order to determine the pest species in chestnut areas of Izmir and Manisa provinces of Turkey in the period 2012-2014 and their economic importance. Sampling was performed in 52 chestnut orchards in total of 4 districts. The knocking method, visual checking and pheromone traps were used in the determination of the species. As a result of the study on the most widespread and most common pest species, the following species were found to be economically significant: *Stephanitis pyri* F. (Het.: Tingidae), *Lachmus roboris* L. (Hem.: Lachnidae), *Alebra albostriella* (Fall.), *Zyginella pulchra* Low (Hem.: Cicadellidae) in the leaves, *Parthenolecanium rufulum* (Cockerell) (Hem.: Coccidae) in the leaves and shoots, *Cydia splendana* (Hbn.), *Pammene fasciana* L. (Lep.: Tortricidae) and *Curculio elephas* Gyll. (Col.: Curculionidae) causing damage to the fruit and *Coccus coccus* L. (Lep.:Coccidae), *Synanthedon vespiformis* L. (Lep.: Aegeridae), *Morinus funereus* Mulsantand, *Prionus basicanus* Fairmaire (Col.: Cerambycidae) causing damage to the woody tissues. It was observed that chestnut cancer (*Cryphonectria parasitica* (Murrill) Barr) was also common in the areas where the study was conducted. It was determined that chestnut cancer was widespread and tree dryness was common in the chestnut areas where woody tissue-harming pests, such as *C. coccus* and *S. vespiformis* were common. *C. splendana* and *C. elephas* usually cause harm in orchards that are at lower elevations and close to settlements. They also cause a significant labour loss as a result of observing wormy fruits at chestnut enterprises. Thus, *C. coccus, S. vespiformis, C. splendana, C. elephas* species are the most significant species that cause economic loss. Alternative control methods against these pests must be developed in the near future.

Keywords:*Chestnut, pests, economic importance, Turkey.*

Introduction

Chestnut (*Castanea sativa* Mill.) is mixed especially with leafy plant species such as oak, hornbeam, beech and linden in the Marmara and Northern Anatolia regions in Turkey. It has a local natural distribution in the Aegean and Mediterranean regions, but it is mostly cultured. Chestnut growing is common in Izmir (Beydağ, Ödemiş, Tire) and Aydın (Nazilli) provinces in the Aegean region (Mağden 1950, Delen 1979, Seçkin 1981).
Chestnut, an important tree species with economic importance in the Mediterranean region, is used in the food industry, as timber in the wood industry and also for landscaping purposes (Santos et al.,2014).
There are 2 008 thousand chestnut trees at the age of fructiferous in Turkey, and 63 750 tons of chestnut are produced (Anonymous, 2015). Turkey is ranked as the second in the world in

terms of chestnut production after China, the biggest chestnut producer in the world. Turkey accounts for about 3% of the world chestnut production. The Aegean region provides about 61% of Turkey's chestnut production. Chestnut is economically produced in Beydağ and Ödemiş districts of Izmir and constitutes the main source of living for producers.

Some insect pests in chestnut areas lead to a decrease in fruit quality and weakening of trees and even drying of them over time by causing significant damages in the fruits, trunk, branches, and shoots, in woody tissue and leaves in chestnut trees (Kaplan and Turanlı, 2011). In recent years, complaints have been continuously received from producers regarding the insect pests in chestnut. Studies on the determination of insect pests in chestnut and the loss ratios of some species in the Aegean region (Önuçar and Ulu 1987; Karagöz and Gençsoylu, 2004) were previously carried out. However, these studies were carried out in a local and narrow area.Therefore, it is necessary to carry out such studies in wider areas.

In this paper, the pest species determined by the observations made in chestnut areas of Izmir (Beydağ, Ödemiş and Kemalpaşa districts) and Manisa provinces in the Aegean region in the period 2012-2014 were evaluated, and information about their economic importance was given.

Material and Methods

This study was carried out in order to determine the pest species in chestnut areas of Izmir (Beydağ, Kemalpaşa, and Ödemiş) and Manisa (Turgutlu) provinces in the Aegean region (Turkey) in a total of 52 chestnut orchards in the period of 2012-2014 and their economic importance.

The surveys were conducted weekly or bi-weekly in the periods during which the pests were intense in April and November. At first, a general observation was made in each chestnut orchard and then the trees at different points to represent the chestnut orchard were checked. The study of Lazarov and Grigorov (1958) was used in the determination of the number of trees examined during surveys. The visual checking, knocking method, pheromone traps and branch counting method were used in the determination of pest species. Fruit samples were taken in some chestnut orchards during the harvesting period, they were cultured, and the adults of the worms inside the fruits were obtained.

Results and Discussion

As a result of the study carried out, a total of 33 insect pests pecies of different orders and families were determined in the chestnut areas of Izmir and Manisa provinces between the period of 2012-2014 (Table 1). From among the pest species, about 11 species causing significant economic losses were determined. The parts of the chestnut trees (leaf, fruit, root, trunk, and branches) on which the species causing significant economic losses are fed were assessed in 3 groups by considering their behaviors. It was determined that the most widespread and important pest species were the species causing damage in the tissue in the trunk and branches.

It was determined that *Coccus coccus* L., *Synanthedon vespiformis* L. and *Prionus basicanus* Fairmaire were the species causing damage to the woody tissues in the trunk and branches of chestnut trees, *Cydia splendana* (Hbn.), *Pammene fasciana* L. and *Curculio elephas* Gyll. were the species causing fruit to get wormy, *Stephanitis pyri* F., *Lachmus roboris* L., *Alebra albostriella* (Fall.) and *Zyginella pulchra* Low were the species causing significant damages in the leaves of trees, and *Parthenolecanium rufulum* (Cockerell) was important pest species in the leaves and shoots.

Important species causing damage to the woody tissues in the root, trunk, and branches of chestnut trees

Synanthedon vespiformis (L.), this pest was found in all chestnut areas of Izmir and Manisa provinces. The damage caused by its larva by feeding between the barky and woody layer of trees was found to be significant. In particular, this pest was observed to be more common in the trees in orchards where chestnut cancer (*Cryhonectria parasitica*) was found. The signs suggestive of yellowing, growth deficiency and graft incompatibility were found in some branches and leaves of trees on which the larvae were found. It was determined that larvae were mainly intense in the parts where the lateral branches connected to the trunk, and that fluid flow was observed in these parts during summer.
It was observed that the flight of adults of *S. vespiformis* continued in pheromone traps in the orchards from the end of June to the end of October. Adult flight became intense between the first week of July and the first week of October. It was determined in previous studies that this species caused significant economic losses to the woody tissues in the chestnut areas of Izmir province (Önuçar and Ulu, 1987) and in the chestnut areas of Aydın province (Karagöz and Gençsoylu, 2004).

Table 1. Pest species determined in the chestnut areas of Izmir and Manisa provinces in the period 2012-2014

Order	Family	Species
Dermaptera	Forficulidae	*Forficula auricularia* L.
Heteroptera	Cercopidae	*Aphrophora alni* Fall.
		Neophilaenus campestris (Fall.)
	Cicadellidae	*Alebra albostriella* (fall.)
		Asymetresca decedens (Paoli)
		Dryodurgades reticulatus (H.S.)
		Ribautiana sp.
		*Zyginella pulchra*Löw.
	Cicadidae	*Lyriste splebejus* (Scopoli)
	Tingidae	*Stephanistis pyri*
	Cixiidae	*Reptalus horridus* (Linn.)
	Psyllidae	*Cyamophila odontopy* Log.
	Lachnidae	*Lachnus roboris* L.
Coleoptera	Curculionidae	*Allandrus* sp.
		Aspidiapion radiolus Kirby
		Oxystoma craccae L
		Protapionnigritarse Kirby
		Squamapion sp.
		Euthrichapion sp.
		Polydrusus (*Conocetus*) sp.
		Curculio elephas Gyll.
		Phyllobius rufitarsis Po.
		Polydrusus gracilicornis Kies.
	Cerambycidae	*Morinus funereus* Mulsantand
		Prionus basicanus Fairmaire
	Scarabaeidae	*Anomola osmanlis* Bch.
		*Polyphylla fullo*L.
		Potosia speciosa Ad.
Lepidoptera	Aegeriidae	*Synanthedon vespiformis* (L.)
	Gracilariidae	*Phyllonorrycter messaniella* Zell.
	Lymantridae	*Euproctis chrysorrhoea* L.
	Tortricidae	*Cydia splendana* (Hbn.)
		Pammene fasciana (L.)

Cossus cossus L., in recent years, its intensity in the chestnut areas in Izmir and Manisa provinces has increased, and it has become a significant pest. It has been more intensely observed in the trees in orchards where chestnut cancer (*C. parasitica*) is found.

It was found that the adult density of *C. cossus* was low in pheromone traps in chestnut orchards. The adult flight was determined to be between June and September. However, it was determined in the observations that the larvae density of the pest was high and that the larvae in different periods during the year were present together in tree trunks and branches. It was determined that the larvae passed to the main trunk and came closer to the soil as the larva stage progressed. It was observed that late-period larvae opened big galleries in the parts where trees' trunks touched the soil at the end of June and in July. Indeed, Anonymous (2008) states that *C. cossus* spends the winter inside the galleries it opens in the root-crown, trunks and thick branches of the trees in the larva period, its adults emerge towards the end of June, cause damage especially in neglected orchards, its larvae cause damage to the trunk and branches of trees closer to the soil by opening galleries, and also cause significant damages by carving the bottom of the tree trunks all around at 10-15 cm soil depth and by destroying transmission pipes, and cause trees to get dry within a few years if they are not controlled.

Important species causing damage to chestnut fruits

As a result of the study, *Cydia splendana* (Hbn) and *Curculio elephas* (Gyllenhal)) were determined to be the pests that cause damage to chestnut fruits and the loss of quality. *Pammene faciana* L. causing getting wormy in chestnut hedgehogs and fruits in the early period was also found.

Pammene faciana L. was determined in all districts where the studies were carried out. Its adult flight was determined to be in July. It was determined that its first damage was found in the period during which the hedgehogs had 0.8 cm external diameter and 0.3 cm internal diameter and that a larva damaged more than one hedgehog.

Cydia splendana (Hbn) causes significant damages to chestnut fruits. It is especially more common in orchards that are at lower elevations and close to village settlements. It is a pest species to which pesticide is applied by producers. It was found in most of the orchards controlled. Its loss ratio was found to be higher in wild species. It was observed that its adults flowed from the first week of July to the middle of October, the harvest time, in nature and that the highest adult emergence was in the last week of August and in the third week of September.

Curculio elephas (Gyll.) was not found to be considerably widespread and intense in the observed orchards. However, its adults were determined during knocking performed in a number of orchards in Beydağ district. A large number of *C. elephas*-infected fruits were determined in the fruit samples taken in chestnut processing plants during the harvest period.

In the study carried out, it was observed that chestnut growers applied post-harvest burial spraying against inner fruit worms and some growers applied green part spraying after observing adults in July-August.

In previous studies, Önuçar and Ulu (1987) determined that *P. faciana* (L.) mainly caused damage to hedgehogs in chestnuts in Izmir province, that *C. splendana* (Hbn) and *C. elephas* (Gyll.) directly caused damage to the fruits and that *P. faciana* and two other pests caused getting wormy in hedgehogs by 15.28% and in fruits by 15.70%, respectively, Karagöz et al. (2007) determined that 15-20% of the total annual production was lost due to the damage caused by *C. splendana* and *C. elephas*, and Speranza and Paparatti (2009) determined that chestnut inner worms were the main pests in Italy, that *Curculio elephas* (Gyll.) and *C. Propinquus* (Desbr.) were found by 5% and 95%, respectively, and that yield loss was between 20-90% due to these species.

Important species causing damage to leaves in chestnut trees

Stephanistis pyri F., It was determined to be the most important species causing damage to leaves in chestnut trees. It was found in all chestnut orchards controlled. This pest can be observed in chestnut trees from May to November. It was observed that the density of *S. pyri* reached the highest value during the period between the end of August and the end of September. Karagöz and Gençsoylu (2003) state that this species is the important pest species in chestnut areas in Aydın province. The adults of *S. pyri* reduce the yield and quality since the leaves will not be able to perform their physiological functions because of yellowing on the top surface of the leaves in chestnut trees as a result of laying eggs, puncture in the leaf epidermis, covering of the leaves with a black substance and because their wastes stick on the surfaces of leaves. Önder and Lodos (1983) point out that *S. pyri* causes harm in different forests and fruit trees.

Lachmus roboris L, It was found in most of the chestnut orchards where studies were carried out in Izmir and Manisa provinces. It was found in the hedgehog's stem and bottom parts in colonies in shooting ends of chestnut trees. It was determined that there was an increase in the density of *L. roboris* in the period between mid-September and early October and that they were fed with the sweetish substance extracted by ants by coming together in the shoots they exist. Bürges and Çal (1982) determined that *L. roboris* is among the species which are considered to be economically important in chestnut orchards in Hungary and lead to defoliation in young leaves when they are intense and fed in the buds of young leaves, Önuçar and Ulu (1987); Karagöz and Gençsoylu (2004) found that this species is economically important in leaves in the orchards of Izmir (Ödemiş and Tire districts) and in Aydın provinces, respectively.

Alebra alostriella (Fall.), It was observed that the density of this species increased between the end of July and the end of September. It was found more especially in chestnut orchards at 800-1100 m elevations. In the leaves of the trees on which *A. alostriella* was intense, it was observed that light-coloured areas emerged in the sucking zones of the pest and leaves were yellowed like spots and defoliated earlier.

Important species causing damage to leaves and shoots in chestnut trees

Parthenolecanium rufulum **(**Cockerell), It was only found in the chestnut orchards in Kemalpaşa (Izmir) and Turgutlu (Manisa) districts where sampling was performed. It was determined that 5.66% of the controlled orchards were infected with the pest. It was determined that the pests were not very common in chestnut areas but were intense in chestnuts around oak forests.

In previous studies, it was determined that *P. rufulum* gave one generation per year in the Aegean region and spent the winter on 1-2 year shoots in the 2nd nymph period. Adult females are formed towards the end of April. It was determined that egg hatching started at the end of June and lasted about two weeks (Kaplan et al., 2016). Ecevit et al. (1987) determined that egg hatching of *P. rufulum* in hazelnut in the Black Sea region started in late June and that egg-laying adults emerged at the end of April, in mid-May and continued for 58 days. Rainato & Pellizzari (2009) state that *P. rufulum* on *Quercus robur* in Italy gives one generation per year, spends the winter in the 2nd nymph period, female adults begin to appear in the middle of April, their females lay eggs between the end of April and the end of May, and that egg hatching is at the end of May.

Conclusions

In conclusion, 11 pest species causing economic damages depending on orchards and region were determined in the chestnut areas of Izmir and Manisa provinces of Turkey. It was determined that the species causing damage to the tissue around the branch, trunk and root-crown were mainly observed in orchards where there were trees with chestnut cancer and that inner fruit worms were less in grafted varieties and more in wild varieties. It has been concluded that cultural precautions are important in reducing the density of the pest species and will be effective if they are applied by all producers in large areas. Chestnut areas in Turkey, by topographic structure, are the places where chemicals are applied at the least, and there is a certain natural balance. Eco-friendly biotechnical struggle studies such as mass trapping and confusion technique should be carried out against *C. splendana, C. elephas, S. vespiformis* and *C. cossus* and their results should be put into practice.

Acknowledgements

Abstract

Total production cost can increase, whereas total revenue and net benefit may reduce, due to an increase in custom fertilizer application cost in a degraded rangelands subjected to mineral fertilization. Therefore, to highlight the benefit response to applications of N, P and K on such a rangeland, the profit or loss was compared in three economic analyses. The data were obtained from an experiment organized during 2013-2015 to increase the productive potential of the rangeland, by fertilization composed of three nitrogen (0, 60 and 120 kg N ha^{-1}) and phosphorus (0, 60 and 120 kg P ha^{-1}) and two potassium (0 and 80 kg K ha^{-1}) rates. In all economical analysis were used total production cost (labour, mineral fertilizers, etc.), total revenue based on hay yield and price (HYP), the relative feed value (RFV) index as a tool for evaluating and marketing (RFVP) or conversion rate of consumable crude protein to meat on the hoof in cow-calf (CMP). The net benefit was higher in analysis based on CMP compared to other analysis. Moreover, the analyses based on HYP or RFVP had a lower profit or higher loss in the N up to 60 kg ha^{-1}. Therefore, NPK fertilization rates did not increase forage production enough to be profitable for animal production based on hay yield or RFV precise. These results indicate that this comparison was important to farmers because they are interested in seeing the criteria required to obtain a given increase in net benefits.

Introduction

Rangelands, which compose ~69% of the world's dryland area (du Toit *et al.,* 2017) are the cheapest feed resource available for domestic ruminants (Louhaichi *et al.,* 2009). The feeding of sheep, goats and cattle is mainly based on the exploitation of rangeland resources in many parts of the world (Kohestani and Yeganeh, 2016; Uzun *et al.,* 2016). Therefore, degradation of rangelands subjected to heavy grazing for a long time is a serious problem in the countries like Turkey, due to the decreased proportion of land desirable for grazing plant species and the decreased density of plant or richness of species as a result of the elimination of the less grazing-tolerant species (Anderson and Hoffman, 2007; Uzun *et al*., 2016). Rangeland rehabilitation and optimal exploitation are the most important scientific and technical efforts with various methods in range management (Kohestani and Yeganeh, 2016).

Because animal performance mainly depends on the quality of forage available to domestic ruminants (Amiri and Shariff, 2012), in practice, performance of animals reflects forage quality, which is a broader term that not only includes nutritive value, but also forage intake. The nutrient value of rangeland forages depends upon their ability to meet nutritional requirements of the grazing animals throughout the year (Amiri and Shariff, 2012).

Disturbances in promoting and maintaining diversity in rangelands are important in terms of forage quantity and quality determining grazing animal performance. In countries like Turkey, rangeland restoration is a goal of Governments with the enactment of the Rangeland Law. Fertilizers have been supplied by government and villagers have inconsiderately used fertilizer on the rangelands (Aydin and Uzun, 2005), because the most practical and effective method to increase the herbage quantity and quality in rangelands is by adequate fertilization with mineral compounds (Aydin and Uzun, 2005; Frame and Laidlaw, 2011). As result, it has increased the use of fertilizer inputs (ie. nitrogen, phosphorous and potassium shorthanded as 'NPK') to achieve that level of real production. The importance of fertilizers in delivering the productivity is still recognised in today's technological world, because rangeland management practices improve livestock productivity and also protect the environmental status. However, total production cost can increase, whereas total revenue and net benefit may reduce, due to an increase in custom fertilizer application cost in a degraded rangelands subjected to mineral fertilization. Today, a number of economic analyses models based on hay yield and price (HYP) or conversion rate of consumable crude protein to meat on the hoof in cow-calf (CMP) that determined economic returns of fertilization has been used for sustainable rangeland management (Guevara *et al.,* 2000; Islam and Adjesiwor, 2005). There is scarce information on whether the relative feed value (RFV) index as a tool for evaluating and marketing (RFVP) as economic analyses model was a new option that can be used. Furthermore, farmers are interested in seeing the criteria required to obtain a given increase in net benefits. Therefore, the aim of this study was the profit or loss was compared in three economic analysis models to highlight the benefit response to applications of NPK in terms of maintaining and improving rangelands degraded by overgrazing.

Material and Methods

The data with respect to hay and protein yields, crude protein content and RFV of this research were obtained from a study carried out in a heavily grazed rangeland in Ondokuz Mayis town of Samsun province, in Turkey (41° 29' 0" N, 36° 4' 0" E, elevation of 10 m) between 2013 and 2015 (Aydın et al. (2016). In this study, the effects of overseeding (unseeded and seeded) and fertilization composed of three nitrogen (0, 60 and 120 kg N ha^{-1}) and phosphorous (0, 60 and 120 kg P ha^{-1}) and two potassium (0 and 80 kg K ha^{-1}) rates on yield and quality of overgrazed rangeland have been studied. As reported by Aydın *et al.* (2016), total precipitation and mean temperature were 578.3 mm and 16.0 °C in the first year and 776.2 mm and 15.5 °C in the second year of the experiment. Soil characteristics of experimental area were as follows: soil texture is loamy; organic matter content is 2.1%; extractable P is 2.6 mg kg^{-1}; K extraction is 43.0 mg kg^{-1}; saturation extract pH is 7.1. The botanical composition of the experimental area consisted of 20% legume, 35% grass and 45% other family plants. The studied rangeland had a ratio of desirable perennial plant species of 10%. In this study, 18 different fertilizer combinations ($N_0P_0K_0$, $N_0P_0K_{80}$, $N_0P_{60}K_0$, $N_0P_{60}K_{80}$, $N_0P_{120}K_0$, $N_0P_{120}K_{80}$, $N_{60}P_0K_0$, $N_{60}P_0K_{80}$, $N_{60}P_{60}K_0$, $N_{60}P_{60}K_{80}$, $N_{60}P_{120}K_0$, $N_{60}P_{120}K_{80}$, $N_{120}P_0K_0$, $N_{120}P_0K_{80}$, $N_{120}P_{60}K_0$, $N_{120}P_{60}K_{80}$, $N_{120}P_{120}K_0$, $N_{120}P_{120}K_{80}$) were selected to support high-quality rangeland composition and growth and environmental stability. The assumptions of these economic analyses models were as follows, to use of fertilizers NPK to repair and to achieve greater production of good quality of forage in rangeland degraded, to utilize the forages from overgrown rangelands improved as hay, to evaluate the conversion rate to meat of forage CP consumed by the grazing animals, and to constitute from hay sale the benefits livestock owners get from the rangelands improved by a fertizer. Therefore, the economic analysis models based on hay yield and price (HYP), the relative feed value (RFV) index as a tool for evaluating and marketing (RFVP) or conversion rate of consumable crude protein to meat on the hoof in cow-calf (CMP) were used to evaluate the profitability (profit or loss) of 18 different fertilizer combinations. Because to determine a fertilization profitability therefore was required the comparison of costs and returns from economical analyses models, in all economical analyses models were used total production cost (Table 1) and total revenue. Net benefit was calculated using the following equation:

Profit/loss ($ ha^{-1}) = total revenue – total production cost (Islam and Adjesiwor, 2005).

All Turkish lira amounts are converted into today's or “present” the United States dollar ($) terms due to the fact that most financial inputs (e.g. prices and costs) and production inputs (e.g. yields, product quality) can be readily varied on a yearly basis.Price data for fertilizers were obtained from local sources in central Samsun. As known, the RFV is an index representing forage quality and is one of the systems used by forage testing laboratories for many years. Thus, the higher the RFV is the higher the quality, and consequently, this means a higher price for that hay. Hay buyers and sellers have used this index for estimating hay quality (Newman *et al.,* 2014). The prices of hay based on RFV as a tool for evaluating and marketing (RFVP) is estimated by using the regression equation:

RFVP ($ kg^{-1}) = 5 + 0.5x,

where x is RFV of produced hay. This equation was based on the prices of hays with the lowest RFV (e.g. wheat straw) and the highest RFV (e.g. alfalfa hay) in Turkey during the last three years. The conversion rate of consumable crude protein to meat on the hoof in cow-calf was assumed to be 1.8 kg (NRC, 1996; Aydin and Uzun, 2005).

Table 1. Parameters and prices used in cost and revenue estimation are shown in Table 1.

Item	Unit	January 2017 Price ($)
Fertilizers		
Ammonium nitrate	kg	0.21
Triple superphosphate	kg	0.57
Potassium sulphate	kg	1.16
Other expenditures		20% of fertilizer prices
Meat on the hoof	kg	4.45
Hay	kg	0.17

Data on hay and protein yields, crude protein content and RFV of rangeland were analyzed by one-way ANOVA with fertilization as the only factor. When differences appeared, Duncan’s test was used at the P = 0.05. All statistical analysis was performed by means of SPSS 11.0 for Windows software (SPSS Inc., NY, USA).

Results and Discussion

Although current findings revealed that, for high-dose N fertilization to be effective on HY of the rangelands (Table 2), the fertilizer with N should be composed of 60 kg N, 120 kg P, 80 kg K ha^{-1}, due to an adverse effect on botanical composition and long-term sustainable production (Aydın *et al.,* 2016). Both P and K fertilization (except for 80 kg K without N and P) without N increased the CP content of the rangelands. Because of high CP content of the rangelands fertilised by fertilizer with high-dose P and K without N or high HY of rangelands fertilised by fertilizer with high-dose N with or without P and K, the CPY of these rangelands had the greatest CPY. The results with respect to hay yields support idea that nitrogen fertilizer application was profitable but might not be sustainable in the long term (Islam and Adjesiwor, 2005).

Table 2. The hay and crude protein (CP) yields, CP content and relative feed value (RFV) of the overgrazed rangeland fertilized with different fertilizer combinations.

The economic analysis models of the costs and benefits from adopting various combinations of fertilization practices indicate that profit and loss conservation can be comparable (Figure 1). Profit is equal the sum of maintenance cost, high productivity and persistence (Islam and Adjesiwor, 2005). Therefore, key indicators as the benefit to cost ratio and net present value must be positive for the analyzed practices taking account of the increases in forage yield and quality in terms of a common botanical composition and long-term sustainable production for various combinations of NPK fertilization. Indeed the highest net returns for HYP, CMP and RFVP were obtained from rangelands fertilized with the $N_{120}P_0K_0$, $N_{120}P_{120}K_0$ and $N_{60}P_{120}K_0$ fertilizers, respectively (Figure 1). Although the HY almost double in fertilizer cases with N without quality share, the net benefits for all fertilization combinations was lower for HYP and RFVP analyses than for CMP model. Therefore, when based on the conversion rate to meat of forage CP consumed by the grazing animals, all fertilization combination used, except for $N_0P_0K_{80}$ were profitable for operations that dominate rangeland use in country like Turkey. Our belief was that improved knowledge and information will not only lead to better decisions of farms, but also to develop and support the use of economic models that inform government and corporate decisions. For a profit maximizing or cost minimizing, the profitability of fertilization can be provided some insights into the decisions to be made. While the profit for most ranchers is not the most important decision criterion in the economic sense, they can generally be assumed to prefer more income to less (Gentner and Tanaka, 2002).

After taking account of the botanical composition and long-term sustainable production (Aydın *et al.,* 2016), the profit of CMP analyse model was more profitable than the other two models by around twice. As in the present study, when rangelands were fertilized with mineral compounds to increase the herbage quantity and quality in rangelands (Aydin and Uzun, 2005; Frame and Laidlaw, 2011) has a serious effect on RFV. The results indicate that net benefit based on RFVP and HYP falls by about $8.12 and 10.38 (as average of application increased the HY) compared to CMP ($39.31). Similar results were obtained for other applications; corresponding values of application that did not affect HY were $0.84-1.51, and 16.36, respectively. This was because profitable results of fertilization based on CMP may be related to less profitable results based on HYP or RFVP. The profit or loss of both HYP and RFVP was resulted in estimated the improvements in rangeland degraded being almost the same as for the assumptions in the present study.

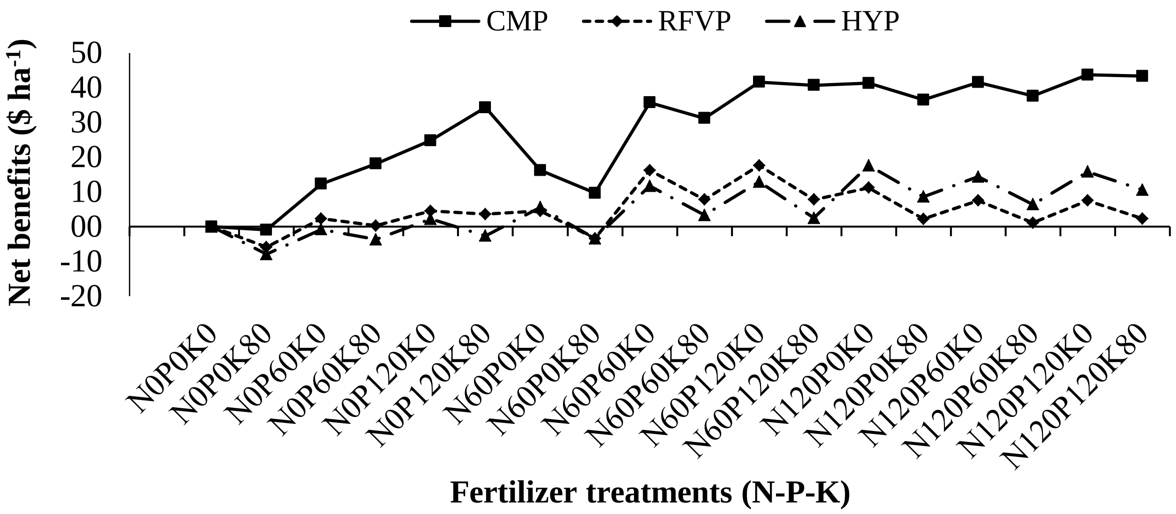

Figure 1. The net benefits from the heavily grazed rangeland fertilized with different fertilizer (NPK) combinations. The economic analysis models based on hay yield and price (HYP), the relative feed value (RFV) index as a tool for evaluating and marketing (RFVP) or conversion rate of consumable crude protein to meat on the hoof in cow-calf (CMP).

Selling the forages obtained from each fertilization application may be brought NPK combinations close to the profitability produced under the assumptions based on HYP or RFVP. Therefore, even with improvement provided in the rangeland degraded, studied NPK combinations were the least profitable in analyses based on HYP or RFVP. The sensitivity of profit or loss to hay yield, CP content and RFV was also tested. The sensitivity of RFV of the forages from the rangelands was more certain, although that of RFV for N_{120} with or without P and K was lower than that of HYP. The results were shown to be more sensitive to assumed CMP and RFVP.

Conclusions

The economic analysis models based on HYP and RFVP were reduced the net benefit compared to CMP. Except for $N_0P_0K_{80}$, all the NPK combinations were produced higher net benefit in the analysis based on CMP. The reductions in net benefit due to the sale of hay from the rangelands fertilized by different NPK may be offset by weight gains of grazing animals and greater productivity of farms. The benefits of the economic analysis model based on RFVP that a new option was indicated to be small to make them worth adopting given the forages available, especially in the rangelands fertilized with high-dose N. In general, the economic analysis models based on HYP and RFVP was not to equate the value of the marginal product to the marginal factor costs. Therefore, it can be said that the grazing of animals in such rangelands may produce just enough income to cover the cost of producing it. The relative values of rangeland outputs have changed depending on the assumptions of the economic analysis models used. In today, questions should be focus on whether rangelands degraded were being managed for economic and ecological sustainability. Based on the results, the precautions should be proposed to repair natural rangelands and achieve greater production of good quality of forage by using different agricultural practices.

Acknowledgments

Financial support for this project was provided by The Scientific and Technological Research Council of Turkey (Project no: 112 O 742).

Abstract

The objective of this study was to determine yield and quality parameters of some early maturing cotton genotypes by comparing them with control cultivars. The study was carried out at the GAP International Agricultural Research and Training Center during 2013 and 2014 cotton growing season. Five advanced lines developed by breeding program and two control varieties namely Stoneville 468 and Fantom were used as material. The experiment was laid out as randomized complete block design with four replications. The results of statistical analysis indicated that there were significant differences among genotypes for investigated characteristics in terms of first picking percentage, fiber fineness, fiber strength, elongation, uniformity and short fiber index. There were significant differences between years for seed cotton yield, ginning percentage, first picking percentage, lint yield, fiber length, fiber strength, elongation, uniformity and short fiber index. All investigated characteristics had high values in 2013 except fiber length and fiber strength. Genotype x year interaction was significantly different only for fiber fineness. The results of research showed that the line coded as 9/8 had highest seed cotton yield, lint yield and first picking percentage, while 19/3, 9/1 and 9/8 lines had highest technological properties.

Keywords: *Cotton, Earliness, Maturity, Yield*

Introduction

Cotton (Gossypium hirsutum L.) is an important fiber crop used in the textile industry in the world and also in Turkey. Turkey is the 7th largest cotton producing country in the world and 4th in world cotton consumption. Average cotton yield of Turkey is second rank after Australia. Cotton breeding program of Turkey mostly focused on the development of cultivars with high genetic potential for yield, high quality and earliness. Earliness is a primary breeding objective of cotton breeders (Braden and Smith, 2004; Hosseini, 2017). Earliness of the crop maturity is important in the avoidance of frost damage, insect and disease buildup, soil moisture depletion and weathering of the open cotton. Earliness also has other advantages, such as allowing rotation with a winter crop or extending the season for harvesting and ginning operations (Panhwar et al, 2002). Early maturing varieties increased the possibility that harvest can be completed before cold and rainy weather (Shakeel et al., 2012). Early maturity is the end result of several growth and fruiting processes, or components, which are interrelated, and which presumably can be manipulated separately in the breeding process (Godoy and Palomo, 1999. Therefore, in order to breed early maturing and good fiber quality cotton varieties through selection and breeding, it is necessary for cotton breeders to have knowledge about the inheritance of plant characteristics related to early maturing, good fiber quality and high yielding traits (Hajazi et al., 2014). Earliness trait in cotton is controlling by additive gene effects and this model of inheritance in cotton is useful in the development of pure lines whereas dominance and epistatic effects can be used to exploit hybrid vigor (Hosseini, 2017). Earliness in cotton is a complex character which is assessed by measuring many plant traits. Plant breeders utilize mostly first picking percentage or percent open bolls technique to measure the relative maturity of cotton varieties (Guthrie et al, 1995). Several other parameters have been used as indicators or estimators of earliness, including rates of blooming and maturation, vertical and horizontal flowering intervals, mean maturity, production rate index and portion of crop harvested by specified dates (Godoy and Palomo, 1999), node of first fruiting branch, number of vegetative branches and etc. (Shakeel et al., 2012). Anjum et al., 2001, revealed that the characters attaining date of 5-NAWF and date of opening first boll were more reliable indicators of earliness as compared to others. The aim of this study was to establish the productive potential and quality fiber indexes of the new cotton cultivars in comparison with the standard cultivars, as well as the combination of other valuable properties.

Material and Methods

The experiment was carried out at the GAP International Agricultural Research and Training Center's (GAPUTAEM) experimental area during 2013 - 2014 growing seasons in Diyarbakir, Turkey. The experiment was laid out as randomized complete block design (RCBD) with four replications. The materials used in the study were developed from cotton breeding program of the GAPUTAEM. In the study, 7 genotypes (5 advanced cotton breeding lines and 2 control) varieties were used as plant materials. Each plot consisted of four rows of 12 m length, between and within row spacing were 0.70 m and 0.15-0.20 m, respectively. Seeds were planted on 7th May 2013 and 5th May 2014 by experiment planting machine. All plots were treated with 20-20-0 composite fertilizer to provide 70 kg ha^{-1} N and 70 kg ha^{-1} P_2O_5. Just before the flowering, 70 kg ha^{-1} N was applied as ammonium nitrate to the trial as an additional N source. Plants were grown under recommended cultural practices for commercial production. Experimental plots were irrigated for the first time, five weeks after sowing, and repeated seven times at ten to twelve-days interval in both years. Furrow irrigation was applied. Herbicides were used only once before sowing. In both years, insect were monitored throughout the experiment and in 2013 at early stage for thrips and at boll formation for red spider, in 2014 two times insecticide were used. Plots were harvested twice by hand and the harvests from the four rows of the plot were weighed and calculated for seed cotton yield and fiber yield. The first harvest was done on 12nd October, 2013 and 24th October 2014 and the second harvest was done on 7th November, 2013 and 13th November, 2014. After the harvest, seed cotton samples were ginned on a mini-laboratory roller-gin for lint percentage. Fiber samples were then analyzed for fiber quality properties by High Volume Instrument (HVI Spectrum). Statistical analysis were performed using JMP 5.0.1 statistical software (http://www.jmp.com) and the means were grouped with LSD (0.05) test. The climatical data was given in Table 1.

Results and Discussion

The findings of experiment were given as tables. According means of two years results the yields of genotypes changed from 3907.1 to 4253.0 kg ha-1 (Table 2). The highest yield was obtained from 9/8 (4253.9 kg ha-1) genotype the control variety Stv 468 followed this genotype (4114.3 kg ha-1). The differences between the genotypes and genotype x years with respect to seed cotton yield were non- significant, but year differences were highly significant (p<0.01) for this trait. The seed cotton yield of 2013 was higher than of that 2014 (Table 2). This differences may be stemmed from climate conditions and cultural practices. Previous researcher reported that 70% of the yield variation is stemming from environmental differences which are occurring year by years and the other 30% is stemming from management process differences (Krieg, 1997).

Table 2. Average values and statistical groups of seed cotton yield and ginning percentage

The first picking percentage is an important earliness criteria. The differences between the genotypes and years with respect to first picking percentage were highly significant (p<0.01), but genotype x years differences was non-significant for this trait (Table 3). According to means of two years first picking percentage of genotypes changed from 92.40 to 96.76%, the highest values were obtained from 9/8 (96.76%), 9/1 (96.50 %) and 15/3 (96.27%). These genotypes shared the same statistical group with control variety Fantom. The Stv 468 control variety had lowest value (92.40%) for this trait. Baloch et al. 2014 revealed that cotton earliness is a quantitative trait which is mainly affected by environment and crop genotype.

The fiber yield of genotypes changed from 1602.8 to 1734.5 kg ha-1. The differences between the genotypes and genotype x years were non-significant, but years differences were significant at 1% level (Table 3). The means of 2013 was 1866.1 kg ha-1, while it was 1425.5 kg ha-1 for 2014. This differences may be stemmed from climate conditions and cultural practices. In 2013, in May, which is the planting month, the precipitation was 98 mm which is higher than year of 2014 and long term period.

The fiber fineness of genotypes changed from 4.16 to 4.72 micronaire. The lowest values were obtained from 6/5 genotype and Fantom control variety, while the highest value was obtained from 15/3 genotype. The differences between the genotypes and genotype x years were significant at 1% and 5%, respectively. Years differences were non-significant (Table 4).

High micronaire is an undesirable trait in a mature fiber, resulting in price discounts (Percy et al, 2006).

In terms of fiber length, the differences between the genotypes and genotype x years were non-significant, but years differences were significant at 1% level (Table 4). The fiber length of genotypes changed from 27.34 (Stv 468) to 28.79 mm (19/3 number line). The fiber length of 2014 (28.57 mm) was higher than that of 2013 (27.86 mm). Although fiber length is a genetic trait it is affected by crop management, soil moisture, the frequency of irrigation and amount of water and temperature variations (May, 2000).

From Table 5 it can be seen that the differences between the genotypes and years were significant at 1% and 5%, respectively. Genotype x years differences were non-significant (Table 5). The fiber strength of genotypes changed from 30.97 to 34.12 g tex-1. The highest values were obtained from 19/3 number genotype (34.12 g tex-1), to 9/8 number genotypes (33.08 g tex-1), while the lowest value was obtained from Stv 468 control variety (30.97 g tex-1) . There was significant differences between years, the values of 2014 was higher than that of 2013. Previous researchers reported that the effect of genotypes more than environment (Bradow and Davidonis, 2000).

In terms of fiber elongation, differences between genotypes and years were significant at 1% level, while genotype x years interaction was non-significant for this trait. The fiber elongation of genotypes changed from 5.87 to 6.88%. The highest values were obtained from 9/1 (6.88%), 9/8 (6.63%), 15/3 (6.46%), while the lowest value was obtained from 6/5 number line. There was significant differences between years, the values of 2013 was higher than that of 2014. Campbell and Jones (2005) reported that elongation is affected from genotype, environment and genotype x environment interaction.

Table 6. Average values and statistical groups of fiber uniformity and short fiber index

Genotype	**Fiber Uniformity (%)**		**Mean**	**Short Fiber Index (%)**		**Mean**
	2013	**2014**	**2013-2014**	**2013**	**2014**	**2013-2014**
1. 9/1	85.45	82.35	83.90 a	8.67	9.00	8.83 d
2.15/3	82.88	81.10	81.98 abc	9.35	10.05	9.70 cd
3.19/3	85.28	82.05	83.66 ab	9.62	9.72	9.67 cd
4. 6/5	80.23	80.70	80.46 c	12.60	9.87	11.23 ab
5.9/8	82.38	82.07	82.22 abc	10.50	9.62	10.06 bcd
6.STV 468 (Control)	81.30	81.57	81.43 bc	12.30	10.42	11.37 a
7.FANTOM (Control)	82.78	81.60	82.18 abc	10.40	9.77	10.08 bc
Mean	**82.89 a**	**81.63 b**		**10.49 a**	**9.78 b**	
CV (%)	2.67			12.04		
Genotype ($LSD_{0.05}$)	2.22*			1.23**		
Year ($LSD_{0.05}$)	1.09*			0.48*		
Genotype x Year ($LSD_{0.05}$)	ns			ns		

*ns: non significant; * and **, significantly different from zero at P ≤0.05 and P ≤0.01, respectively.*

From Table 6 it can be seen that differences between the genotypes and years with respect to fiber uniformity were significant at 5% level. Genotype x years differences were non-significant (Table 6). The fiber uniformity of genotypes changed from 80.46 to 83.90%. The highest values were obtained from 9/1, while the lowest value was obtained from 6/5 number line. There was significant differences between years, the values of 2013 was higher than that of 2014.

In terms of short fiber index from Table 6 it can be seen that the differences between the genotypes and years were significant at 1% and 5%, respectively. Genotype x years differences were non-significant (Table 6). The short fiber index of genotypes changed from 8.83 to 11.37%. The highest values were obtained from Stv 468 control variety, while the lowest value was obtained from line 9/1 (8.83%). There was significant differences between years, the values of 2013 was higher than that of 2014.

Conclusions

The study was carried out to develop high yielding and early maturing cotton varieties. With this objective 5 advanced cotton lines and two cotton varieties were used as material. The results of statistical analysis indicated that there were significant differences among genotypes for investigated characteristics in terms of first picking percentage, fiber fineness, fiber strength, elongation, uniformity and short fiber index. There were significant differences between years for seed cotton yield, ginning percentage, first picking percentage, lint yield, fiber length, fiber strength, elongation, uniformity and short fiber index. All investigated characteristics had high values in year of 2013 except fiber length and fiber strength. Genotype x year interaction was significantly different only for fiber fineness. The results of research showed that the line coded as 9/8 had highest seed cotton yield, lint yield and first picking percentage, while 19/3, 9/1 and 9/8 lines had highest technological properties. The results of study indicated that 9/8 coded line is promising line for being nominate for registration.

Abstract

This study was conducted to determine total yield and profitability of legume x cereal mixtures and silage corn rotation during 2013-2014 and 2014-2015 growing seasons in Yozgat, Turkey. Firstly, Hungarian vetch (*Vicia pannonica* Crantz) and cereals (*Hordeum vulgare* L., *Triticum aestivum* L. and T*riticosecale* Wittmack) were sown as binary mixtures with different seed rates (100:0%, 70:30%, 60:40%, 50:50% 40:60%) and harvested at the flowering and milk dough stages. Then silage corn was sown. The experiments were arranged in split plot design with four replications. According to combined results the highest total hay and total crude protein yield were obtained from the Hungarian vetch + barley mixture with 70:30% seed rate cutting at flowering stage and fallowed by silage corn (32.4 t ha^{-1} and 3.13 t ha^{-1}, respectively) while they were the lowest in silage corn sowing over the fallow at the second sowing time (19.5 t ha^{-1} and 1.44 t ha^{-1}, respectively). Profitability analysis was pereformed in two ways; hay price and meat conversion of hay. The maximum profit was obtained from Hungarian vetch + barley mixture with 70:30% seed rates and first cutting time treatment as 4776.60 $/ha and 13213.09 $/ha, respectively based on hay price and meat conversion of hay methods. As a result, Hungarian vetch + barley mixture with 70:30% seed rate and cutting at flowering stage of barley may be the most appropriate treatment for both Hungarian vetch + cereal mixtures and silage corn in terms of yield and economic return in Middle Anatolian conditions.

Keywords: *Hungarian vetch + cereals mixture, silage corn, hay yield, crude protein yield, profitability.*

Introduction

Crop rotation is the practice of growing a series of different types of crops in the same area in sequenced seasons (Tugay, 1988; Sencar *et al.*, 1994). Growing the same crop in the same field for many years in a row disproportionately depletes the soil of certain nutrients. With rotation, a crop that leaches the soil of one kind of nutrient is followed during the next growing season by a dissimilar crop that returns that nutrient to the soil or draws a different ratio of nutrients. In addition, crop rotation mitigates the buildup of pathogens and pests that often occurs when one species is continuously cropped, and can also improve soil structure and fertility by increasing biomass from varied root structures.

A great advantage of crop rotation comes from the interrelationship of nitrogen fixing-crops with nitrogen demanding crops. Legumes, like alfalfa and vetch, collect available nitrogen from the soil in nodules on their root structure (John *et al.,* 2010). When the plant is harvested, the biomass of uncollected roots breaks down, making the stored nitrogen available to future crops. So that the yield of the next product increases (Anonymous, 2016). In addittion crop rotation systems have resulted to increase farm production and profitability per unit land area in selected crops (Anoymous, 2017).

The objective of this study was to determine hay yield and profitabilty of Hungarian vetch x cereals mixtures and silage corn rotation.

Material and Methods

Experiments were conducted during the growth seasons of 2012-2013 and 2014-2015 in the Agricultural Research Station of Bozok University, Yozgat, Turkey, which is located at 34° 28′ 0″ E, 39° 37′ 0″ N. Soil proporties of the experimental area of both year were clay –loam type with pH of 8.18-8.15 and 7.90-7.93% CaCO3, 82.0-85.2 kg ha^{-1} phosphorus, and 1.85-1.91% organic matter at the depth of 30 cm (Table 1).

Table 1. Physical and Chemical Proporties of Soil in Research Area*

Proporties	2013-2014	2014-2015
Structure	Clay-loam	Clay-loam
CaCO3 (%)	7.90	7.93
Total salt (%)	0.020	0.018
P_2O_5 (kg ha^{-1})	82.0	85.2
K_2O (kg ha^{-1})	480.2	501.2
Ph	8.18	8.15
Organic matter (%)	1.85	1.91

* Turkish chamber of agriculture cooperation.

The Table 2 shows the climatic conditions of the experimental area long-term and during the growth season, including monthly average temperature, monthly total precipitation and avarage moisture. Total precipitation of the long-term 574.4 mm and growing season was 568.4 mm for 2013-2014 and 717.1 mm for 2014-2015 (Table 2).

Firstly, Hungarian vetch (*Vicia pannonica* Crantz "Altınova 200") and cereals (*Hordeum vulgare* L., "Tarm 92", *Triticum aestivum* L. "Pehlivan" and T*riticosecale* Wittmack "Karma 2000") were sown as binary mixtures with different seed rates (100:0%, 70:30%, 60:40%, 50:50% 40:60%) and harvested at the flowering and milk dough stages. Then silage corn (*Zea mays* L. "Cadız") was sown. The experiments were arranged in split plot design with four replications, main plots were cutting times and sub plots were seed rates.

Hungarian vetch+cereal mixtures: The experimental plots had 8 rows with a row spacing of 20 cm and a row length of 5 m. The seed proportions were calculated on the basis of recommended sole seeding rate and barley 220 kg/ha^{-1}, wheat 180 kg/ha^{-1},Triticale 200 kg/ha^{-1}, Hungarian vetch 100 kg/ha^{-1}.The P fertilizer 80 kg ha^{-1} P_2O_5 was uniformly applied to the soil during sowing. The plots were harvested on the basis of cereals that harvested at the flowering and milk dough stages.

Silage corn: Plot size was 5 x 1.5 m = 7.5 m^2 and distance between rows were 50 cm. Also Hungarian vetch + cereals mixtures were comparison stubble being control. Plant density was 120.000 seed for per hectar. The full dose nitrogen (50 kg N ha^{-1}), phosphate (80 kg P_2O_5 ha^{-1}) were applied at sowing. Additional nitrogen fertilizer (50 kg N ha^{-1}), was applied at the stage when the plants were 40-50 cm. In the study, five irrigation were applied and weeds were controlled by hoeing. Silage corn harvested in dough stage.
Plant samples were dried 65 $^{\circ}$C until constant weight to determine their hay yield. Crude protein of hay was determined by using Near Reflectance Spectroscopy (NIRS, 'Foss 6500') with software package program 'IC-0904FE'.
Treatments of entries in the study were calculated separately and determined how much boned meat meets that total amount of protein obtained from silage corn with hungarian vetch + cereal mixtures (1.8 kg protein = 1 kg boned meat) (Aydın and Uzun, 2005). The amount of boned meat obtained was calculated by multiplying the price of boned meat. The amount of hay is multiplied by the price of hay and the income account is determined and, the input costs were deducted from the income of each process to determine profit. Profitability analysis were given Table 3.

Results and Discussions

Total hay yield, total crude protein yield and profitability analysis of Hungarian vetch + cereals mixture and silage corn were given Table 4, 5 and 6.
Acording to combined years, total hay yield was significantly ($p \leq 0.01$) different between years, while it was not significant between harvesting and sowing times (Table 4). As a result of combined years, hay yield was the highest (28.1 t ha^{-1}) in Hungarian vetch + barley mixture with 70:30% seed rate and it was the lowest in stubble (20.8 t ha^{-1}). Hungarian vetch + cereal yield increased with delayed harvest, while silage corn yield decreased with delayed sowing time. Also, silage corn hay yield that obtained with the delayed sowing was more than Hungarian vetch + cereal hay yield that obtained at the second harvest time. So, Hungarian vetch + cereal and silage corn hay yield in the first harvest time was more than second harvest time. Silage corn that sowing after previous plant had more than hay yield stubble plots (Table 4). This may be due to the organic material at the soil that left by the pre-plant. Because, both mixtures and silage corn were been given at the same amount fertilizer. Also, in the second year total hay yield was more than first year. This may be due to the second year was more than rainy to first year. Because, Hungarian vetch + cereal hay yield obtained was more highset at the first year. Total crude protein yield was not significantly different among the treatments and years. (Table 4). As a result of combined years, the highest crude protein yield was 2639.2 kg ha^{-1} (Hungarian vetch + barley mixture 70:30% seed rate), the lowest was 1613.1 kg ha^{-1} (stubble). Total crude protein yield at the first harvesting time was more than second harvesting time (Table 4). This is due to the hay yield with crude protein ratio of silage corn determined at the first sowing time was more than second sowing time.

(*) 0.05, (**) 0.01; 1: Flowering stage; 2: milk dough stage; HV: Hungarian vetch; B: barley, W: wheat; T: Triticale

Acording to combined years result of, the lowest profit of hay yield with silage and boned meat was determined stubble plots (1439,81 and 4313,20 \$/ha) at the second harvesting time, while the maximum profit was (4776,60 and 13213,09 \$/ha) in Hungarian vetch + barley mixture 70:30% seed rate at the first harvesting time (Table 5 and 6). The profit obtained at the first harvest time was higher than the second harvest time. This is due to the hay and crude protein yield of silage corn is higher at the first harvest time. Because, there is no differences in terms of input prices between harvesting or sowing times. In the analysis of profitability with hay and silage yields and boned meat, the highest profit was obtained from Hungarian vetch + barley mixture 70:30% plot at the first harvesting time (Table 5 and 6). This may be due to the input prices of Hungarian vetch and barley less than wheat and triticale and the hay yield of Hungarian vetch + barley mixtures was more than wheat and triticale mixtures.

Abstract

Forage pea is an important annual leguminous plant that can be grown solely or together with other cool season cereals as a hay, pasture or silage plants. It has huge potential in Turkey because of its ability to adapt to humid and cool climatic conditions. There is no research on forage pea sowing rates and frequency in Black Sea region of Turkey. The aim of this study was to determine the best sowing rate and sowing frequency by using Golyazi cultivar. The experiment was established in a split plot design with 3 replicates on 28 February 2017. The sowing rates were 80, 100 and 120 viable seeds m^{-2}; inter row spacing distances were 20, 30 and 40 cm. The harvest was carried out on 8 June, when the legumes started to grow on the lowest nodes. During harvest, 500 g of sample was taken from each plot and dried in an oven at 70 ^{o}C until it reached a constant weight. Hay ratio and yield were calculated from the dry to fresh weight ratio. The samples were then ground and analyzed for protein, ADF, NDF and mineral content. The highest hay yield (708 kg da^{-1} was obtained from the crop sown by 120 seeds m^{-2} with 20 cm inter row spacing. The hay yield was significantly increased in 120 seed m^{-2} plots and there was no difference between 80 and 100 seeds m^{-2} plots. When observed by inter row spacing distance, the highest hay yield was obtained from the crop sown at the distance of 20 cm. The hay yield sharply decreased at 30 cm and slightly increased again at 40 cm. There were also some significant differences among the treatments in terms of other characteristics.

Keywords: *Forage pea, yield, quality, sowing rate.*

Introduction

Pea (*Pisum sativum L.*) is an annual cool-season legume crop that can be grown as forage or pulse winter crop without irrigation in all coastal areas of Turkey (Sayar, 2007; Uzun *et al*., 2017). Forage pea is usually grown solely or as a mixture with cool-season cereals for hay, pasture, green manure and silage production. Forage pea has high levels of quality protein (it is especially rich in the amino acid lysine) (Manga *et al*., 2003), is rich in phosphorus and calcium, and is a good source of vitamins, especially A and D (Uzun *et al*., 2017); thus it is used as an alternative protein source in the animal feed industry in Europa (Tan *et al*., 2014). Additionally, forage pea is a very suitable crop in annual crop rotation, because its growing period is relatively short, its forage yield is high and it provides biological nitrogen for the plants after them. Determining the optimal sowing density is an important factor. Sowing density can affect crop yield, quality, evaporation, light interception and competitive ability with weeds (Yavuz *et al*., 2011; Uzun *et al*., 2017). Optimum sowing density in forage pea can range greatly depending on genotypes, growing purpose and climatic conditions (Uzun and Acikgoz, 1998). Some studies conducted in different regions on forage pea have shown that yield usually increases with an increasing sowing density until it reaches an optimum level and then decreases (Townley Smith and Wright, 1994; Jovaisiene *et al*., 1998; Tan *et al*., 2014; Uzun *et al*., 2017). There is no research on forage pea sowing density in Black Sea Region of Turkey. The aim of this study was to determine the best sowing rate and sowing density by using Golyazi cultivar.

Material and Methods

The experiment was conducted in the Agricultural Research Center of Ondokuz Mayis University, Samsun, Turkey under rainfed conditions in 2017. Experiment soil is loamy-clay, slightly acidic (pH:6.45), without lime and salt, and poor in organic matter. Annual total precipitation is 706 mm and average temperature is 14.50 ^{o}C. Field experiment was established on 28th February, 2017 according to split plot design with 3 replicates by using Golyazi forage pea cultivar. In the experiment, sowing rates were 80, 100 and 120 viable seeds m^{-2}; inter row distances were 20, 30 and 40 cm. Plot areas were 4 m^2, 6 m^2 and 8m^2. 3 kg da^{-1} N applied just after seeding. There was no other fertilization or irrigation.

Harvest was carried out on 8 June when the legumes started to grow on the lowest nodes. During harvest, 500 g samples were taken from each plot and dried in an oven at 70 ^{o}C until a constant weight. Hay ratio and yield were calculated from dry to fresh weight ratio. The samples were then ground and analyzed for crude protein, ADF, NDF and mineral content (Ca, Mg, K and P) with Near Infrared Reflectance Spectroscopy (NIRS Foss 6500) by using IC-0904FE program. Statistical analysis was performed with SPSS 17.0 program according to split plot design.

Results and Discussion

Different seeding rates and row spaces had significant effects on hay yield of forage pea (Table 1 and figure 1,2). Increasing seeding rates and row spaces increased hay yield. When considering seeding rates, the highest hay yield was obtained from 120 viable seeds m^{-2} (566 da^{-1}) and 40 cm row spacing (531 kg da^{-1}). The differences between 20 and 30 cm row spaces and between 80 and 100 viable seeds m^{-2} were found to be statistically insignificant. In general, the hay yield obtained from forage pea is increases when row spacing is inclined until 40 cm (Tan et al., 2014) and the highest hay yield can be taken from 150 viable seeds m^{-2} (Turk et al., 2011). Previous studies conducted with the same cultivar showed that average hay yields were 500 kg da^{-1} (Turk et al., 2011), 686 kg da^{-1} (Uzun et al., 2017). The different results amongst the studies can be attributed to different conditions. Comparing seeding rates and row spaces, the effect of seeding rates on hay yield is higher than row spaces (Table 1; Figure 1 and 2). As shown in Table 1, the effects of seeding rates and row spaces on crude protein yield obtained from forage of Golyazi pea variety were statistically significant. In terms of crude protein yield, effects of seeding rates and row spaces was similar to hay yield (Table 1; Figure 3 and 4).

The highest crude protein yield was obtained from 40 cm row spacing (127.4 kg/da1) and 120 viable seeds m^{-2} (128.8 kg da^{-1}). Narrowing row spaces and decreasing seeding rates decreased crude protein yield. Turk et al. (2011), reported that increasing seeding rates linearly increased crude protein yield of forage pea until 150 viable seeds m^{-2} but Uzun et al., (2017) found that though crude protein yield increased at 125 viable seeds m^{-2}, it decreased after that level. Crude protein yield of Golyazi cultivar was observed between 94 and 160 kg da^{-1} in previous studies (Turk et al., 2011; Uzun et al., 2017). The effects of different seeding rates and row spaces on crude protein ratios were found to be insignificant. Crude protein ratios of Golyazi forage pea cultivar grown at different seeding rates and row spaces varied between 20.11 - 25,91% (Table 1). Increasing seeding rates also increased crude protein ratios of forage pea until 125 viable seeds m^{-2} (Uzun et al., 2017), but Tan et al. (2014), reported that there was no significant effect of seeding rates and row spaces on crude protein ratios of forage pea.

*There are no significant differences amongst the number are shown with the same letter in the same line and column

Effects of seeding rates and row spaces on K, Ca, Mg, K/(Ca+Mg), P, ADF and NDF characteristics of forage pea were not significant (Table 1). K content of forage pea varied from 2,57% to 3,45%. These data are higher than values of maximum 0,8% suggested (NRC, 1996). High K concentration may cause Mg deficiency and as a result, tetany risk for ruminant increases (Loreda et al.,1986). Grass tetany or hypomagnesemic tetany in cattle is caused by an imbalance of K, Ca and Mg in the diet.

Mean Ca content of forage pea ranged between 1.18% - 1.26% (Table 1). Tajeda et al.(1985), reported that forage crops should contain Ca at least 0,3% for ruminants. The American National Research Council (NRC, 1984) recommended that forage crops should contain 0.31% Ca for beef cattle. Ca concentration of forage pea obtained from this study was enough for livestock. Mg content of forage pea ranged from 0,22% to 0,26%. There were few alterations. Recommended Mg concentrations for forage crops are 0,2% for ruminants (Tajeda et al., 1985) and 0,1% for beef cattle (NRC,1984). Mg content of pea forage was sufficient for ruminants. In order to maintain good animal health, the balance of mineral nutrient elements in forage or animal diets is very important and these elements should be in a certain ratio (

Abbasi et al., 2009). Ayan et al. (2010) reported that K/(Ca+Mg) ratio should not exceed 2.2 in forage. The value 2.2 or greater in forage can cause tetany (Jefferson et al., 2001). In this study K/(Ca+Mg) ratios varied between 1.78 - 2.37 (Table 1). Some of the data determined in this study are slightly higher than 2.2 (Table 1). It has been reported that P requirements of gestating or lactating beef are 0.18 - 0.39% (NRC,1996; Tekeli and Ateş,2005). P content of forage pea ranged from 0.39% to 0.47% (Table 1). Results obtained for P concentration in this study are slightly higher than requirements (Table 1).

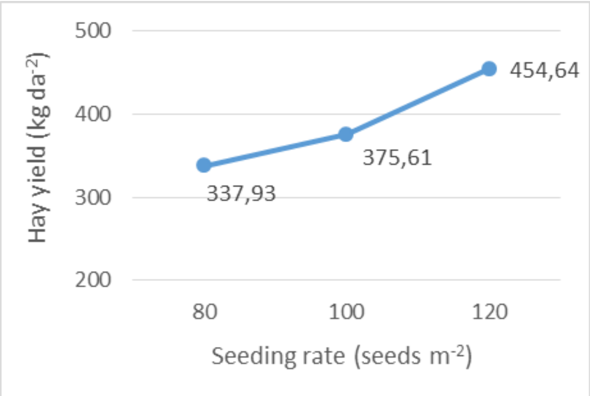

Figure 1. Effects of seeding rate on hay yield

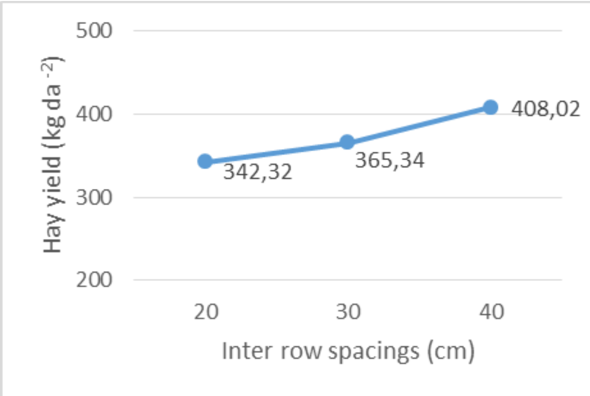

Figure 2. Effects of row spaces on hay yield

The ADF fraction includes cellulose with lignin and it is a slowly digestible material in forage (Acikgoz et al., 2013). As ADF increases, forage quality declines (Joachim and Jung,1997). In this study ADF contents of hay were under 30% and this value corresponded to prime quality according to forage standard (Yavuz et al., 2009). ADF ratios varied from 21 to 34% in previous studies (Tan et al., 2014; Uzun et al., 2017). These researchers reported that the effects of seeding rates on the ADF ratio of forage peas were significant. If the NDF value increases, dry matter intake generally decreases, and the rumination period increases (Van Soest et al.,1991). NDF contents of hay were between 36.10% - 43.46% in this study (Table 1). The NDF fraction includes cellulose, lignin and hemicellulose and as with ADF, this value is an important factor in determining forage quality. When NDF content decreases, dry matter intake will increase (Kebede et al., 2014). NDF results obtained from this study were similar to the NDF ratios reported by other researchers (Tan et al, 2014; Uzun et al., 2017).

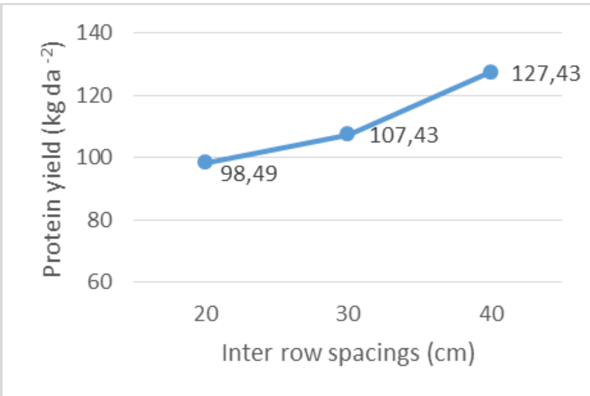

Figure 4. Effects of row spaces on hay yield

Conclusion

Forage pea is an important annual winter forage crop in Turkey. Considering climatic conditions and other factors, it has a huge production potential in the Black Sea Region of Turkey. In light of the results obtained from this one year research, forage pea should be cultivated in 40 cm row spacing with 120 viable seeds per m^{-2}.

Abstract

In the process of developing calibration models, use of chemometric methods and data pretreatments help to improve the accuracy of estimation. The objective of this study was to compare five wavelength selection techniques and seven pretreatments for oil content estimation in NIR spectroscopy. Flour samples from 250 different maize genotypes were used as experimental material. Soxhlet extraction was performed to determine the oil content of the samples as a reference method. Derivatives (FD and SD), standard normal variate (SNV), and multiplicative scatter correction (MSC) were used as data pretreatment. To select informative wavelengths for improving the accuracy of the models developed, several techniques were used, such as MAXR, successive projections algorithm (SPA), uninformative wavelength elimination (UVE), competitive adaptive reweighed sampling (CARS) and random frog (RFROG) methodologies. Partial least squares (PLS) and multiple linear regressions (MLR) were used for model development. Full range of scanned interval (1200-2400 nm) and selected wavelengths by the chemometric techniques were designed as predictor variables in the models. Internal and external validations were performed to compare the robustness of the models developed. The best prediction performance (RMSEC=0.516, SEC=0.518, R^2_{Cal}=0.905, RMSEP=0.463, SEP=0.465, R^2_{Val}=0.823 and RPD=2.37) was obtained from the FD-MSC-CARS-PLS model combination. Our results showed that the prediction accuracy of the NIR calibration models for oil content could be improved by using novel techniques of chemometrics. Three different wavelength intervals (1200-1400 nm, 1600-1800 nm and 2000-2400 nm) within the scanned region turned up to be effective in estimating oil content of maize grain.

Introduction

Plant oils have an important share in human nutrition as well as in industrial use. Increasing oil content has become one of the main breeding purposes in most agricultural crops. Although maize is not considered as an oil plant, it contributes a considerable portion of oil consumption in many countries. This brings about intensive studies to increase oil content of maize kernel. A main requirement of success in these breeding studies is an accurate and fast way of determination of the oil content in analysed samples.

Several apparatus have been used to determine the oil content of oil seeds such as Soxhlet, Goldficsh, Butt, and Bailey-Baker (Matthäus and Brühl, 2001). These systems are based on the use of organic solvents. There are also several solvent extraction systems such as Folch, Bligh and Dyer, Sheppard methods for oil determination. The prevalent method in most laboratories for determining oil content in food and feed products is Soxhlet system. However, it requires large volume of organic solvents and excessive time for extraction (Matthäus and Brühl, 2001). Therefore, there is a need to develop alternative methods for analysing the oil seeds.

NIR spectroscopy offers an eligible alternative to estimate oil content, being a non-destructive and user friendly technique (Teye *et al*., 2013). This technique entails a calibration model that could be developed by using standard chemical methods. In the process of developing calibration models, use of chemometric methods help to improve the accuracy of estimation. Different chemometric techniques are available (Reich, 2005; Roggo *et al.*, 2007), which can be viewed in three steps: data pretreatment, wavelength selection and model development/validation. Data pretreatment is commonly applied to reduce the unwanted effects such as nonlinearity, baseline effect and particle size. Derivatives, Multiple Scatter Correction (MSC), Standard Normal Variate (SNV) and detrending or combination of these are mostly used pretreatment methods in spectroscopic studies (Singh *et al*., 2006).

The literature lacks publications that report the use of different pretreatment and wavelength selection techniques collectively in the estimation of oil content in maize. Therefore, it would be useful to reveal the possible effects caused by different combinations of spectral pretreatments and wavelength selections on oil content analysis.

From this point of view; this study aims to investigate the prediction potential of different chemometric method and pretreatment combinations for determination of oil content in maize kernel.

Material and Methods

Two hundred and fifty maize samples were used as a plant material in this study; including breeding materials, open pollinated landraces and commercial hybrids. The experiment was conducted in the Agricultural Biotechnology and Field Crops Laboratories of Çanakkale Onsekiz Mart University in Turkey. Oil contents of maize samples were determined by Soxhlet extraction. For this purpose, kernel samples were grinded out with 0.5 mm sieve using laboratory mill (Fritsch pulverisette 14, Germany). Samples were extracted with diethyl ether for 6 hours using a commercial Soxhlet system (MXTOPS, Korea). Then, the solvent was evaporated under vacuum with diagonal rotary evaporator (Hahn Vapor, Korea). Crude oil samples were weighed with a laboratory balance (Denver Instrument, USA). In order to develop prediction models, spectra were taken from the ground samples within the interval of 1200-2400 nm in default mode of NIRS instrument (Spectrastar 2400D, Unity Scientific, USA). Rotating cup mode was used and spectra were taken from 24 different points of each sample. Then, all spectra were combined into one file for model development. Derivatives (FD and SD), standard normal variate (SNV), and multiplicative scatter correction (MSC) were used as data pretreatment. All pretreatment applications were performed in Unscrambler 10X software (Camo, Norway). Different techniques were used for elimination uninformative variable or informative ones before creating the prediction models, such as MAXR, successive projections algorithm (SPA), uninformative wavelength elimination (UVE), competitive adaptive reweighed sampling (CARS) and random frog (RFROG) methodologies. MAXR selection was performed in SAS statistical software as described in Abdel-Nour et al. 2009, SPA selection was applied using SPA-GUI toolbox of Matlab 7.0 (Galvão *et al.*, 2008), and uninformative wavelength elimination (UVE), competitive adaptive reweighed sampling (CARS) and random frog (RFROG) selection were performed using libPLS package (Li *et al*., 2014) of Matlab 7.0 statistical software. Partial least squares (PLS) and multiple linear regressions (MLR) were used for model development. Sample set were divided into two parts using Kernard-Stone Algorithm, one of which for developing the prediction models and the other for performing the external validation. Modelling studies was performed in Unscrambler 10X software for obtaining uniform output from different techniques. Prediction accuracy of the developed models was evaluated by RMSEP, R^2Cal, R^2Val, r, and RPD values.

Results and Discussion

Descriptive statistics for calibration (n=200) and external validation sets (n=50) are summarized in Table 1. Oil content values of the calibration set had a broad variation, with an average of 5.14%. The samples in external validation set had the range within the limit of calibration samples (Table 1). The range of the oil values in this study was quite wide compared to some previous studies. Fassio et al. (2015) used 128 maize samples having a range of 3.1-5.3% to develop a NIR prediction model for oil content. In another study, a PLS calibration was developed to predictthe oil content of the samples (n=70) having a range of 2.62%-6.08% oil (Tallada *et al.*, 2009). Wider range could support the prediction accuracy of developed models.

Table 1. Descriptive statistics for the oil contents (%) of the samples used in calibration and validation sets.

	n	Mean	Minimum	Maximum	Standard Deviation
Calibration set	200	5.14	2.35	10.9	1.68
External validation set	50	4.79	3.07	9.54	1.10

n: Number of samples.

Results of the evaluation parameters for the developed models are summarized in Table 2. Full spectrum (1200-2400 nm) with no pretreatment yielded an acceptable prediction accuracy in the calibration (RMSEC=0.667, SEC=0.669, R^2_{Cal}=0.841) and validation sets (RMSEP=0.519, SEP=0.522, R^2_{Val}=0.784, RPD=2.11). Different pretreatment and wavelength selection combinations showed significant variability for prediction performance. However, it could be said that applying the spectral pretreatment and inclusion of informative variables to prediction models gave more robust prediction results. Nevertheless, transforming the second derivative spectra with SNV or MSC methods had lower RPD values compared to first derivative spectra. This implies that first derivative is a more suitable transformation for the spectra from maize flour samples. The best prediction performance (RMSEC=0.516, SEC=0.518, R^2_{Cal}=0.905, RMSEP=0.463, SEP=0.465, R^2_{Val}=0.823 and RPD=2.37) was obtained from the FD-MSC-CARS-PLS model combination. Wavelengths used in the prediction models can be seen in Figure 1. Additionally, the numbers of wavelengths used in the models are given in Table 2. A careful look into these outputs helps to understand that 3 different regions within the scanned area (1200-2400 nm) are important for the prediction of oil content: 1200-1400 nm, 1600-1800 nm and 2200-2400 nm. Numbers of wavelengths within this spectral region varied in the developed models. To be able to make estimation for a variable in NIR instrument, the energy carried by the electromagnetic spectrum should interact with the targeted variable. This interaction is based on the vibration of the chemical bonds found in the structure of the matter. The wavelengths determined to be related with oil content and included as predictors in the developed models seem to be located in the spectral regions where C-H and O-H bonds, related with oil, are interacted. Our study supports the earlier studies (Siesler *et al.*, 2002; Egesel and Kahrıman, 2012) reporting certain spectral intervals related with oil content.

*WN is wavelength number in prediction models; Abbreviations are explained in material and methods

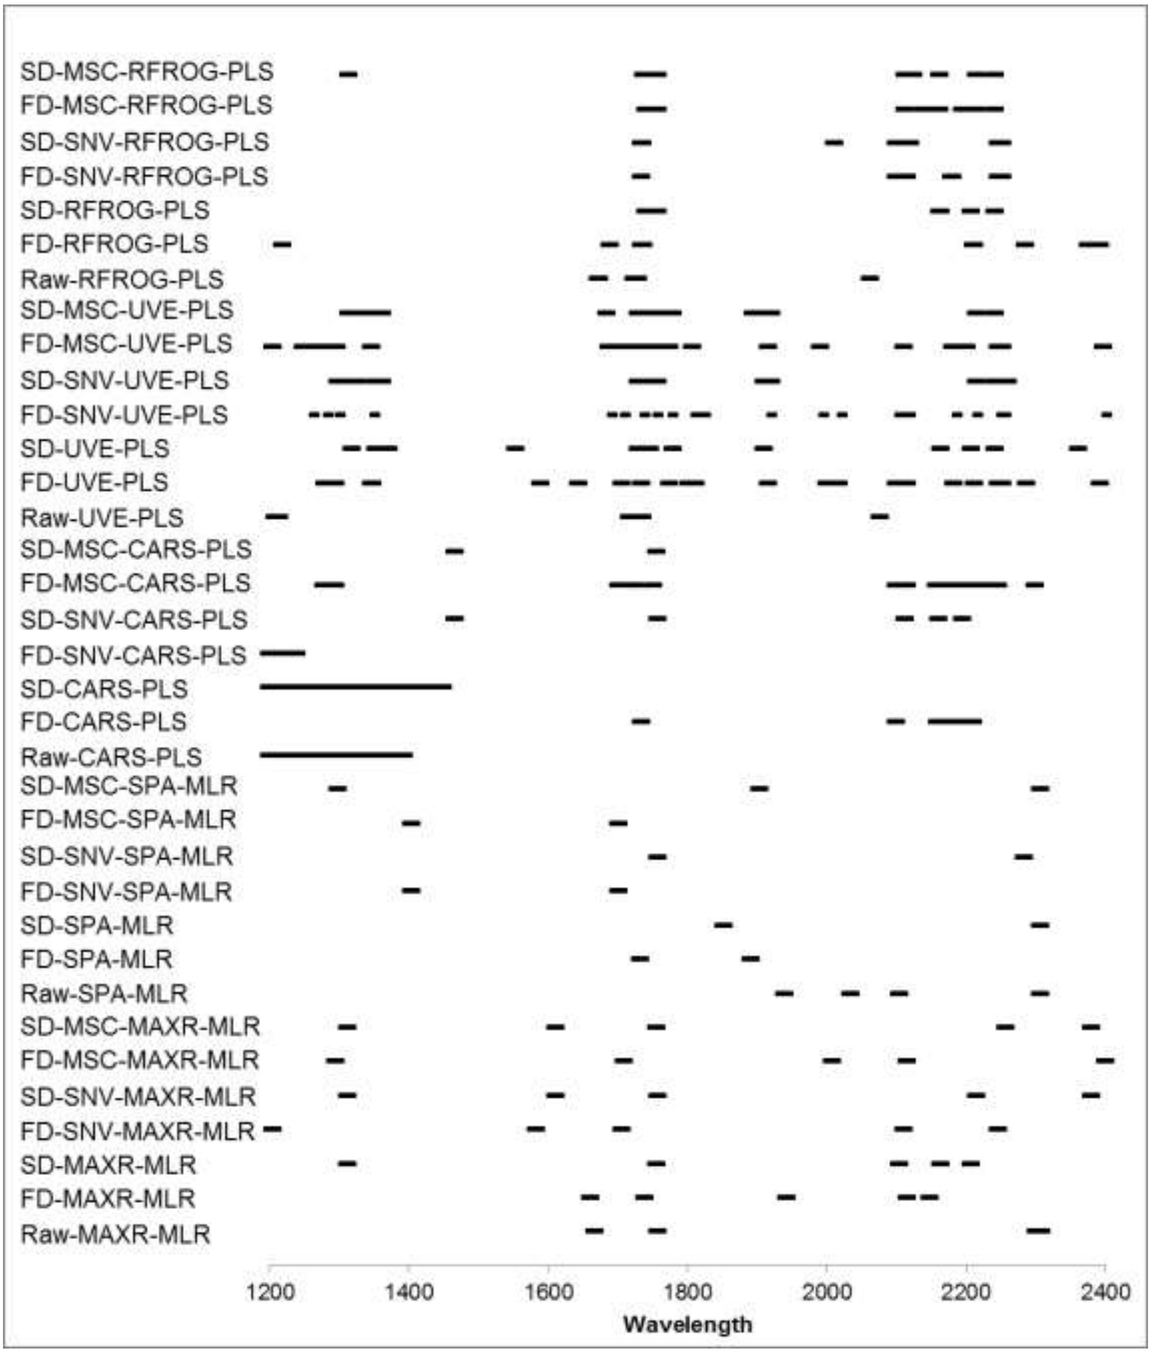

Figure 1. Wavelengths used in the developed models for prediction of oil content.

Conclusions

In conclusion, chemometric applications used here improved the prediction ability of NIR calibration models for oil content. Inclusion of related wavelengths in the prediction models and exclusion of others provide a clear contribution to the model performance. Different pretreatment and wavelength selection methods may be applied to increase the robustness of the developed calibration models for NIR instruments. Unfortunately, most of the traditional softwares do not have effective wavelength selection and pretreatment methods. Inclusion of such techniques into the current softwares may possibly improve the robustness of the calibration models. Also, other model development techniques such as artificial neural network and support vector machines may be utilized in future studies with similar objectives.

Abstract

Iodine is an essential trace element for human health and is involved in the production of the thyroid hormone. Recently, a new idea has emerged: to meet people's need for daily iodine by increasing the iodine content of vegetables. This study was carried out with iodine foliar application and root application methods to determine which application was more appropriate and to see the effect of iodine on germination. Germination experiments were conducted in an incubator according to a random block design, with 5 doses of iodine and five replicates. The yield experiment was conducted according to the same design in a greenhouse, with 5 doses of iodine, two application methods and three replicates. At the end of the germination experiment, the germination rate, root fresh and dry weight and root length were determined and at the end of the yield experiment, the plant fresh and dry weights were determined. The germination rate was not affected by the application. Root fresh and dry weight decreased with application doses. Applications reduced the root length by 50%, compared to the control plants. According to the yield results, the plant fresh and dry weight decreased with the increase in doses in two applications. It is important that no loss of yield occurred with the applications to increase the iodine content of the vegetables. After comparing foliar and root application methods, it is thought to be more appropriate to apply iodine by foliar spraying. In addition, the application dose should be selected carefully in order to avoid harming the plant.

Key words: *Iodine, Rocket, Vegetable, Thyroid.*

Introduction

Iodine is an essential element for humans and animals, while not necessarily a nutrient for plants. Iodine, which is involved in thyroid hormone production, is an essential element for normal growth and development and for brain and body functions (Erbaş, 2008).

The amount of iodine in rocks is generally low. Iodine concentrations are between 0.2 and 0.8 ppm in basic extrusive. In acid eruptive, metamorphic rocks and some sedimentary rocks, the amount of iodine varies from 1 to 2 ppm. The average iodine content of the soil surface is stated as 5 ug g^{-1}. The iodine content of the soil is more than 20-30 times that of rocks (Halilova, 2004). According to Whitehead (1984), the basic source of iodine in the soil is atmospheric iodine and the main sources of atmospheric iodine are seas and oceans (Tsukada et al., 2008). Iodine can easily evaporate under the influence of daylight and temperature. Iodine, which is mixed with the atmosphere, reaches land with rain (Halilova, 2004). The losses which occur during the process of the iodine reaching the soil cause a small amount of iodine to be found in the soil and in the crops grown in these soils. According to the WHO, ICCIDD (International Council for the Control of Iodine Deficiency Disorders), Global Network and UNICEF, the daily amounts of iodine that people should take are as follows: 0-6 years - 90 micrograms (μg), 7-12 years - 120 μg, over 12 years - 150 μg and pregnant and lactating women - 250 μg. When the daily iodine requirement is not satisfied, a series of developmental and functional diseases known as Iodine Deficiency Disorders can occur. Although iodine deficiency can be cured, it remains a health problem for about 35% of the world's population (Pearce *et al.*, 2004; Winger 2008; Landini, 2011). According to recent WHO surveys, around 2 billion people in the world are still confronted with insufficient iodine intake. Compared with the WHO regions, the European continent has the highest rate of iodine deficiency, at 45% of the population (Anderson *et al*., 2012; Daum *et al*., 2013). In Turkey, iodine deficiency remains an important public health problem.

The visible sign of iodine deficiency is the goiter which is seen in all age groups. The total prevalence of goiter in Turkey is as high as 30.5% and the visible goiter rate is around 6.7% (Yordam *et al*., 1999).

Iodine deficiency causes growth retardation, deafness, dwarfism and hypothyroidism in infants, growth retardation, school failure, difficulties in understanding and learning in children and adolescents, hypothyroidism, inadequate mental functioning, weakness and inefficiency in adults (Pekcan, 2008). At the same time, iodine deficiency was found to reduce IQ by 13.5 points (Pekcan, 2008; Zimmermann, 2012). There is an increased risk of death in newborns with a lack of iodine. The prevention of iodine deficiency in China and Zaire has been shown to reduce the risk of newborn mortality (Erbaş, 2008).

In the human body and animals, 80% of the iodine is naturally supplied by edible vegetables (Welch and Graham, 2005; Weng *et al*., 2013) and the bioavailability of iodine in these vegetables is about 99%. The concentration of iodine in the soil in which vegetables are grown is usually too low to supply the needs of the human body (Weng *et al.,* 2013). The iodine content of the plant that grows in soil with a high amount of iodine is high.

Diet is the only way to take iodine into the body (Vitti *et al.*, 2001; Pekcan, 2008). The use of iodized salt is the most common approach for iodine supplementation (Delange and Lecomte, 2000; Andersson *et al.,* 2005). However, during activities such as cooking, storage and transportation, it is difficult to control the loss of iodine and iodine supplementation causes many problems during food processing (Winger *et al.*, 2008; Landini *et al.,* 2011). The level of iodized salt usage in our country is inadequate to control iodine deficiency (Özkan *et al*., 2004). Increasing iodine levels in food with vegetables which have a high rate of bioavailability and assimilation is a more effective way of controlling iodine deficiency in a cost effective manner. (Dai *et al.,* 2004; Weng *et al.,* 2009; Landini *et al.,* 2011)

Food consumption in Turkey is largely composed of foods which are of cereal origin. In addition, leafy vegetables play an important role in the nutrition program. The rocket plant (*Eruca vesicaria*) is a vegetable with leaves consumed as a salad and recently its consumption has increased. The rocket plant is rich in vitamin C and also has antioxidant properties.

Considering that rocket production and consumption is increasing in Turkey, that it is consumed raw in salads daily, and that iodine can be accumulated in the leaves, this study aimed to determine which method is more appropriate to increase the iodine content of rocket plants, namely, spraying iodine on the leaves or applying it to the roots and to see the effect of iodine on germination.

Materials and Methods

The yield experiment was developed under greenhouse conditions at Canakkale Onsekiz Mart University in Turkey. The rocket plant was chosen as study material because of its consumption as raw leaves. The experiment was conducted with a randomized block design with 5 doses of iodine in the form of potassium iodide (0, 1, 2, 4, 8 mM), two application methods (foliar and root application) and three replicates. The plants were grown with a Hoagland nutrient solution. At the end of the experiment, the plant’s fresh and dry weights were determined. After harvesting, the fresh weight (FW) of leaves was directly determined.

For dry weight (DW) determination, the leaves were dried at 70°C for 48 h and weighed. Germination experiments were conducted in an incubator at 25°C according to a random block design, with 5 doses of iodine and five replicates. Fifty seeds sterilized with 10% hypochlorite were placed in each petri dish. At the end of the experiment, germination rate, root length, root fresh and dry weight were determined. The results were subjected to analysis of variance according to the randomized block experiment design using the MINITAB 17.0 statistical package program and the averages of the data with significant differences between them were compared with the LSD.

Results and Discussion

The fresh weight data obtained from the soil and foliar iodine application to the rocket plant are given in Table 1. When Table 1 is examined, it can be seen that the highest fresh weight is 65.25 g and the lowest is 30.73 g. Interactions between the application form and the doses created a statistically significant difference (P<0.01) in plant fresh weight. In soil applications, the plant's fresh weight was reduced in parallel to the increasing dose of iodine. In foliar applications the change was not as great as in soil applications.

Table 1. Plant fresh weight (g) averages and multiple comparison results

Method of Application	**Iodine application doses (mM)**				
	0	**1**	**2**	**4**	**8**
Soil	65.25±0.68 A	46.95±3.82 BCD	41.07±0.77 CDE	35.88±0.72 DE	30.73±1.82 E
Foliar	55.02±2.04 AB	57.27±1.52 AB	53.35±11.9 ABC	55.75±5.2 AB	48.90±1.72 BCD

Mean values marked with the same letter in columns do not differ significantly (P<0.01) from each other.

The dry weight data obtained from the soil and foliar iodine application to the rocket plant are given in Table 2. When Table 2 is examined, it can be seen that the highest dry weight is 10.05 g and the lowest is 5.51 g. The highest weight was obtained in soil with 0 mM (control) iodine dose and the lowest weight was obtained in soil with 8 mM iodine dose. Interactions between the application form and the doses created a statistically significant difference (P<0.01) in plant dry weight. In a study carried out in lettuce, iodine (0.25 and 0.50 kg ha^{-1}) applied to the leaves increased the content of iodine in the edible parts of the plant without reducing the yield and quality of the product (Daum *et al.*, 2013). The results of our study are not similar to this study, especially with the soil application reduced the yield.

Table 2. Plant dry weight (g) averages and multiple comparison results

Method of Application	**Iodine application doses (mM)**				
	0	**1**	**2**	**4**	**8**
Soil	10.05±0.36 A	6.90±0.30 CD	6.57±0.20 CD	5.77±0.40 D	5.51±0.16 D
Foliar	8.54±1.95 ABC	9.26±0.26 AB	9.58±0.66 A	8.43±0.70 ABC	7.35±0.12 BCD

Mean values marked with the same letter in columns do not differ significantly (P<0.01) from each other.

The seeds were placed in petri dishes and germinated seeds started to be counted one day after iodine application. The counting continued until the eighth day and the germination percentages of the seeds were calculated. Table 3 gives the number of germinated seeds in petri dishes with 0 (control), 1 and 2 mM iodine (I) applied.

Table 3. Number of germinated seeds in 0 (Control) 1 and 2 mM iodine applications

Replicate		**1**	**2**	**3**	**4**	**5**	**Average**	**Rep.**	**1**	**2**	**3**	**4**	**5**	**Avg.**	**Rep.**	**1**	**2**	**3**	**4**	**5**	**Avg.**
0 mM I	**1. Day**	35	37	38	32	37	36	**1 mM I**	38	34	40	40	41	39	**2 mM I**	37	39	37	36	41	38
	2. Day	43	46	46	43	46	45		45	43	43	49	46	45		40	43	47	43	49	44
	3. Day	46	47	47	45	46	46		47	43	46	50	46	46		44	44	48	44	50	46

	5. Day	47	49	47	46	46	47		47	45	47	50	47	47		45	45	48	45	50	47
	6. Day	47	49	47	47	47	47		47	45	48	50	48	48		45	45	48	47	50	47
	7. Day	47	49	47	48	47	48		47	45	48	50	48	48		45	45	48	47	50	47
	8. Day	47	49	47	48	48	48		47	46	48	50	48	48		46	46	48	47	50	47

When Table 3 is examined, it can be seen that 48 seeds of 50 seeds in the control group were germinated at the end of the eighth day. The germination percentage was calculated as 96%. At the end of the eighth day, 48 seeds were germinated from 50 seeds which had been applied 1 mM iodine, and the germination percentage was calculated as 96%. In the group with 2 mM iodine applied, 47 seeds of 50 seeds were germinated and the germination percentage was found to be 94%. Table 4 gives the number of germinated seeds in petri dishes with 4 and 8 mM iodine (I) applied.

Table 4. Number of germinated seeds in 4 and 8 mM iodine applications

Replicate		**1**	**2**	**3**	**4**	**5**	**Average**	**Rep.**	**1**	**2**	**3**	**4**	**5**	**Avg.**
4 mM KI	**1. Day**	32	33	43	38	30	35	**8 mM KI**	40	33	34	38	29	35
	2. Day	42	41	47	44	42	43		47	46	46	47	45	46
	3. Day	43	45	48	45	45	45		47	49	46	47	46	47
	5. Day	45	46	48	46	47	46		48	49	46	47	46	47
	6. Day	45	46	49	47	47	47		48	49	46	47	46	47
	7. Day	45	46	49	47	47	47		48	49	46	47	46	47
	8. Day	45	46	49	47	48	47		48	49	46	47	46	47

When Table 4 is examined, it can be seen that 47 seeds of the 50 seeds in 4 mM iodine application had germinated by the end of the eighth day. Germination percentage was found to be 94%. It can be seen that 47 seeds of the 50 seeds in the 8 mM iodine application had germinated at the end of the eighth day. The percentage of germination was calculated as 94%. If we compare the germination percentages, it can be seen that the iodine application does not have a negative effect on germination. Root length data obtained from germinated seeds after iodine application are given in Table 5.

Table 5. Root length per plant (cm) averages and multiple comparison results

Root length (cm)						
Replicate	**1**	**2**	**3**	**4**	**5**	**Average**
0 mM	4.3	3.9	4.2	4.1	4.4	4.2 A
1 mM	3.5	3.4	3.3	3.3	3.7	3.4 B
2 mM	2.6	2.8	3.1	3.1	3.0	2.9 C
4 mM	2.9	3.2	2.5	2.7	3.0	2.9 C
8 mM	2.0	2.0	2.1	2.4	1.8	2.1 D

Mean values marked with the same letter in columns do not differ significantly ($P<0.01$) from each other.

When the table is examined, it can be seen that the iodine concentrations were determined to have no negative effect on germination, to adversely affect root development and to cause a decrease in root length. There was a 50% reduction in root length between the control group and the highest dose of 8 mM iodine. The doses applied created a statistically significant difference ($P< 0.01$) in root length. Root fresh weight data obtained from germinated seeds after iodine application are given in Table 6.

Table 6. Root fresh weight per plant (g)

Root Fresh Weight (g)						
Replicate	**1**	**2**	**3**	**4**	**5**	**Average**
0 mM	0.0100	0.0114	0.0122	0.0071	0.0160	0.0114
1 mM	0.0114	0.0086	0.0105	0.0098	0.0100	0.0100

2 mM	0.0071	0.0103	0.0096	0.0095	0.0096	0.0092
4 mM	0.0089	0.0094	0.0078	0.0084	0.0097	0.0088
8 mM	0.0058	0.0055	0.0078	0.0076	0.0072	0.0068

When the table is examined, it can be seen that the iodine concentrations negatively affect root development without any adverse effect on germination. The highest weight was obtained with 0.0114 g in the control group, while the lowest weight was obtained with 0.0068 g in 8 mM iodine concentration. Between the control group and the highest iodine concentration, the root fresh weight was reduced by 40%. However, this change was not statistically significant. Root dry weight data obtained from germinated seeds after iodine application are given in Table 7.

Table 7. Root dry weight per plant (g)

Root Dry Weight (g)						
Replicate	**1**	**2**	**3**	**4**	**5**	**Average**
0 mM	0.000511	0.000531	0.000556	0.000463	0.000558	0.000524
1 mM	0.000395	0.000314	0.000409	0.000422	0.000400	0.000388
2 mM	0.000324	0.000378	0.000391	0.000390	0.000404	0.000378
4 mM	0.000324	0.000353	0.000375	0.000351	0.000382	0.000357
8 mM	0.000258	0.000273	0.000333	0.000310	0.000306	0.000296

When the table is examined, it can be seen that the root dry weight decreases in parallel with increasing iodine doses. Between the control group and the highest iodine concentration, the root dry weight decreased by 44%. However, this change was not statistically significant.

Conclusions

Consequently, according to the germination experiment, the highest root fresh and dry weights were obtained in the control group and the lowest weight was obtained in 0.8 mM iodine dose. Applications also affected the root length and a difference of 50% was found between the control group and the highest dose. Iodine doses did not cause a difference in germination percentage. According to the results obtained from the yield experiment, plant fresh and dry weights were affected by the method of application. Plant fresh and dry weights decreased in parallel with increasing iodine doses in soil applications. In foliar applications, there was no significant decrease in plant fresh and dry weight compared to the control.

It is important that the method of application and the iodine concentration to be applied to increase the plant iodine content does not adversely affect the plant growth, or does not cause yield loss. Comparing soil and foliar applications, foliar application is considered more appropriate. In addition, the iodine concentration should be carefully selected so that root growth is not adversely affected.

Abstract

This study investigated the effect of humic acid on the growth of lettuce and on some properties of soil under Cd pollution conditions. This work was carried out at the agriculture faculty of Canakkale Onsekiz Mart University in Turkey. An experiment was conducted according to a random block design, in a greenhouse with four doses of humic acid (0, 4, 8, 12 L da^{-1}), three doses of Cd (0, 1.5 and 3 mg kg^{-1}) and three replicates. The source of humic acid application was “TKİ-Humus’’, a trademarked product, and the “Yedikule-5701’’ variety of lettuce was used. At the end of the experiment, the fresh weight (g) and dry weight (g) of the plants, leaf length (cm), leaf width (cm), soil reaction (pH), electrical conductivity (EC,µS/cm), and calcium carbonate (% of $CaCO_3$) were determined. The results were subjected to a one-way ANOVA in the MINITAB 17.0 statistical package program. Differences which were statistically significant according to the results of variance analysis of the variables/elements were compared with an LSD test. The humic acid application showed a statistical difference ($P>0.01$) for leaf length. A statistical difference ($P<0.05$) was also observed in the plant’s fresh and dry weight and leaf width with regard to the interaction of the humic acid application and cadmium application. In contrast, no relationship was found between soil properties and humic acid except in the case of electrical conductivity. Humic acid and cadmium applications created a statistically significant difference ($P<0.05$) in electrical conductivity.

Key words: *Cadmium, Humic Acid, Lettuce, Soil*

Introduction

The use of synthetic fertilizers has dramatically increased food production worldwide, but the unintended costs to the environment and human health have been substantial. Agricultural practice has changed a great deal in the last 30-40 years. Intensive farming techniques, especially aggressive N applications, have caused many environmental problems. Low-input and organic farming are two of the new challenging methods developing in agriculture all over the world (Rehber and Turhan, 2002). Many positive developments have been made to improve the quality and quantity of agricultural production. Unsuitable soil conditions for plant growth usually arise from the lack of organic content in the soil. The effect of organic matter on the physical, chemical, and biological properties of the soil has been well known for a long time. The organic matter content of soil in Turkey is generally low (Eyupoglu 1998). To solve this problem, additional humic substances have started to be applied to the soil, to improve the crop yield. Humic substances are derived from the breakdown of organic plant material, mainly by soil bacteria, and consist mainly of humus, humic acid, fulvic acid and trace minerals. Humic substances are usually applied to the soil, and favourably affect the soil structure and soil microbial populations. According to the International Humic Substances Society (IHSS), humic substances (HS) are complex and heterogeneous mixtures of polydispersed materials formed in soils, sediments, and natural waters by biochemical and chemical reactions during the decay and transformation of plant and microbial remains (a process called humification). It was reported that humic substances affect physical and chemical properties of soils (Boyle et al. 1989; Schnitzer 1992). However, their effects on soil have not yet been clearly explained. Some reviews (Chen and Aviad, 1990; Varanini and Pinton, 1995) summarize the effects of humic substances on plant growth and the uptake of macro and micro elements. Another important aspect is the effect of heavy metals being present in the soil. Heavy metals are commonly defined as those having a specific density of more than 5 g cm^{-3}. Heavy metals in urban soils may come from various human activities. Most heavy metals also pass through the food chain, which can damage human health. Although adverse health effects of heavy metals have been known for a long time, exposure to heavy metals continues and is even increasing in some areas. Exposure to cadmium (Cd) can have effects such as lung cancer, bone fractures, kidney dysfunction and hypertension. Humic substances with molecular weights ranging from several hundreds to millions constitute the bulk of natural organic matter and can appreciably affect the consequences of heavy metals in the environment (Davis and Bhatnahgar 1995). The objective of this study was to study the effect of humic acid on the growth of lettuce and on some properties of soil under Cd pollution conditions.

Materials and Methods

This study was carried out with the Yedikule 5701 lettuce variety (*Lactuca sativa L.*) in the greenhouse of the Soil Science and Plant Nutrition Department of the Agricultural Faculty, Canakkale Onsekiz Mart University. The soil characteristics are presented in Table 1.

Table 1. Physical and chemical properties of the soil

Texture	**Electrical Conductivity (mS/cm)**		**Soil Reaction (pH)**		**Calcium Carbonate (%)**	**Organic Matter (%)**	
Loamy	0.39		7.59		7.25	0.42	
Available P, mg kg^{-1}	**Available K, mg kg^{-1}**	**Available Ca, mg kg^{-1}**	**Available Mg, mg kg^{-1}**	**Available Cu, mg kg^{-1}**	**Available Zn, mg kg^{-1}**	**Available Fe, mg kg^{-1}**	**Available Mn, mg kg^{-1}**
6.65	7.91	4 097	251.80	0.10	0.41	1.96	1.65

For the analyses of soil, the texture was determined by the Bouyoucus (1951) hydrometric method, the pH by the Jackson (1958) 1: 2.5 soil-water suspension method, the lime content with 5 replicates by calcimetric methods (Allison & Moodie, 1965), the level of organic matter by the modified Walkley Black method (Walkey, 1947), the salt by the Richards (1954) method, and the soil samples were prepared by the wet digestion method and the plant nutrient contents were determined by ICP-MS. In the experiment, TKİ HÜMAS produced by Turkish Coal Enterprises was used as material. The humic acid used contained 5% total organic matter by weight and 2% water-soluble potassium oxide by weight and its pH was between 11-13. The experiment was conducted according to a random block design, in a greenhouse with four doses of humic acid (0, 4, 8, 12 L da^{-1}), three doses of Cd (0, 1.5 and 3 mg kg^{-1}) and three replicates. At the end of the experiment, the fresh weight (g) and dry weight (g) of the plants, leaf length (cm), leaf width (cm), soil reaction (pH), electrical conductivity (EC,µS/cm), and calcium carbonate (% of $CaCO_3$) content were determined. The results were subjected to a one-way ANOVA in the MINITAB 17.0 statistical package program. Differences which were statistically significant according to the results of the variance analysis of the variables/elements were compared with an LSD test.

Results and Discussion

The fresh weight data obtained from humic acid and cadmium applications to the lettuce plants are given in Table 2. When Table 2 is examined, it can be seen that the highest fresh weight is 74.71 g and the lowest is 25.68 g. Interactions between humic acid and cadmium applications created a statistically significant difference (P< 0.05) in the plant fresh weight. The plants' fresh weight increased parallel to the increasing doses of humic acid applications until 12 L da^{-1} and then decreased at this dose. The dry weight data obtained from humic acid and cadmium applications to the lettuce plants are given in Table 2. When Table 2 is examined, it can be seen that the highest dry weight is 4.36 g and the lowest is 1.57 g. The highest weight was obtained with the 4 L da^{-1} humic acid and 0 mg kg^{-1} cadmium application and the lowest weight was obtained with the 4 L da^{-1} humic acid and 1.5 mg kg^{-1} cadmium application. Interactions between the humic acid and cadmium created a statistically significant difference (P< 0.05) in plant dry weight.

The leaf length data obtained from humic acid and cadmium applications to the lettuce plants are given in Table 3. When Table 3 is examined, it can be seen that the highest leaf length is 25.00 cm and the lowest is 15.00 cm. The humic acid application created a statistically significant difference (P< 0.01) in leaf length. The leaf length increased parallel to the increasing dose of humic acid applications.

Mean values marked with the same letter in columns do not differ significantly (*P*< 0.01** *P*< 0.05*) from each other.

The leaf width data obtained from humic acid and cadmium application to the lettuce plants are given in Table 3. When Table 3 is examined, it can be seen that the highest leaf width is 12.22 cm and the lowest is 7.16 cm. The highest width was obtained with the 12 L da^{-1} humic acid and 1.5 mg kg^{-1} cadmium application and the lowest weight was obtained with the 0 L da^{-1} humic acid and 0 mg kg^{-1} cadmium application. Interactions between the humic acid and cadmium applications created a statistically significant difference ($P< 0.05$) in leaf width. The soil reaction, electrical conductivity, and calcium carbonate content data obtained from humic acid and cadmium applications to the soil are given in Table 4. When Table 4 is examined, it can be seen that soil reaction varied between 8.69 and 8.93. This change was not statistically significant. When Table 4 is examined, it can be seen that the highest electrical conductivity was 232 EC,µS/cm and the lowest was 103 EC,µS/cm. The highest electrical conductivity was obtained with the 0 L da^{-1} humic acid and 0 mg kg^{-1} cadmium application and the lowest electrical conductivity was obtained with the 12 L da^{-1} humic acid and 3 mg kg^{-1} cadmium application. Humic acid applications and cadmium applications created a statistically significant difference ($P< 0.05$) in electrical conductivity. The soil calcium carbonate content data are given in Table 4. When Table 4 is examined, it can be seen that the highest calcium carbonate content was 1.33 and the lowest was 0.88. Although the highest and lowest data showed a numerical difference, there was no statistical difference.

Conclusions

Consequently, according to the experiment, the highest plant fresh weight and leaf length and width were obtained with the 12 L da^{-1} humic acid and 1.5 mg kg^{-1} cadmium application and the lowest fresh weight and leaf length and width were obtained with the 0 L da^{-1} humic acid and 0 mg kg^{-1} cadmium application. Applications also affected the plant dry weight. It was reduced by humic acid and cadmium applications. Humic acid and cadmium applications did not cause a difference in soil reaction and calcium carbonate content. According to the results, humic acid and cadmium applications reduced electrical conductivity. Humic acid applications increased the growth of lettuce under cadmium pollution conditions. Plant fresh weight, leaf length and width increased with the 12 L da^{-1} humic acid application. It is thought that this situation is related to the uptake of plant nutrients. Humic acid could be used to promote plant growth under cadmium pollution conditions, but the application doses should be determined by detailed studies.

Abstract

This investigation was carried out to determine the highest CP (Crude protein), NDF (Neutral Detergent Fiber), ADF (Acid Detergent Fiber), ADL (Acid Detergent Lignin), DMD (Dry matter digestibility), DE (Digestible energy), ME (Metabolizable energy), DMI (Dry matter intake), and RFV (Relative feed value) of silage corn varieties grown as the second crop under Igdır ecological conditions. Ten corn hybrids (72 MAY 80, OSSK644, TK 6063, OSSK 596, TK 6060, HIDO, RX 9292, 71 MAY 69, SHEMALL and OSSK 602) were used. The completely randomize block design were set up with three replications in the experiment areas of the Agricultural Faculty of the Igdır University in the 2015. According to results of the trial, the crude protein ratio (7.02-8.45%), NDF (40.24-54.16%), ADF (20.03-28.30%), ADL (1.76-2.93%), DMD (69.5-73.3 %), DE (3.13-3.40 Mcal/kg^{-1}), ME (2.66-2.79 Mcal/kg^{-1}), DMI (2.22-2.99 Mcal/kg^{-1}), RFV (115.0-170.0) were ranged. The results showed that crude protein ratios were not statistically significant between corn varieties. It was concluded that TK 6060 corn variety was found to be more nutritious than other corns, as it was suggested NDF, ADF and ADL values are low and DMD, DE, ME, DMI and RFV values are high in terms of animal feeding.

Keywords: *Silage corn varieties, Crude protein, Fiber, Lignin, Dry matter digestibility, Digestible and metabolizable energy, Dry matter intake, Relative feed value*

Introduction

Maize (*Zea mays* L.), which is a warm climate plant, has become the most important grain product with its versatile used in the modern world and it is the most used plant after the wheat and paddy in human nutrition and the majority of production in developing countries is for human consumption and in the developed world it is mainly used for industrial purposes and animal feed (FAO, 1992 and Kırtok Y, 1998). It ranks as the third most important cereal grain in the world and traditional criteria for selectin maize hybrids have been based primarily on agronomic factors, including grain production, disease resistance, drought tolerance (Zilic et al. 2011). The value of a good quality fodder for animal production depends upon the nutrient concentration as well as fodder intake by animals.Long-term research on corn production has emphasized the complex on demonstrate a clear relationship between corn crop growth, grain yield, soil quality and its linkages with soil nutrients, especially nitrogen and phosphorus; soil organisms; and physical characteristics (Lal, 1998). Although many varieties have been cultivated in the region, comprehensive nutritional evaluation of maize cultivars fodder has not been undertaken on the nutrient content in Igdır region. Therefore, this investigate was made to determine the nutritive value of some corn plants of with particular references cultivar differences.

Material and methods

The ten corn cultivars used for this research were chosen on the basis of area with loam and sandy, in texture of the Agricultural Faculty of the Igdır University in last week of June 2015. The experimental design was a randomized complete block with three replications. The soil lime with % 6.53, soil pH 7.98, soil electrical conductivity with 1.8 dS m^{-1}. The plots sizes were 5 m x 3.5 m, having a row spacing of 0.70 m and a within-row spacing of 0.20. Before planting, and half of the total nitrogen with 15 kg pure N (ammonium sulphate with 21% N) and all phosphorus with 10 kg P_2O_5 were applied for all plots and the rest of nitrogen were applied the plants were reached to 40-50 cm height. The mean temperature from April to September was 22.8 ^oC, relatively moisture 43.2, mean precipitations 23.8 mm and the lowest precipitation was 4.7 and 5 mm in August month of the 2015 and it seems to be ideal for growing corn in terms of temperature (Anonym, 2015). The corn of plants was harvested at the physiology stage at 25 August 2015. At harvest, 30 randomly selected corn cobs from each plot was stripped of ears by hand and then mixed. From this mixture about 0.500 g sample was subjected to chemical analysisfor quality measurements by grounding to pass through a 1 mm screen. For the purpose of traits measurements such as CP, NDF, ADF, ADL, and DMD of corn varieties at each plot, ten corn were selected from each plot and then were ground with screen and analyzed. The total nitrogen was determined according to the method of Micro Kjeldahl in 0.3-0.5 g milled samples and then the nitrogen ratios were multiplied by a coefficient of 6.25 and the crude protein was determined according to Kacar, (1972) and Akyildiz, (1984). For analysis of NDF (Neutral Detergent Fiber), ADF (Acid Detergent Fibre and ADL (Acide Detergent Lignin) samples between 0.950 and 1.050 g were weighed on the sensitive scale together with the Filterbag weight, and analyzed with the ANKOM fiber analyzer using the method developed by Van Soest et al., (1991). DDM (Digestible Dry Matter) rate were determined by Oddy et al., (1983) formula= 88.9 - (0.779 x% ADF). DE (digestible energy, Mcal kg^{-1}) was calculated using 0.27 + 0.0428 x (% KMS) formulated by Fonnesbeck et al., (1984). Metabolic energy (Mcal kg^{-1}) = 120/(% NDF) was calculated according to the formula used by Khalil et al., (1986).

Statistical analysis The data on various parameters were subjected to statistical analysis using of variance technique and Duncan' multiply range test was applied to compare treatment means by using SPSS (17.0) package statistical program.

Results and discussion

The corn varieties with the highest nutrient content in accordance with the regional conditions were crude protein (CP), Neutral Detergent Fiber (NDF), Acid Detergent Fiber (ADF), Acid Detergent Lignin(ADF) (digestible dry matter (DDM) were presented in Table 1. There were some significant differences between the varieties in terms of all traits examined. However, although the crude protein rate in grain ranged from 7.05% and 8.45% of silage corn plants, significant crude protein differences between hybrids were not found (Fig. 1). Carter et al. (1991) stated that protein is not considered a major factor for corn forage evaluation, due to the low protein concentration of corn compared with legume forages. The findings 6.21-8.65% by Vartanlı and Emekliler (2007) were compatible with this study, on the contrary, were low according to results by Sade et al. (2002), Ayrancı and Sade (2004) and Koca et al. (2006), Koca and Erekul (2011). Öner (2015) suggested that crude protein rate in corn grain may change may change depends on locations Leno and Larkins (1991) and Uribelelarre et al. (2004) note that the composition of the grain can vary according to plant species, endosperm genetic structure and environmental conditions. Julian et al. (2010) reported that the protein and starch concentrations of the grain could be changed depending on genotype or N applications. Because nutritive value of forages is variable, producer encouraged to submit samples to commercial feed test labs for chemical analysis. The ADF content can be used to predict the energy content of forage. While predictions of DMI from NDF are poor, the NDF are poor, the NDF content of forage should be used in diet formulation to ensure adequate fiber (Beacuhemin, 1996). NDF, ADL, ADF, and DMD of rations of corn grain were significantly differences between hybrids found in Table 1, Fig 2, 3, 4 and 5. The highest and lowest NDF and ADF rates (54.16 and 40.24%) and (28.60 and 20.03%) was obtained from OSSK 644 and TK 6060 varieties, respectively. However, ADL concentrations of grain corn ranged from 1.76 to 2.93 percent and the highest value was OSSK 602 with 2.93% variety. Teke and Gül (2014) stated that the amount of NDF and ADF in ration or diet is important for some physiologic periods of ruminants in terms of preventing various the metabolic diseases such as acidosis, laminitis and rumen parakeratosis. Although ADF and NDF are good indicators of fiber contents in forages, they do not measure how digestible that fiber is. The reason for the lack of NDF in feeds is metabolic diseases caused by lack of energy due to the change in the rumen fermentation (Calsmiglia et al., 2008), so it is not desirable that the daily consumption of animals is 45.8% for the NDF content, 25% for the ADF content and 10% (NRC, 2001). DMD (%) of corn varieties were significantly significant and ranged from 66.8 % with OSSK 644 and 73.3% with TK 6060 varieties, respectively.

Digestible energy, Mcal kg^{-1} (DE), metabolic energy Mcal kg^{-1} (ME), dry matter intake (DMI %), Relative feed value (RFV) are given in Table 1, Fig.6, 7, 8, and 9. Although the energy values are very close to each other, there is a statistical difference between the varieties with small differences. The highest DE, Mcal kg^{-1} value were obtained from TK 6060 and the lowest value was obtained from OSSK 644 with 3.13 value. Similarly, the highest values of ME, DMI and RFV values of hybrid maize varieties were 2.79 Mcal kg^{-1}, 2.99% and 170.0, respectively, and the lowest values were 2.57 Mcal kg^{-1}, 2.22 % and 115.0%, respectively. Although the energy values are very close to each other, there is a statistical difference between the varieties with small differences. The highest value was obtained from TK 6060 and the lowest value was obtained from OSSK 644 with a value of 3.13. Consequently, extensive variation was not observed indigestibility of energy DE, ME and DMI of corn hybrids and the less variation is explained by indifferences in these ingredients of grain of hybrids of commercial corn. These findings were not similar to previously described by Denek and Deniz (2004), stated that the organic matter digestibility of corn were 83.90%, Digestible energy 15.94 MJ/kg DM, metabolizable energy 8.41 MJ/kg DM, net energy 8.41 MJ/kg DM for content of grains. Differences were detected for quality, and were similar to previously described characteristics of the hybrids.This confirms earlier findings of hybrid differences for digestibility (Vattikonda and Hunter, 1983). Noblet and Perez (1993) reported that the DE and ME values increased with the concentration CP and EE and decreased with the concentrations of minerals, crude fiber, NDF, or hemicellulose.However,it is important to recognize that corn varieties has a higher concentration of crude protein, crude fat, and crude fiber than any of these alternative sources, which makes it the most valuable feed ingredient derived from ethanol production. Corn is a primary source of energy in dairy industry, and its nutritive value is related to digestibility (Carter et al., 1991). Forages with higher ADF are lower in digestible energy than forage with lower ADF, that means, as the ADF level increase, digestible energy levels decrease. In conclusion that TK 6060 corn variety had the lowest the ADF 20.03% among the varieties and therefore values of DM 3.40 Mcal kg^{-1}, ME 2.79 Mcal kg^{-1}, DMI 2.99 % and RFV with 170.0 was the highest in present trial. However, Deinum and Bakker (1981) found digestibility differences among corn hybrids and concluded that yield and quality should be taken in consideration when selecting hybrids for forage. Zilic et al. (2011) nutritive and technological value of grains is of great interest for the use of corn in the diet. The highest nutritive value was recorded in sweet maize hybrids from ZemunPolje (ZP) and had the highest content of total protein, albumin, tryptophan, sugars and dietary fibres. According to Sosulski and Cadden (1984), lignin is the most chemically active component for the cell wall, being responsible for interactions with other dietary components. Generally, in this trial, the gain RFV was negatively correlated to the NDF content (r^2=-0.9875, p<0.05), the ADF content (r^2=-0.851, p<0.05), respectively.

Conclusion

From the results obtained, it can be concluded that TK6060 corn variety had the highest nutritious among the hybrid corns, as it was suggested NDF, ADF and ADL values are low and DMD, DE, ME, DMI and RFV values are high. Moreover, as a means of results of varieties, there were a negative and significant relationship between NDF and ADF with RFV values, r^2=-0.9875 and r^2=-0.851, respectively. However, to make a final decision, it is concluded that the evaluation of varieties differences among corn hybrids and concluded that yield and quality should be taken in consideration when selecting hybrids for forage.

Abstract

The goal of this investigation was to assess yield, agricultural and nutritional components of four winter hairy vetch varieties (Aday (Ceylan), Efes-79, Menemen-79 and Selçuklu-2002) at Agricultural Station of Hatay province and Ceylanpınar district of Turkey, in 2012. The experiment was arranged as completely randomized block design with four replications. Experiment results indicated that all traits of hairy vetch varieties were highly significant, except for winter hardiness and plant height in Ceylanpınar, and winter resistance and main stem height in Hatay location. Aday (Ceylan) with hairy vetch had the highest green herbage and dry matter yield in both agricultural stations of Hatay and Ceylanpınar. Furthermore, it was concluded that Aday seemed to be the most suitable from agricultural point of view, erect growing, high-yielding and winter-hardness, as well as a promising variety regarding nutrient content for animal nutrition.

Keywords: *Hairy vetch, varieties, yield, nutritional values.*

Introduction

Herbage and seeds of the vetch plant are high in protein, vitamins, minerals, and because they are delicious, they are used as animal feeds for agriculture, hay, silage and grain (Erdurmuş et al. (2010). The plant is enriched with nitrogen and organic matter. For this reason, the vetch under the fruit gardens is plowed during the flowering period and buried in the soil, contributing to the maintenance of soil fertility (Açıkgöz 2001). One of the most important way to increase the feed crop areas in order to provide quality feed to animals in Turkey and reduce extreme animal oppression on the grassland is to spread the cultivation of winter and summer second crops.

Vetch (*Vicia sativa* L.) is an annual leguminous plant that is grown in plant-animal production systems for agriculture and horticulture, green fertilization and grain production in many parts of the world and is widely used in ruminant feeding (Cabellero et al., 2001; Chowdhurry et al., 2001). In addition, vetch is versatile in terms of its potential end use, producing hay/silage, grain, pasture or green manure (Matic et al., 2005; Jong et al., 2013). In recent years, many varieties have been developed in forage plants of vetches. However, the varieties developed up to this day were mostly developed taking into account the plant yield in the unit. However, it is known that herbaceous quality is very important in addition to yielding while growing varieties. In breeding studies to be carried out with feed plants, the development of varieties with high herb yield as well as high herbaceous quality and presentation of them to the service of the producer comes from the most important tissues. One of the most important problems encountered in vetch farming is the need for a company plant that will not grow up vertically due to the gentle and thin stem form.

Ünal et al. (2016) recommended that common vetch (*Vicia sativa* L.) is a spring crop and extensively grown in semiarid areas of Turkey. Its yield potential is strictly limited by short growing season. For this purpose, this study was carried out to compare some agricultural characteristics, mainly yield Aday (Ceylan) widely used such as Menemen-79, Selçuk-2002 and Efes-79 varieties of in Ceylanpınar and Hatay locations, two different locations were used.

Material and method

In the previous studies, Aday (Ceylan) compared to Menemen-79, Selçuk-2002 and Efes-79 varieties were used as standard varieties selected for the present study on dry matter production and herbage quality, which are hopeful in terms of herbage yield in both Ceylanpınar and Hatay conditions in 2011-2012. Flowers of vetches Aday (Ceylan) compared to Menemen-79, Selçuk-2002 and Efes-79 varieties were Rhs Colour Chart 81/a, Rhs Colour Chart 71/a, Rhs Colour Chart 80/a, and Rhs Colour Chart 71/a. The result of analysis of the soil sample taken at 0-30 cm depth in the experimental area in Hatay and Ceylanpınar; is as follows: soluble salts (EC=0.38 and 0.69 dsm^{-1}), high $CaCO_3$ (22.37% and 25.4%), organic matter (0.84% and 2.26%), and a pH value of 7.82 and 7.81 respectively. Available phosphorus (P_2O_5) in Hatay and Ceylanpınar were 83.5 and 4.2 (kg/ha^{-1}); potassium (K_2O) 1381.3 and 1125.0 (kg/ha^{-1}), respectively. The main air temperature of Hatay and Ceylanpınar was 13.7 ^oC and 10.9 ^oC, total precipitation was 705.8 mm and 179.5 mm; the humidity were 71% and 62.2%, respectively. The precipitation of January, February and March in the Hatay location were higher than in the other agricultural experiment (Anonimous 2015). The plot area was arranged as 5x1.5=7.5 m^2. Each plot was manually planted in 6 rows with 25 cm spacing, with 100 kg ha^{-1} seeds. Before planting, 50 kg N $ha^{-1}$and 100 kg P_2O_5 ha^{-1} were used as fertilizer. The study was carried out with 4 replications according to randomized blocks trial design. The material in the study was planted on 02 November 2011 and harvesting was from 26 April to 5 May 2007.After drying and weighing 500 g vetch samples taken from each parcel, all were prepared by grinding with a mill having a diameter of 1-2 mm. The nitrogen (N) content was determined using the Kjeldahl method. The crude protein (HP) was determined by the Nx6.25 formula (AOAC, 1995). Neutral detergent fiber (NDF) and acid detergent fiber (ADF) contents, which constitute the cell wall components of the feed, were obtained from Van Soest et al. (1991), using ANKOM 200 Fiber Analyzer (ANKOM Technology Corp). The number of days of flowering of vetch lines (day), main stem height (cm), main stem thickness (mm) and number of main stem (number), age and hay yield (kg da^{-1}), physiological maturation (kg da^{-1}), grain yield (kg da^{-1}), 1000 grain weight (g) and harvest index (%), number of beans per day (number) have been studied in the present study.

Experimental Design and Statistical Analysis

The experimental design for the field experiment was a randomized completely block with four replications. Analysis of variance was used to analyze the data using PROC GLM (general linear models) procedure of the Statistical Analysis System (SAS Institute, 2002). Means were compared with LSD.

Results and discussion

The Number of flowering days: Significant statistical differences were found in the combined average of both vetches and locations between the common vetch line and varieties in terms of flowering days number. Flowering times ranged 161.0-168.5 days in Ceylanpınar, 160.0-169.0 days in Hatay, and 151.0-168.0 days in the two location average. Aday (Ceylan) was found to be the earliest, while the Menemen-79 type was the latest both by locations and by the averages (Table 1, 2 and 3). These findings of flowering days number were much higher than results of flowering days with 144.2 days concluded by Çakmakçı et al. 1999); it has been reported that it changed between 162.3-172.3 days (Albayrak et al., 2005) in Samsun conditions and between 132.3-164.3 days (Yücel et al., 2007; Yücel et al., 2008) in Adana conditions, and 194-198 day (Sayar ve ark., 2009) and Erdurmuş et al. (2010) between 126.4-133.5 days.

Main stem height(cm): The main stem heights of the varieties were not statistically important in the province of Hatay, but they were important in both in Ceylanpınar and as means of locations emerged as the highest type of Aday (Ceylan) with 101.4 cm main stem height. In studies conducted with different genotypes in different ecologies, the main stem height was 94.7-100.8 cm (Albayrak et al., 2005) in Samsun conditions were nearly similar to results of this present study and 97.8-136.3 cm in Adana conditions (Yücel et al., 2008) were higher and Erdurmuş et al. (2010) pointed out that main stem height with 58.4-81.1 cm were lower. However, Al-Doss A. A., (1996) stated that lines of vetch were highly significant for all traits, while the year effect was significant for days to flowering and highly significant for biological yield and harvest index. Year × line interaction was also highly significant for all studied characters in both seasons except for plant height.

Main Stem Thickness (mm): Main stem thickness of vetch had statistically significant differences between both vetches and location. The main stem ranged 2.0-2.39 mm in Ceylanpınar, 2.33-2.79 mm in Hatay, and 1.66-2.0 mm in two location average. Aday (Ceylan) had the maximum main stem thickness (2.0 mm) in as a means of two location and Efes-79 vetch of lowest main stem thickness (1.66 mm) are presented in (Table 1, 2 and 3). Erdurmuş et al. (2010) found that main stem thickness, 2.98-4.29 mm. on different species was higher than our test results.

Natural Plant Height (cm): Although there were some slight differences between locations in terms of main stem height, it is not statistically significant between of vetch varieties. Sayar et al. (2009) pointed out that natural plant height was 27.0-44.3 cm, meal stem thickness 1.53-2.26 mm and green herbage and dry matter yield were 668-2119 kg da^{-1} and 211-584 kg da^{-1} respectively, in Çukurova Agricultural Research Institute, Adana, Turkey.

Number of Main Stem: As are presented in Table 2, 3 and 4, significant statistical differences were found in the mean of both varieties and as means of locations in terms of main stems number. In addition, the vetch variety x location of interaction was also found to be statistically significant. The highest number of main stems was found to be 3.3 in Ceylanpınar and 3.0 in Hatay province. In the two-year combined average, Menemen-79 with 1.8 had the highest number of main stem.

Lodging: In general, common vetches have a long, thin, easily lodging stem, therefore, it is of great importance for agricultural development to be upright without company plants. Although the vetch varieties differed according to the scale 1-5 and according to the locations in terms of lodging there was a clearer average. According to the average, Aday (Ceylan) had 2 values according to the average are promising in terms of agricultural development. Vetches are usually grown up without friends planting and always prone to lie down and the new breeding Aday (Ceylan) variety is very important in this respect.

Winter Hardness: Winter resistance of all vetch varieties ranged from 2 to 3 in Ceylanpınar, 2 to 4 in Hatay and there was no difference between the varieties despite different climatic conditions. Abd El-Moneim, (1993) stated that there was considerable variation among entries with the same species, entries of *V.ervilia* were the earliest in flowering and maturity, and *V. villosa* ssp. *dasycarpa* almost the latest by 45 days. *V.sativa*, was the most affected by frost whilst both *V. villosa* ssp. *dasycarpa* and *V. ervilia* proved to be winter hardy.

Herbage Yields of Vetches: The yields of particular forages varied with seasonal conditions, soil type, drainage and location. Vetch varieties in terms of herbage yields had significant differences th at were statistically found in both location and varieties. The herbage yields of varieties examined in the study varied between 2543.3-2866.6 kg da^{-1} in Hatay province, 1138.21354.9 kg da^{-1} in Ceylanpınar district and 1938.3-2084.9 kg da^{-1} in the combined average of the lo (Table 1, 3 and 3). The results of green herbage yields with (3686.3-5232.9 kg da^{-1}) obtained by Mutlu Z. (2002) that were higher than yields of this present study. Hakyemez (2006) cited that no significant differences between winter dates in seed and seed protein yield and suggested common vetch should be sown during the winter period for seed and forage production. As are presented in Table 1, 2 and 3, the highest dry matter yields were from Aday (Ceylan) variety and others followed this vetch in both Hatay and Ceylanpınar locations. However, dry matter yields ranged from 553.4 and 638.5 kg da^{-1} in Hatay, 323.4 kg da^{-1} and 412.3 kg da^{-1} in Ceylanpınar location. Yields of vetches in Hatay province were much 1.5 times more than the yields of Ceylanpınar. Depending on the genetic structure of the materials used and ecological factors and compound effects, different yields were obtained in different regions. Karadağ and Büyükburç (2001) green herbage yields of vetches were 2936.6-3965.2 kg da^{-1}; dried herbage yields were 354.2-536.5 kg da^{-1}. Yücel et al. (2007), dry matter yield in Adana base conditions is 576-801 kg da^{-1}, 407-709 kg da^{-1} in Çukurova base conditions. Numerous researchers reported that interactions of year x variety are important in common vetch, due to green weed yield, hay yield, flowering time and biological yield and harvest index (Yücel et al., 2006; 2008).

Table 1. Yield and Yield Components of vetches grown in Hatay Province

Cultivar name	Days to flowering	Plant height (cm)	Main stem tichness(mm)	Natural Plant height (cm)	Number of main stem	Loging (1-5)	Winter Hardnes (%)	Green forage yield (kg da^{-1})	Dry matter yield (kg da^{-1})

Nutritive Value of Vetch Hay: In the study, water content of vetch herbage ranged from 7.9 to 10.2%, dry matter of herbage ranged from 89.8 to 92.1%. The crude ash ranged from 9.76% to 13.04% with Aday (Ceylan) and Selçuk-2002 varieties, respectively (Fig 1). As seen in Table 4, there were statistically significant differences between varieties in crude protein ratios (CP, %) in the means of locations. CP ratios were found to be the highest CP ratios in Aday (Ceylan) and Efes-79 with 21.33% and 21.26 % and the lowest ratio of crude protein (14.89%) with Selcuk-2002 vetch variety in Table 4 and Figure 2. This difference in protein between genotypes may be related to the rate of leaf stalk and genotypes development status. Studies conducted in different genotypes and different ecologies have been reported by many researchers whose crude protein ratios vary between 9.08-22.30% (Karslı et al., 2005; Yolcu et al., 2009; Yücel and Ayaşan, 2010). On the other hand, crude oil ranged from 1.41 to

1.66%, the highest crude oil (CO) had 1.41% with Menemen-79 variety in Table 4 and Figure 3. However, there were statistically significant differences between the varieties in terms of neutral detergent fiber (NDF), ranged from 45.67 to 511.55 % as a means of locations. In similarly, ADF contents ranged from 37.42 to 45.53% of vetch varieties, the highest NDF and ADF content had Efes-79 with 51.55% and 45.53% between varieties. In Table 4 and Figure 5 and 6. ADL content of vetch was 7.27-8.39%. Common vetch may be harvested at different stages depending on the quality of the forage required. As the plant matures, dry matter digestibility (DMD), leaf matter and crude protein (CP) decrease, and neutral detergent fibre (NDF) and acid detergent fibre (ADF) increase. NDF values reported by many researchers vary between 34.97-66.7% (Karslı et al., 2005; Ammar et al., 2010; Parlak et al. 2011). Temel et al. (2015) cited that for hay yield ranged from 213.35 to 547.88 kg da^{-1}, from 15.15 to 20.69% for CP, from 40.63 to 47.27% for NDF, from 28.94 to 35.71% for ADF, from 4.39 to 7.06% for ADL, from 61.08 to 66.35% for DMD.

It is known that ADF values vary between 18.6% and 41.8% in studies performed with different genotypes and different ecologies (Badrzadeh et al., 2008; 2010; Parlak et al., 2011). Ammar et al. (2010) reported that NDF and ADF values increased in parallel with the period of ripening in the vetch, and the quality decreased. Desalegn and Hassen (2015) highest crude protein (CP), acid detergent fiber (ADF) and acid detergent lignin (ADL) contents were recorded in *Vicia dasycarpa*, 18.9% DM, 37.3 %DM and 10.76% DM respectively. A strong positive correlation was found between NDF and ADF ($r=0.977^{**}$). In addition, there were positive and significant relations between NDF and ADL ($r=0.711^{**}$); ADL and CP ($r=0.578^{*}$). Furthermore, there was a negative and significant relationship between crude cellulose and water, dry matter, crude ash. However, relationship between crude cellulose and crude protein was negative and very significant ($r=-0.694^{**}$). These findings appear to be among the values mentioned in the studies. Many factors such as ripening period, vegetation type, harvesting and storage, climate and soil conditions and variety of feed crops in feed crops. However, Georgieva et al. (2015) stated that it could be concluded that vetch breeders should consider traits such as seed weight per plant, pod height, 1000 seed weight and seeds per plant when selecting high-yielding genotypes for seed yield. In addition, Lauk et al. (2007) suggested that legume-cereal mixes are particularly suited for the conditions of organic farming as they ensure a relatively good harvest and a high protein yield. Marley et al. (2017) indicated that common vetch has the potential to be used as a source of high-protein fresh forage in spring to support lactating ewes and their lambs. Lithourgidis at al. (2006) concluded that highest forage quality was achieved when common vetch was grown as a monoculture or when at a high proportion in mixtures, especially with oat.

Conclusion

Aday (Ceylan) hairy vetch had the highest green herbage and dry matter yield in both agricultural stations of Hatay and Ceylanpınar. From agricultural and animal nutrition of point of view, Aday (Ceylan) seemed to be the best suitable in Hatay Province.

Abstract

The objective of this study was to compare performances of four winter vetch varieties (Aday (Ceylan, Efes-79, Menemen-79 and Selçuklu-2002) subjected to different locations of Agricultural Station of Hatay and Ceylanpınar of Turkey in 2012. Seeds of four winter vetchs species were sown in plots in complete randomized block with four replications in both Ceylanpınar district and Hatay province.The experiment results indicated that all traits of winter hairy vetch varieties except for winter hardiness and plant length in Ceylanpınar and winter hardiness and length of the main stem in Hatay location were highly significant. Aday (Ceylan) with winter hairy vetch had the highest dry matter yield in both agricultural stations of Hatay and Ceylanpınar. Furthermore, it was concluded that Aday (Ceylan) seemed to be the most suitable for agricultural point of view, erect growing, high-yielding and winter-resistant, as well as a promising variety regarding nutrient content for animal nutrition.

Keywords: *Vicia sativa*, varieties, agronomic traits, nutritional values

Introduction

All efforts made in animal husbandry are aimed at increasing the efficiency to be provided from the unit head or animal group in spite of unit production. This, on the one hand, is dependent on the use of high yielding/qualified animal breeds, and on good care and nutrition. Making a good feed can be accomplished by the fact that feed or feedstuffs used are adequate and balanced in the field. The chemical composition of legume feeds varies according to species, variety, geographical area and agricultural practices, and the protein content varies between 20-45% (Abreu and Bruno-Soares, 1998). Grain of leguminous is used as alternative protein sources in areas where the production of oilseed crops is low or expensive due to high crude protein content. Lauk R and Lauk E. (2009) stated that Vetch-cereal intercrops produced considerably higher protein yields on the soil without any N-fertilizer than sole cereal crops and were regarded as highly suitable for organic farming. Common vetch (*Vicia sativa*) seed has been used in animal feed as an alternative source of protein in poultry diets (Darre et al., 1999). In identifying the differences between feeds, it is important to identify the chemical composition of feed and energy and digestible nutrients. This study was carried out in order to compare the quality of the genotypes with the yield and yield components of vetch widely used in the growing season of 2012.

Material and Methods

Four vetch varieties Aday (Ceylan), Efes-79, Menemen-79 and Selçuklu-2002 were compared for growth yield traits in a field trial in two separate locations Ceylanpınar and Hatay in Turkey. The experiment was carried out in an experimental field in both Ceylanpınar and Hatay Agricultural Experimental Enterprise in 2010-2011. The sites of the experiment in Hatay and Ceylanpınar; soluble salts (EC=0.38 and 0.69 dsm^{-1}), high CaCO3 (22.37% and 25.4%), organic matter (0.84% and 2.26%), and a pH value of 7.82 and 7.81 respectively. Available phosphorus (P_2O_5) in Hatay and Ceylanpınar was 83.5 and 4.2 (kg ha^{-1}); potassium (K_2O) 1381.3 and 1125.0 (kg ha^{-1}), respectively. Plot size was 7.5 m^2, with 0.25 cm spacing distance and 5 m plot length. The plot was arranged in a completely randomized block design with four replications. Sowing rate was 100 kg ha^{-1}. The four genotypes of vetch were ridge-sown in 0.7 cm interval on 2 November 2011 and fertilized basically with 50 kg ha^{-1} for each of N, P_2O_5 and P_2O_5 by a chemical compound fertilizer. Each plot was fertilized with 100 kg ha^{-1} each of P_2O_5 and K_2O with top dressing of some fertilizers. Weed control was performed manually several times as required by workers. Vetch genotypes were harvested at 5 cm above the ground level 24 May 2012. Total nitrogen was determined by Kjeldahl method AOAC (1990). Crude protein (CP) was calculated as Nx6.25. Ash was determined by complete burning of the feed samples in a muffle furnace at 500 °C overnight according to the procedure of AOAC (1990). Neutral detergent fiber (NDF), acid detergent fiber (ADF) and acid detergent lignin (ADL) was analyzed using ANKOM Analyzer (Van Soest et al. 1991).

Statistical analysis

The obtained data of Ceylanpınar and Hatay locations was evaluated separately and combined using SAS statistical package program. The LSD test was used to compare the difference between the averages (SAS Institute, 1999).

Results and discussion

Climatic Conditions

The main air temperature of Hatay and Ceylanpınar in the experiment period was 13.7 ^oC and 10.9 ^oC; a total precipitation was 705.8 mm and 179.5 mm; the humidity was 71% and 62.2%, respectively (Table 2). The precipitation in January, February and March in the Hatay location were higher than in other agricultural experiments. Although precipitations of Hatay were higher than in both Ceylanpınar and long years, the plants were not observed in either location (Anonymous, 2012).

Number of flowering day of the Four Vetch (*Vicia*) varieties

Flowering days for varieties in Ceylanpınar ranged from 151.0 to 168 day; from 160 to 169 day in Hatay; Aday (Ceylan) had early flowering genotype in both locations as is presented in Table 2 and 3 and 4. That is why Aday (Ceylan) genotype seen to be earliest among varieties of vetch. According to the quotation by Fırıcıoğlu (2009) from Turner (1997), early flowering can be able to permit a long grain-filling time during, and early flowering and podding combined with vigorous early growth resulted from rapid canopy development and dry matter production, which laid the potential for a larger total biomass and higher seed yield. Therefore, selection for more rapid crop growth in spring is likely to increase the common vetch yield. Color of all the varieties used in the study was RHS.

Number of Physiology Maturing Day of the Four Vetch (*Vicia*) varieties

A number of Physiology Maturing Day in Ceylanpınar and Hatay ranged from187 to 202;195 to 204; means of locations were 191 and 203 days. Selçuk-2002 variety in both places and means of locations were the earliest variety that reached physiological maturing (Tables 2, 3 and 4). These of a number of Physiology maturing days were quietly close together results of Sayar et al. (2009) cited that days to physiological seed maturity (194.0-198.4 days).

Lodging of Vetch Varieties of the Four Vetch (*Vicia*) varieties

Growing form of vetch varieties was observed from different scale; Efes-79, Menemen-79 and Selçuk-2002 had the semi-erecting growing. In contrast to these varieties Aday (Ceylan) had the highest erect form among the varieties as was presented in Tables 2, 3 and 4. In generally, common vetches have a long, thin, easily lodging stem. Therefore, it is of great importance for agricultural development to be upright without company plants. Lodging was not prominent in any of the four cultivars and did not affect forage yields. It is seen that the average value of 2 points according to Candidate (Ceylan) 1-5 scale in varieties and two values according to the average are promising regarding agricultural development.

Winter Hardiness of the Four Vetch (*Vicia*) varieties

Winter resistance of all vetch varieties in Hatay and Ceylanpınar was found to be the quite high performance in addition to there was no the difference between the varieties despite different climatic conditions. However, studies of winter hardiness on common vetch in Turkey is very limited. To improve winter hardiness and adaptation in common vetch, it is imperative to know the magnitude of genotypic variability present, as this will provide the basis for efficient selection (Fırıncıoğlu et al. (2009).

The Number of Pod per Plant of the Four Vetch (*Vicia*) varieties In Ceylanpınar, the number of pod per plant ranged from 17.3 to 33 with the highest value Aday (Ceylan) and pod/plant were between 46.6 to 60.4 in Hatay, there was a statistically significant difference between both locations regarding this feature. These differences can be attributed to amount of precipitation in Hatay was higher than Ceylanpınar (Table 1). The number of pod per plant were between positive and significant correlation Seed/pod (S/P) and on the contrary, was negative between Lodging (L).

The Number of Seed per Pod of the Four Vetch (*Vicia*) varieties

The number of seed per pod is a crucial yield character of the plant as well as all other in both cereal and forage crops as a yield parameter. Seed number per plant in Ceylanpınar and Hatay, 3.2-4 and 4.4-5.6 was measured. However, the highest seed number per plant of four vetches according to locations had Aday (Ceylan) and followed the variety Menemen-79, Efes-79 and lowest seed per pod were Selçuklu-2002. However, a strong positive correlation was found between seed number/pod (SN/P) and seed/pod (S/P) (r=0.685**). Similarly, Sayar (2014) showed that pod numbers per plant were significantly and positively correlated with SDY. The yield component traits were highly significantly positively correlated with seed yield.

Biological Yield of the Four Vetch (*Vicia*) varieties Regarding biological yield, vetch varieties showed different groups according to their locations. In Ceylanpınar, yielding of

Aday (Ceylan) were higher than the other varieties and on the other hand, Selçuk 2002 showed lower yields than the other varieties. As a mean of locations, Aday (Ceylan) with 50.5 t ha^{-1} played prominent genotype among varieties in respect of biomass/biological yield in Table 2, 3 and 4. Environmental conditions such as precipitation and temperature and cultivars in the field experiments could cause such a difference. Also this, biomass were in both positive and significant correlation between seed/pod (S/P), seed number/pod (SN/P). However, Tamkoç and Avci, (2004a) are thought biological yields depends on a wide range of agronomic applications with ecological and climatic factors as well as genotypic differences. Similarly, Moneim (1992) also stated that most of the lines had wide adaptation to dry areas in terms of both grain yield and stability. Climate, except early spring rains, had little effect on biological and grain yields.

The Seed Yield of the Four Vetch (*Vicia*) varieties

The observed seed yield of vetches, Aday (Ceylan) vetch genotype did not show significant differences in terms of seed yield except for Selçuklu-2002 in Hatay location.However, there were significant differences on seed yield between the locations. Aday (Ceylan) and Menemen-79 varieties were the almost the same according to as a means of locations. The results seed yields of the present were higher than findings by Desalegn and Hassen (2015) found that the average grain yields were varied ranging from 12.16 t ha^{-1} to 14.29 t ha^{-1} in *Vicia purpurea* and *Vicia sativa* respectively. Albayrak et al. (2005) found that the seed yield in common vetch genotypes was between 980-1600 kg ha^{-1} in a different ecology in the black sea region. Nizam et al. (2012) found that genotype x environment interaction was statistically significant in hay yield and seed yield of common vetch genotypes. However, correlations between seed yield and seed/pod (S/P), seed number/pod (SN/P) and biomass (B) were both positive and significant as have been confirmed by Çakmakçi et al. (2004) stated that positive correlation was observed between seed yield and number of seeds per plant, and number of pods per plant. However, Zaman at al. (2012) stated that high seed density resulted in the greater dry matter and seed yield than the low seed density.

The Straw Yield of the Four Vetch (*Vicia)* varieties

The straw yields of vetch ranged from 29.5 to 36.9 in Ceylanpınar; from 51.7 to 54.9 t ha^{-1} in Hatay location and as a means of results, from 42.9 to 45.6 t ha^{-1}. Although the vetch varieties in the locations have some irregularities in the straw yields, the highest straw yields were obtained from according to the average the varieties and locations in Table 2, 3 and 4. The straw yield was a positive and strong correlation between seed/pod, seed number/pod and biomass. These findings were verified by Aydoğdu and Açıkgöz (1995), Çakmakçi et al. (2003) and concluded that seed yield strongly correlated with straw yield.

1000-Seed Weight of the Four Vetch (*Vicia*) varieties

Concerning 1000 seed weights (39.3-40.0 g), there was no a statistically significant difference among the varieties in the mean, although there were some irregulates in the locations in Table 2, 3 and 4. Orak and Nizam (2004) concluded that 1000-seed weight of genotypes (31.92- 63.52 g) was higher than findings of the present study. On the contrary, Uzun et al. (2004) and Zaman et al. (2012) based on the 2-year results, no significant differences were found among two cultivars in any of the measured characteristics except 1000- seed weight.

Harvest Index of the Four Vetch (*Vicia*) varieties

The statistical analysis showed the significant difference among the vetch (Vicia) species as prepared in Table 5. The highest harvest index was recorded in Aday (Ceylan) in both Hatay and Ceylan location, but there were no significant differences between vetch species according to as a means of location in Table 5. Findings of harvest index (15.8-18.3) were lower than results by Sayar et al. (2009) harvest index 33.92-47.41%. However, the results of the Orak and İlker (2004) verified the results of the 1000-piece weight we obtained in separately obtained at both sites except for as a means of locations.

The Chemical Composition (%) of the Four Vetch (*Vicia*) varieties

The Chemical Composition (%) of the four vetch (*Vicia*) varieties varied from water content (7.9-12.3%), dry matter (87.7-92.6), crude ash (3.60-4.35 %), crude protein (26.27 -28.17%), crude oil (0.30 -0.51%), crude cellulose (0.19-0.23) in Fig. 1, NDF (34.78-40.09), ADF (12.22 -15.16%) and ADL (2.813.65%) of four vetch (*Vicia*) species Table 6 in Fig.2. Among the evaluated four vetch (Vicia) variety found to be the promising one in terms of its water content 12.3% with Aday (Ceylan) dry matter 92.6% with Menemen-79, crude protein 28.17 % with Selçuk-2002, Crude Oil 0.51%, with Aday (Ceylan), Crude cellulose 0.23% with Efes-79, NDF 40.09 % with Efes-79, ADF 15.16% with Aday (Ceylan) and ADL 3.65 and 3.48 % with Aday (Ceylan) and Menemen-79 respectively. Numerous authors have reported that among the varieties of common vetch crude protein ratios vary between 9.08-22.30% (Yücel et al., 2013; Yılmaz and Erol, 2015). Karslı et al. (2004) the concentrations of DM and ADIN-N did not differ, concentrations of organic matter (OM), CP, NDF, and ADF varied significantly among different vetch varieties. Karadağ and Yavuz (2010) Seed yields ranged from 1160 to 1459 kg ha^{-1}, CP content ranged from 24.94 to 27.86%, ADF content ranged from 5.81-8.45%, NDF ranged from 9.89 to 11.42% and CF content ranged from 1.16 to 3.23% based on the averages of the two years results. These results of ADF was positively correlated to NDF (r = 0.850) in the present study were consisted of findings by Badrzadeh et al. (2008). The results of ADF was negatively correlated to CP (r =-0.99) and DDM (r = -0.98) and positively to NDF (r = 0.96) Yılmaz and Erol, 2015, genotypes differences were determined to significant in terms of other characters except for ADF ratio. Therefore, year x genotype interaction was also found to be significant for most of the characteristics except for crude protein ratio, NDF ratio and crude ash ratio. Maršalkienė N. (2015) suggested that according to the crude protein content in the plant above ground mass, the stem, leaf and inflorescence ratio in the plant mass of *V. villosa* and some samples of *V. angustifolia* were more valuable than in that of cultivated *V. Sativa*. On the other hand, Moneim at al. (1990) concluded that as plants matured IVDMD, CP and leafiness decreased, and NDF and ADF increased. For all the genotypes maximum digestible dry matter (DDM) and CP yields were more or less attained at 50–100 % podding. In addition to these findings, seed yield and chemical compounds of common vetch lines can be affected by adverse agricultural conditions (Milczak et al., 2001). Contrary to results of the present, Temel et al. (2015) concluded that crude protein ranged from 15.15 to 20.69 %, 40.63 to 47.27% for NDF, form 28.94 to 35.71% for ADF, from 4.39 to 7.06% for ADL. Kebede et al.(2013) indicated that forage dry matter yield was positively associated with days to forage and seed harvests, plant height, crude protein and digestibility.

Conclusion

On the basis of these results, it is concluded that most of the tested vetch varieties are adapted to the region of Ceylanpınar and Hatay conditions in terms of both agricultural traits and chemical analysis. Leguminous grain foods are used as alternative protein sources in areas where the production of oilseed crops is low or expensive due to high crude protein contents. The best variety was Aday (Ceylan) with winter hairy had the highest and dry matter yield in both agricultural stations. Furthermore, Aday (Ceylan) seemed to be the best suitable for agricultural from the stand point of view, erect growing, high-yielding and winter-hardiness, as a grain variety regarding nutrient content animal nutrition.

Abstract

This research was conducted to determine hay yield and some quality traits of alfalfa cultivars at the three years old stand. The experiment was established in 2013 autumn and the data were collected in the third year after planting (2016). As plant material Bilensoy, Kayseri, Verko, Gea, Plato, Victoria, Emiliano, Sunter, Nimet and Basbag cultivars of the alfalfa was used. The study was conducted as a randomized complete block design with 3 replicates. Plant height (PH), dry matter yield (DMY), protein yield (PY), ADF, NDF, phosphorus, potassium, calcium and magnesium content of alfalfa cultivars were determined in the study. All data was calculated as a mean or total of four cuttings. As a result of this study, among the cultivars, plant height ranged between 53.9 (Verko) and 72.8 cm (Sunter). The highest and lowest hay yield was obtained in Bilensoy (9.8 t ha^{-1}) and Victoria (1.5 t ha^{-1}). The CP content of cultivars varied from 22.2 to 23.8 %. The highest total protein yield was determined in Victoria and Sunter (3.3 and 3.2 t ha^{-1}), while the lowest Bilensoy (2.3 t ha^{-1}). ADF, NDF, phosphorus, potassium, calcium and magnesium ratio of cultivars varied from 27.8 to 31.0 %, 39.0 to 42.6 %, 0.36 to 0.39 %, 2.20 to 2.41 %, 1.45 to 1.54 % and 0.26 to 0.29 %, respectively. In the third year of the establishment, Victoria and Sunter cultivars kept high performance with regard to hay and protein yield, and the other traits.

Key words: *ADF, alfalfa, hay yield, protein yield*

Introduction

Forage crops are reliable and continuous roughage sources for livestock (Akman et al., 2007). They have a significant place in agricultural activities and constitute a sort of insurance for agricultural and livestock activities. Since forage crops are cheap feed sources, contain required nutrients for ruminants, rich in vitamins and minerals, improve reproduction power of the animals and provide high-quality animal products, they have quite significant place in animal nutrition. Turkey has quite high deficit in roughage and the greatest reason of such deficit is not to place forage crops in cultural activities sufficiently (Ayan et al., 2006). Forage crops are cultivated only over 8% of agricultural fields. Natural pastures and meadows are other sources of roughage, but they are exposed to heavy grazing and turned into sources unable to meet roughage needs because of low yield levels (Soya et al., 2004). Efficient management strategies should be implemented to reduce heavy grazing pressure, to improve the yields and to meet roughage needs. Forage crops should also be incorporated into cropping patterns both as a main and second crop. Alfalfa is the queen of forage crops. It has quite high adaptation capacity, can be harvested several times in a vegetation period. It is a perennial high yield crop, rich in various nutrients and some cultivars can be grazed. Therefore, it has a special place among forage crops. Turkey is the gene source of alfalfa and the oldest records indicate that alfalfa was cultivated in Turkey as a forage crop almost 3300 years ago. In Yozgat province of Turkey, agricultural fields are mostly used for cereal cultivation (about 59.5% of total agricultural lands) and cereals are respectively followed by industrial crops (4.8% of agricultural lands), legumes (3.6% of agricultural lands) and forage crops (2.79% of agricultural lands) (Anonymous, 2015). Among the forage crops, mostly vetch, alfalfa and trefoil are cultivated in the province. Among the alfalfa cultivars, Bilensoy and Kayseri alfalfa cultivars are commonly grown. Forage crops are not sold or exported. Farmers grow forage crops just to meet their own needs. However, current productions are not sufficient to meet the existing roughage deficits, thus producers have various problems in their livestock activities. In this sense, it was targeted to increase and improve alfalfa cultivated lands. In this study, yield and quality parameters of different alfalfa cultivars were determined for two years under ecological conditions of Yozgat province. The primary objective was to determine appropriate alfalfa cultivars for Yozgat province.

Material and Methods

Experiments were conducted over the experimental fields of Bozok University Agricultural Faculty located in Yerköy town of Yozgat province in 2016. Ten different alfalfa cultivars (Bilensoy, Kayseri, Verko, Gea, Plato, Victoria, Emiliano, Sunter, Nimet and Başbağ) were used as the plant material of the present study. Yerköy town in which experiments were conducted is 40 km away from Yozgat province. Long-term annual average precipitation of the experimental site is 574.2 mm and the precipitation in 2016 was 564.2 mm. Long-term average temperature is 9.0 ^{O}C and average temperature in 2016 was 9.67 ^{O}C. Long-term average relative humidity is 66.8 % and average relative humidity in 2016 was 62.5 %. Experimental soils have clay-loam texture. Soils were poor in organic matter, medium in phosphorus, rich in potassium and medium in lime. Soils had unsaline and alkaline structure.

Experiments over the experimental fields of Bozok University Agricultural Faculty were conducted in randomized blocks design with 3 replications. Experimental plots were 5 m long and each plot had 8 rows with 20 cm row spacing. Sowing was performed in autumn (9 October 2013) as to have 20 kg seeds per hectare with a plot seeder. Soil analyses were performed before sowing and 40 kg N /hectare and 80 kg P_2O_5/hectare were applied at sowing. DAP (Di Ammonium Sulfate) was used as the phosphorus source and Ammonium Sulfate was used as the nitrogen source. The data presented in this study were obtained from the third year of alfalfa facility. Cuttings were performed at 10% flowering stage and a total of 4 cuts were performed (Manga et al., 2003). Irrigation was performed after each cutting. Randomly 10 plants were selected from each plot and plant height was measured from the soil surface of main shoot to the tip of the plant. Average of 10 measurements was taken as the plant height. About 50 cm sections from the top and bottom of the plots and one row from each side were omitted as to consider side effects. The remaining part was cut and resultant green herbage was weighted. Resultant weights were then converted into green herbage yield per hectare. Then, 500 g samples were taken from each plot and samples were dried at 60^{0}C until a constant weight. Dried samples were weighted to get % dry matter ratios. Dry matter ratios were multiplied by green herbage yields to get dry herbage yield (kg) per hectare. Dried samples were ground in hand mills and made ready for further analyses (Hoy et al., 2002). Crude protein, ADF, NDF, K, P, Ca and Mg contents of ground samples were determined in a Foss NIR System (Model 6500, Win ISI II v1.5) by using IC-0904FE calibration program. Resultant crude protein ratios were multiplied by dry herbage yields to get crude protein yields. Resultant data were subjected to statistical analyses in accordance with randomized blocks design. Duncan's multiple range tests was used to compare and group the treatment means (Gulumser et al., 2006).

Results and Discussion

Average plant heights of each alfalfa cultivar obtained from 4 cuts of the third year are provided in Table 1, dry herbage yields are provided in Table 2 and crude protein yields are provided in Table 3. Highly significant differences were observed in plant heights, dry herbage and protein yields of the cultivars ($p<0.01$).

Table 1. Variation of plant height in alfalfa cultivars by cuttings at the third year after planting.

Cultivars	Plant Height (cm)				
	1thCut**	2thCut**	3thCut**	4thCut**	Mean**
Bilensoy	59.5 abc	92.7 a	53.3 c	46.7 f	63.0 cde
Kayseri	65.9 a	76.7 cd	44.7 d	46.3 f	58.4 e
Verko	55.7 bc	61.3 e	53.3 c	45.0 f	53.9 f
Gea	63.7 ab	65.0 e	59.7 bc	52.0 e	60.1 de
Plato	50.2 cd	88.0 ab	66.7 ab	62.0 d	66.7 bc
Victoria	60.4 ab	83.0 bcd	67.3 a	63.3 cd	68.5 ab

Mean	*56.4*	*76.6*	*61.2*	*60.3*	*63.4*

***Mean values within same columns with different letters are statistically different p<0.01*

Plant heights varied between 43.4 – 65.9 cm in the first cut, between 62.0 – 92.7 cm in the second cut, between 53.3 – 73.3 cm in the third cut and between 45.0 and 77.0 cm in the fourth cut. As the average of cuts, the greatest plant height (72.8 cm) was obtained from Sunter cultivar and the cultivar Victoria with an average plant height of 68.5 cm was placed in the same statistical group. As the average of cultivars, the greatest plant height (76.6 cm) was obtained from the second cut (Table 1). Present findings were higher than the plant heights reported by Şeker (2003); but complying with the findings of Töngel and Ayan (2010). Besides environmental factors, plant heights mostly depend on plant genetics.

As the total of 4 cuts, dry herbage yields varied between 9.8 – 14.9 t ha^{-1} with the greatest yield (14.9 ton) from Victoria cultivar. As the average of the cultivars, the greatest dry herbage yield (4.5 t ha^{-1}) was obtained from the first cut. The dry herbage yields decreased in each cut and the lowest value (2.1 ton) was obtained from the fourth cut (Table 2). In previous studies, dry herbage yields were reported as between 1.0 – 1.7 t ha^{-1} under Diyarbakır conditions by Başbağ et al. (2002). Those values were lower than the present ones. Current hay yields were complying with the ones reported by Kavut et al. (2013).

Table 2. Variation of hay yield in alfalfa cultivars by cuttings at the third year after planting.

Cultivars	Hay Yield (t ha^{-1}) 1thCut**		2thCut**		3thCut**		4thCut**		Total**	
Bilensoy	2.8	f	4.1	a	1.6	e	1.4	e	9.8	e
Kayseri	4.6	bcd	3.3	b	1.6	e	1.5	e	11.0	d
Verko	4.8	bc	2.9	bc	1.8	e	1.6	e	11.2	d
Gea	5.3	b	2.9	bc	1.7	e	1.9	d	11.9	cd
Plato	4.0	cde	3.3	b	3.1	b	2.1	cd	12.6	c
Victoria	6.8	a	3.2	bc	2.8	c	2.2	bc	14.9	a
Emiliano	3.3	ef	2.5	d	3.7	a	2.4	b	11.9	cd
Sunter	4.9	bc	3.3	b	2.9	c	2.6	a	13.8	b
Nimet	4.9	bc	3.0	bc	2.3	d	2.3	bc	12.5	c
Başbağ	3.6	def	2.8	cd	2.9	bc	2.6	a	11.9	cd
Mean	*4.5*		*3.1*		*2.4*		*2.1*		*12.2*	

***Mean values within same columns with different letters are statistically different p<0.01*

Protein yields of alfalfa cultivars varied between 0.65 – 1.33 t ha^{-1} in the first cut, between 0.51 – 0.95 t ha^{-1} in the second cut, between 0.30 – 0.81 t ha^{-1} in the third cut and between 0.30 – 0.68 t ha^{-1} in the fourth cut. As the total of four cuts, the greatest protein yields were obtained from Victoria (3.31 t ha^{-1}) and Sunter (3.19 t ha^{-1}) cultivars. Since these varieties have higher protein contents than the other varieties, protein yields are also higher. As the average of cultivars, the greatest protein yield (0.98 t ha^{-1}) was obtained from the first cut and the lowest value (0.51 t ha^{-1}) was obtained from the second cut. Present findings on protein yields comply with the values reported by Töngel and Ayan (2010) for alfalfa cultivars grown in Samsun provinces. Since protein yields are obtained by multiplying hay yields with crude protein ratios, the changes in those values also influence protein yields.

As the average of four cuts, the lowest ADF ratio (27.8%) was obtained from Kayseri cultivar and the greatest value (31.0%) was obtained from Victoria and Nimet cultivars. As the average of cultivars and cuts, the average ADF ratio was calculated as 29.1%. ADF ratio of the hay is a significant indicator of energy in ruminant rations (Tekçe and Gül, 2014). According to alfalfa hay quality directive of Western America Hay Center present ADF ratios revealed that alfalfa herbage of the present study was in good and very good quality. In previous studies, ADF ratios of alfalfa hays were reported as between 31.97 - 41.55% by Güngör et al. (2008); as between 16.8 - 33.3% by Başbağ et al. (2009); as 34.3% by Gündel et al. (2014); and as 31.86% by Çaçan et al. (2015). Present findings were complying with all those earlier ones.

The greatest NDF ratio (42.6%) was observed in Nimet cultivar and the lowest NDF ratio (39.0%) was observed in Sunter cultivar. As the average of cultivars and cuts, the average NDF was calculated as 40.8%. NDF ratio indicates how much of the cell wall could be digested (Marsalis et al, 2014) and digestion of NDF components (cellulose, hemicellulose and lignin) is quite difficult (Mertens, 2009).

Table 3. Variation of protein yield in alfalfa cultivars by cuttings at the third year after planting.

Minerals have significant effects on both plant and animal metabolisms (Eğritaş and Aşcı, 2015). Calcium, phosphorus, magnesium, potassium, sodium, chlorine and sulphur are the most important macro minerals with significant roles in animal feeding (Kutlu et al., 2005). Phosphorus (P) contents varied between 0.363 – 0.390%, potassium (K) contents between 2.203 – 2.413%, calcium (Ca) contents between 1.453 – 1.547% and Magnesium contents between 0.257 – 0.290%. Calcium has a significant place in animal nutrition (Ayaşan, 1998). Insufficient calcium nutrition results in poor general appearance, poor bones and low live weights. Rickets may be seen in cattle, bone weakness can be seen in cows, milk yield may decrease and milk fever may be seen in dairy cows. In ruminants freely consuming legume roughages, both survival and yield Ca needs could be met (Kutlu et al., 2005; Ayaşan et al., 2012). Present Ca values were higher than the needs of ruminants (Tajeda et al., 1985). Magnesium exists in several tissues of the body. Half presents in bones and the other half presents in soft tissues and body fluids. Mg performs its function in bone formation together with Ca. Majority of animal feeds contain sufficient amount of Mg. To secure the animal needs, Mg is also supplemented at certain portions in mineral mixtures. Mg content of roughage should be between 10-15% (Kutlu et al., 2005). Phosphorus needs of cows and sheep respectively vary between 0.17 – 0.39% and between 0.16 – 0.38%. Considering these values, present phosphorus contents were found to be sufficient. Potassium deficiency is a rare case, but may be observed in beef cattle primarily fed by concentrate feed (Kutlu et al., 2005). Alfalfa hay is quite rich in Ca, Mg, K and beta carotene (Alp et al, 2016). Çaçan et al. (2015) also reported lower Ca (0.90%) and Mg (0.20%) contents and higher P (0.69%) and K (5.14%) contents than the present values.

Conclusions

Alfalfa is the most commonly grown perennial forage crop in Yozgat province and Bilensoy and Kayseri are the most common cultivars produced in the province. Of the 10 experimented alfalfa cultivars in this study, Victoria and Sunter cultivars with quite higher yields were found to be quite available to be produced under ecological conditions of Yozgat province. It was also concluded that all of the experimented cultivars were sufficient in ADF, NDF and minerals.

Abstract

The objective of this study was to determine the effects of cultivars in different sowing densities on microelements iron (Fe), nicel (Ni), zinc (Zn) and sodiım (Na) and grain yield of chickpea (*Cicer arietinum* L). Field experiment was performed in research farm at the University of Bingol (Turkey) in 2016. A complete blocks design in two varieties i.e. Arda and ILC-482 were in main plots, whereas five chickpea seeding density (20, 30, 40, 50 and 60 seed m^{-2}) were in sub plots. The results indicated that seeding densities significantly affected grain yield and Ni content while Fe, Ni and Zn were not affected significantly. Variety ILC-482 produced the maximum grain yield (86,26 kg/da) by 60 seed/m^{-2} and Arda gave the lowest grain yield (19,80 kg/da) by 30 seed m^{-2}. The highest Ni conten has been obtained from ILC482 variety (6.66 ppm) and the lowest Ni content has been obtained from Arda variety (6.20 ppm).

Keywords: *Chickpea, microelements, seeding density, variety*

Introduction

Chickpea (*Cicerarietinum L.)* is an annual grain legume or pulse crop sold into human food markets. Chickpea is the third most important food legume crop and India is the largest producer contributing to 65% of world’s chickpea production (FAOSTAT, 2012). According to Akhtar and Siddiqui (2009) during last decade the production of chickpea have declined. Its foundation is believed to be in south-eastern Turkey neighboring Syria and Iran (Ladizinsky, 1975). The earliest residue of chickpea seeds date back to around 7000 B.C in Syria and Turkey. In Turkey, it occupies about 388.518 hectare area with production of 450.000 tonnes and an average productivity of 1158.2 kg ha^{-1} (TUIK 2014). In spite of the importance of this crop in human daily diet and in agricultural production, productivity of this crop is low in Turkey. Hulse (1991) reported that legume is one of the oldest groups of agricultural plants and food legumes are the second most important human’s food supply after the cereal grains, which their grain contain 38 to 59% carbohydrate, 4.8 to 5.9% oil, 3% ash, 3% fiber, 0.2% calcium, and 0.3% phosphorus. In general, pulse crops contain a range of nutrients including low digestible carbohydrates, protein, essential amino acids, fatty acids, and a range of micronutrients (Bhatty, 1988). Bueckert et al (2011) reported that chickpea seeds contained from 29 to 52 mg/kg Zn, 77–112 mg/kg Fe, 1,448–2,457 mg/kg Mg, 1,211–2,457 mg/kg Ca, to 3.8–9.0 mg/g phytic asid. Cereals like wheat and rice combined with pulses are major dietary components for billions of people, and the potential for microelemet biofortifcation of pulses is high. Chickpea is an important source of microelements like Fe, Zn, Mg, and Ca in vegetarian diets (Abbo et al., 2000; Ereifej et al., 2001). Whereas, limited information is available on chickpea (*Cicer arietinum* L.) mineral biofortification. Micronutrient concentrations in the pulse lentil may vary depending on the geographical location, plant genotype, soil factors, temperature, and other growing season conditions (Thavarajah et al., 2010; Bueckert et al., 2011). The use of high plant density in chickpea production decreases soil water evaporation late in the growing season when plant cover closure is low. In difference, low plant density may allow weeds to grow more aggressively and limit crop yield possible. Plants grown at lower plant density are usually shorter and branchy, which increases losses during combine harvest (Turner et al., 2001). In a study in Canada, a plant population density of 55 plants m^{-2} produced a 23% to 49% seed yield above that of the recommended plant population density of 44 plants m^{-2} (Vanderpuye, 2010). Plant population is a type component of the production of chickpea. The yield of chickpea can be improved by planting of best density of chickpea cultivars. The objectives of this study were to determine the effect of plant density and varieties on grain yield and some microelemnts characteristics of chickpea under agro-climatic conditions of Bingol, Turkey.

Materials and Methods

The present study was conducted throughout spring season in 2016 at the research experiment field of the Bingol University (Turkey) located at 38^o 48 N latitude and 40^o 32 E longitude (10 km South Bingol) and at an altitude of 1090 m. Experimental field location receives annual rainfall of 938 mm. During the study in 2016, the lowest minimum temperature was fell down below to -5.6 ^{o}C in January. Total rainfall level of 2016 is lower than the total precipitation level of previous years. But during the first half of 2016, the total of precipitation was higher than the previous years. The amount of rainfall on the chickpea products was 98.4 mm (Figure 1, Figure 2 and Figure 3). The soil of experiment field is loamy, with contents of organic matter of around 1.9% and pH 6.57. Microelement values were taken from Demir (2016). The soil analysis result for physical and chemical characteristic of the study area are given in Table 1.

Table 1. Soil analysis result for physical and chemical characteristic of the study area

Soil depth	Soil texture	pH	Salt Content	Organic Matter	P_2O_5	K_2O	Lime	Fe	Zn	Na
Cm			%	%	Kg/ha		%		ppm	
0-30	Loam	6.57	0.0315	1.905	7.91	24.51	0.36	14.15	0.33	0.78

Two registired cultivars kabuli type(Arda and ILC-482) , adapted to South Easten Anatolia Turkey were chosen with a morphological traits (Table 2). The seeds were drilled 5-8 cm deep in previously opened furrows on 05th April 2016. In this study, the whole dose of P (6 kg P da^{-1}) with half of dose of nitrogen (5 kg N da^{-1}) were applied at sowing time and the remaining nitrogen (5 kg N da^{-1}) was top-dressed as Ammonium nitrate (%33) with flowering time on 26 July.2016. Rhizobium bacteria nodules were not observed in the roots of chickpea parsels.Weeds were controlled by hand after germination.

Table 2. Name and geographical origins of investigated cultivars

Cultivar	Plant height cm	First pod height cm	100 kernel wight g.	Plant type	Origin
Arda	64-85	33-37	34-40	Erect	GAPUTAEM
ILC-482	40-45	20-26	28-31	Semi-prostrate	GAPUTAEM

Experimental design and management: Two factorial trial was set up as a split-plot design (RCBD) with two comparing chickpea varieties (Arda and ILC-482) as main plots and fiwe seed densities (20, 30, 40, 50 and 60 seed m^{-2}) as split-plots. The main plots were randomised in a block design with three repilications. The density treatments were randomised in the main plots. Each variety was sown in four-row plots of 5 m length with between- and within-row spacing of 30 cm. Plot size was 1.2 m x 5 m (6 m^2). Spacing of 0.4 m and 1 m were allocated between plots and blocks, respectively

Microelemnts analysis: Fe, Ni, Zn and Na compositions of whole chickpea flour were determined by the method of Hwang et al.(1997) and; Choi et al. (2013) with slight modifications. One gram of chickpea flour was wet-digested in a mixture solution of HNO3(10 ml) and H2SO4 (10 ml) with heating on a hot plate. After extraction cooled, in hood opening carefully to pass the gas and put it to another tub that contain nearly 5ml of distilled water slowly and completed to 25ml by distilled water. This solution was ready for using to determine elements. Fe, Ni and Zn minerals determined by atomic absorption spectrophotometry (Perkin Elmer, AAS 800)

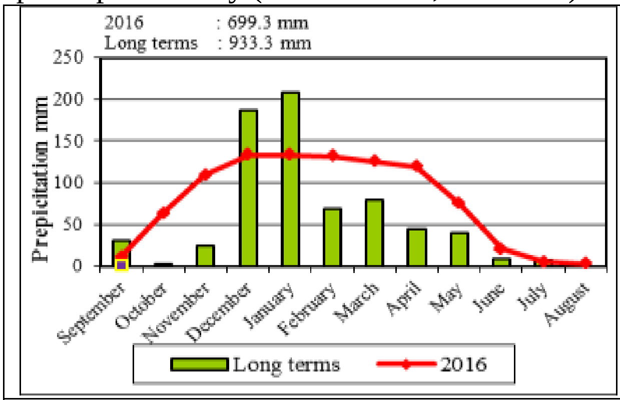

Figure 1 Total prepicitatiom (mm) in the growing environment

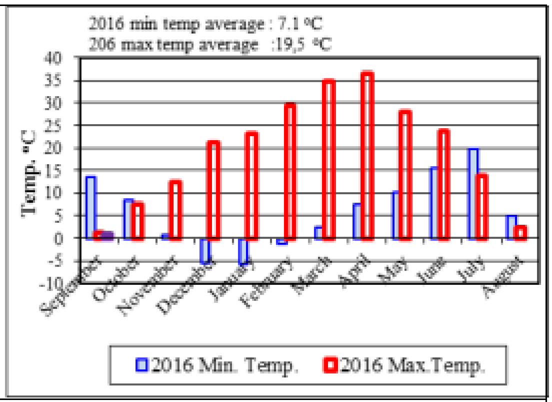

Figure 2. Max and Min temperatures (°C) in the growing environment

Statistical Data Analysis: Results were evaluated to analysis of variance SAS (Statistical Analysis Systems) program (SAS Institute 1999) and mean separation was performed by Fisher's least significant difference (LSD) test when F test was significant at P<0.05. Regression analysis was conducted to estimate linear and quadratic effects of plant density when results of the analysis of variance indicated these effects were significant at P<0.05.

Results and Discussion

Table 3. Analysis of variance of grain yield (kg/da) of different chickpea varieties and densities.

Sources	DF	Mean Squares				
		Grain yield	**Fe**	**Ni**	**Zn**	**Na**
Replication	2	15.2629	4,6972	0,1256	0,8051	1,6032

Error-2	16	61.24	2,5505	0,0896	0,5715	1,8078

*: Significance at 5 % probability, **Significance at 1 % probability, ns = non-significant

Grain yield (kg/da): Table 3 and Table 4 revealed that there were highly significant (P<0.01) differences among the varieties and seed densities. The interaction between the two factors was, however, significant. Variety ILC-482 produced the maximum grain yield (86,26 kg/da) by 60 seed/m^{-2} and Arda gave the lowest grain yield (19,80 kg/da) by 30 see/m^{-2}. Gan *et al*. (2003) concluded that increasing yield of chickpea at high density and they found strong positive relationship between seed yield and plant population densities. Bahr (2007) also noticed that high plant density (50 plants m^{-2}) gave higher seed yield as compare to low plant density (26 plants m^{-2}) in chickpea. Grain yield was increased with increasing in seed density was presented by regression equation in Figure 4 and Figure 5. These results were in line with those of Valimohammadi et al. (2007) reported that plant density has no significant effect on yield. While, Shamsi (2011) and Gana et al. (2007) reported that density does not have a significant effect on yield of chickpea. Regression analysis revealed that the grain yield increased linearly (R^2 = 0.48, 0.82) with seed rate for Arda and ILC-482 (Figure 4 and Figure 5).

1

Extraction minerals seeds component: Chickpea (Cicer arietinum L.) belonging to the family Leguminosae, is one of the world's most important pulse crops. Chickpea seeds are nutrient-dense foods providing rich content of protein and certain dietary minerals such as iron and phosphorus, thiamin, vitamin B6, magnesium and zinc contents are also present in Khatoon and Prakash (2004). The chickpea is a good source of protein and carbohydrate and its protein quality is better than other legumes such as pigeon pea, black gram and green gram. It also supply some minerals (Ca, Mg, Zn, K, Fe, P) and vitamins like thiamine and niacin (Vilche et al. 2003). In our study researched and foundation percentage of (ppm) some metal such as (Fe, Ni, Na and Zn).

Iron (Fe): In this study, variety, density and interaction (P<0.05) had non significant effect on Fe elemen. The summerised Fe values are showed in Table 3 and Table 4. It was observed that the concentration and peak intensity value of iron (Fe) element. The highest value has been obtained from ILC-482 (6.53 ppm) by 60 seed m^{-2}. The lowest value of Fe has been obtained from Arda variety (3.14 ppm) by40 seed m^{-2}. Haytowitz and Matthews (1983) reported that cooking in boiling water caused great lossesof K (24%), Cu (15%) and Fe (8%). According to regression analyses, there was neither linear nor quadratic relationship between fe content and seed rate for both cultivars.

Nicel (Ni): The results of the (Ni) element are presented in Table 3 and Table 4. The main effect of variety was significant ($P<0.05$) but density and interaction had non significant. In our study was working in laboratory center in Bingol university to finding overage of Ni element contain. The highest value has been obtained from ILC-482 (6.73 ppm) by 50 seed m-2. The lowest number has been obtained from Arda variety was (5.85 ppm) by 40 seed m-2. Micronutrient availabilityfor the plant depends, among other factors, texture organic matter and mainly soil (Ali et al., 2002). According to regression analyses, there was neither linear nor quadratic relationship between Fe content and seed rate for both cultivars.

Zinc (Zn): The results of variance analysis of Zn element value of different sample chickpea seed varieties are givenin Table 3 and Table 4. The main effects of variety and the interaction effects of variety x density had non-significant influence on the Zn element. Table 39 and Table 40 suggests that the highest average of Zn has been obtained ILC-482 variety (4.30 ppm) by 20 seed m-2. Wherease, the lowest value was obtained Arda verity (1.91 ppm) by 40 seed m-2. Zn plays an important role in plant reproductive development for initiation of flowering, floral development, male and female gamete genesis, fertilization and seed development (Liu et al., 2005). (Khan, 1998; Ahlawat et al., 2007). A comparisonbetween several crop species has shown that chickpeais more sensitive to Zn deficiency than cereal and oil seeds. Arda showed a quadratic trend ($R2 = 0.335$) for Zn content for the different seeding rates. while regression equation was not significant in ILC-482 (Figure 6)

Sodium (Na): The results of the Na element are presented in Table 3 and Table 4. The main effect of variety, density and interaction had nonsignificant effct by ($P<0.05$). The highest Na value of chickpea has been obtained from ILC-482 variety (5.03 ppm) in 30 seed m-2. While, the lowest value of Na has been obtained from Arda variety (3.67 ppm) by 20 seed m-2. (Ali et al., 2002). Micronutrient availabilityfor the plant depends, among other factors, texture,organic matter and, mainly, soil pH. Micronutrient availability for the plant depends, among other factors, texture, organic matter and mainaly soil pH. According to regression analyses, there was neither linear nor quadratic relationship between fe content and seed rate for both cultivars.

Conclusion

The results of the present research showed that maximum yield of grain was observed with ILC-482 related to 60 seed/m^{-2} density. The main effects of variety and the density had non significant influence on the Fe, Zn and Na elements, except Ni. However, density x variety interaction was significant only in Zn element.

Abstract

Hazelnut (*Corylus avellana* L.) is one of the oldest cultivated agricultural products. Anatolia is the gene centre of hazelnut. The richness of our country on genetic variation of this species provides facility for achievement in breeding studies in a short period of time. Because this fruit is cultivated on some regions of Anatolia, it is extremely important to develop cultivars proper for some regions. Turkey is the largest producer and exporter of hazelnut in the world. The world has 713.451 tons of total hazelnut production. According to 2015 statistics Turkey has 646.000 tons of total hazelnut production. Considering the total hazelnut production by the Regions in Turkey, East Blacksea and Marmara regions rank first and second with 353.427 and 161.905 tons of hazelnut productions respectively as West Blacksea Region is the third with a production of 130.114 tons. Considering the total hazelnut production of the provinces in the our country, Ordu and Giresun provinces rank first and second with 200.938 and 105.023 tons of hazelnut productions respectively as Kütahya province comes last with a production of only 2 tons. In this study, through presenting the existing status of the hazelnut production of Turkey, it was aimed to increase the awareness and set light to decision makers for making use of and directing the existing potential in future plans of our country.

Key words: *Hazelnut, Production potantial, Development opportunities, Turkey.*

Introduction

Turkey has a large potential of fruit species and fruit production (Simsek and Kara, 2016). It is a gene centre for many fruit species such as apricots, figs, hazelnuts, almonds, walnuts, pomegranates, pistachio, apple and cherry. According to archaeological research, It has been known that many fruit species were grown in Anatolia a few thousand years ago (Ozbek, 1975; Bostan and Islam, 1999; Gercekcioglu *et al.*, 2014). The total annual world hazelnut production is about 736.946 tons (reference needed). Turkey is the most significant country of the world in terms of hazelnut production (450.000 tons). After Turkey, Italy, Georgia, USA, Azerbaijan and China produce 37.400, 32.659, 29.796 and 23.520 tons of hazelnut annually, respectively (FAO, 2014). But, according to the data of 2015, Turkey's hazelnut production is reported to be 646.000 tons (TUIK, 2015). Hazelnut (*Corylus avellana* L.) belong to order *Fagales* and family *Betulaceae*. This species can grow up to 6-7 meters in damp and cool ecological conditions but 2-2.5 meters in arid south-facing land (Doganay, 1991). Traditionally, hazelnut is one of the commercially important fruit species grown for domestic consumption as a food, raw material for industry and export (Dizdaroglu, 1985).
This important nut has been grown for about 2500 years in Eastern Black Sea Region of Turkey (Kayalar and Ozcelik, 2012). In this study, through presenting the existing status of the hazelnut production of Turkey, it was aimed to increase the awareness and set light to decision makers.

Some Important Hazelnut Cultivars in Turkey

Hazelnut cultivars such as Tombul, Palaz, Çakıldak, Foşa, Mincane, Sivri, Kalınkara, İncekara, Allahverdi, Acı, Kan, Yassı Badem and Yuvarlak Badem are grown in Turkey (HRID, 2017). However, hazelnut production in Turkey is mostly based on cultivars such as Tombul, Palaz, Çakıldak, Foşa, Mincane, Sivri and Kalınkara (Balık *et al.,* 2015).

Figure 1. Kalinkara cultivar (Anonim, 2017a).

Figure 2. Tombul cultivar (Anonim, 2017b).

Figure 3. Allahverdi cultivar (Anonim, 2017c).

Hazelnut Productıon Potentıal of Turkey by Regıons

Hazelnut production potential of the regions was given in Table 1. According to this Table, climatic conditions of the Southeast Anatolia region is not suitable for hazelnut cultivation.

Eastern Black Sea was the most significant region of Turkey in terms of hazelnut production (353.427 tons). Marmara, Black Sea and Mediterranean regions produce 161.905, 130.114 and 376 tons of hazelnut, annually, respectively (TUIK, 2015) as Central Anatolia region ranks the last with respect to hazelnut production (17 tons).

On the other hand, Aegean was the most significant region of Turkey in terms of hazelnut yield (10.92 kg/tree). After Aegean, Mediterranean, and Central Anatolia and Eastern Anatolia regions have 10.20 kg/tree and 10.00 kg/tree of hazelnut, respectively (TUIK, 2015). Eastern Black Sea region is the last place with respect to hazelnut yield (1.61 kg/tree).

Table 1. Hazelnut trees's numbers and production of Turkey's regions (TUIK, 2015).

Regions	Area covered by bulk fruit (ha)	Production (ton)	Average yield per tree (kg)	Number of fruitful trees	Total number of trees
Aegean	4.5	51	10.92	4.670	6.650
Mediterranean	67.4	376	10.20	36.848	43.410
Central Anatolia	2.9	17	10.00	1.700	2.710
Eastern Anatolia	400	110	10.00	11.000	35.000
West Blacksea	132.195	130.114	1.94	67.232.447	72.067.621
Eastern Blacksea	422.718	353.427	1.61	219.632.423	222.371.260
Marmara	147.240	161.905	2.27	71.228.790	71.486.056
Turkey	702.628	646.000	1.80	358.147.878	366.012.707

Hazelnut Productıon Potentıal of Some Important Provınces in Turkey

Hazelnut production is carried out in 29 provinces, which are Afyon, Antalya, Amasya, Artvin, Bitlis, Çanakkale, Bursa, Bilcik, Bolu, Bartın, Düzce, Giresun, Gümüşhane, Istanbul, Isparta, Kahramanmaraş, Kastamonu, Kütahya, Kocaeli, Sakarya, Sivas, Sinop, Samsun, Ordu, Rize, Yalova, Zonguldak, Tokat and Trabzon, of Turkey. Eleven province of Turkey have more than 5000 tonnes of hazelnut production capacities (Table 2). Ordu was the most significant province of Turkey in terms of hazelnut production (200.938 tons). After Ordu, Giresun, Samsun and Sakarya produce 105.023, 90.857 and 82.708 tons of hazelnut, annually, respectively (Table 2). Kütahya province is the last place with respect to hazelnut production (2 tons) (TUIK, 2015). Ordu was the most significant province of Turkey in terms of number of hazelnut's trees (121.514.355). Ordu province was followed by Giresun, Samsun and Sakarya provinces with 59.551.900, 42.994.955 and 35.910.420 trees of hazelnut, annually, respectively (Table 2). Afyon province is the last place with respect to hazelnut trees (250 trees) (TUIK, 2015).

Table 2. Hazelnut Productıon Potentıal of Some Important Provınces in Turkey.

Provinces	**Area covered by bulk fruit (ha)**	**Production (t)**	**Average yield per tree (kg)**	**Number of fruitful trees**	**Total number of trees**
Artvin	8.665	6.314	2.32	2.721.150	2.814.260
Bartın	6.000	6.765	1.82	3.720.000	3.810.000
Düzce	62.685	69.344	2.17	31.978.800	31.991.657
Giresun	117.111	105.023	1.76	59.551.900	60.540.595
Kastamonu	7.471	5.213	1.79	2.907.980	3.280.644
Kocaeli	8.062	7.530	3.74	2.015.756	2.035.894
Sakarya	72.598	82.708	2.30	35.910.420	36.063.420
Samsun	90.623	90.857	2.11	42.994.955	46.470.880
Ordu	227.183	200.938	1.65	121.514.355	121.556.855
Zonguldak	23.593	22.572	1.43	15.813.152	16.410.427
Trabzon	65.350	39.126	1.15	33.954.918	35.563.200

Development Opportunıtıes of Hazelnut in Turkey

1. Hazelnut producers need to develop policies to get the expected profit from shell nuts together with production plans for domestic consumption and exports
2. Hazelnut producers need to make regular cultural processes to reduce profit inefficiency
3. Authorized institutions need to reform nut subsidy purchases and subsidy pricing policies.
4. Nut yield and quality will increase in case of more contribution to scientific research and will made a positive contribution to the economy both hazelnut producers and the country
5. Hazelnut plantation owners at the active age and dependent on hazelnut for the livelihood, and resident in the village, should be given first priority in support payments to keep them in their own places.
6. It is necessary to speed up the breeding works to develop new hazelnut varieties to be suitable for different ecological conditions and breeding systems.
7. Excessive amounts of hazelnut production should be avoided and forest land should be protected.

8. Necessary measures should be taken and timely and regularly done to prevent *Xanthomonas arboricola* pv. *Corylina*, *Botrytis cinerea*, *Xyleborus dispar* (Fabricius), *Lymantor coryli* (Perris), and to control printer insects and aflatoxin in hazelnut.
9. Technical and scientific studies must be done to reduce input cost
10. In order to expand the use range of hazelnut products, exporters should support and encourage policies in export procedures.
11. Producer associations and cooperatives must be established and the existing ones need to be strengthened to sell their products properly of hazelnut producers.
12. In order to achieve good quality production, hazelnut producers should consider the quality certification.
13. Hazelnut producers have to make agricultural insurance for the loss of natural disasters.

Conclusion

Supply-demand balance should be monitored in hazelnut potential production. Therefore, hazelnut producers should act in cooperation with other institutions and organizations, for example, faculties of agriculture and other colleges and institutes of the universities, under the coordination of provincial governors.

YIELD AND BIOCHEMICAL DIFFERENCES OF CAULIFLOWER (*Brassıca oleracea* L. *cv. Botrytis*) UNDER DIFFERENT IRRIGATION LEVELS

Okan ERKEN*, Murat YILDIRIM

Canakkale Onsekiz Mart University, Faculty of Agriculture, Department of Irrigation and Farm Structures, Canakkale 17100, Turkey.
*Corresponding author: oerken@comu.edu.tr

Abstract

Generally, winter vegetables are transplanted at the time when the irrigation water is deficit, so that, the plants may be exposed to drought stress at the beginning of development periods. For this reason, the effects of different irrigation applications on morphological and biochemical changes in cauliflower were investigated in the field conditions. Research was conducted in Dardanos research and application center at Canakkale Onsekiz Mart University in 2015 between July and October. Irrigation levels were applied at intervals of 4 days according to the changes determined from the class-A pan evaporation chamber. Irrigation levels are control (I1.0), which the amount of evaporation applied, mild stress which the 70% amount of evaporation applied (I0,70), severe stress which the 30% amount of evaporation applied (I0,70) and the waterless (I0) which no any irrigation applied to the plants until the harvest. The amount of seasonal irrigation water applied to treatments varied between 46.8 and 360.9 mm. The effects of irrigation water applied in different quantities on yield, some quality parameters and some physiological effects were evaluated statistically. According to the results obtained, reducing sugar and total sugar levels increased with the increasing stress. On the other hand, it has been determined that the changes in the amounts of some organic acids are significant statistically, depending on the stress conditions.

Key words : *Cauliflower, organic acids, drought, water stress, Class-A pan, drip irrigation*

Introduction

Brassica oleracea is one of the versatile species (Ordas and Cartea, 2008). Cauliflower (*Brassıca oleracea* L. *cv.* Botrytis) and broccoli (*Brassica oleracea var. italia*) are traditional European crops that have become widespread in Asia in recent decades whereas their presence in Europe has been quite stable (Branca, 2008).
Irrigation and fertigation have an extremely important effect on yield and quality in crop production. Water resources are decreasing in quantity and quality day by day. Increasing water demands are increasing because of the population growth, which creates heavy burden on existing water resources. Nowadays, research carried out on irrigation emphasizes the optimum water requirements during drought conditions rather than obtaining the highest yield for sustainable agriculture and also identification of drought resistance varieties of all crops for each climatic conditions has been becoming an important issue.
Cauliflowers (*Brassica oleracea* L. var. Botrytis) are a source of phytonutrients, acting as antioxidants, such as glucosinolates, ascorbic acid and polyphenols (Scalzoa et al., 2008). Violet cauliflower extracts show significant antioxidant properties, among which are the scavenging activity of the very reactive hydroxyl radical (Pizzocaro et al., 2000).
The health benefits of broccoli are derived from the unique mixture of nutrients, minerals and vitamins and organic compounds that are found in cauliflowers. Organic acids are a group of organic compounds containing carboxylic groups. Organic acids have important functions as

flavor enhancers and natural antimicrobial agents. Organic acids influence the color of vegetables since pigments are natural pH indicators. Ascorbic acid known as vitamin C is organic acid with antioxidant properties. Vitamin C is involved in the absorption of iron and calcium. It assists in the healing of wounds and burns, in preventing blood clotting and bruising and in strengthening the walls of the capillaries, since vitamin C is a biological antioxidant, is also linked to the preservation of cataract, certain cancers, and cardiovascular disorder. Plants are seriously affected by some environmental factors (climate, available organism, geologic materials, soil, atmospheric conditions and so on) during all phases of growth and development (Haferkamp, 1987). Sarah et al. (2011) observed green color and bioactive compounds of broccoli (*Brassica Oleracea* L.) under low and optimal soil water content in greenhouse conditions. Pek et al.(2012) reported that the contents of glucosinolate and flavonoids changed under different water applications, except for sulphoropane content, but the harvesting time has an effect on the amount of sulphoropane, especially harvesting in fall period increases the amount of it. The content of ascorbic acid in vegetables is strongly affected by growth conditions, application of nitrogen fertilizers, as well as by storage conditions and processing (Sinha et al., 2011).

Organic acids are used in food preservation because of their effects on bacteria, since they can penatrate the bacteria cell wall and disrupt the normal physiology of certain types of bacteria. Within the organic acids, the malic, tartaric, lactic, succinic acids and acetic acids prolong the shelf-life of fresh-cut broccoli (Irkin et al., 2015).

The main objectives of this research were to determine both the yield, optimum water requirement of cauliflowers and changes in plant development and quality parameters under different irrigation levels.

Materials and Methods

Experimental site and soil description

The field experiment was carried out at Dardanos Agricultural Research Station of Canakkale Onsekiz Mart University in 2015, near the Dardanelles straits in Canakkale province, Turkey. The location of the experimental area was 40.08° N, 28.20° E at an elevation of 3 meters. Dates of transplantation for the cauliflowers (*Brassıca Oleracea* L. *cv. Botrytis*) were 10 July, 2015 at spacings of 0.6x0.4 m. The chemical characteristics of the soil are given in Table 1.

Table 1. Physical and chemical properties of soil in experiment.

Depth (cm)	Field capacity (%)	Wilting Point (%)	Bulk Density (g/cm^3)	pH*	Total changeable sodium (mg/l)*	Cation Exchange capacity (me/100g)*	$CaCO_3$ (%)*	Organic matter (%)*
0-30	21.0	10	1.30	7.69	135	22.3	13.5	2.29
30-60	24.4	11	1.57	8.00	195	26.2	12.0	1.26
60-90	25.0	13	1.63	8.08	98.5	24.3	10.4	1.41

*taken from Ozcan et al. [16]

Each plot was arranged in 4 rows including 120 plants per row. The experiment was laid out using a randomized complete block design with 3 replications.

Data were saved into the data logger at 1-hour intervals throughout the experiment. The electrical conductivity of the irrigation water (ECw), measured with an EC59 pyranometer (Milwaukee Instruments, Inc.), was 0.410 ds m^{-1}, which is reported as no restriction on use by Ayers and Westcot (1985).

Climate parameters

Climate parameters; temperatures (min., max., and mean), relative humidity and solar radiation at the site were measured by a mini climate station at 1.5 m above the canopy of the plants, and also prolonged temperature values are given in fig.1.
The climate parameters of solar radiation (W m-2), temperature (0C) and relative humidity (%) at the site were measured above the canopy of the plants All data were measured by a HOBO U12 data logger, including sensors.

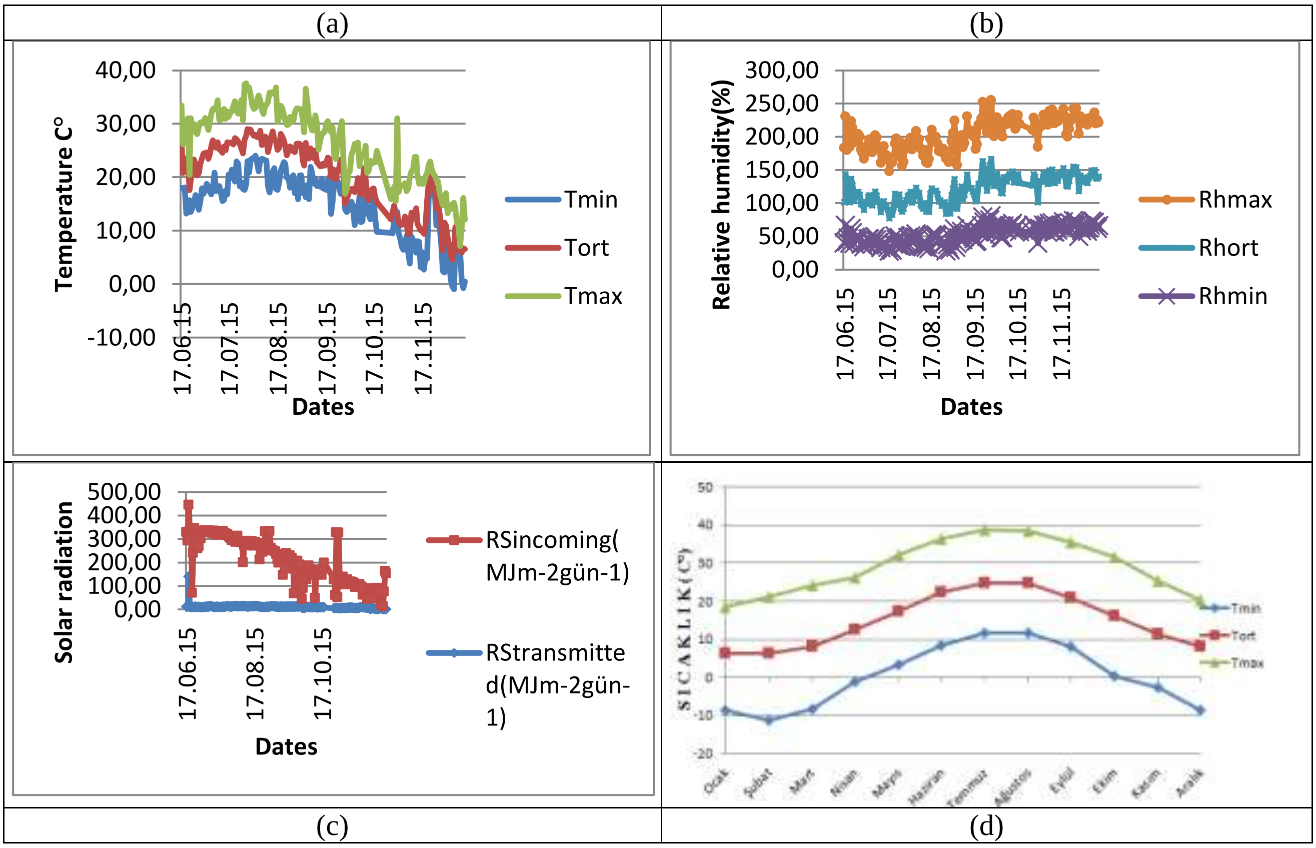

Figure 1. Meteorological data for period of experiment (a) Temperatures(° C), (b) Relative humidity (%), (c) Solar radiation(MJm^{-2}), (d) prolonged temperatures parameters (1975-2000)

Irrigation practice

Each plot in the experiment took the same amount of fertilizer by the drip irrigation system. The total amount of fertilizer was applied three times, first at planting then at 15 and 20-day intervals. The irrigation program was run according to full irrigation ($I_{1.0}$). Hence, the irrigation treatments included four gradient irrigation levels from full water to severe water stress. Only in the full irrigation (control treatment) was water refilled in the root zone up to field capacity at 4-day intervals. All treatments were equally irrigated for 20 days after transplanting in order to root development of all plants, then water was applied according to the irrigation treatments. Following this, they were then irrigated according to the irrigation treatments.
In the deficit treatments, water was applied at 70% ($I_{0.7}$), at 30% ($I_{0.3}$), and at 0% (I_0) of full irrigation. Class-A Pan was located next to the experimental plot. All amounts of evaporation from the class-A pan throughout the whole growing season were measured every 4 days for all growing period. In calculation of the applied water in the full irrigation, pan evaporation was used according to the equation given by Kanber (1984).

$$I = A \times E_{pan} \times Kpc \quad (1)$$

where I is the amount of irrigation water applied (mm), A is the plot area, E_{pan} is the cumulative evaporation at irrigation interval (mm), Kpc is the pan coefficient (Kpc=1 in the $I_{1.0}$, Kpc=0.7 in the $I_{0.7}$, Kpc=0.3 in the $I_{0.3}$ and Kpc=0 in the I_0) . Evapotranspiration (ET) was calculated by the water balance equation below:

$$ET = I + P \pm \Delta SW \qquad (2)$$

where ET is evapotranspiration (mm), P is rainfall (mm) and ΔSW is the change in soil water content (mm) at a depth of 60 cm from the soil surface, and soil water content was determined by the gravimetric method at 30 cm intervals.

Plant and fruit quality parameters

All plant weights (steam, leaf and fruit) were determined using a digital balance (±0.01 g) and diameters were measured with a digital clipper (±0.01 mm). Fresh weights (stem, leaf and fruit) were determined separately by weighing. After that, they were all oven-dried to a constant weight at about 65°C for two days to determine the dry weight of whole plants in each treatment.

Leaf area

Three plant samples from each plot were selected randomly for leaf area measurements. The green leaf portions were separated and leaf area was measured using a CI-202 Portable Laser area meter (CID, Inc., USA).

Organic acid extraction and analysis

Cauliflowers pulp (3 g) was extracted by stiring with 30 mL of metaphosphoric acid for 15 minutes, then mixed with distilated water to 50 mL and subsequently filtered throgh Whatman no.4 paper (Vazquez et al.,1994). The volume was adjusted to 10 ml and passed through a 0.45µm filter before examination. The process was performed for each sample using a HPLC system with a UV/VIS detector. The reagents used included chromatography-grade standards for ascorbic, oxalic, tartaric, malic, lactic, malanoic and citric acids.

Statistical differences with p-values under 0.05 were considered significant and means were tested by Duncan's Multiple Range Test at the probability level of 1% and 5% ($p<0.01$, $p<0.05$).

Results

Irrigation water, evapotranspiration (ET) and yield

The irrigation events were performed succesfully between 209th and 293th days of the year. Cauliflowers were harvested at the 325th day of the year, hence broccoli development period lasted 116 days. Different irrigation treatments in the experiment had a significant effect on the yield and vegetative development of cauliflowers. The irrigation amounts (I), evapotranspiration (ET), WUE and IWUE values are given in Table 2.

Table 2. Measured irrigation depth (I), Evapotranspiration (ET) and Yield.

Treatments	Irrigation depth (mm)	Yield* (g plant^{-1})	Yield* (kg ha^{-1})	Evapo transpiration (mm)
$I_{1.0}$	587,65	1415,3 ± 63,7 ^{A}	5892,08 ± 132,2 ^{A}	714,7 ± 32,2 ^{A}
$I_{0.7}$	411,36	1138,5 ± 64,6 ^{A}	4743,75 ± 92,6 ^{A}	574,9 ± 32,6 ^{A}
$I_{0.3}$	176,30	811,0 ± 104 ^{B}	3379,16 ± 52,8 ^{B}	409,5 ± 52,8 ^{B}
$I_{0.0}$	65,00	179,4 ± 13,5 ^{C}	747,5 ± 16,83 ^{C}	90,59 ± 6,83 ^{C}

*P<0.05, **P<0.01, ***P<0.001

As seen in Table 2, evapotranspiration increased as the amount of applied water increased. The peaks of yield, 714.7 kg ha^{-1} and 574.9 kg ha^{-1} were obtained from the $I_{1.0}$ and $I_{0.7}$ treatments, respectively. Therefore, the applied water of 411.36 mm in the $I_{0.7}$ treatment produced the yield to 574.9 kg ha^{-1}, which can be considered as the critical level for cauliflowers production (Table 2) since the lower than this amount causes plants to decrease the yield value. Therefore, the amount of water applied in the treatment of $I_{0.7}$ may be considered as a threshold value if water source is scarce.

Measurements of plant development parameters for the whole growing season are given in Table 3. Parameters related to plant development; plant height, diameters were negatively affected as the amount of water decreased from 411.4 to 65 mm. Plant sizes in terms of height and diameters were reduced by 30% ETc irrigation as compared to 100% ETc irrigation (Table 3). Therefore, deficit irrigation at 70% ETc can be considered as the threshold level in terms of both yield and quality to obtain an economical yield.

Table 3. Effect of different water levels on plant development parameters

Treatments	Diameter- x* (cm)	Diameter- y* (cm)	Height (cm)*	Leaf area (cm^2)*
$I_{1.0}$	19,01 ± 0,40 ^{A}	18,35 ± 0,49 ^{A}	14,89 ± 0,31 ^{A}	19523 ± 708 ^{A}
$I_{0.7}$	17,64 ± 0,49 ^{A}	17,64 ± 0,38 ^{A}	13,61 ± 0,31 ^{B}	14430 ± 212 ^{B}
$I_{0.3}$	14,34 ± 0,20 ^{B}	13,76 ± 0,34 ^{B}	11,08 ± 0,29 ^{C}	9279 ± 242 ^{C}
$I_{0.0}$	8,59 ± 0,45 ^{C}	8,73 ± 0,29 ^{C}	8,73 ± 0,12 ^{D}	3942,1 ± 27,8 ^{D}

*P<0.05, **P<0.01, ***P<0.001

The various sugars perform different functions in the tubers, but they all can provide energy, glucose is the main source of energy because the most complex sugars and carbohydrates breakdown into glucose (Yildirim et al, 2009). The total and reduced sugar contents were the highest in the $I_{1.0}$ as 4.76 and 3.69 g/100g, respectively. Therefore, full treatment caused cauliflowers plants to store more energy.

Treatments	Reduced sugar (mg 100g^{-1})	Total sugar (mg 100g^{-1})	Sucrose
$I_{1.0}$	3,693 ± 0,181 A	4,766 ± 0,023 A	1,020 ± 0,151 ns
$I_{0.7}$	3,375 ± 0,202 AB	4,310 ± 0,142 AB	1,171 ± 0,160 ns
$I_{0.3}$	3,343 ± 0,289 AB	4,559 ± 0,163 AB	1,439 ± 0,227 ns
$I_{0.0}$	2,511 ± 0,091 B	4,210 ± 0,094 B	1,614 ± 0,176 ns

Organic acids

The organic acids (ascorbic, tartaric, lactic, citric, malic, malanoic and oxalic acid) in cauliflower (*Brassica Oleracea* L. cv. Botrytis) are given in table 4. The organic acid contents in cauliflower varied from 52.4 mg g^{-1} in the treatment that full water demand of cauliflower was met to 60.5 mg g^{-1} in the severe stress treatment. As seen, the amount of total organic acid increased when the level of water stress increased.

The changes in the amount of organic acids are given in table 3. The dominant organic acids in cauliflower (Brassica Oleracea L. cv. Botrytis) were ascorbic, oxalic, and malic acid , respectively. The ascorbic acid content exhibited the highest content as compared with other organic acids given in table 3. The ascorbic acid ranged from 38.6 mg g^{-1} in the full water application to 47.4 mg g^{-1} in the stress treatment ($I_{0.0}$), which was almost accounting of 76 % of the total organic acid content, oxalic and malic acid were 17.6 % and 4.42 % of total acid. The minor organic acids in cauliflower were citric (0.1 to 0.9 mg g^{-1}), lactic (0.5 to 0.7 mg g^{-1}), tartaric (0.3 to 0.4 mg g^{-1}) and malanoic acid (0.2 to 0.3 mg g^{-1}), and these accounted for very less amount of total acids. The content of each individual organic acid increased with increasing water stress, and the differences between the individual organic acids were significant.

Table 4. Organic acids (mg/g)

Treatments	Ascorbic	Tartaric	Lactic	Citric	Malic	Malanoic	Oxalic
$I_{1.0}$	0,3858 ± 1,04 B	0,491 ± 0,005 ns	0,571 ± 0,084 ns	0,974 ± 0,110 A	2,315 ± 0,124 B	0,232 ± 0,012 C	9,240 ± 0,017 ns
$I_{0.7}$	0,4177 ± 0,09 B	0,439 ± 0,018 ns	0,793 ± 0,042 ns	0,323 ± 0,179 B	2,945 ± 0,225 A	0,318 ± 0,007 A	9,128 ± 0,368 ns
$I_{0.3}$	0,4291 ± 0,22 AB	0,393 ± 0,027 ns	0,550 ± 0,080 ns	0,124 ± 0,009 B	3,299 ± 0,062 A	0,330 ± 0,006 A	8,829 ± 0,736 ns
$I_{0.0}$	0,4741 ± 1,81 A	0,377 ± 0,018 ns	0,543 ± 0,036 ns	0,172 ± 0,023 B	2,780 ± 0,018 AB	0,278 ± 0,001 B	8,979 ± 0,228 ns

Therefore, organic acid content in cauliflower (*Brassica Oleracea* L. cv. Botrytis) was higher than other fruits. Soyer et al. (2003) found that the dominant organic acid in the 11 different white grape cultivars was tartaric acid (4.07 to 4.92 g L^{-1}) and citric acid (31 to 181 mg L^{-1}), malic acid (1.36 to 3.47 g L^{-1}), respectively. Sha et al. (2011) determined 10 organic acids in the pear fruit (P. ussuriensis) and the total organic acid content ranged from 3.04 to 9.13 mg L^{-1}.

Conclusion

Careful attention in irrigation must be paid to determine the optimum water requirements of all crops without causing too much loss in yield and nutritional contents of food.

In the experiment, cauliflower (*Brassica Oleracea* L. cv. Botrytis) exhibited to be a water-sensitive plant to water shortage, Yield of cauliflower was affected according to the different water levels and produced the highest yields in $I_{1.0}$ and $I_{0.7}$ treatments, in which the amount of water applied were 587.6 mm and 411.4 mm. These findings are well agree with the findings of Erken et al.(2013). Applying irrigation water for cauliflower between 411.4 and 587.6 mm seems to be more appropriate level for getting an economical yield.

An increment in the organic acid content was observed, as water stress level increased, and there was statistical differences in each organic acid content under different irrigation levels. Within the organic acids, ascorbic acid (Vitamin C) was dominant in cauliflower and also the content of it was very high as compared with many fruits. Therefore, cauliflower can be considered in terms of ascorbic acid as an important antioxidant in the foods.

EFFECTS OF THE PICKING PEDICLE AT DIFFERENT STAGES ON TULIP GROWTH

Özgür KAHRAMAN*

*Canakkale Onsekiz Mart University, Faculty of Architecture and Design, Department of Landscape Architecture, Terzioglu Campus, 17020 Canakkale, Turkey
*Corresponding author: ozgurkahraman@comu.edu.tr

Abstract

Tulip is one of the bulbous plants that show up with the beautiful flowers in the landscape areas and gardens in the winter months. The bulbs of the tulip must have over certain circumference of the bulbs to be able to bloom. The circumference of the bulb affects the flowering positively. This research was carried out to determine the effects of pedicle picking at different stages on plant growth and bulb parameters between November 2015 and May 2016 in pot culture. The bulbs of *Tulipa gesneriana* L. "Golden Parade" with 9 cm circumference were used as a plant material. After the bulbs were treated with fungicide, they were planted on November 23, 2015 in plastic pot filled with a mixture of peat (50%) and perlit (50%). The research was designed according to randomized plot design with 3 replications and each plot (plastic pot) had 5 tulip bulbs. Three different treatments were applied to the pedicle of tulip. The pedicle was picked as soon as it was seen in first treatment (T1). In second one (T2), the pedicle of the tulip was picked under its receptacle before blooming. The pedicle was not plucked in the control application (C). Some parameters such as bulb diameter, bulblet number, bulblet diameter, leaf number, leaf width, leaf length and leaf width were measured. As a result of statistical analyses, treatments have a significant effect on bulb diameter but there were no significant differences between the treatments for the other parameters. The highest bulb diameter was found in T1 (31.46 mm) and T2 (30.87 mm). The bulblet number was determined between 1.17 and 1.50 piece.

Introduction

Tulip is one of the natural flower bulb species and has ornamented with beautiful flowers in our garden over four centuries. Although tulips are native species to Central Asia, generally these are associated with the Netherlands (Tuyl and Creij, 2006). Turkey familiarised tulips to Europe and they started to be seen in the Netherlands in 1574. They become quite popular in 1630's. They were used extensively in the garden design during the Ottoman Empire. Tulips have been a source of inspiration for fine arts such as architecture, marbling art and glazed tile. The name was given to a period "Tulip Period". They have been started to be used in parks and gardens by metropolitan municipalities such as İstanbul, Konya and district municipalities. They are also used for cut flowers and flowering potted plants in the ornamental plants sector. They have the most production area (122727 da) in the world and they are at the head of the bulbous flowers that are traded (Benschop *et al*., 2010). The tulip production in Turkey is carried out by a private company in Çumra district, Konya. Tulip is one of the natural flower bulbs belonging to *Liliacaeae* family. *Tulipa gesneriana* L. species is a bulbous plant having pear-shaped hard brown tunics. Tulips are commonly propagated with vegetative propagation methods. They need a low temperature period to bloom their

beautiful flowers (Rietveld *et al.*, 2000). In addition, the bulb of tulip must be in critical size (6-9 cm) to be able to bloom (Rees, 1966). Enlargement of bulbs is taking a long time.
This research was conducted to determine the effects of pedicle picking at different stages on plant growth and development of bulb.

Material and Methods

This research was conducted between November 2015 and May 2016 in pot culture in a private residential garden in Çanakkale, Turkey. In this research, the bulbs of *Tulipa gesneriana* L. "Golden Parade" with 9 cm in circumference were used as a plant material (Figure 1). These bulbs were treated in 1% Captan and 0.5 % Mancozeb for 20 minutes against fungal diseases. As a growing media, 50 % peat + 50 % perlite mixes were prepared (Figure 2). After plastic flowerpots were filled with growing media prepared as much as half of pot's depth, the bulbs of tulip were planted on November 23, 2015 (Figure 3). Later on, the bulbs were watered until drainage out. During tulip growing season, three different treatments were done. The first treatment (T1); the pedicle of tulip being picked as soon as it was seen. The second treatment (T2); the pedicle of the tulip being picked under its receptacle before blooming. The pedicle was not plucked in the control application (C) (Figure 4). The research was established according to randomised plot design with 3 replications and each replication had five tulip bulbs (Figure 3). From the study, parameters such as bulb diameter (mm), bulblet number (piece/bulb), bulblet diameter (mm), leaf number (piece/bulb), leaf width (cm), leaf length (cm) and leaf thickness (mm) were measured. Variance analysis with SPSS 23 statistical software and Duncan's multiple comparison test ($p < 0.05$) were applied to this data.

Figure 1. The bulbs used in the experiment

Figure 2. Peat, perlite and 50% peat + 50% perlite mixture

Figure 3. Planting of tulip bulbs

Figure 4. The picking pedicle at different stages (T1, T2, C)

Results and Discussion

According to the variance analysis, in this research, it was determined that picking pedicle at different stages had a statistically significant effect ($p<0.01$) on bulb diameter. The highest bulb diameter was determined in T1 (31.46 mm) and T2 (30.87 mm) treatments where the pedicle was picked (Figure 5). The lowest bulb diameter (27.78 mm) was in control treatment (Figure 6). However, picking pedicle treatments had any statistically significant effect on bulblet number and diameter. Bulblet number was between 1.17 piece (T1) and 1.50 piece (T2). The maximum result for bulblet diameter was found with an average value of 22.03 mm in C, also minimum value was found in T1 (21.60 mm). Kahraman (2016) also had similar results for bulb diameter and bulblet number in picking pedicle of Madonna lilly.

Figure 5. Effects of the picking pedicle at different stages on diameter of bulb (T1, T2, C)

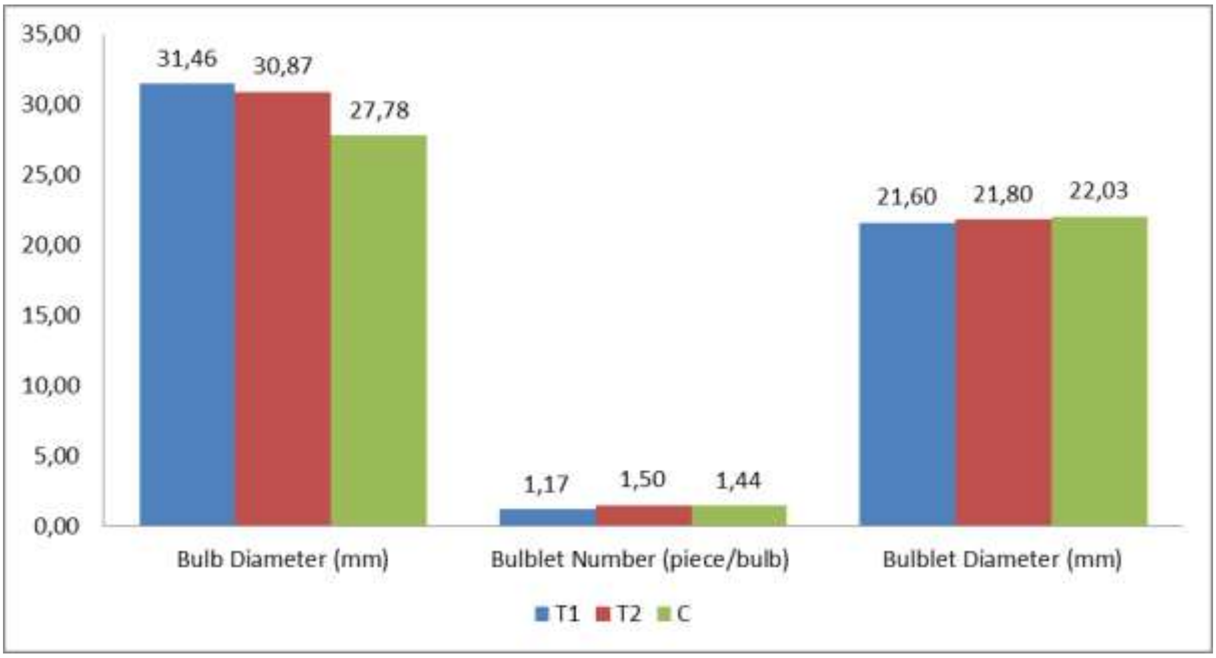

Figure 6. Effects of the picking pedicle at different stages on bulb parameters (T1, T2, C)

The effect of picking pedicle treatments on leaf number, leaf length, leaf width and leaf thickness was found to be insignificant. Leaf number occurred between 4.14 and 4.67 piece (Figure 7). The highest leaf length was found in control (13.08 cm). The leaf width was found between 6.63 cm (T1) and 7.19 cm (T2). Kottayam *et al. (2014*) found approximate value for leaf number (3.33-4.66 piece) in different two tulip cultivars (Apeldoorn and Golden Oxford).

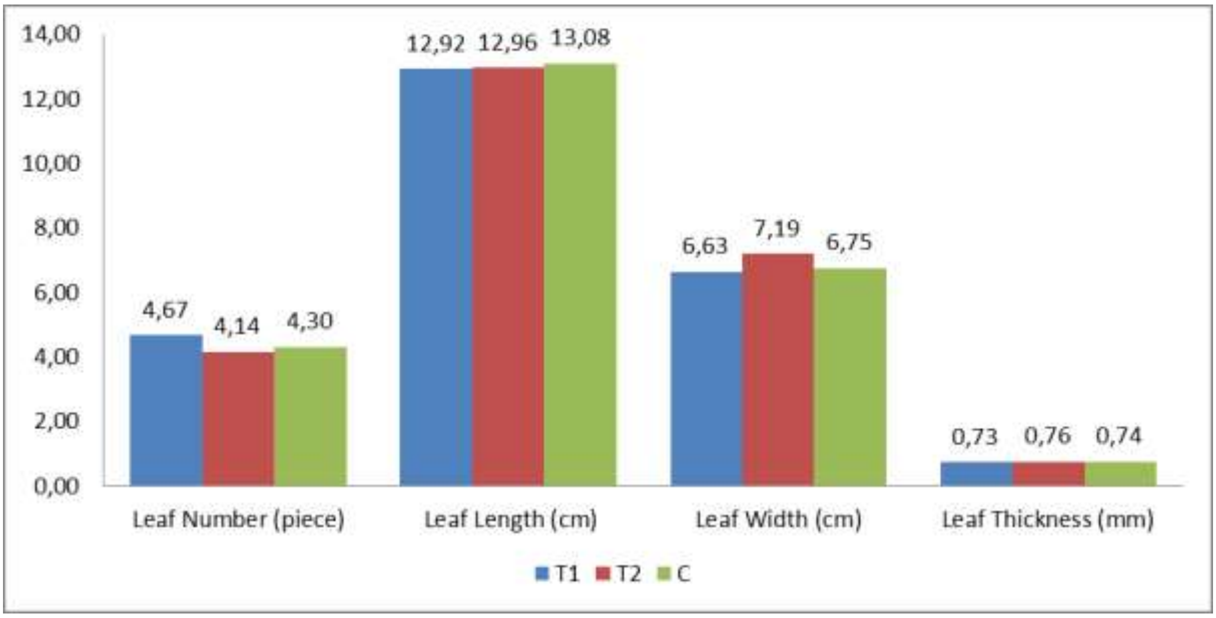

Figure 7. Effects of the picking pedicle at different stages on leaf parameters (T1, T2, C)

Conclusions

The results showed that in *Tulipa gesneriana* L. cultivation, picking pedicle at different stages (T1 and T2) effect on bulb size. However, the effect of picking pedicle treatments on some parameters such as bulblet number, bulblet diameter, leaf number, leaf length, leaf width and leaf thickness is insignificant. T1 and T2 treatments can be used in *Tulipa gesneriana* L. cultivation to enlarge the bulb size.

Abstract

Turkey is ranked first regarding dry Fig production in the world. In terms of organic farming, Turkey is ranked second regarding dry Fig production after olive production. Main aim of the project was to determine impacts on soil characteristic parameters of 'Sarilop' dried fig variety applying different natural fertilization techniques on organic agriculture system. That research was carried out in a farmer orchard which consisted of Sarilop dried fig variety, located in Isafakilar village, Incirliova, Aydin in Turkey, in the period 2002-2005. This experiment was designed in completely randomized blocks with four replications and each replication was comprised of one tree. Totally six applications were applied: (control, vetch, natural vegetation, 20, 40 and 60 kg farmyard manure applications respectively). Soil samples were taken after harvest for three years. In this soil samples, soil texture, pH, $CaCO_3$ (%), total salt (%), organic matter (%), N, P, K, Ca, Mg analyses were done. According to analysis results, natural fertilization applications increased total salt and pH contents in the second year. Organic matter and N contents increased among the years. The highest organic matter was obtained by application of farmyard manure. P, K, Ca and Mg contents increased as parallel with increasing doses and reached the highest values by application of 40 kg farmyard manure.

Introduction

Ecological agriculture (=biological agriculture, organic agriculture) is designated as the most important and effective alternative in the solution of the environmental problems caused by the use of agricultural inputs getting intensified year by year in the present day. When studied over years, ecological agriculture containing eco-credential production techniques and targeting the enhancement of welfare from producer to consumer dates back to the first half of the 1900s when the use of chemicals started in agriculture. The pioneers in the matter in Europe displayed different approaches to the soil fertility concept and thus constituted the foundation of ecological agriculture (Aksoy, 2001).

Worldwide, Australia occupies the first place with 11300000 ha of organic agricultural production area and it is followed by such countries as Argentina (2800000 ha) and Italy (1052000 ha) respectively. Organic agricultural production area is 103190 hectares in Turkey. It was determined that the share of these organic production areas in the total agricultural land of each country varied between 0.22% and 6.86 percent. Organic agricultural production area is 103190 hectares in Turkey and its share in the total agricultural land (26000000 ha) is 0.39 percent (SOEL, 2005).

In a study in which the effect of soil characteristics on the fresh and dried fruit properties in fig trees, it was determined that the nitrogen content of the soil had an affirmative effect on the number of sound fruits and reduced the sun blight. It was reported that there was a positive relationship between the phosphorus content of the soil and the number of leaves not affected by blight (Anac et al., 1991).

In a study carried out in order to identify the nutritional status in the fig orcahards in the vicinity of Germencik, the researchers determined that the potassium contents of the leaf blade and stalk were effective on the fruit quality and that it increased the rate of split fruit while reducing the rate of sun-blighted fruit and stated that the same relationship was also valid for calcium in the reverse way (Aksoy et al., 1987).

In a study they carried out in the vicinity of Germencik, Aksoy et al. (1987) stated that the nitrogen contents of the leaf blade and stalk affirmatively affected the vegetative growth and number of fruits of fig trees but reduced the fruit size in dried fruits and increased the number of sun-blighted and dark-coloured fruits and reduced the quality of dried fruit. They further determined that phosphorus also affirmatively affected the fresh and dried fruit size.

In a study in which the effect of potassium nitrate and calcium nitrate applications via leaves in figs on some nutrient contents and fruit quality properties were studied, it was stated that potassium applications had an affirmative effect on the fruit colour and hardness as well as fruit size.

Anac et al. (1991) stated that there was an affirmative relationship between the potassium content of the soil and the number of sound fruits not showing sun blight in fresh and dried figs. It was further reported that the calcium content of the soil reduced the fruit size and that there was a significantly affirmative relationship between the calcium carbonate content of the soil and the number of non-split sound fruits.

In a study in which the effects of organic fertilization on the leaf and fruit quality in figs, it was stated that fertilization was effective on the Ca and Zn contents of the leaf stalk and that animal manure applications was effective on the Fe content of the leaf stalk and the fruit. Further, it was reported that organic fertilization increased the vegetative growth and was effective on shoot length, width and node number (Mordogan et al., 2002).

The objective of this study is to study the effect of the use of different doses of different organic matters and cattle manure used in organic agriculture as fertilizing material in organic fig growing on the physical and chemical properties of the soil.

Material and Method

The study material is comprised of the grower orchard cultivated with the Sarilop fig variety in the Isafakilar village of the township of Incirliova (Turkey) The study was carried out by applying three different doses of cattle manure and spring vetch (vicia sativa) in the fertilization of figs, and mulching was made by mowing weeds and leaving them on the soil surface.

The trial was set up by the random blocks trial pattern and the applications consisted of 4 repetitions and each repetition consisted of one tree. Applications were six in number and they were:

<u>Control (C)</u>: Methods being used by the grower were maintained.

<u>Natural Vegetation (NV)</u>: Natural vegetation on the soil was mowed and left on the soil.

<u>Spring Vetch (SV)</u>: 12 kg/da spring vetch was calculated and sown in October and November and mixed into the soil at the beginning of blossoming.

<u>20 kg manure/tree</u> (20 CM): Cattle manure to the projection of the tree’s crown.

<u>40 kg manure/tree</u> (40 CM): Cattle manure to the projection of the tree’s crown.

<u>60 kg manure/tree</u> <u>(60 CM)</u>: Cattle manure to the projection of the tree’s crown.

Soil samples used in the study were taken from a depth of 0-30 cm and analysed three times, i.e. prior to trial, in the year when the trial was applied and after trial. Chemical analyses were carried out on the organic fertilizer used in the trial (Table 1). In the soil samples, composition was analyses by Bouyoucous (1951) method; pH by Jackson (1958) method; % total salt by US Salinity Staff (1951) method; % $CaCO_3$ by Caglar (1958) method; % organic matter by Walkey-Black (Anonymous, 1980) method; variable K, Ca, Mg, Na by Kacar (2009) method; obtainable P by Olsen et al. (1965) method. Statistical analyses of the data obtained in the study were carried out by the randomized plots trial pattern and SPSS package programme was employed.

Table 1. Results of analysis of the organic fertilizer used in the trial

Organic fertilizer properties*											
Percent				mg kg^{-1}							
Salt	**OM**	**N**	**pH**	**P**	**K**	**Ca**	**Mg**	**Na**	**Fe**	**Zn**	**Mn**

* OM = organic matter; interpretation of the results: SL = saltless, SA = strong alcalic, VH = very high, H = high, M = medium

Results and Discussion

Evaluation of the changes in the physical and chemical properties of the soil samples taken from the plots where application was made prior to trial and for 3 years afterwards is given in Table 2. It is observed that different organic matters applied to the soil have changed the % total salt content of the soil as compared to the control. According to the limit values by Soil Survey Staff, 1951, while it was not salty in terms of % total salt in the 1^{st} and 3^{rd} years, a danger of slight salinity appeared in the 2^{nd} year. When the averages of the three years are examined in Table 2, a danger of slight salinity is involved in spring vetch and 20-40 kg organic fertilizer applications and that there is no problem in terms of salinity in the other applications. In the statistical evaluation made, it was determined that there was difference between the applications and years but that the interaction of year*application was not significant (Table 2).

* C = control; NV = natural vegetation; SV = spring vetch; CM (kg/tree)

While the pH content of the soil was of slightly alkali reaction at control, natural vegetation (NV), spring vetch (SV) and 20 kg fertilizer (20 kg) in the 1st year by Kellog, 1952 and in Table 2, it was determined to be of alkali reaction at 40 kg fertilizer (40 kg) and 60 kg fertilizer (60 kg) doses. Looking into the average of the years, it was determined that there was no difference between the applications but there was difference between years. No statistical relationship could be identified in year*application.

Organic matter contents of the soil are at a low level for all applications according to Schlichting and Blume, 1962. The applied materials increased the organic matter content of the soil but did not change the limit values. Differences were obtained between the applications in statistical terms and the best result was obtained in the 60 kg fertilizer application. Organic matter contents were determined to be higher than the control every year but no significant statistical relationship was identified between the years and in the year*application interaction. Çelik et al. 2004, the compost and manure-treated plots significantly decreased soil bulk density and increased soil organic matter concentration compared with other treatments.

* C = control; NV = natural vegetation; SV = spring vetch; CM (kg/tree)								

Applied organic materials increased the N % content of the soil despite the absence of changes in the organic matter content of the soil Table 3. Increases caused the limit values to change, i.e. to rise from the very low level to the medium level. Differences were identified between years, applications and year*applications. The highest value was obtained by spring vetch in the 20-40-60 kg fertilizer applications. The highest year was the 3rd year in natural vegetation. Hernandez et al. (1994) explained in a research which was made to determine 6 different irrigation and 6 different nitrogen levels on quality and nutrient contents of fruits in fig trees, nitrogen affected positive direction on total soluble solids of fruits in only one season, but nitrogen declined calcium (Ca) content of leafs.

When evaluated according to Olsen et al. (1965), P contents of the soil are at sufficient levels. Only in the 1st year, the limits values changed and became high. In the applications, the highest P value was obtained in the 40-60 kg fertilizer applications in Table 4. The lowest value was determined in the natural vegetation. Al others were higher than the control and at sufficient limits. Aksoy et al. (1987) declared in the research paper which was conducted to determine nutrition status of fig orchard located in Germencik province, average dried fruit weight which was dried in natural conditions and methods, was 16.3 g and it was explained phosphorous nutrient matter increases dried and fresh fig weight and impacts positive approaches.

* C = control; NV = natural vegetation; SV = spring vetch; CM (kg/tree)								

According to Pizer (1967), K content of the soil was increased by the applications and difference were identified between applications and year*applications. The highest K value was obtained in the 40 kg fertilizer application. Considering in terms of limit values, the soil was determined to be at high level in terms of K and increased as compared to the control (Table 4). It was determined that there was no difference between years. It was indicated in a research study which was made by Aksoy et al. (1987) on ‘Sarilop’ dried fig cultivar, potassium content of leafs impacts sunburn damages of the fruits significantly and there are positive correlations with potassium content of leafs and good fruit rate. Aksoy et al. (1991), (1992) reported that the K/Ca ratio was so important and that it had a negative effect on sun blight.

Evaluating according to Loue (1968), it was determined that the applied organic matters were effective on the Ca contents of the soil, that 2005 was the year in which they were most effective on the Ca content and that there were differences between the years, applications and year*application. The highest Ca value was obtained in the applications other than the natural vegetation. There are also differences between years and the applications. It was reported that $CaCI_2$ applications increased the sun blight in fruits but it was not significant in statistical terms. Aksoy and Anac (1994) reported that $CaCI_2$ applications were effective on the fruit split percentage; Raese (1989) and Klein et al. (1990) reported in their studies on Bursa Siyahi, Sarilop and Goklop varieties that Ca did not affect the fruit quality. Shear (1975) determined deficiency of calcium was caused cracking on apple, cherry, dried plums and carrot.

According to Loue (1968), there are differences in Mg contents of the soil as in the case of Ca contents. In terms of applications, the highest Mg content was obtained in the 20-40-60 kg fertilizer applications. Differences were determined between years, applications and year*applications. The highest Mg content was obtained in 2004.

LSD	Year	Fertil.	Interaction	
	9.24	13.07	ns	
* C = control; NV = natural vegetation; SV = spring vetch; CM (kg/tree)				

According to Pizer (1967), Na content of the soil was determined to be different with the applications as compared to the control but not to be significant. Differences were identified between applications and between the applications and year*applications. The highest Na value was obtained in the 60 kg fertilizer application. It was determined that there were no differences between the years.

Conclusion

In terms of the effect of the organic matters applied to the fields where fig is grown on the physical and chemical properties of the soil, the total salt content of the soil increased as compared to the control but it was at the lowest level in 2005 in terms of years. While the relationship between the applications and between year*applications was insignificant in terms of pH value of the soil, the relationship between the years was found to be significant. Organic matter content of the soil increased with the applications and the best increase was obtained in the case of 60 kg cattle manure application. The highest N content was obtained in the spring vetch and cattle manure applications. In the case of years, the highest N content was obtained in 2005, i.e. in the third year and this shows us that the organic matter turned to nitrogen. While the highest P and K amounts were obtained in the cattle manure applications, it was determined that the year and applications had a significant effect in the case of P and the applications were effective in the case of K. In the case of Ca and Mg contents, it was determined that the cattle manure applications were more effective in Mg content but spring vetch applications in N value and that years were effective on all three elements. In consequence, it was determined that what increased the nutrient content of the soil in fig growing was 60 kg cattle manure, followed by 40-30 kg cattle manure and spring vetch.

Abstract

This research was carried out to investigate the nutritional status of industrial tomato in the lower basin of Great Meanderos. For this reason, soil, leaf and fruit samples were taken from 39 different areas where industrial tomato was grown. N, P, K, Ca, Mg, Fe, Zn, Mn, Cu and B in the leaf as well as width, length, weight, hardness, brix, pH and titratable acidity analyses in the fruit were done. The macro nutrients contents of the leaves were examined. While 76.92 % of total lands for N, 48.72% of total lands for P, and 56.41 % of total lands for K and Ca levels were found as low, Mg values were sufficient. When the contents of micro-elements of leaves were examined, in all samples, Fe contents were found at low levels. Mn levels of 61.54% of leaves were found as insufficient, but Cu, Zn and B elements were determined as sufficient. According to results of fruit morphological analysis, it was observed that fruits had the desired quality criteria for industrial tomato.

Keywords: *Industrial tomato, plant nutrient content, fruit quality*

Introduction

Homeland of tomato is the narrow western coast of America extending from the equator to Chile and it spread all over the world from Mexico. Tomato growing which first started in Adana and Thrace in our country after the World War I spread throughout the country over time (Bayraktar, 1970). A significant part of world's tomato paste production takes place in Spain, Italy, Turkey, Chile, Portugal, Greece and Brazil as well as USA and China. Turkey occupies the fourth place with 11.350.000 tons of production over an area of 300.000 hectares in the world (FAO, 2013). When tomato growing is studied by regions, the top three places are occupied by the Mediterranean, Aegean and Western Black Sea regions.

In tomato growing, higher water retaining capacity of the soil has an affirmative influence on the plant growth and yield. The soil should have a pH value between 5.5 and 7.0. Nutritional element need of industrial tomato through its vegetative organs is 35-50 kg nitrogen, 10-13 kg phosphorus, 60-85 kg potassium, 75-90 kg calcium and 22-30 kg magnesium over an area of one hectare. For one ton of tomato fruits, 1.5-2.5 kg nitrogen, 0.6-1.0 kg phosphorus, 3.5-5.0 kg potassium, 0.20-0.25 kg calcium and 0.25-0.40 kg magnesium are needed (Colakoglu, 1985).

A plant nutrition should be provided at a balanced and sufficient amount in order to obtain crops of high quality and yield. For the enhancement and maintenance of soil productivity, plant nutritional elements removed from the soil together with the crop and lost through different ways should be added to the soil again. In this way, the amount of plant nutritional elements in soil may be maintained at a level which may satisfy the requirements of the plants grown.

The objective of this study is to determine the nutritional statuses of the fields of industrial tomato which has recently started to be grown in the Lower Meander Basin of Aydin. It is to determine whether or not the plots of land are suitable for industrial tomato growing and the shortages of nutritional element through the analyses carried out on the plant samples taken from these plots.

Material and Methods

Samples of soil, leave and fruit comprising the research material were taken from 39 sampling plots to represent the areas where industrial tomato is grown in the Lower Meander Basin in 2012 and sample leaves were taken at the leave harvest time and fruit samples at harvest time appropriate for tomato. Analyses were carried out in the Soil Science and Plant Nutrition Laboratory of the Faculty of Agriculture of the Adnan Menderes University.

Upon the suggestion of ZER Tomato Paste Factory, the growers applied 30-100 kg/da of 15:15:15 composed fertiliser; 20-50 kg/da of 21% ammonium sulphate fertiliser; 20-40 kg/da of 33% ammonium nitrate and, in addition to all these, 10-20 kg/da of potassium nitrate or complex liquid fertiliser made from leaves (mixed micro element fertiliser) to the plots of study.

The total nitrogen content of the leave samples was measured by modified Kjeldahl method; phosphorus by the vanadomolybdo phosphoric yellow colour method on samples made ready for analysis by applying wet decomposition; K, Ca and Na contents in plant extract in a flame photometer and Mg, Fe, Zn, Mn and Cu in an Atomic Absorption Spectrophotometer (AAS) (Kacar and Inal, 2008).

On fruit samples, fruit width-length, fruit weight, hardness (hand-held penetrometer), water soluble dry matter (Brix), pH, titratable acidity analyses were carried out on 25 fruits selected from each plot at random (Karacali, 2009).

Results and Discussion

Minimum, maximum and average values concerning the analysis results of the plant samples taken from the plots where industrial tomato is grown in the Lower Meander Basin are given in Table 1 and Table 2. The limit values of the tomato plant are evaluated according to Jones et al. (1996).

As given in Table 1, it was determined that the total nitrogen values of the leaves varied between 1.747% and 4.637 percent. In the study carried out on industrial tomato seedlings by Guler (1990), it was determined that the N values of the seedlings varied between 0.18% and 0.76 percent. In the study carried out on greenhouse tomato prior to the first harvest by Kaplan et al. (2004), it was determined that the nitrogen values of the plants were 2.79-4.99% at Kumluca and 2.82-4.36% at Finike. When classified according to Jones et al. (1996), it was determined that the 76.92% of the plots was at deficient and 23.08% sufficient level by the plant nitrogen values. Importance should be placed on nitrogenous manure for quality tomato growing on these plots. Plant phosphorus values are between 0.151% and 0.429% in Table 1. In Guler’s study (1990) tomato’s P value was determined to be 2.04-4.26% and in that of Kaplan et al. (2004), to be 0.21-0.49% at Kumluca and 0.18-0.48% at Finike. Phosphorus values of the tomato plants were at a deficient level by 48.72% and sufficient level by 51.28% according to Jones et al. (1996). It will be therefore better for the nutrition of the tomato plants to add phosphorous fertiliser in the soil of the basin.

It was determined in Table 1 that the plant potassium values varied between 0.655% and 3.580 percent. In the study carried out on industrial tomato seedlings by Guler (1990), it was determined that K value was 0.29-1.88% and in that of Kaplan et al. (2004), it was determined that it was 1.69-4.11% at Kumluca and 1.32-3.80% at Finike. When K values were classified according to Jones et al. (1996), it was determined that 56.41% of the plots was at a deficient level and 43,5% at sufficient level. Importance should be placed on using potassium fertiliser in the deficient plots in order to be able to obtain fruits of better quality.

Table 1. Plant Macro Nutritional Element Contents (%)

Calcium values of the plants vary between 1.388% and 7.390% in Table 1. Guler (1990) found the Ca value as 0.20-0.83% and Kaplan et al. (2004) as 3.01-5.45% at Kumluca and 2.77-5.88% at Finike. When classified according to Jones et al. (1996), 56.41% of the plots were determined to be at a deficient and 43.59% at a sufficient level. Therefore, attention should be paid to calcium fertilising of the tomato plants included in the calcium-philic plants group, and foliar fertilising may be preferred so that the plant may take in calcium better in cases where deficiency is too severe.

As given in Table 1, magnesium values of the plants vary between 0.35% and 1.78 %. Guler (1990) determined the Mg value as 0.26-1.22% and Kaplan et al. (2004) as 0.71-2.26% at Kumluca and 0.80-2.07% at Finike in the study he carried out on greenhouse tomatoes. When classified according to Jones et al. (1996), it was determined that 2.56% of the plots was at deficient level, 17.95% at sufficient and 79.49% at high level in terms of magnesium values. No significant problem was observed in terms of magnesium nutrition. Ca and Ca+Mg were applied to the tomato plants growing in soil with a slightly acidic character and it was determined that the total yield and amount of water-soluble dry matter per unit area increased. It was found out that calcium has an affirmative effect on blossom-end rot (Candilo, 1993). As given in Table 1, the plant sodium values vary between 0.033% and 0.383%. Guler (1990) determined the Na of the leaves to be 1.67% and 4 %.

Table 2. Plant Micro Nutritional Element Contents

As given in Table 2, the plant iron values were determined to vary between 3.20 and 26.05 ppm. In the study carried out on in the seedling period of the industrial tomatoes by Guduk (1990), he determined that Fe contents were 340-1660 ppm. As a result of the study which Kaplan et al. (2004) carried out on greenhouse tomatoes in the towns of Kumluca and Finike, they found the plant Fe contents to be 54.80-79.60 ppm at Kumluca and 55.00-84.00 ppm at Finike. When classified according to Jones et al. (1996), iron values of the plants show deficiency in all of the plots. While 2.56% of the plots was deficient, 5.13% critical, 79.49% sufficient, 7.69% high and 5.13% toxic by the soil iron values, the fact that all plots are at an insufficient level by plant limit values constitutes a contradiction (Ozdogan and Seferoglu, 2015). The reason for this situation may be considered to be the fact that the high pH and calcium levels of the soil prevents the plant from taking in iron.

Manganese contents of the plants were determined to be 21.30-82.40 ppm given in Table 2. While it was determined in the study carried out by Guduk (1990) that the Mn content of the leaves was 54-350 ppm, it was determined to be 92.4-426.60 pm at Kumluca and 61.00-304.00 at Finike by Kaplan et al. (2004). It is in consistence with the indicated values.

Manganese values of tomato plant are classified according to Jones et al. (1996) and it was determined by the manganese values of the plants that 61.54% of the plots was at deficient level and 38.46% at sufficient level.

As given in Table 2, it was determined that the zinc values of the plants varied between 16.91 ppm and 39.28 ppm. In the study which Guduk (1990) carried out on industrial tomatoes, he determined that the zinc values of the plants varied between 21 ppm and 97 ppm. Kaplan et al. (2004) determined that the plant zinc values varied between 20.60 ppm and 183.40 pm at Kumluca and 21.60 ppm and 164.20 ppm at Finike. According to Jones et al. (1996), zinc values of the plants were at a deficient level in 2.56% of the plots and sufficient level in 97.44thereof. It was determined that there was no significant problem with zinc.

As given in Table 2, the copper values of the plants vary between 13.00 ppm and 160.90 ppm. In the study carried out by Guduk (1990), Cu values in the seedling period were found to be between 10 ppm and 348 ppm. Kaplan et al. (2004) determined that the Cu values were 12-328 ppm at Kumluca and 6-382 ppm at Finike. According to Jones et al. (1996), it was determined that 38.46% of the plots was at a sufficient level and 61.54% thereof was at an excessive level and that there was no problem in terms of copper.

When one examines the boron values of the plants in Table 2, they vary between 40.89 ppm and 254.32 ppm. In the study he carried out, Guduk (1990) determined the B values of the leaves varied between 17 ppm and 45.5 ppm. According to Jones et al. (1996), 76.92% of the plots were determined to be at a sufficient level and 23,08% at a high level in terms of boron. In the plots with a high boron level, irrigation water analyses must be definitely carried out.

Analysis results of the fruits picked from the plots selected to represent the Lower meander Basin and taken in a manner which will represent each plot best are given in Table 3.

As given in Table 3, according to the physical fruit analysis results, fruit length were found as 47.77-72.46 mm and fruit width as 43.25-66.07 mm. Fruit weight was determined as 54.78-170.56 g and 92.59 g on average and fruit hardness between 1.95-3.83 kg/cm^2 and 2.41 kg/cm^2 on average. In the study carried in the Lower Meander Basin by Dura (2001), he determined the fruit weight of industrial tomato as 53.94 g on average and the hardness value as 1.811 kg/cm^2 on average, and they show similarities to those values.

In tomato fruits, pH analysis results were found to be between 4.16 and 4.63 and 4.35 on average and the industrial tomatoes grown in the area were determined to have proper pH values. The average pH value of the industrial tomato had been determined as 4.61 in a study carried out in the region earlier (Dura, 2001). pH value of the tomato fruits varies between 4,0 and 4.5 (Jones, 2008). pH is required to be between 4.2 and 4.4 in industrial tomatoes (Diez et al., 2008).

Table 3. Fruit Morphological Analysis Contents

Water soluble dry matter values were found between 4.00% and 6.20% and 5.20% on average. In the industrial tomato variety study he carried out in the Lower Meander Basin, Dura (2001) found the highest brix value as 5.60% in the Sun-8687 variety. Yoltas et al. (1993), found the highest brix value as 5.36% in the Shasta variety as a result of their studies in the basin. Five percent and higher WSDM is required in industrial tomato varieties (Diez et al., 2008). In the varieties developed in industrial tomato breeding by Francis et al. (2002), they found the WSDM value between 4.65% and 5.32 % When compared with other studies, the average of the brix values so determined is observed to be good.

According to the results of the titratable acidity analysis carried out on industrial tomatoes, a value between 0.32% and 3.33% and 0.55 on average was obtained. The titratable acid amount is approximately 0.6% in tomato fruits (Karacali, 2009).

Conclusions

In the plots of land where industrial tomato is grown in the Lower Meander Basin in Aydin, according to the results obtained upon the examination through plant and fruit analyses, nitrogenous fertilisation was found to be insufficient in a majority of the plots by the leave analysis results while the 48.72% of plots was found to be deficient and 51.28% thereof sufficient in terms of P contents. In 56.41% of the plots, potassium values show deficiency and attention should be paid to fertilisation. Despite the soil contains Ca at a sufficient level, the Ca contents of the leaves were found to be deficient and Mg contents to be sufficient. Importance should be placed on Ca fertilisation.

In terms of micro nutritional elements, Fe was found out to be low in all plots and Mn, Zn and Mg to be at sufficient level. And B content was found out to be usually at a sufficient level, but to be high in very few plots. Irrigation water analysis should be carried out in those plots with high B content.

Looking into the values of the fruit analyses carried out on the fruit samples taken from the study plots, it is determined that the results have proper values in terms of width, length and weight measurements as well as pH, brix and acidity which are important fruit quality criteria for industrial tomato. Nutritional problems experienced in the plant do not reduce the quality criteria in the fruit, but increase varying between 7 tons and 9 tons per decare may be achieved in yield by overcoming the nutritional problems.

Selection of proper variety as well as nutritional element requirement of industrial tomato should be taken into consideration according to the results of the soil analysis to be carried out prior to sowing. First of all, that farmers should be made conscious on fertilisation and that necessary importance should be placed on the addition of organic matter and other technical practices along with well-balanced fertilisation are included in the most important issues for quality and highly efficient production in tomato cultivation.

Abstract

Irrigation water is one of the main sources of high soil B levels resulting in toxicity. Thermal water containing high level boron; may be used as irrigation water. This study has been carried out based on previous experiment in which different levels of boron contained irrigation water on the cotton cultivation in 2011 and 2012 as the same coordinates were used. The aim of this study was to determine the effect of phosphorus fertilizer in different levels of boron contained soil conditions on yield and quality of soybean. The study was conducted as a split plot experimental design. The main plots were different level B contained soil (1.45, 3.26, 6.64 and 13.28 mg B kg^{-1}), sub plots were phosphorus applications (0 and 7 kg P_2O_5 da^{-1}). Soybean (*Glycine max* L. Umut 2002) cultivar was used. As the soil B level reach the toxic level, seed yield, plant height, 1000 seed weight, number of pods per plant and first pod height decreased. On the other hand, protein content of seed, leaf P and B contents increased under B toxic conditions. Phosphorus application resulted in increase in seed yield and plant height, while leaf B content resulted in decrease under B toxic conditions. Its effect on the other observed parameters were not important. In terms of decreasing plant B content in high/toxic level B contained soil, phosphorus applications were effective and may be used to increase the yield.

Keywords: *Glycine max, boron toxicity, phosphorus, seed yield*

Introduction

Soybean has been the most valuable food source of Asian countries for thousands of years (Hymowitz and Newell 1981, Singh 1992). It is consumed mostly in Asia, and it is regarded as a source of protein and fat in more industries in the west (Singh, 1992). Soybean is one of the most important agricultural products in the world because of rich nutritional value, minerals and vitamins (Stauffer, 2003). Soybean is an important leguminous plant, both production and international trade (Denis, 1994), it has high protein content. Additionally, its oil is the most produced and consumed oil in the world and its custard is the most used raw material in the feed industry (i.e. milk, cheese, sauce, ice cream etc. productions) (Stauffer, 2003). It is also used extensively in biofuel production. Soybean is used mainly in the feed industry as well as the food industry in Turkey. However, its production is insufficient for all of consumption and which imported every year in varying amounts. Phosphorus is an important macro element in the structure of nucleoproteins that plays a role in cell division and increases the resistance in plants by potassium uptake, root development and maturation (Brohi and Aydeniz, 1994). Depending on the application of phosphorus, the root development is increased and the root surface of the root is enlarged so that the utilization rates of other nutrients of the plants are increased (Marschner, 1995). Phosphorous fertilizers are highly effective in increasing seed yield and quality (Arıoğlu, 1994). However, the yield of seed may vary according to the variety of soybean used (Önder, 1987). Furthermore, the seed yields in soybean varieties depend on the genotypic properties, but also influenced by differences in environmental conditions (Yaman and Cinsoy, 1997). On the other hand, many researchers indicated that phosphorus application into the soil could be sufficient to economic soybean seed production and growth (Çetin and Öztürk, 2012; Malik et al. 2006). Boron toxicity, which is one of the environmental factors, has a negative impact on the soybean growth and seed yield. Boron is a micronutrient element that is essential for good plant growth and good yield when evaluated in terms of plant nutrition. In addition, it is the only non-metallic element in micronutrients. Its deficiency or toxicity, leads to significant yield loss in plant. Due to its deficiency and toxicity range is very low in plants, the management of the boron in soil is very difficult (Nable, 1988). The main sources of boron toxicity are irrigation water, well water, application of drainage water to the soil, surface fertilization and industrial wastes and chemicals. However, the effects of boron toxicity are observed in the soil accumulation and dissolution of the soil (Shani and Hanks, 1993). The most important effect of irrigation water is that it causes soil boron content to increase in all of the potential sources. The boron concentration is generally high in salty soils or in saline well waters (Dhankhar and Dahiya, 1980). There is a high amount of boron in the water coming from the geothermal sources in Aydin (western Turkey). A significant part of these waters contaminate to irrigation water. The effect of the boron level on soybean development is not well known. The aim of this study was to investigate the effects of different levels boron-contained soil and phosphorus application in the soil on soybean plants growth morphological characters, yield and some quality parameters of the seed.

Material and Methods

The Climatic Conditions

Monthly average temperature, relative humidity and precipitation and long-term (1975-2013) values of experimental site were given in Table 1. The average temperature in august was higher than long term mean. Moreover, there was no precipitation observed in august.

Table 1. Some climatic parameters of experimental site in 2013 and long term

Years	Climatic Parameters	May	June	July	August	September	October	November
2013	Average Temperature (°C)	20.3	24.0	27.2	28.2	23.6	19.5	14.4
	Relative Humidity (%)	65.4	55.1	54.5	55.4	62.1	66.0	64.6
	Precipitation (mm)	17.8	44.8	0.6	0.0	36.8	37.0	78.5
Long Term	Average Temperature (°C)	20.9	25.9	28.4	27.5	23.4	18.4	13.3
	Relative Humidity (%)	74	49	47	48	52	60	66
	Precipitation (mm)	34.3	12.6	4.0	1.8	12.9	42.1	80

Soil Material

At the beginning of the study, some physical and chemical properties of the soil from the control plot were given in Table 2.

Table 2. Some physical and chemical properties of soil

Texture[1]	Sand	Clay	Silt	Saturation	pH[2]	Salinity	Organic Matter[3]	$CaCO_3$	N[4]
	%	%	%	(ml)		%	%	%	%
SL	72.90	10.10	17.00	39.4	8.35	0.0178	1.68	4.48	0.09

P[5]	K[6]	Ca[6]	Mg[6]	Na[6]	Fe[7]	Zn[7]	Mn[7]	Cu[7]	B[8]
mg kg^{-1}									
12	127	2502	202	75	7.96	0.41	2.79	1.23	1.45

1 Bouyoucos; 2 1:2.5 Saturasyon; 3 Walkley-Black; 4 Kjeldahl; 5 Olsen; 6 A. Asetat; 7 DTPA; 8 Azomethin-H

As a results of soil analysis, texture sandy loam, pH alkali, % total organic matter low and high $CaCO_3$ were found. In terms of soil nutrients was assessed, potassium, magnesium and zinc values were found deficient and boron, phosphorus, calcium, sodium, manganese and copper values were found sufficient. Additionally, soil Fe content was found critical.

The Previous Experiment

This research had been carried out at Adnan Menderes University Agricultural Faculty, in 2011-2012. The study had been designed in a split plot experimental design with four replications. In this study four different levels of boron (B) (0.6- 1.8- 5.4- 16.2 mg l^{-1}) contained irrigation water had been used on the cotton cultivation. During the two years experiment, the total amount of applied water by drip irrigation had been 1039.9 mm. Sodium octaborate had been used as source of boron. After this experiment, barley had been cultivated at same coordinates in winter period 2012 to 2013.

The Current Experiment

This study was started after the barley harvest in 2013. Soybean (*Glycine max* L. Umut 2002) was used as a test species in this experiment. The amounts of soil available boron, accumulated in the soil at previous study, were evaluated as the boron levels in this experiment. The main plots were different level B contained soil (1.45, 3.26, 6.64 and 13.28 mg B kg^{-1}) and sub plots were phosphorus treatments (0 (control) and 70 kg P_2O_5 ha^{-1}). The Boron levels were called B1-B2-B3-B4 and phosphorus also called P1-P2 respectively. As a source of phosphorus, triple super phosphate fertilizer was used and applied into soil before sowing. The other nutrients were kept on same levels.

Observations and Plant Analyzes

Before the plant nutrients analysis, when all the plants were harvested, developed leaves were collected from the middle of plant (neither young nor old leaves) for each replicate in all cultivars from both treatments. All leaves were immediately settled in an ice box for transfer to laboratory. All samples were washed twice with distilled water, dried at 70°C for 48 h. Leaf B concentration determinations were made by dry ashing 0.5 g of dry tissue material, placed in porcelain crucibles and heated a muffle furnace at 500°C for 6 h (Kacar and İnal, 2008). The ash was dissolved in 0.1 N H_2SO_4 and B was determined colorimetrically (430 nm) by the Azomethine-H method (Wolf, 1974). P was determinated by spectrophotometry (Shimadzu UV-160 A) (Kacar, 1972). 50 gram of seed were taken from each plots, and they were burned at 420 ºC for 30 minutes. Nitrogen contents were determined by using Kjeldahl apparatus, protein content of seed was calculated as% by multiplying the resultant nitrogen amount by the coefficient of 6.25. The results were analyzed using the SPSS statistical software system (PASW Statistics, Ver.: 18.0). Mean separations were performed by the LSD-test at a significance level of $P<0.05$.

Results and Discussion

It was determined that phosphorus fertilizer had a statistically significant impact on the soybean which cultivated in boron contaminated soil in Table 3 (ANOVA table).

Table 3. Results of variance analysis and LSD values for each characteristic examined for different boron and phosphorus

Variation Source	FD	SY	PH	TSW	NPPP	FPH	SPC	LPC	LBC
B	3	**	**	*	**	*	ns	**	**
P	2	*	**	ns	ns	ns	ns	**	**
B x P	3	ns	**	ns	ns	ns	ns	*	*
$LSD_{0.05\ B}$		23.12	6.17	7.6	14.3	0.28	-	1.95	8.9
$LSD_{0.05\ P}$		11.54	5.15	-	-	-	-	-	12.1
$LSD_{0.05\ BxP}$		-	14.29	-	-	-	-	-	-

B: Boron, P: Phosphorus, SY: Seed yield, PH: Plant height, TSW: 1000 seed weight, NPPP: Number of pods per plant, FPH: First pod height, SPC: Seed protein content, LPC: Leaf phosphorus content, LBC: Leaf boron content.

Seed yield, plant height, 1000 seed weight, number of pods per plant, first pod height, leaf P contents, leaf B contents were found statistically significant in terms of boron application. Regarding the application of phosphorus, seed yield, plant height, number of pods in plant, leaf P and B contents were found statistically significant but other characteristics were not significant. In terms of boron×phosphorus interaction, only plant height was found statistically significant and other features were found insignificant.

Table 4. The residual effects of different boron applications and the effect of phosphorous fertilizer on some properties of soybean

Treatments		Seed Yield (kg da^{-1})	Plant Height (cm)	1000 Seed Weight (g)	Number of Pods per Plants (piece $plant^{-1}$)	First Pod Height (cm)	Seed Protein Content (%)
P1	B1	321	98.2	156	79.1	13.12	30.3
	B2	322	97.4	155	78.0	13.32	31.5
	B3	251	76.7	147	65.6	10.40	32.2
	B4	145	65.4	139	45.2	9.89	32.1
Mean		260	84.4	149	66.9	11.68	31.5
P2	B1	335	101.3	154	81.1	13.24	33.2
	B2	336	103.4	153	82.0	12.56	32.7
	B3	265	82.2	148	67.5	10.78	31.8
	B4	158	71.0	138	44.1	9.76	32.5
Mean		274	89.5	148	68.6	11.59	32.5

Seed yield was decreased while soil B content was increased (Table 4). Average seed yields were found 328, 329, 258 and 152 kg da^{-1} in applications B1, B2, B3 and B4, respectively. According to B1, the yield of seed was decreased by 21.3% in B3 and 53.8% in B4. Phosphorus application caused a slight increase in seed yield. The average seed yields in control and 7 kg P_2O_5 da^{-1} applications were 260 and 274 kg da^{-1}, respectively. Many researchers have also reported that soybean plants are adversely affected by boron toxicity (Schon and Blevins, 1990, Nable et al., 1997, Oluk and Latif, 2008). Many researchers have also reported that seed yields are increased by phosphorous fertilizers (Bhangoo and Albritton, 1972; Atakis and Arıoğlu, 1983; Dadson and Acquaah, 1984; Mercado Pineda et al., 1991; Çetin and Öztürk, 2012). On the other hand, this study is consistent with the finding that phosphorus fertilizer is effective in reducing plant B concentration in boron-high soils and therefore the yield can be increased (Soy and Güneş, 2003; Kaya et al., 2009). Plant

height, 1000 seed weight, number of pods per plant and first pod height were decreased while soil B content was increased, especially in B3 and B4 treatments (Table 4). Compared to B1, plant height decreased by 17.6% in B3 and by 28.9% in B4. Phosphorus application caused a slight increase in plant height. Similarly 1000 seed weight decreased by 4.8% in B3 and by 10.3% in B4. Phosphorus application was determined that no significant effect observed on 1000 seed weight. Number of pods per plant were decreased by B3 and B4 treatments 16.9% and 44.2% respectively under the B toxicity conditions. Similarly, first pod height was decreased in B3 (19.7%) and B4 (25.4%) under the B toxicity conditions. The protein contents of seed were not affected significantly under the both B and P treatments conditions.
B toxicity has reduced plant weight has also been reported by different researchers (Nable et al., 1997; Sutton et al., 2007). Phosphorous fertilization which have increased has also been reported by many researchers who have increased plant height (Atakişi and Arıoğlu, 1983, Dadson and Acquaah, 1984). It's known that, B toxicity reduced seed size also seed weight. Therefore, 1000 seed weight values was found similar to the findings of Torun et al., 2001; Bakoğlu and Ayçiçeği, 2005; Reid, 2010. The number of pods is closely related to the variety, our findings were found similar to Yetim (2008) findings, but higher than findings of Bakoğlu and Ayçiçeği (2005). Our first pod height values were found similar to Yetim (2008) findings, but lower than values of Sincik et al. (2005) findings. Soybean protein content is usually high and can vary according to many factors. Mercado Pineda et al. (1991) found no significant effect on seed protein content of phosphorus fertilization in field trials in Mexico. Our protein content values was found slightly below than the findings of Yılmaz and Efe (1998).

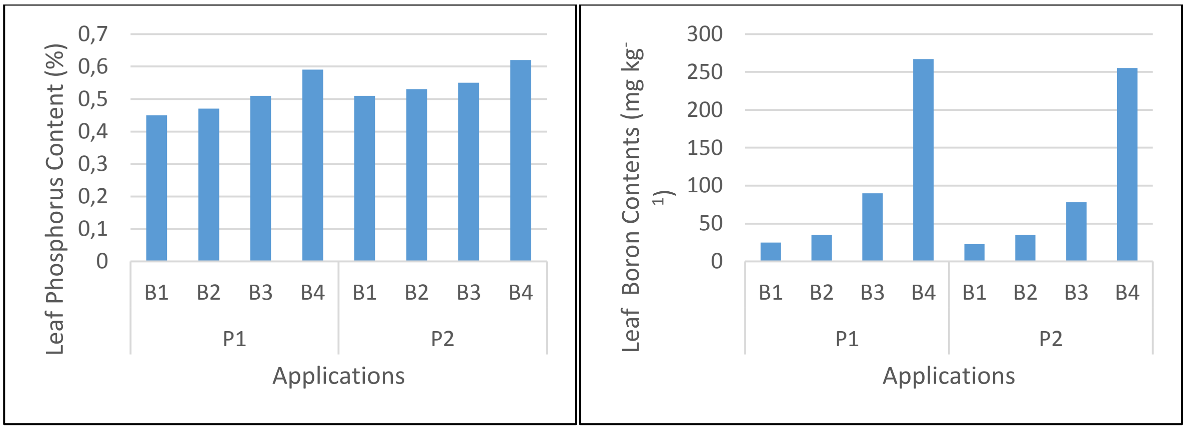

Fig 1. The effect of phosphorus application on the leaf phosphorus (left) and leaf boron (right) content in different soil B content conditions

Leaf P concentration values of B1, B2, B3 and B4 applications were 0.48, 0.50, 0.53 and 0.61% respectively (Fig 1). These values are higher than the critical P concentration of 0.25% (Jones et al., 1991) determined for soybean. This indicates that there is no P inadequacy in this study. The effect of phosphorus application on leaf P content was found significantly. Leaf P contents can vary depending on the available P content of the soil, fertilization and soil characteristics (pH, lime, Zn, etc.). Bhangoo and Albritton (1972) reported that phosphorus fertilizer effects on leaf P content were significant in studies conducted for three years in the USA.
The B1, B2, B3 and B4 applications and leaf B concentration values were found to be 24, 35, 85 and 261 mg B kg $^{-1}$, respectively (Fig 1). These values are higher than the critical boron concentration of 21 mg B kg^{-1} determined for soybean (Jones et al., 1991). B3 and B4 treatments were found toxic levels for soybean in particularly B4 treatment. The effect of phosphorus application on leaf B content was found significant. Leaf B content was decreased by an average of 104 mg B kg^{-1} to 98 mg B kg^{-1} by phosphorus application. Leaf B content is

more likely to vary depending on the B content of the soil, the irrigation water content of the irrigation water. Buyer and Öncel (2008) investigate the possible antagonistic activity of boron against boron toxicity in bread-borers (*Triticum aestivum* L. cv. Kirac 66) and susceptible pasta (*Triticum durum* Desf (cv. Kunduru 1149)). A similar finding has been reported by Kaya et al., 2009. A similar finding has been reported by Kaya et al., 2009. Güneş and Alpaslan (2000) stated that phosphorous fertilizer in corn production may be effective in reducing leaf B content.

Conclusion

With this study, the use of phosphorous fertilizer has been discussed in the effect of high boron content of the soil, which continues to be a problem in the region, and the removal of this negative effect. It has been found that phosphorus fertilizers are effective in reducing plant B concentration in soil containing B in the high-toxic level, and thus the yield can be increased.

Abstract

The research was conducted to determine feed quality of three Sorghum varieties (Rox, Early sumac and Leoti) two Sorghum bicolor x Sorghum sudanense varieties (Nutri honey and Hayday) and one Sudan grass variety (Gozde 80) grown as second crop under Igdir ecological condition. This research was established according to randomized complete blocks experimental design with three replications. In this study, Crude protein (CP), Neutral detergent fiber (NDF), Acid detergent fiber (ADF), Acid detergent lignin (ADL), Dry matter digestibility (DMD), Digestible energy (DE), Metabolizable energy (ME), Dry matter intake (DMI), and Relative feed value (RFV) of sorghum varieties was determined. According to results; The CP, NDF, ADF, ADL, DMD, DE, ME, DMI and RFV contents of some silage sorghum varieties ranged from 5.93 to 8.88%, 51.98 to 65.64%, 27.94 to 40.44%, 4.73 to 7.07%, 57.39 to 67.13%, 2.72 to 3.14 Mcal kg^{-1}, 2.23 to 2.58 Mcal kg^{-1}, 1.83 to 2.31%, 81.82 to 120.16, respectively. The highest DMD (67.13%), DE (3.14 Mcal kg^{-1}), ME (2.58 Mcal kg^{-1}), DMI (2.31%) and RFV (120.16), and the lowest NDF content (51.98%), ADF (27.94%) and ADL (4.73%) were determined in Rox variety. In the present study, it was found that Rox variety was suitable for animal feeding in terms of all desirable quality parameters examined except for CP. According to the results, Rox variety was suggested as second crop under Igdir province and similar ecological conditions.

Key words: Sorghum species and hybrids, second crop, feed quality, Igdir

Introduction

All plants used for the aim of silage take an important place in animal feeding as it provides animal succulent feed especially in winter season. For this purpose, plant that is grown mostly for silage in the world is maize (Geren and Kavut, 2009; Ozata et al., 2012). But in the lands that unfavorable climatic conditions prevail for maize farming and are irrigation-free and nutrient-poor, alternative plant is undoubtedly the species of Sorghum (Barnes et al., 1995; Tiryaki 2005; Marsalis, 2011). Because the types of Sorghum, according to maize especially used as a silage are preferred as they are much more durable to hot and dry periods and dry matter yield is high (Cigdem and Uzun, 2006; Macedo et al., 2012). In field agriculture, the species of Sorghum with a short growth period provide important source for roughage for animals by being grown as second crop. Such environment conditions are too high in Turkey, alternative for maize, besides sugar beet leaves, various cereals, legume-cereal blends and sunflower plants, sorghum species are used as silage if less.

Sorghum, sudanese and Sorghum x Sudanese hybrids are C4 plant, thanks to their morphological and physiological properties especially during the summer when the temperatures are suppressed by continuing their growth and development produce a feed of higher quality and higher quality compared to cool-season forage crops. Generally these species produced for silage and green hay during the summer season, meet the agricultural establishments' need for fresh feed and provide the animals with a delicious, succulent feed during this winter period. In addition, as Sorghum species and hybrids form more than once a year and after the form, they grow fast and gain importance in the provision of emergency feed needs (Grant et al., 1995; Acar et al., 2001; Ozaslan Parlak and Sevimay, 2007). In particular, the feed Sorghum when compared to other materials used for silage purposes; are preferred as they have a higher dry matter content, a lower milk acid formation, a lower undesirable butter and vinegar acid formation and pH values at desired levels (Baytekin et al., 1991; Uzun and Cigdem, 2006; Getachew et al., 2016). Therefore, the species of Sorghum have great precaution in animal feeding for reasons such as silage can be made without any additives.

In the types of Sorghum that have an important area use in the production of meat, and in particular in dairy farming enterprises, rotation pasture, daily green feedstuffs and silage production and the investigation of their ability of being grown especially while being considered as a silage bait, the knowledge of nutrient values such as crude protein, dry matter digestibility and energy content has great importance (Baytekin et al., 1996; Pedersen, 1996; Getachew et al., 2016). Additionally, after the harvest in early summer of the crops grown in the autumn, in giving birth to production of the not-used agricultural areas, identification of suitable forage crops species and varieties is important. Therefore, when a feed based on qualified roughages is intended, for high and high quality animal products (Pimentel et al., 2013), determination of high varieties of nutrient content suitable for regional ecology is seen as a great advantage. For this purpose, with this present study; types of fodder Sorghum and determination of nutrient contents of hybrids that are being examined in the province of Igdir which is located in the east of Turkey and is different from region’s areas due to climate and soil structure has been aimed.

Materials and Methods

This study was carried out in the trial field of Igdir University Agricultural Application and Research Center in 2015 with 3 stages according to the Randomized Blocks Experiment Design. The height of the test area from the sea level is 876 m. As plant material, 3 types of fodder (silage) Sorghum (Rox, Early sumac and Leoti) registered in Turkey 2 Sorghum x sudan grass hybrid (Nutri honey and Hayday) and a sudan grass (Gozde 80) are used. With the year of 2015 when the experiment was conducted and long-term average climate data are given in Table 1. Accordingly, the total amount of rainfall measured during vegetation (June-September) and average relative humidity values are lower than the average for many years, average temperatures are high. According to these results, the period during which the test was conducted was drier than the average for many years.

Table 1. Some climate features of Igdir province for long years and growing season of 2015*

Months	Temperature (^{o}C)		Rainfall (mm)		Relative humidity (%)	
	Growing season	1950-2014	Growing season	1950-2014	Growing season	1950-2014
June	28.50	20.10	27.80	36.70	40.00	47.30
July	31.80	23.60	0.30	14.20	33.60	44.70
August	30.20	23.40	14.30	10.90	40.70	46.70
September	27.20	18.80	1.40	18.70	42.40	51.00
Mean/Total	**29.43**	**21.48**	**43.80**	**80.50**	**39.18**	**47.43**

*MGM, 2015

Soil samples have been taken 0-20 cm deep from the area where the experiment was performed and some physical and chemical properties of the surveyed land have been determined. According to the results of analysis on the soil sample done by Soil Science and Plant Feeding Laboratory of Igdir University, the soils in the test area; in alkali reaction (pH = 8.32) that has clay-loam and non-saline feature, the amount of organic matter is low (0.77%) and it is rich in lime content (20 and 34 %). Favorable phosphorus and potassium content in the soil have been determined to be 50.57 ppm and 544.80 ppm, respectively (Erdogan, 2013).

Sowings were manually done to the draws opened with marker for all varieties, for the decare 9523 pieces of seeds in 70 cm row spacing with 15 cm intra row on trial plots prepared in 5 m x 3.5 m dimensions after the harvest of barley on 24th of June 2015. In research, the plot length is 5.00 m, the width is 3.50 m and the plot area is 17.5 m^2. After sowing, sprinkler irrigation was done to provide the germination and seedling emergence. Irrigation periods of plants were determined by soil water potential measuring device. Irrigation, when 50% of the useful water in the soil was consumed, was made with rain until plants reached 1.5 m length, after that it was made by flooding irrigation method. In the present study, 160 kg N and 80 kg P_2O_5 were used each hectare for together with planting. All of the phosphorous fertilizer that was used and half of nitrogen fertilizer was used with planting and the other half of the nitrogenous fertilizer was given when the plants reached 50 cm. Ammonium sulphate (21% N) was used as a nitrogen fertilizer and triple super phosphate (40% P2O5) was used as a phosphorus source in the research. During the growing season of plants, the weeds emerged between the rows and above were controlled by the mechanical method of struggle.

The harvests of the plants were done manually during the hard dough stage. In each parcel one row from the edges and 50 cm from both sides were taken as edge effect and the remaining 8.4 m^2 (4.00 x 2.10 m) area was harvested. Then, a representative sub-sample (0.5 kg) of the cut material was dried at 78 ^oC in an oven for 48 h. Later, dried samples ground in a Wiley mill to pass through a 1 mm screen prior to analyses. All analyzes belonging to quality parameters were performed in double recurrence. The nitrogen content (N) of the samples was determined by the Kjeldahl method and the resulting N% value was multiplied by a factor of 6.25 to calculate the crude protein (HP) ratio (AOAC, 1997). NDF, ADF and ADL were measured by Van Soest et al. (1991) using the specified method. Rates of plants' % dry matter digestible (DMD) was determined by Sheaffer et al. (1995) with using the formula developed (DMD% = 88.9 – (0.779 x ADF%). Then the DMD values, digestible energy (DE) values of feeds were estimated with using the regression equation notified by Fonnesbeck et al. (1984). (SE = 0.27 + 0.0428 * DMD%). Then SE values were converted to metabolic energy (ME) with using equation developed by Khalil et al. (1986). (ME Mcal kg-1 = 0.821 * SE (Mcal kg-1). After that, by using the equations developed by Sheaffer et al. (1995) (DMI = 120 /% NDF), firstly dry matter consumption (DMI = 120 /NDF%) after that relative feed values (RFV) were calculated (RFV = DMD * DMI/1.29). Data obtained in the study were subjected to analysis of variance according to the randomized blocks design of experiment using the SPSS statistical package program and in the comparison of the significant averages Duncan test was used (SPSS, 1991).

Results and Discussions

In this study that aims to determine the varieties of sudanese, sorghum and hybrids that can be grown as second crop in Igdir geography that has microclima feature, it was determined that there were significant differences among the varieties in terms of CP (Table 2). According to these results, while the highest HP ratio was determined in the varieties of Nutri Honey and Hay Day that belong to Sorghum x Sudanese hybrids, the lowest values were obtained from Rox that belongs to Sorghum and Gozde 80 species that belongs to sudanese species. In a study on this subject, it was revealed that the Rox (%8.98) variety harvested during the hard drough stage has a lower HP ratio than early sumac (%10.20) and Gozde 80 (%10.10) species (Atis et al., 2012). Similar findings have been reported by Cigdem and Uzun (2006) in their study that related to some silage Sorghum varieties which can be grown as a second crop in order to determine nutritional content and they were determined that Rox varieties (8.98%) have a lower HP ratio than Early sumac (10.20%) and 80% (10.10%) varieties. This change between varieties in CP terms shows similar results to ours. Again, in second crop study conducted in Samsun, Aydin and Albayrak (1995) determined that 4 Sorghum (Fs 25E, Early Sumac, Leoti, Rox), 1 Sudan grass (Gozde-80) and 1 Sorghum x sudanese hybrid (Sugar Leaf) harvested in the period of soft dough stage had 8.3%, 8.9, 8.6, 6.9, 7.6 and 8.5 crude protein ratios, respectively. The CP content obtained in both studies was higher than our results; this may be due to the harvesting of varieties during early soft drough stage. With regard to the subject, Salman and Budak (2015) found that Nutri Honey variety had the mean 8.52% CP content in a study conducting in Bayindir and Odemis districts of Izmir. These results are slightly lower besides similar to our findings.

Table 2. CP, NDF, ADF, ADL, and DMD values of sorghum varieties

Varieties	CP (%)	NDF (%)	ADF (%)	ADL (%)	DMD (%)
Rox	5.93 ^{c}	51.98 ^{b}	27.94 ^{b}	4.73 ^{d}	67.13 ^{a*}
Early Sumac	8.12 ^{ab}	64.75 ^{a}	38.43 ^{a}	5.71 ^{bcd}	58.95 ^{b}
Leoti	7.90 ^{ab}	65.20 ^{a}	37.86 ^{a}	6.73 ^{ab}	59.40 ^{b}
Nutri Honey	8.88 ^{a}	65.64 ^{a}	37.95 ^{a}	6.39 ^{abc}	59.33 ^{b}
Hay Day	8.74 ^{a}	64.97 ^{a}	37.60 ^{a}	5.53 ^{cd}	59.60 ^{b}
Gozde 80	6.66 ^{c}	65.26 ^{a}	40.44 ^{a}	7.07 ^{a}	57.39 ^{b}

*Values indicated with different letters are significantly different at $P<0.01$.

NDF ratios of Sorghum, Sorghum x sudan grass hybrid and sudan grass varieties grown as second crop showed statistically significant (Table 2). When Table 2 was examined, all of the other varieties except the Rox variety were included in the same statistical group and these varieties had the highest NDF ratio. This value obtained from the Rox variety is similar to the findings of Atis et al. (2012). The NDF content reflects the chemical quality of the herb and for this reason it is used in quality determinations (Kutlu, 2008). That NDF content is high in roughage reduces animal consumption (Yavuz, 2005). NDF ratios of the Sorghum obtained in the study are similar to the findings of Carmi et al. (2005) and Mwangi (2016), they are not similar to the results of Karadag and Ozkurt (2014). This can be said to be due to the different ecological conditions, variety and agronomic practices in which the experiment was conducted. On the other hand, Uzun and Cigdem's (2005) study on the different Sorghum x sudan grass, they determined the mean NDF ratio of the varieties as 68.0% and these rations are higher than our findings. It is thought that this may be caused as the used varieties are different and the agronomic applications are different.

Significant differences were found statistically in terms of ADF ratio among Sorghum, Sorghum x sudan grass hybrids and sudan varieties grown as second crop, in between Sorghum x sudan grass hybrids and sudan varieties (Table 2). While the lowest ADF ratio according to these results was determined in the Rox variety, all of the other varieties had a higher ADF ratio than the Rox and these took part in the same statistical group. The ADF content is an indication of the quality criteria of the grass chemically and has a feature that reduces the quality as it increases (Kutlu, 2008). As ADF ratio is inversely proportional to digestibility the varieties with a low ADF ratio are more important for animal feeding (Balmuk, 2012). In studies carried out with different types of Sorghum in different ecological conditions of Turkey, Atis et al. (2012) found that the lowest ADF ratio among varieties was 32.44% in Rox variety and also in Karadag and Ozkurt (2014) 39.46% in Rox variety, but these results were found higher than our results. Mwangi (2016) also found that the varieties of Sorghum harvested during the hard drough stage had a 41.98% ADF ratio in Kenya. This can be said to be due to the different ecological conditions and breeding techniques in which the experiments were conducted. In a study conducted again with x Sorghum x sudan grass hybrids, the varieties that are harvested during the spike season, they found the average ADF content was 42% (Uzun and Cigdem, 2006) and these values were higher than our findings. This is thought to be originated from differences of varieties that are used and their being harvested at different times

The ADL ratio of Sorghum, Sorghum x Sudanense grass hybrid and Sudanense grass varieties used in this study have been found important statistically and the ADL ratio of varieties has varied between 4.73% and 7.07% (Table 2). The highest ADL ratio was found in Gozde 80 and the lowest value was found in the variety of Rox. As related to the subject, Atis et al. (2012), in a study carried out in Antalya, found ADL ratios of Rox, Early sumac and Leoti Sorghum varieties as 4.62%, 4.62% and 4.86%, respectively and these values were higher than our results. Again, in a study conducted with three different varieties of Sorghum, Mahanta and Pachauri (2005) found that the average ADL content of the varieties was 4.21%, Mwangi (2016) found that the types of Sorghum had an ADL of 7.38% during the hard drough stage and these results are not compatible with the values obtained in our current study. This can be said to be due to the different ecological conditions, from variety, care and practice under which the tests were conducted.

Sorghum, Sorghum x sudan grass hybrid and sudan grass varieties examined in terms of DMD showed very important differences statically and the Rox variety has a higher dry matter digestibility (DMD) than the other varieties (Table 2). In a study conducted in Antalya with four types of Sorghum, the highest DMD ratio was determined in the Rox variety (63.92%), but these values were lower than our findings. It can be said that this is due to the difference in ecological conditions and agronomic work carried out by the experiment. On the other hand, the meane DMD ratio of examined Sorghum variaties in our study was determined as 61.82% and while these results are similar to findings of Carmi et al. (2005), but with the findings of Mwangı (2016). In another study conducted on the subject, Uzun and Cigdem (2006) have found the DMD ratio of Sweetreat, Sorgo 10, and Pioneer 931 big maize x sudan grass hybrids as 57.06% in the period of harvested spike season, but these results are lower than our findings. It is thought that this may be due to differences in used types and applied agronomic processes.

The digestible energy (DE) and metabolic energy (ME) values of the sorghum varieties used in the present study showed statistically significant differences and the highest values for both parameters were obtained from the Rox variety (Table 3). As seen in Table 3, SE and ME values of other varieties except for the Rox variety showed similarity and these five varieties had the same statistical group. Related to the subject, Sohail et al. (2011) have determined the mean ME value of sorghum varieties harvested during the soft drough stage as 2.08 Mcal kg^{-1} and these values were lower than our findings. This can be said to be due to the different ecological conditions and varieties in which the experiments were conducted.
Among Sorghum varieties examined for dry matter intake (DMI), there was significant differences statistically and DMI ranged from 1.83% to 2.31% (Table 3). When looked at Table 3, it can be seen that the Rox variety has a higher DMI value than the other varieties. As related to the subject, Atis (2012) were found that the highest DMI among four Sorghum varieties was in the Rox variety with 2.32% and these results were similar to our findings.

Table 3. DE, ME, DMI and RFV values of sorghum varieties

Varieties	DE (Mcal kg^{-1})	ME (Mcal kg^{-1})	DMI (%)	RFV
Rox	3.14 ^{a}	2.58 ^{a}	2.31 ^{a}	120.16 ^{a*}
Early Sumac	2.79 ^{b}	2.29 ^{b}	1.85 ^{b}	84.68 ^{b}
Leoti	2.81 ^{b}	2.31 ^{b}	1.84 ^{b}	84.65 ^{b}
Nutri Honey	2.80 ^{b}	2.30 ^{b}	1.83 ^{b}	84.38 ^{b}
Hay Day	2.82 ^{b}	2.31 ^{b}	1.84 ^{b}	85.32 ^{b}
Gozde 80	2.72 ^{b}	2.23 ^{b}	1.83 ^{b}	81.82 ^{b}

*Values indicated with different letters are significantly different at $P<0.05$.

Sorghum, Sorghum x Sudan grass hybrid and Sudanese varieties examined in relation to relative feed value (RFV) has shown important differences statically (Table 3). While the highest RFV in the study was found in the Rox range with 120.6, the RFV of the other five varieties were similar and it was included in the same statistical group. Atis et. al. (2012) determined the highest RFV in the Rox variety (114.6) among the four Sorghum types harvested during the hard drough stage, but this value was lower than our findings. This can be said to be due to the different ecological conditions, care and practice under which the tests were carried out.

Conclusions

In this study, which is aimed to determine Sorghum, Sorghum x Sudanese grass hybrid and sudanese varieties which can be grown as second crop in Igdir geography, it has been revealed that the Rox variety was appropriate in terms of all quality parameters examined and it can be grown in similar ecologies in terms of animal nutrition.

Abstract

The purpose of this study was to investigate the effects of different varieties and harvesting dates on yield, yield components and technological characteristics of sugar beet in Kahramanmaraş, Turkey. The experiment was conducted according to split plot experimental design with three replications 2011 and 2012. Sugar beet varieties (Dozer, Dioneta, Cassandra, Leila, Agnessa) in main plots and harvesting dates (8 th September 2011, 27 th September 2011, 10 th October 2011, 1 st November 2011; 12 th September 2012, 1 st October 2012, 20 th October, 8 th November 2012) in the sub-plots were placed. The variety x harvesting date interactions was significant, the investigated characters were changed according to variety, harvesting date. The highest sugar yield (9660.10 kg ha^{-1}) were obtained from Agnessa, the highest root yield (60.05 ton ha^{-1}), α-amino N (0.062 mg 100 g^{-1}), ash ratio (3.335 %), clear juice purity (87.25 %), dry matter percentage (23.22 %) were obtained from Leila variety. According to harvesting date for the highest root yield (50.88 ton ha^{-1}), sugar yield (9570.15 kg ha^{-1}) were obtained from third harvesting date, α-amino N (0.06 mg 100 g^{-1}), dry matter content (% 23.13) were obtained from fourth, the highest sugar content (16.44 %) were obtained from second harvesting date.

Key Words: *Sugar beet, variety, harvesting dates, root yield, sugar content.*

Introduction

Sugar beet producing roots in first year and seeds in second year is a biennial herb grown. Sugar Beet is a major source of sugar in temperate countries. The crop matures in April-May. Original forms of sugar beet derived white Silesian beet, which are used as a fodder, contained only 4 % sugar. Repeated selection and breeding have raised the sugar content to its present level. Sugar beet is grown between 35 °N to 60 °N latitutes. It can be grown successfully in any region with temperature ranging from 12 to 45 °C during the crop season (October-May). The favourable soil temperature for the germination of sugar beet seed is around 15 °C. An average temperature for proper growth of the plants and sugar accumulation is about 20-22 °C. Temperatures above 30 °C retard sugar accumulation because of high respiration rate. Sugar beet prefers well-drained loam to clay loam fertile soil. The acidic soils are not suitable for raising sugar beet. Sugar beet profits are based on three key factors: sugar beet yield, sucrose content, sucrose recovery efficiency. Sugar beet yield include biomass, root and sugar yield, economic characters are storable root and percentage of sugar (Koocheki et al., 1996). Time of harvest is one of the factors that affects on yield and quality of sugar beet crop. The root dry matter percentage, increases with passing growth period of plant and amount of sugar reaches to 20-26 % at the time of harvest. Delay in sugar beet harvest till the end of autumn leads to decrease in sugar beet root and sugar yield and white sugar content (Laurer, 1995). The highest root yield (52.53 t ha^{-1}) was obtained from early sown (5 April) and late harvested (1 November) beet, while highest sugar content (% 17.4) was obtained from late sown and late harvested (1 November) beet (Akınerdem et al., 2008).

Sugar beet pre-harvest begins anytime from 1 September through 15 September whose purpose is to bring the processing factories into sugar production efficiently before full harvest begins. Full harvest usually begins about 1 October. Significant differences between harvest dates were determined for all measured traits (root yield, sugar content and raw sugar yield) in 2008 and 2010. With the delay of harvest date, root yield and raw sugar yield increased in 2008 and 2010. Sugar content was dependent on climatic condititons between two harvest dates. Heavy rainfall immediately before harvest date would lead to decrease of sugar content (Curcic et. al., 2012). Selecting the proper time of harvesting is necessary to obtain the maximum yield, many investigators reported that delaying harvest date of sugar beet up to 200 or 210 days after sowing improved significantly the individual root characters and juice quality, as increased significantly root and sugar yields (Abd El Razek 2006). During harvest time, sugar beet growing degree days continue to accumulate, as does change, usually positive, in harvest weight (Draycott, 2006). Delaying harvest date up to 210 days from sowing gave the highest root dimension (length and diameter), root yield the best quality and root , sugar yields compared with harvesting at 180 days from sowing (Al-Sayed et al., 2012). Research determined that impurities within the root decreased between early and late harvest in each year of the trial; thus, sucrose concentration increased (Eckhoff, 1995).

Material and Method

The study was established as 3 repetitions according to experimental design of split plot in growing season of 2011–2012 in Kahramanmaraş conditions in Turkey with five sugar beet species. The species (Dozer, Dionetta, Cassandra, Leila, Agnessa) were placed into main parcels, while harvest seasons (8 th September 2011, 27 th September 2011, 10 th October 2011, 1 st November 2011; 12 th September 2012, 1 st October 2012, 20 th October 2012, 8 th November 2012) were placed into sub-plots. Seed sowing was applied in 10 th March by beet seeder of 5-rows, 80 kg N and 60 kg P_2O_5 for each hectar and the plants were grown with irrigation. Irrigation was performed 5 times in 2011 (22 th June, 6 th July, 16 th July, 27 th July, 4 th August) and in 2012 6 times (1 th June, 19 th June,4 th July, 17 th July, 11 th August, 27 th August). In the study, root yield (ton ha $^{-1}$), head+leaf yield (ton ha $^{-1}$), root diameter (cm), root lenght (cm), birfucated root ratio (%), head+leaf weight (g plant $^{-1}$), root weight (g plant $^{-1}$), sugar content (%), α-amino N (mg 100 g $^{-1}$), ash ratio (%), clear juice purity (%), dry matter percentage (%), marc content (%), sugar yield (kg ha $^{-1}$), harvest index (%), leaf area index were investigated. Data regarding investigated features was analysed by using MSTATC statistical program package.

Result and Discussion

It can be seen in the tablo 1 the highest root yield was obtained from Agnessa (57.50 ton ha $^{-1}$) and Leila (56.92 ton ha $^{-1}$) in the 2011, in 2012 respectively Cassandra (68.08 ton ha $^{-1}$), Leila (64.17 ton ha $^{-1}$). The lowest root yield were obtained from Dozer and Dionetta in both years. A similar result was seen in the both years and both years ratio. The lowest root yield was obtained Dozer (48.04 ton ha $^{-1}$) and Dionetta (48.50 ton ha $^{-1}$); the highest root yield was obtained from respectively Leila (60.54 ton ha $^{-1}$) and Cassandra (59.08 ton ha $^{-1}$) varieties in the both years ratio. There is a important differences among varieties in terms of years and year x variety interaction was obtained important.

The highest root yield was obtained from third harvest date (H_3) (56.27 ton ha $^{-1}$) in 2011, in the second year the highest root yield was obtained from (62.67 ton ha $^{-1}$) last harvest date. In the both years ratio the highest root yield obtained from third harvest date (58.87 ton ha $^{-1}$). As harvest date was delayed, root yield increased; in the both years ratio even there is no important differences between harvest dates, there was insignificant decrease in the fourth harvest date.

The values regarding root yield in the study and formed groups are given in Tablo 1.

LSD (% 5)	0.39	0.59	0.35
Years	16.30	15.73	Year LSD(% 5):0.39
(*) 2011	8 th September (H_1) , 27 th September (H_2), 10 th October (H_3), 1 st November (H_4);		
(*) 2012	12 th September (H_1), 1 st October (H_2) , 20 th October (H_3), 8 th November (H_4)		

In the two years and both years ratio the highest sugar content (%) was obtained from Dozer and Agnessa; the lowest sugar content was obtained from Cassandra variety. The low sugar content of Dionetta, Cassandra and Leila varieties is due to the high ash content of these varieties. In 2011, the highest sugar content was obtained from third harvest date (% 17.13), in 2012 was obtained from second (% 16.20) harvest date. In the both years sugar content decreased at last harvest date. Harvest date had greater effect than variety on yield, sucrose content, juice purity.

It seems that since 75 % of root dry matter includes sucrose (Tognetti et al. 2003), the reason for the higher sugar content at delayed harvest is the increase of the root dry matter percent. Postponing harvest time improved sugar beet quality but sugar content loss and technical quality of sugar beet after harvest and during storage (Malec, 1992). According to average values for two years, variety affected all traits except for marc content, while harvesting dates affected all traits except for harvest index, sugar yield, marc content, clear juice purity, and root weight. Interaction between variety and harvesting date was significant for all the investigated traits except for root height, marc content, sugar yield, harvest index, leaf area index.Biomass yield in 2012 increased due to the advances in harvest time, the highest biomass yields were obtained from fourht, in 2011 were obtained from third harvest date. In 2011, the lower biomass yields were obtained from fourth harvesting date, which can conclude that complete phsiological maturity period. In 2012, compared to 2011 to obtain a higher yield of biomass and body, receiving more rainfall than in 2012, is said to be effective. The values regarding to α-amino N and formed groups are given Table 3.

Table 3. Different Varieties and Harvesting Dates Values Regarding α-amino N (mg/100g) and Formed Groups

Sugar beet quality is important issue, the main purpose to cultivate sugar beet is production of a maximum amount of white sugar. The sucrose content in the beet is a major factor affecting white sugar yield. The composition of sugar beet root affects the recovery of crystalline sugar in the factory considerably. Root impurities especially α-amino N are important factors, which influence the production of white sugar yield. According to Table 3, in the first year of the trial the highest α-amino N was obtained from Leila variety (0.050 mg/100g); the lowest was obtained from Dozer variety (0.037 mg/100g); in the second year the highest α-amino N level was obtained from Agnessa (0.074 mg/100g) variety. According to harvest date , in 2011 last harvest date gave the highest α-amino N (0.065 mg/100g) level. In 2012 the highest α-amino N was obtained from second and third harvest date (0.072 mg/100g). The harvest dates had significantly influenced on α-amino N levels, the interaction year x harvest date and variety x harvest date had significant at the level of 5 % probability. Generally, the delay harvest date increased α-amino N level.

Conclusion

Since sugar beet variety trials are usually harvested at the end of the growing period, information about the effect of harvest date on yield and quality of sugar beet root can be very valuable.

In 2011, the highest sugar content was obtained from third harvesting date, 2012 was obtained from second harvesting date, sugar content decline in both years was observed. The most suitable sugar beet harvesting date should be done in the physiological maturity period, in the next period spend respiratory beet sugar produced from sugar can be concluded to be lower.

In 2011 and 2012, the fourth lowest sugar content at harvest began in this period of obtaining sugar content in rainy and cold weather ad it can be stated that there was no adverse effect on the yield. In rainy and cold weather, excess water in the soil is absorbed by the sugar beet root; therefore beet-root sugar content decreased.

In the light of the results obtained in this study, delaying the harvest time in Kahramanmaras conditions to increase the sugar content, it can be concluded that the optimal harvest date would be October 10^{th} and 20^{th} October.

Abstract

Turkey is one of the main walnut producer countries in the world. In 2015, Turkey ranked fourth in world production with 180,807 tons of production. It can be said that main part of walnut trees in Turkey have been grown without using of pesticides and chemical fertilizers, so that production shows organic qualifications. Continuous seed propagation in Turkey has given rise to a great number of seedling walnut trees, which represent valuable walnut gene resources. The number of native trees is estimated to be over 9 million and they possess large genetic variability in yield, nut and kernel characteristics, late bud breaking, late flowering, winter hardiness, tolerance to diseases. Thousands of walnut trees had been cut down in the eastern part of Turkey and sold abroad after the 1980's. After recognition of the importance of propagation by grafting and budding by growers in recent years, the orchards are being established with standard cultivars. These standard walnut orchards are generally established with Californian and French cultivars. The Ministry of Food, Agriculture and Livestock and The Ministry of Forestry and Water Affairs of Turkish Republic have important new policy on walnut development program in Turkey. The most important climate restrictions for walnut production are spring frosts in Turkey. Turkish walnut breeding program is abounding with cultivar breeding. There are no adequate studies on rootstock breeding. Harvesting cannot be made mechanically because native trees are large in size. Turkey's walnut production is expected to increase about 40,000 tons in the next 10 years with the initiation of production from newly established orchards.

Keywords: *Walnut production, import, marketing.*

Introduction

Turkey is one of the important gene resources of the world due to its position on Silk Road throughout the ancient ages. The history of walnut in Turkey is very old. In the tomb of King Midas in Gordion, near Polatlı in Turkey, it is determined by wood analyses that furniture embedded with King Midas had been made from *J. regia* L., *Taxus baccata* L., *Cedrus libani* Loud., *Juniperus foetidissima* Willd., *Buxus semperviERNS* L. and *Pinus sylvestris* L. Members of the *Juglandaceae* family have been founded in Konya-Süber from Neolitic ages (Aytuğ, 1967). In the Akçaabat county of Trabzon province, a fossil walnut fruit was founded in the Plio-Quaternary sediment. The fossil had been completely and well protected (Aytuğ, 1987). In Turkey, many fruit species (walnut, almond, apricot, chestnut, and rosehip) have been propagated from seed over centuries. In this species, rich genetic resources occur throughout the country because of seed propagation. There are 4 districts, 12 towns and 40 quarter named with 'ceviz' means walnut in English in Turkey (Şen, 2005). Due to more suitable ecological conditions such as average temperatures, precipitation and soil characteristics and especially the interest of local peoples, walnut trees are spread almost in all regions of Turkey. The aim of this paper is to reveal the current situation of Turkey's walnut growing activities in different aspects and with changes that occur over time.

Position of Turkey in production and trade

The most commonly grown walnut species in Turkey for fruit production is *Juglans regia* (Şen, 1986). Recently, *Juglans nigra* and *Juglans hindsii* are also being grown only for personal forestation and personal arboretum (Akça and Polat, 2017). But in recent years, timber walnut plantations have been established with *J. nigra* and *J. hindsii.*

Walnuts are generally grown in USA, Europe and Asia. Over 3.5 million tons shelled walnut are produced annually in the world (FAO, 2013). According to the FAO statistics, China leads production with 1.7 million ton, followed by the USA (425,000 t), Iran (454.000 t) and Turkey (212,000 t) (Table 1).

Table 1. Production area and production of countries

According to the agricultural statistics of 2015 year in Turkey, walnut plantation area is around 86,853 ha, and the annual production is around 180,807 tons and the average yield is about 25 kg/tree, and the total number of walnut tree is 15,044,456. Turkey's annual shelled walnut import value is 34,285 ton and export values are significantly lower. (Turkstat, 2016) (Table 2).

Table 2. The value of Turkey walnut production and trade

Years	Production (ton)	Imports (ton)	Exports (ton)	Per person consumption (kg)
2007/2008	172 572	39 572	2 915	2.8
2008/2009	170 897	35 018	3 859	2.7
2009/2010	177 298	46 004	6 383	2.9
2010/2011	178 142	31 076	7 309	2.6
2011/2012	183 240	46 338	13 711	2.8
2012/2013	203 212	40 009	11 998	2.9
2013/2014	212 140	30 479	14 171	2.8
2014/2015	180 807	34 285	8 407	2.5

Government supported projects are being implemented to reduce walnut imports. The Ministry of Food, Agriculture and Livestock and also The Ministry of Forestry and Water Affairs of Turkish Republic have important new policy on walnut development in Turkey (OGM, 2012). Ministries give financial supports to the farmers who will establish walnut orchard. However, other regular orchards have been established by using Californian and French walnut cultivars without government support in the last 15 years.

Usage of walnut

Walnut is named ‘Ceviz’ or ‘Koz’ in Turkish. Walnut has an important place in Turkish culture (Şen, 2005). The walnut tree is known as the protein tree in Turkey, with its fruit known to be an aphrodisiac and source of energy. Turkish people use the fruits, leaves, green husks and roots of walnut trees. Turkish people in undeveloped regions and rural areas get a large portion of their protein needs from walnut fruits. Bread with walnut is an indispensable nutrient for people in rural areas (Şen, 1986).

Turkish people use medicines from walnut foliages to prevent hair loss, in the treatment of pimples, in skin care, as a bath lotion and to fight parasites (Şen et al., 2006). Teas made from leaves are used for reducing triglyceride and cholesterol levels. Also, Turkish people believe that walnuts can strengthen the liver. It is believed that eating a preparation of walnut with fig, garlic and flower of rue (*Ruta graveolens* L.) prevents food poisoning. It is known that a little walnut foliage used in beach oils and perfumes ensure a good sun tan. However, there is no study, to our knowledge, reporting such an effect. In Turkish culture, it is believed that walnut fruit brings abundance and luck. Traditionally, meals have been made with walnut on holidays and special days. Nutritious and energizer meals especially for proteins and fats have been made by using walnuts in sweets. In Turkish cuisine, ‘kek’, ‘batrak’, ‘aşure’, ‘kek’, ‘cevizli helva’, ‘cevizli ekmek’, ‘baklava’, and ‘kadayıf’ are important meals made with walnut. In short, walnuts are multipurpose fruits in Turkish cuisine (Şen et al., 2006).

Propagation of walnut in Turkey

In Turkey, walnut had been propagated only by seeds until 1970. The numbers of grafted saplings have increased to 2,5 million in 2016. Most commonly, the patch budding method is used for propagation of walnut in Turkey. Generative rootstocks of *J. regia* are used for budding (Ertürk and Akça, 2012). But, in recent years, Paradox and *Juglans hindsii* generative rootstocks have been started to use. Many studies on the propagation walnut plants with tissue culture continue in a lot of laboratories. Saplings are marketed potted or bare root. The price of the grafted walnut sapling is 4-5 Euro. In 2016, 250,000 grafted walnut saplings are exported to Spain, Bulgaria and Greece from Turkey (Various nurseries, personal comm.)

Breeding studies

Walnut breeding studies are abounding with cultivar breeding. There are no adequate studies on rootstock breeding. Turkey is one of the important genetic resources of walnut and has been offering important opportunities to plant breeders with its genetical potential. Even so, there are many walnut types that are late leafing, resistant to diseases and insects and highly lateraly fruitfull, and have good fruit quality. Especially, types that are resistant to bacterial blight (*Xanthomonas campestris pv. juglandis*), codling moth (*Cydia pomonella*), and anthracnose (*Gnomonia leptostyla*) are interesting (Akça, 2016).

The important problem of walnut production in Turkey is the damage of spring frosts. Turkish walnut cultivars are considerably early leafing and they bear fruits on terminal buds. The selection breeding method was the most widely used in walnut variety breeding of Turkey. Great number of selection study has been done among the rich native populations

(Akça and Şen, 2001; Akca and Ozongun, 2004; Karadağ and Akça, 2011; Simsek et al., 2011; Asma, 2012; Kırca et al.,2014; Akça et al., 2015). Superior walnut varieties that have high fruit quality were selected from native walnut populations of Turkey and then these selections have been released to use. All Turkish walnut cultivars were selections from native walnut populations until 2016. A few new cultivars obtained from crossing were released at the end of the 2016 year (TTSM, 2016). In initial breeding studies, breeders had mostly focused on fruit quality characters and chose large fruited trees. Other characteristics such as late leafing, lateral fruitfulness and resistance to disease and insects had been omitted. The walnut varieties with lateral fruiting and late leafing walnut types same as Californian cultivars have not been found from seedling population of Turkey by selection. And it is understood that it is hardly possible to found late leafing and also lateral bud fruitful genotypes in seedling walnut populations due to the degree of heritability and contraindications of these two characteristics.

Cross breeding method was used in only fourth studies until today (Akça, 2001; Sütyemez, 2008; Anonymous, 2012; Akça et al., 2016). Breeding efforts was focused to provide new walnut cultivars by crossing for the Turkish walnut industry. The primary objective of Turkish walnut scion breeding program was to develop new cultivars with late leafing, lateral bud fruitfulness, disease resistance, high yield, and good kernel quality (Anonymous, 2012). In walnut breeding program, late leafing parents were crossed with lateral bearing parents. In regions with late spring frosts in Turkey, late fruiting walnut varieties can be used economically. Therefore, new varieties are required with high fruit quality and yield that will not effected by spring frosts.

During 1998 and 2015 years, fourth main different variety breeding programs were made to find new walnut genotypes with late leafing, lateral bud fruitfulness and high nut quality. In first variety breeding program, Turkish walnut selections were crossed with Payne and between them in 1998-1999: 'Niksar 1' × 'Niksar 2', 'Niksar 1' × 'Payne', 'Niksar 1' × 'Şebin', 'Turhal 1' × 'Niksar 2', 'Şebin' × 'Niksar 2'. 757 seedlings from controlled crosses were obtained in 1998 and 624 seedlings were obtained in 2000 (Akca, 2001). In second study conducted in Kahramanmaraş Sütçü İmam Üniversity in Turkey, 7239 F1 walnut plants had been obtained from 56 different crossing combinations (Sütyemez, 2008). In third variety breeding program, 'Niksar 1', 'Şebin', 'Hartley', 'Topak', 'Chandler', 'Akça 2', 'Oğuzlar 77', 'Franquette', 'Sütyemez 1', 'Sütyemez 2' and 'Maraş 12' walnut standard cultivars and selections were used between 2008-2012 by the support of TUBITAK. 1340 seedlings under evaluation from this breeding program (Anonymous, 2012). In fourth variety breeding program, between 2012-2015, the following controlled crosses were made to found the new walnut genotypes with tolerant to bacterial blight, late leafing and lateral bud fruitfulness, high nut quality: 'Pedro' × 'Chandler', 'Pedro' × 'Fernette', 'Pedro' × 'Midland', 'Fernor' × 'Pedro', 'Fernor' × 'Chandler', 'Fernor' ×'Fernette', 'Fernor' × 'Howard', 'Fernor' × 'KZK1', 'Howard' × 'Fernor', 'Howard' × 'Chandler', 'Fernette' × 'Howard', 'Fernette' × 'Chandler', 'Fernette' × 'KZK 1', 'Chandler' × 'Kaman 1', 'Chandler' × 'KZK1'. A total number 1633 F1 seedling were obtained (Akça et al., 2016).

Genetic erosion

In Turkish tradition, chests made of walnut wood have been gifted to girls to get married. Also an important portion of home furniture have been veneered with walnut wood. Villagers in rural areas that earn little money from walnut fruits have been cutting trees to sell as timber. Thousands of walnut trees had been cut down in the eastern part of Turkey and sold abroad after the 1980's (Şen, 1986). Old and healthy trees were logged because of high timber prices that caused important genetic erosion and a decreased nut production. Recently, the number of logged trees has decreased under pressure by the Civil Society Associations and legalities.

Due to regulations in acts, the preliminary condition to get a cutting license is the property of the land where the trees are needs to be belonging to someone other than state and non- forest area. Cutting of walnut trees in these properties needs a positive report that is given by a commission established by a forest engineers and an agronomists. A cutting license is issued after approval of the positive report of the commission by authorized offices. Unavoidable conditions of destruct are looked for giving a cutting license to walnut trees; these trees should not yield due to disease and age, trees should be damaged from natural disasters (flood, wind, strike, etc.), dried, left in compulsory construction and establishments like road, dam, etc, damage neighbor's property. Otherwise cutting of these trees are not permitted (Akça, 2016). However, genetic erosion has continued as a result of imported late leafing and laterally fruitful cultivars such as 'Chandler', 'Pedro' and 'Fernor', and senseless and unrestrained logging of native trees.

Important diseases and pests

Most common diseases and insect pests observed in Turkey are anthracnose (*Gnomonia leptostyla*), bacterial blight (*Xanthomonas campestris* pv. Juglandis), root rot (*Phytophthora* spp.), codling moth (*Cydia pomonella*), and walnut aphids (*Chromaphis juglandicola*). In Turkey, there is no spraying against diseases and pests on the seedling-grown old walnut trees. However in walnut newly-established orchards, there are methodical spraying programs against to pests and diseases. Biological agents are not commonly applied. CLRV was determined in some walnut growing regions (Ozturk et al., 2008).

Harvest and post-harvest

Harvesting cannot be made mechanically because native trees are big but rather with long sticks by hitting the branches. This operation affects and limits the following year's yield, and because of the long harvest time the kernel quality can decrease. In recent years, studies have been attempted to adapt shaker machines used in olive trees to walnut harvest.

Harvested fruits with a green husk are usually clumped together and kept for a long time for separation of the husk itself. This process causes darkening of the shell and kernel (Ünal, 2005). But, in the recent years, green husks of fruits are skinned with machine. Harvested walnuts must be dried as soon as possible and moisture content must be decreased to 4-5 %. Problems with the drying process of fruits in Turkish walnut production cause a loss of quality. Mechanically skinned walnuts are dried in shadow for 5-7 days. However, in recent years growers have been using drying machines in big orchards (Yalçın et al., 2012).

Organic walnut production

It can be said walnut trees in Turkey have been grown without the use of pesticides and chemical fertilizers so that production shows organic qualifications (Ozkan, 2005). Furthermore, in recent years, in appropriate areas and policies have started to organic walnut production.

Processing of walnut and walnut industry

Mechanization is not used in the cracking process of shelled walnuts but is rather done manually, in general, by women workers. Shelled walnuts are stored in cool storage and presented for consumption throughout the year. If the temperature can be dropped down to 3 °C, quality losses drop down to a minimum. Nuts can be stored between -15 °C to -20 °C without quality losses. Kernels are marketed in vacuum packages. Walnuts are commonly used in the dessert production industry. Also, by using mulberries and grapes special products such as 'pestil' and 'köme' are made. Walnuts also are used in ice cream and halva production, and in the dried fruit industry.

Marketing

Marketing channels of walnut have been developed in Turkey. There is a lot of different walnut company. There are grower unions that marketed in local bazaars, markets and gather growers to market their production.

Conclusion

Each year 2.5 billion grafted saplings have being produced by which thousands of hectares of walnut orchards have been planted in Turkey. As a result of newly established orchards, Turkey has started to produce standard walnuts. In orchards, 8×4, 7×7, 7×6, and 7x5 m planting distances are used. Unfortunately, the walnut growers indicate that important tree deaths in orchards with a Chandler cultivar. Drip and mini spring irrigation systems have been used in this orchard. Contestation with diseases and insects is being made well. Product of these orchards is being sold at 3 times higher prices than products of native trees.
Turkey's walnut production is expected to increase about 40,000 t in the next 10 years with the initiation production of newly established orchards. Turkey will have exported walnuts and became an important producer.

Abstract

This study was carried out in order to determine adaptation and some quality traits of some cool season turf grass cultivars at randomized plot design with 4 replicates in Ondokuz Mayis University Experimental Area during 2010-2012 years. Plot size was 2 m² (1×2 m). In the research 5 cultivars of *Festuca arundinacea* (FA), 6 cultivars of *Lolium perenne* (LP), 5 cultivars of *Festuca rubra commutate* (FRC), 6 cultivars of *Festuca rubra rubra* (FRR), 5 cultivars of *Festuca ovina* (FO), 7 cultivars of *Poa pratensis* (PP), 2 cultivars of *Poa trivalis* (PT), 1 cultivar of *Agrostis stolonifera* (AS), 2 cultivars of *Agrostis capillaris* (AC), 1 cultivar of *Agrostis tunius* (AT) and 1 cultivar of *Festuca rubra trichophylla* (FRT)were used. Time to emergence (day), time to covering (day), winter hardiness (1-9), covered ratio (1-9), regeneration trait (1-5), tiller number (1-5), general appearance (1-9), weed ratio (1-5), sparsely ratios (1-9) were investigated. In terms of time to emergence and time to cover the earliest values were obtained from LP cultivars (16.12 and 42.66 days, respectively), the latest values were observed to FRR and FO cultivars. When consider together with winter tolerance, covered ratio and regeneration traits, cultivars of FA were the best. The highest tiller number and the least sparsely ratios were determined to FA cultivars. Weed problem was not observed for all cultivars but PP and PT. There were no differences in terms of general appearance among the cultivars except for PP and PT cultivars. Consider the all investigated characteristics of cultivars, price and abundance of seed and cultivation process, *F. arundinacea*, *Lolium perenne* and some *Festuca rubra* cultivars are very suitable in order to use green areas in Black Sea Region of Turkey.

Key words: *Turf grass, adaptation, quality, winter hardiness*

Introduction

In the contrary of urbanization and industrialization, recreation area is decreasing day by day. In order to supply human shelter requirement concrete apartment building increased, view of the cities changed and consequence of those issues. Life quality decreased while stress of humanity is rising. Human is trying to live in congested areas, started to create small green areas inside the cities. After that researches on grass species that can be used in green areas increased (Avcıoğlu, 1997).

Turfgrass have important functions on sports areas, in addition to around the houses. Turfgrass species and cultivars selected for sports areas should be resist to pressing on. This trait is crucial for a turfgrass, if it is used in sport areas (Yazgan *at al.*,1992). Before establish a sport or recreation area, turfgrass cultivars should be suitable to climatic conditions of the region. To know the adapted cultivars in the region is definitely necessary. Cool season grass are suitable to North, East and Central part of Turkey, however warm season grass are more common in South and South-West regions.

Turfgrass plants, in addition to climatic adaptation, should satisfy expectations in terms of harmony of each other, persistence, appearance and aesthetic. Indicator of satisfaction is evaluated as turfgrass quality. Quality of turfgrass is divided two parts. The first one is individual quality of plants like as; colour, growing speed, growing structure, root growing, resistance to cutting depth and frequency, pressing on, drought, heat, disease and insects. The second one is general characteristics like as; harmony each other, uniformity, appearance, smoothness, density and hay yield (Beard, 1973; Altan, 1989; Uzun, 1989; Acikgoz, 1994; Avcioglu, 1997). Aim of this study was to determine adaptation and some quality traits of some cool season turf grass cultivars.

Material and Methods

In this study 41 cool season grass cultivars (5 FA, 6 LP, 5 FRC, 6 FRR, 5 FO, 7 PP, 2 PT, 1 AS, 2 AC, 1 AT, 1 FRT) were used. The experiment was established according to randomized block design with four replicates in Samsun Conditions in Turkey in November, 2010. Plot sizes were 2x1=2 m^2. Seeding rate was altered 25-90 g/m^2 according to 1000-seed weight and plant characteristics. The seeds scattered with hand on plots and compressed. Time to emergence (day), time to covering (day), winter hardiness (1-9), covered ratio (1-9), regeneration characteristic (1-5) tiller number (1-5), general appearance (1-9), weed ratio (1-5), thinning ratio (1-9) were investigated. The average temperature of Samsun was 13.9^{0}C in long-time period, while in 2011 and 2012 it was measured as 14.2^{0}C and 15.2^{0}C, respectively. For many years, the total annual rainfall of Samsun was 707.0 mm as the average while in 2011 and 2012, this value was determined to be 671 and 999 mm, respectively. Statistical analysis was performed with SPSS 17.0 program according to randomized plot design.

Result and Discussion

Time to emergence

There are highly significant differences amongst the species regard time to emergence. Average time to emergence was 16.1 days for *Lolium perenne*, 19.5 days for *Festuca arundinacea*, 25-27 days for *Festuca rubra* and *Agrostis* sp., 31.6 days for *Poa trivialis*, 33.7 days for *Festuca ovina* and 34.8 days for *Poa pratensis* (Table 1 and Figure 1).

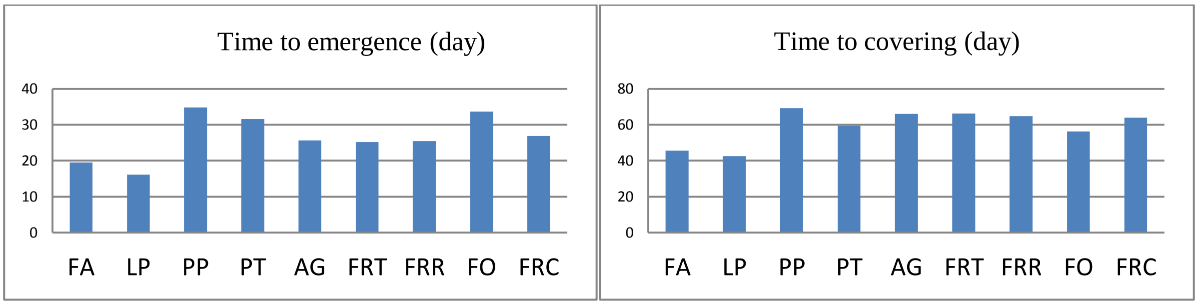
Table1. Some characteristics of the cultivars*

Species	Traits				
	Time to emergence (day)	Time to cover (day)	Winter hardiness (1-9)	Covered ratio (1-9)	Regeneration characterisric (1-5)
FA	19.50 (b)	45.60 (b)	6.60 (ab)	8.60 (a)	2.10 (ab)
LP	16.12 (a)	42.66 (a)	5.25 (c)	7.25 (bc)	2.50 (ab)
PP	34.83 (c)	69.33 (c)	3.33 (d)	6.99 (c)	4.66 (c)
PT	31.62 (d)	59.50 (d)	3.75 (d)	5.00 (d)	5.00 (c)
AG	25.66 (e)	66.08 (e)	7.33 (a)	7.33 (bc)	2.66 (ab)
FRT	25.25 (e)	66.25 (e)	7.50 (a)	7.00 (c)	1.50 (a)
FRR	25.50 (e)	64.85 (f)	5.80 (bc)	6.80 (c)	2.70 (b)
FO	33.65 (f)	56.25 (g)	5.90 (bc)	8.30 (a)	2.80 (b)
FRC	26.90 (g)	63.90 (f)	6.10 (bc)	7.70 (b)	2.20 (ab)

*There is no difference amongst the number indicated same letter in the same column

Time to covering

There was a partly similarity between time to emergence and time to covering values of the species. In term of time to covering highly significant differences were found amongst the species. The earliest time to covering values were obtained from *Lolium perenne* Topgun and Eveningshade cultivars (41 days) and this species followed by *Festuca arundinacea* (46.6 days), *Festuca ovina* (56.3 days), *Poa trivialis* (59.5 days), *Festuca rubra commutata* (63.9 days), *Festuca rubra rubra* (64.9 days), *Festuca rubra trichphyla* (66.3 days) and *Poa pratensis* (69.3 days), respectively (Table 1 and Figure 2).



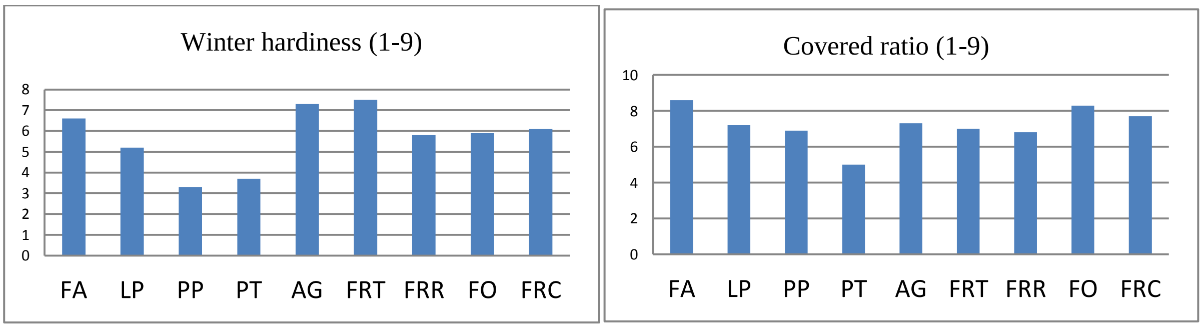
Figures 1 and 2. Time to emergence and time to covering days of the cultivars

Winter hardiness

Winter hardiness values of cultivars were evaluated according to 1-9 scale (Table 1 and Figure 3). There were significant differences amongst the species and cultivars, regard the winter hardiness and the first rank was occupied by all *F. arundinacea, Agrostis* sp. and some *F. rubra* (Zamboni and Cassanova) and *F. ovina* (Bornito and Nordic) cultivars (6.5-7.5). The worst winter hardiness values were obtained from *P. pratensis* and *P. trivialis* cultivars (3.4). Winter hardiness values of species has similarity with the other researchers results, except for *P. pratensis* (Uzun,1992; Altan,1989; Arslan and Cakmakcı, 2004; Cockerham *et al.*,1989). When we consider literature information, winter hardiness value of *P. pratensis* would be higher than it is. Probably, higher summer temperature and rust disease declined resistance of plants.

Covered ratio

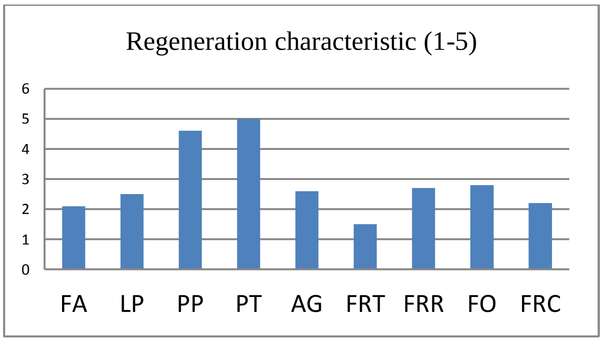
According to statistical analysis, there were highly significant differences amongst the cultivars. The highest covered ratio value was obtained from 4 *F. arundinacea*, 2 *F. ovina* and 1 *F. rubra commutata* cultivars as 9 point. The cultivars Starlite and Cypress of *P. trivialis* (5), Gondolin of *F. rubra rubra* (5) have the lowest covered ratio (Table 1 and Figure 4).

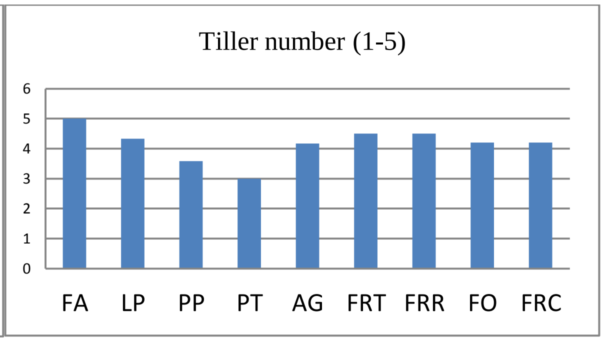


Figures 3 and 4. Winter hardiness and covered ratio values of cultivars

Regeneration characteristic

In the consideration of regeneration characteristics that was made before second cutting in the spring, there were highly significant differences amongst the cultivars. The cultivars Jaguar and Apachi of *F. arundinacea* and Zamboni of *F. rubra trichophyla* performed the highest regeneration with 1.5 point. The lowest regeneration values were obtained from *Poa* sp. cultivars (4.5-5.0) (Table 1 and Figure 5).





Figures 5 and 6. Regeneration characteristics and tiller numbers of cultivars

Tiller number

Tiller numbers of the cultivars were observed just after the second cut and are given at Table 2 and Figure 6. 11 different cultivars tiller very densely and their mark was 5. Especially tiller numbers of all FA cultivars were higher and their appearance was very frequent. Tillering value of all perennial rygrass and other fescue cultivars were altered between 3.5 and 5.0. The least tillering was observed on the cultivar Compact of *Poa prastensis*.

General Appearance

General appearance of the plots was evaluated according to uniformity, colour, texture, liveliness, weeds ratio, damage of the insects and disease in four seasons as using 1-9 scale. Jaguar of *F. arundinacea* and Highlanbent of *Agrostis tenius* were rewarded 8 points over 9 and their general appearance was the best. The worst general appearance was observed on *Poa* cultivars (Table 2 and Figure 7). In this case general appearance of *Poa* cultivars were evaluated as bad, and the others as good or very good.

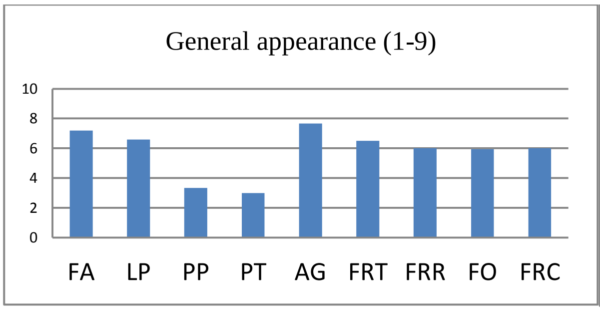
Table 2. Some other traits of the cultivars*

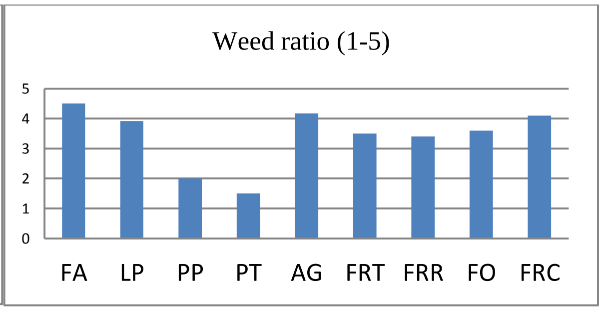
	Traits			
Species	Tiller number (1-5)	General Appearance (1-9)	Weed Ratio (1-5)	Thinnig Ratio (1-9)
FA	5.00 (a)	7.20 (a)	4.50 (a)	8.20 (a)
LP	4.33 (abd)	6.58 (a)	3.91 (a)	5.91 (b)
PP	3.58 (bc)	3.33 (b)	2.00 (bc)	4.91 (c)
PT	3.00 (c)	3.00 (b)	1.50 (c)	1.50 (d)
AG	4.16 (bd)	7.66 (a)	4.16 (a)	5.16 (bc)
FRT	4.50 (ad)	6.50 (a)	3.50 (ab)	3.50 (e)
FRR	4.50 (ad)	6.00 (a)	3.40 (ab)	3.50 (e)
FO	4.20 (bd)	5.95 (a)	3.60 (a)	5.50 (bc)
FRC	4.20 (bd)	6.00 (a)	4.10 (a)	4.70 (c)

*There is no difference amongst the number indicated same letter in the same column

Weed ratio

Weed ratio of the plots were determined after the last cut in the second year as using 1-5 scale. The differences amongst the cultivars were found as highly significant in terms of weed ratio. The highest weed ratio was determined into cultivars of *Poa* sp. (1.5-2.5). Weeds had no chance to grow into cultivar Jaguar of *F. arundinacea* that its regeneration characteristic and tiller number were high (Table 2 and Figure 8). In fact weed ratio of all cultivars was acceptable, except for *Poa* cultivars and Redskin cultivar of *F.rubra rubra*.





Figures 7 and 8. General appearance and weed ratios of cultivars

Thinning Ratio

Thinning ratio of the plots was observed at the end of the vegetation period in the second year and was appreciated as using 1-9 scale. The results are given at Table 2 and Figure 9. There were significant differences amongst the cultivars at the end of the second year, thinning ratio of cultivars were appreciated as follow: Cultivars of *F. arundinacea* were dense/highly dense, cultivars of perennial rygrass were dense, cultivars of *Poa pratense*, *Agrostis* sp. and the other fescue were middle dense, but cultivars of *Poa trivialis* were very thin.

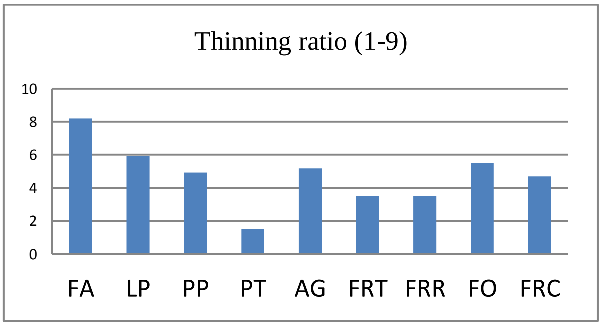


Figure 9. Thinning ratios of cultivars

Conclusion

Consider the all investigated characteristics of cultivars, price and abundance of seed and cultivation process, *F. arundinacea*, *Lolium perenne* and some *Festuca rubra* cultivars are very suitable in order to use green areas in Black Sea Region of Turkey.

Abstract

The aim of this study was to define grain yield and the quality traits of local oat cultivars grown in different region of Turkey. Fourteen oat genotypes were evaluated in a randomized block design with four replicates over the three locations for two consecutive years. Effects of genotype, location, year, genotype × location and genotype x year interaction on grain yield and quality traits were statistically found important. The oat genotypes showed variations for grain yield (2.39–4.65 t ha^{-1}), test weight (41.26–45.59 kg), groat percentage (70.02–74.44 %), protein (11.40–13.11 %), ash (2.41–2.90 %), starch (42.40-52.69 %), β-glucan (2.99-3.52 %), ADF (14.16–17.78 %), NDF (32.54–36.69 %), and fat (5.50–6.83). Linoleic, oleic, palmitic, stearic and linolenic acid contents of the genotypes varied between 35.20 to 38.98 %, 37.15 to 41.30 %, 17.54 to 19.26 %, 2.53 to 2.76 % and 1.23 to 1.46 %, respectively. According to the average of locations, the genotype G8 had the highest grain yield. Also, this genotype had high values for the desired quality traits.

Keywords: *Avena sativa, grain yield, quality, protein, oat.*

Introduction

Oat grown for food, feed and forage in several regions of the world is an important grain cereal. Its production for food is gradually increased due to its unique nutrition content for healthy diets. Oat as human food is used mostly in hot and ready-to-eat cereals, and some in granolas, cookies, breads and other cereal products (Özcan et al., 2006). The use of oat grain relies on its agronomic characteristics, physical traits and chemical composition features (Peterson et al., 2005). Hectoliter weight, kernel weight, groat percentage, milling yield, protein, oil and β-glucan concentrations determining the quality of oat grain are the most important physical and composition traits (Doehlert et al., 2001; Peterson et al., 2005). All these characteristics are affected by the growing condition, genetic factors as well as by interactions between them (Peterson et al., 2005; Hısır et al., 2012).Oat grains contain about 12.4 to 24.4% protein, 3 to 11% oil, 1.8 to 7.5% β-glucan. Oats are a rich source of soluble fiber, well-balanced proteins, several vitamins and minerals essential for the human health (Charalampopoulos et al., 2002; Demirbas, 2005). Oats also include comparatively high amounts of lipids compared with other cereal grains, with a substantial level of essential linoleic acid (Hareland and Manthey, 2003). A number of studies indicate that oat oil content is under genetic control, thus it is possible to alter oil content via breeding (Holland et al., 2001). Oat oil is generally good for human nutrition due to a high percentage of unsaturated fatty acids such as oleic acid and linoleic acid. The success of plant breeding in the last century has mainly depended on the utilization of natural or mutant modified genetic variation accompanied with efficient selection and suitable methods in target environments. Local cultivars, is a significant natural genetic source, provide a many opportunities to breeders for developing a new varieties with a high yield and quality. Due to the climatic and geographic location, Turkey is the origin of many wild and cultivated plants. So the genetic diversity is very high. There are many different local and wild oat varieties in Turkey. Therefore, Turkey is considered to be one of the important origin centers of the oat (Dumlupınar et al., 2011). Plant breeders have been endeavoring to improve genotype with higher grain yield, quality and other suitable traits for different environmental conditions. In the present study, various physical and chemical properties of local oat genotypes were evaluated.

Material and Methods

In this study, a total of 14 oat genotypes (12 local cultivars and 2 registered varieties) were included. This study was performed in two successive years (2011-2012 and 2012-2013) at three different locations, namely Amasya, Samsun-Bafra and Samsun (Table 1) in Turkey. Fourteen genotypes of oat were grown in a randomized complete block design with four replications at each site under rain fed conditions. Sowing was done with plot size of 7.2 m^2, wherein 6 rows were sowed within the plot, with 20 cm row spacing, with 550 seeds m^2. In this study grain yield, some physical (test weight, groat percentage) and some chemical properties (protein, starch, ash, fat, β-glucan, acid detergent fiber (ADF), and neutral detergent fiber (NDF), and fatty acid composition) were determined. A Grain yield (GY) per hectare was calculated from the harvested area of each plot. Physical and chemical analyses were carried out according to Buerstmayr et al. (2007) and Mut et al., (2016a). Some climatic data and soil characteristics of the experimental areas are given in Table 1. Analysis of variance (ANOVA) of the phenotypic data was performed using GLM procedure of the statistical analysis System (SAS Version 6, 1990). Where ANOVA indicated significant treatment affects, the means were separated by the least significant difference (LSD) at the 0.05 probability level.

Results and Discussion

The effects of year, genotype, location, and genotype × location interaction (except for β-glucan) were found to be statistically significant ($P < 0.01$) for all traits, namely grain yield, test weight, thousand grain weight, groat percentage, protein content, ash, starch content, β-glucan content, acid detergent fiber (ADF), neutral detergent fiber (NDF) and fat content (Table 2 and 3).The significant G × L interaction demonstrated that the answers of the genotypes altered depending on environments. Grain yield of genotypes averaged over all locations ranged from 2.39 t ha^{-1} for genotype G1, to 4.65 t ha^{-1} for genotype G8; the overall mean was 3.39 t ha^{-1}. The highest grain yielding was Bafra location (4.23.8 t ha^{-1}), followed by Samsun and Amasya (3.67 t ha^{-1} and 2.28 t ha^{-1}), respectively (Table 2). Grain yield in the first year (3.64 t ha^{-1}) was also higher than that of the second year (3.14 t ha^{-1}). The variation in grain yield of genotypes may be attributed to genetic characteristics and adaptability of these varieties to different environmental conditions. The influences of genotype and climate conditions are significant parameters affecting yield and quality of oat (Burstmayer et al., 2007). Factors determining yield and quality in field crops can be categorized into several groups: genotype efficiency, soil fertility, agricultural practices, and meteorological conditions (Abunyewa et al., 2017). According to the average of the tested locations, the groat percentage varied from 70.02 to 74.44 %, and G6, G8 and G9 numbered genotypes had the highest groat percentage (Table 2). The highest groat percent was Bafra location (73.58 %), followed by Samsun and Amasya locations (Table 2). Gorat percentage in the first year (75.30 %) was also higher than that of the second year (69.81 %). Low hull content is particularly important for the achievement of high milling yield, which is an important criteria for hulled food oat (Cowan and Valentine, 2004). Mut et al. (2016b) stated that groat percentage varied from 70.4 to 76.6 % in different oat genotypes.

Test weight of genotypes averaged over all locations ranged from 41.26 kg for genotype G10, to 45.59 kg for genotype G6; the overall mean was 72.62 (Table 2). The highest test weight was Amasya location (45.07 kg), followed by Bafra and Samsun (43.60 and 41.39 kg), respectively (Table 2). Test weight in the first year (42.01 kg^{1}) was also higher than that of the second year (44.70 kg). The results obtained in this study were in agreement with those acquired in previous studies on the quality of oat grain, which also showed that the quality of oat grain depended on the genetic factors and environmental conditions throughout the growing season (Rhymer et al., 2005; Buerstmayr et al., 2007; Mut et al., 2016b).

Protein content of the grain is one of the basic parts which report the usage of grain. Grain crude protein content was significantly affected by genotypes, locations, years and genotype × location interaction (Table 2). According to the average of the tested locations, the protein content varied from 11.40 (G1) to 13.11 % (G8), and G3, G6, G8, G11, G12 and G13 numbered genotypes had the highest protein content (Table 2). The highest protein content was Amasya location (13.33 %), followed by Samsun and Bafra locations (12.39 and 11.63 %), respectively (Table 2). Protein content in the second year (12.97 %) was also higher than that of the first year (11.93 %). Australian genotypes of husked oats varied from 10.0 to 18.0 % of CP (Farrell et al., 1991). Yanming et al. (2006) and Mut et al. (2016b) showed that genetic variation was important for protein content. Starch content of genotypes averaged over all locations ranged from 44.84 % for genotype G3, to 50.69 % for genotype G13; the overall mean was 46.57 (Table 2). The highest starch content was Samsun location (49.14 %), followed by Amasya and Bafra (49.05 and 41.53 %, respectively) (Table 2). Starch content in the second year (48.06 %) was also higher than that of the first year (45.08 %). Environment was the dominant factor contributing to the total variation of starch content (Rhymer et al., 2005). Mut et al. (2016b) reported that starch ranged from 34.85 kg to 47.72 % in different oat genotypes.

β-glucan concentration was significantly affected by genotypes, locations, years and genotype × location interaction (Table 2). According to the average of the tested locations, the β-glucan concentration varied from 2.98 (G9) to 3.52 % (G8), and G1, G5, G8 and G10 numbered genotypes had the highest β-glucan concentration (Table 2). The highest β-glucan concentration was Bafra location (3.60 %), followed by Samsun and Amasya locations (3.14 and 3.02 %), respectively (Table 2). β-glucan concentration in the second year (3.60 %) was also higher than that of the first year (2.89 %). β-glucan aids to decrease blood glucose and cholesterol (Demirbaş, 2005). Mut et al. (2016b) indicated that starch ranged from 1.33 to 2.58 % in different oat genotypes. ADF and NDF content of genotypes averaged over all locations ranged from 14.16 to 17.78 % and 32.56 to 36.69 %, respectively. ADF and NDF values in the first year were higher than that of the second year. Both ADF and NDF values of 1, 2, 3, 4, 5 and 11 numbered genotypes were higher than overall means. The highest ADF and NDF values were Bafra location (16.78 and 36.01 %), followed by Samsun and Amasya locations (15.63 and 33.89 %, 14.98 and 33.21), respectively (Table 2). ADF and NDF values in the first year (17.38 and 35.71 %) were also higher than that of the first year (14.22 and 33.06 %), respectively. NDF content of oat may be in excess of 30 % of dry matter similarly, ADF comprises 10 to 15% of oat grain (National Research Council, 2001). Ash content of genotypes averaged over all locations ranged from 2.43 % for genotype G13, to 2.90 % for genotype G4; the overall mean was 2.64 (Table 3). The highest ash content was Bafra location (2.96 %), followed by Samsun and Amasya (2.49 and 2.48 %, respectively) (Table 3). Ash content in the first year (3.12 %) was also higher than that of the second year (2.17 %). Owing to the valuable fatty acid composition of oat grain fat, the oat has a high nutritional potential. Oat genotypes usually include more fat than other small cereal grains. In this study, fat concentration in oat genotypes varied between 5.50 to 6.83 %, the overall mean was 6.26 %. Ash content in the first year (6.41 %) was also higher than that of the first year (6.11 %) (Table 3). Mut et al. (2016b) reported that fat concentration ranged from 5.86 to 8.47 % in twenty-five oat genotypes. In a study of more than 4000 oat genotypes, the fat content of the genotypes ranged from 3.1 to 11.6 % (Martinez et al., 2010). Linoleic acid content of the genotypes varied between 35.20 % (G6) and 38.98 % (G13), oleic acid content varied between 37.15 (G3) and 41.30 % (G6), palmitic acid content varied between 17.54 % (G1) and 19.26% (G14), stearic acid content varied between 2.53 % (G1) and 2.76% (G13) and linolenic acid content varied between 1.23 (G14) and 1.46% (G3). Linoleic, palmitic and stearic acids were found to be higher in the Amasya location while oleic and linolenic acids were higher in the Samsun location. Linoleic, palmitic and stearic acids in the first year (36.77, 21.05 and 2.77 %) were also higher than that of the second year (36.51, 16.69 and 2.59 %), respectively. acid profile of oat is quite remarkable for both human and animal nutrition. Oleic and linoleic acid contents designate oil quality and final use of the products (Özcan et al., 2006). High oleic and linoleic acid contents were also reported by Zhou et al. (1999).

Conclusions

There were significant differences in grain yield, test weight, groat percentage, starch, protein, β-glucan, ADF, NDF ash and fat contents among different oat genotypes, years and locations. Also, fatty acids were significantly different from genotypes, locations and years. According to the combined results of location and years, G8 (4.65 kg ha^{-1}) numbered genotype had the highest grain yield. In addition, this variety was found above the overall mean in terms of quality traits such as protein, groat percentage, starch, and β-glucan contents.

THE EFFECT OF DIFFERENT SOWING DATES AND SOWING DENSITIES ON GRAIN YIELD AND SOME YIELD COMPONENTS OF DIYAR-95 CHICKPEA VARIETY UNDER DRY CONDITIONS IN DIYARBAKIR (TURKEY)

Zubeyir TURK

Dicle University, Agricultural Vocational High School, Diyarbakır, Turkey
*Corresponding author: zubeyirturk@gmail.com

Abstract

This study was carried out to determine the effect of different sowing date and sowing density on the yield and yield components of chickpea during 1995-96 and 1996-97 growing seasons in Diyarbakır rainfed conditions (Turkey). In the experiment, Diyar-95 chickpea variety was used, and it was sown at five sowing times (15 November, 15 December, 15 January, 15 February and 15 March) and five sowing densities (22.2, 27.7, 33.3, 38.8, 44.4 plant m^{-2}). The result of this study indicated that the grain yield was significantly influenced by the different sowing dates and sowing densities. According to average two years grain yield changed from 1092 to 2193 kg ha^{-1} with respect to sowing date. The highest grain yield was observed in 15-th December sowing date (2193 kg ha^{-1}), whereas the lowest grain yield was observed in 15-th March sowing date (1092 kg ha^{-1}). The grain yield varied with the different sowing density. According to average two years grain yield changed from 1464 to 1997 kg ha^{-1} with respect to the different sowing density. The highest grain yield was obtained with the most density (44.4 plants m^{-2}), whereas the lowest grain yield was obtained with the most widely space (22.2 plants m^{-2}).

Keywords: *Cicer arietinum L., Sowing Date, Sowing Density, Yield, Yield Components.*

Introduction

The chickpea grain is of great importance in human nutrition due to its high percent and valuable protein content. In protein content of chickpea are found valuable aminoacids for human nutrition such as, leucine, lysine, isoleucine, phenylalanine, threonine. Protein content of chickpea genotypes can be ranged from 16.4% to 31.2% depending on genotypes, growing techniques and environmental conditions (Beech, 1977, Sehirali, 1988). Also chickpea has importance in terms of reducing fallow lands in plant rotation systems in dry conditions. Thanks to its short growing season and its resistance against drought, high temperatures, poor soil conditions and the other adverse conditions (Eser, 1978). Due to these superior properties, the chickpea is shown among the important crops that can be grown organically in the region as well (Cetinkaya et al 2013).

Chickpea (*Cicerarietinum* L.) is the second most important edible legume plant in the world. And, it is grown worldwide inat least 33 countries, including South Asia, West Asia-North Africa (WANA) region, East Africa, Southern Europe, South America and Australia. Percentage of chickpea cultivation area and production amount in edible legume plant of the world account for 14.8% (10.2 million Ha) 13.4% (7.9 million tonnes) respectively (Singh and Saxena, 1996). Annually, 429.132 tons chickpea crop is produced in Turkey in 347.337hectares land size. Average chickpea grain yield in the country is 1260 kg ha^{-1}. Southeastern Anatolia Region of Turkey, including Diyarbakır province, is shown among the places of Motherland of Kabuli type, coarse grained, chickpeas. However, average chickpea yield in the region is higher than the average yield of the country, 1460 ha^{-1}. Currently, chickpea cultivation area is 32.494 hectares, and its production is 44.609 tons in the region (Anonymous, 2016).

In the region generally chickpea is grown for human nutritionby using kabuli type, yet in some places of the region desi type chickpea, with black seed coat, is grown for using in animal nutrition (Sayar, 2014).Chickpea is cultivated without using any fertilization and irrigation in the Southeastern Anatolia region, Moreover, as a legume species, chickpea contributes to increased nitrogen content in the soil for subsequent crops in crop rotation systems.

The aim of this study was to determine effects of different 5 sowing dates (15 November, 15 December, 15 January, 15 February and 15 March) and 5 sowing densities (22.2, 27.7, 33.3, 38.8 and 44.4 plants in m^2) on the yield and yield components ofDiyar-95 chickpea variety in order to increase the productivity and prevent the waste of seed input in chickpea.

Material and Methods

This study was carried out in the experimental areas of the Southeastern Anatolia Agricultural Research Institute in Diyarbakır (Turkey) for two years in 1995-96 and 1996-97. In the experiment, “Diyar-95” chickpea variety was used. In this study, the effect of five different sowing dates (15 November, 15 December, 15 January, 15 February and 15 March) and five different sowing density (22.2, 27.7, 33.3, 38.8 and 44.4 plants in m^2) on yield and the yield properties of Diyar-95 chickpea variety were investigated.

Soil and Climatic Conditions of Experimental Area:

The research fields were flat, or nearly flat, with very little erosion, with a deep or relatively deep soil profile. According to the soil analysis, the experimental area soils had a clay loam texture, and were red-brown in color. The soils were rich in terms of calcium and potassium contents, whereas organic matter and phosphorus contents of soil were poor.

Continental climate prevails in the experimental area, where summers are dry and hot and winters are moderately cool and rainy. The total rainfall amount for long years average was 496.8 mm. On the other hand, it was recorded as 557.8 mm and 343.3 mm for 1995-96 and 1996-97 growing seasons respectively. Mean relative humidity values varied between 82-38% in the first year and 86-26% in the second year, respectively, and the relative humidity ratios of the two years were higher than those of the long years average (77-24%). The average temperature in the first year of the experiment was recorded as 15.5 °C and the average temperature in the second year was 15.9 °C. The average temperature for long years was 15.9 °C. As can be understood from this, the average temperature for the test years has been similar to the average temperature for many years.

Experimental Design

The trial was set up according to Split Plots Trial Design with four replications. In the experiments, sowing times were located in the main parcels and sowing frequency were located in the sub-parcels. Each plot consisted of 5 rows 5 m in length with 30 cm spacing between rows. So each plot size was 7.5 m^2 (5 row x 5 m x 0.30 m = 7.5 m^2). In taking experimental data, a half-meter at the beginning and end of each plot, side rows were neglected to avoid edge effects. And the evaluations were made over the area of 4 m x 0.9 m = 3.6 m^2. 25 kg of N and 60 kg of P_2O_5 as Diammonium Phosphate fertilizer together with the planting were given. As the parcels got thicker, they were harvested by hand.

Investigated Traits

The plant yield (g), plant height (cm), height of first pod (cm), were investigated. The investigated traits were determined according to Tosun and Eser, (1975).

Statistical Analysis

The values obtained from the study were subjected to variance analysis in the MSTAT-C statistical package program according to the "Split Plots Trial Design”, the differences between means were compared using the least significant difference (LSD) test at the 0.05 probability level.

Results and Discussion

Average values of grain yield (kg ha^{-1}), plant height (cm) and first pod height (cm) obtained from different sowing time and sowing densities, LSD values (%) and CV values (%) are given in Table 1 and Table 2.

Grain yield (kg ha^{-1})

Wheneffect of sowing time and sowing density was examined on the grain yield trait in Table 1, highly significant ($P<0.01$) differences were found among sowing dates and sowing densities of each year separately, and among the two years averages. As expected, grain yield determined from sowing dates generally were found higher, when sowing date was made earlier. However, the highest grain yield was obtained in the first year from three earlier sowing dates, 15 November, 15 December, 15 January, and it was obtained in second year and the two year average from the first two sowing dates, 15 November, 15 December. In accordance with our findings, Dennis (1980), Haddad (1983) and Bennet and Mcneil (1985) reported that early sowing dates extends the vegetative period of chickpea, and this leds to obtaining higher grain yield from chickpea genotypes. On the contrary, Chowdhury et al (1982), Kaiser and Hannan (1985), Arvadia and Patel (1990) reported that they found insignificant differences for grain yield among sowing dates in chickpea. The views are in conflict with our results. This probably stemmed from differences among the environmental conditions and the used genotypes.

For all of the planting times, the grain yield of the first year was found higher than those of second year (Table 1). This probably caused by from differences of precipitation amount among the growing years. Precipitation amount in the first year was higher than from second year rainfall amount. And this caused obtaining higher grain yield in first year. On the other hand, anthracnose disease occurred during the first year due to excessive rainfall and this prevented the grain yield from increasing at the first sowing date. With late sowing dates adverse effect of anthracnose disease on chickpea decreased in first year. In the second year, although the seed yield dropped from the first sowing date, the grain yield in the first year began to fall after the second sowing date.

The most grain yields were obtained from the highest densely (44.4 plants m^{-2}) sowing treatment in the two years and the two year average. And, as plant density declined, linearly grain yield of chickpea was decreased. In other words, in the both years, grain yield increased regularly as the planting density increased (Table 1). Similarly, many researchers cited that grain yield of chickpea were increased, with increasing plant density (Bascur, 1980; Singh, 1981; Photiodes, 1984; Abdul-Aziz, 1990; Aydın, 1988; Sarawgi et al., 1990; Yadav et al., 1990).

Plant Height (cm)

Wheneffect of sowing time and sowing density in chickpea for plant height trait was examined on Table 1, highly significant ($P<0.01$) differences were determined among sowing dates and sowing densities of each year separately, and among the two years averages in terms of plant height. The highest plant height was recorded from the earliest sowing date, 15 November, in first year, second year and the two years average respectively as; 62.35 cm; 49.90 cm and 56.13 cm. Similarly, the lowest plant height was determined in the latest sowing date, 15 March, for first, second year and the two years average respectively as; 43.05 cm; 37.00 cm and 40.03 cm. Similar findings reported by Poma et al. (1983) and Photiodes

(1984). They reported that plant height of chickpea genotypes were longer in early and winter sowings due to longer vegetation period in the sowings.

In the study positive relation was observed between plant height and plant sowing density. In the first year, second year and the two years average the highest plant height were recorded in the densely sowing treatment, (44.4 plants m^{-2}). The highest plant heights were determined as 55.85 cm, 46.55 for first year and second year respectively. The lowest plant heights were recorded in the sparsest sowings, (22.2 plants m^{-2}) both in the first (51.30 cm) and in second (42.10 cm) year. Our findings confirmed by findings of Hussain (1980), Kamel et al. (1980) and Aydın (1988). They reported that in densely sown plants, plant have higher plant heights, this is due to the competition among the plants to reach the sunlight. On the other hand, Tosun and Eser (1975) and Hadjichristodoulou (1984) expressed opposing views on this matter. They reported that effect of sowing density hadn't on the plant height. Contrary; plant height mostly affected by the climatic and soil conditions and plant genetic trait.

First Pod Height (cm)

An analysis of variance revealed that sowing date effect on first pod heights of the chickpea variety were highly statistically significant (P<0.01) for both of the years and the two years mean. On the other hand, effect of sowing densities on first pod heights of chickpea variety varied from sowing date effect. Even though sowing density effect on first pod heights of chickpea was found insignificant (P>0.05) in the first year, the effect were found were highly statistically significant (P<0.01) in the second year and the two year averages (Table 2). The first pod height of the chickpea variety ranged from 23.70 cm to 32.70 cm among the sowing dates in the growing years. The highest first pod heights were recorded in the early sowing dates, 15 November, 15 December, in both of the years, whereas the lowest first pod heights were determined in the late sowing, 15 March, for the two years.

Plant first pod heights of the chickpea variety ranged from 23.35 cm to 30.95 cm among the sowing densities in the growing years. Additionally, the highest first pod heights recorded in the most densely sowing, 44.4 plants m^{-2} for the two years. The lowest first pod heights were determined at the sparsest sowings, (22.2 plants m^{-2} for the two growing years. In accordance our findings, researchers reported that densely sowings negatively affected the plants to reach sunlight, which affect the photosynthesis capacity of plants. As the number of plants in the unit area in this direction increases, it can be said that the first pod height increases due to the light insufficiency in photosynthesis even if the plant has sufficient water and nutrients in the medium (Hussain, 1980; Kamel et al., 1980). On the other hand, the findings of Tosun and Eser (1975) and Hadjichristodoulou (1984) indicated that the planting density does not have a significant effect on the first pod height indicates that the first pod height is influenced by climatic and soil conditions as well as the genetic characteristics of the pod.

Table 2. Effect different sowing dates and sowing densities on first pod height (cm) of chickpea

Application	First Pod Height (cm)					
	I. Year		II. Year		Two-Year Average

Conclusions

Results of the study showed that different sowing dates and sowing densities were highly effective on grain yield, plant height and first pod height traits of Diyar-95 chickpea variety. Accordingly, it was observed that when plant sowing date delayed and used seed amount per unit area in sowings is decreased, grain yield, plant height and first pod height falled in the chickpea variety. Therefore, when decided to grow chickpea in ecological conditions of Southeastern Anatolia Region, winter (autumn) sowing date and 44.4 plant m^2 plant density can be recommended.

Abstract

This investigation was carried out to study of some agronomic characters (plant height, first pod height, 1000-seed weight andgrain yield) and estimate genetic variability parameters for the studied traits of chickpea.The study was carried out as randomized block design with four replications in the research area of GAP International Agricultural Research and Training Centerin Diyarbakir, during 2000, 2001 and 2002 growing seasons. In the study, eighteen chickpea advanced lines provided from ICARDA and two control cultivar (Diyar-95 and ILC-482) were used. According to the average of three years, plant height ranged from 45.3 to 56.6 cm, this character was exhibited high heritability (0.90). The mean first pod height of chickpea genotypes ranged from 24.2 to 34.5 cm, this character showed high heritability (0.85). The mean 1000 seed weight of chickpea genotypes ranged from 264.1 to 354.9 g, the 1000 seed weight showed high heritability (0.89). The grain yieldvaried from 1316.0 to 1851.0 kg ha^{-1}, itshowed moderate heritability (0.52).The study showed that some parameters(plant height and thousant grain weingt) can be use as selection criteria in Chickpea, because of high heriability values.

Keywords: *Cicer arietinum,Genetic Variability, Yield, Traits.*

Introduction

Chickpea (Cicer arietinum L.) is an annual, selfpollinated, diploid (2n=16) grain legume crop grown in a wide range of environments including the Mediterranean, South and West Asia, North America, and North and East Africa (Singh and Saxena, 1999). Vavilov (1926) recognised the Mediterranean, Central Asian, Near Eastern, Indian and Ethiopia as the probable centres of origin (diversity) of the chickpea. Turkey and India are two major centers of diversity.

Chickpea is valued for its nutritive seeds with high protein content, 25.3-28.9 %, after de-hulling (Hulse, 1991). The basic information on heritability of various plant-parameters, along with genetic advance, are needed to decide about the breeding-strategy for development of appropriate genotypes.Chickpea has high variation for various qualitative and quantitative characters that can help breeders to release better and superior lines and varieties (Dasgupta *et al.*, 1987; Singh, 1997). For maintenance and efficient utilization of germplasm, it is important to investigate the extent of genetic variability and its magnitude for the determination of the success of a breeding programme (Smith *et al.*,1991).The presence of genetic variability is of utmost importance for any breeding program and for that reason the plant breeders have emphasized the evaluation and characterization of germplasm for the improvement of crop yield (Virmani *et al.*, 1983; Bakhsh *et al.*, 1992) as well as for selection of core collection for utilization in breeding programs. Thus the evaluation of germplasm is not only useful in selection of core collection but also for its utilization in breeding programmes.An initial step in a breeding program is the assembly of germplasm with a wide range of genetic variability. The utility of a germplasm collection would be enhanced if the unique features of each genotype were to be describedand recorded, so that the researcher could choose those genotypes in the collection, which have the genetic characteristics, desired for his specific objectives (Shah, 1999).Ali *et al.* (2008) found high broad sense heritability coupled with high genetic advance for plant height and grain yield. The average yield of this crop is generally low, because of drought, susceptibility to disease and low yield potential of varieties. For improvement of this crop, knowledge on variability and heritability of various plant-parameters, along with genetic advance, is needed to decide about the breeding strategy for development of appropriate genotypes.

The aim of this study was to identify variability and heritability estimates of economically important grain yield and some important yield components in chickpea.

Materials and Methods

The experiment was carried out in rainfall conditions at the GAP International Agricultural Research and Training Center's trial field in Diyarbakir, Turkey, during 2000, 2001 and 2002 growing seasons. Soil of experimental area was clay loam and 2.03% organic matter and with pH 7.9. Eighteen genotypes of chickpea which provided from ICARDA and two control cultivar (Diyar-95 and ILC-482) were used in this study.

The design of experiment was a randomized complete block design with four replications. Each of the 20 genotypes were sown in four rows plots, 4 m long. Row spacing was 0.45 m. The trials utilized 4 m x 4 rows x 0.45 m = 7.2 m^2 plots. Plants in the middle 2.7 m^2 of the plots were harvested at full maturity depending on the experiment. The sowing was carried out on March 01, February 02 and January 24 in 2000, 2001 and 2002 respectively.Fertilizer was applied basally at rate of 25 kg N and 60 kg P_2O_5 ha^{-1} at sowing time(Minhas *et al.*, 1987).Genotypes were evaluated for quantitative traits including plant height (cm), first pod height (cm), 1000 seed weight (g) and grain yield (kg ha^{-1}).

The data were analyzed, through computer software MSTAT-C, for the analysis of variance (Steel and Torrie,1960).Differences among means were separated according to LSD's Multiple Range Test. For all of the statistical analyses we used the procedures of Duzgunes*et al*. (1987) at 5 and 1% probability levels.The genotypic and phenotypic coefficient of variation and heritability were calculated as suggested by Comstock *et al*., (1963).

Results and Discussion

A combined analysis of variance on 20 chickpea genotypes over three years is given Table 1. The means of the studied plant height (cm), first pod height (cm), 1000 seed weight (gr) and grain yield (kgha^{-1}) characters of the chickpea genotypes and LSD groups showing the differences among means (means of three years) are shown in Table 2.Estimated of variances components and heritability of some characters on 20 chickpea genotypes over three years are given in Table 3.

Plant Height (cm)

Differences among genotypes and years with respect to plant height were significant. The genotype x year interaction was no significant; this result revealed that environmental effect with respect to this character was no significant(Table 1).

The means of genotypes for plant height trait ranged from 45.20 to 56.60cm. Whereas the tallest plant height was recorded from F97-28C with 56.60, the shortest plant height was recorded from ILC-482, F97-221C, F97-123C as 45.3, 45.3 and 45.2 respectively (Table 2). Previously; ranging of plant height trait for chickpea genotypes were reported by researchers from 29.5 cm to 67.67 cm (Turk, 1999; Akhtar *et al.* 2011, Khan *et al.*2011). The difference in plant height may be attributed to genetic and climatic factors.

Plant height was exhibited high heritability with 0.90 (Table 3). It was found that the effect of phenotypic was higher than that of genotypic for this character. Khan *et al.* (2011), Saleem *et al*. (2008), Durga *et al*. (2007), Hakim *et al*. (2006), Ghafoor *et al*. (2004) found similar results and observed high heritability in chickpea for plant height. High estimates of heritability of the traits under study could be due to the greater genetic variability of the germplasm.

First Pod Height (cm)

Differences among genotypes and years with respect to first pod height were significant. The genotype x year interaction was significant; this result revealed that environmental effect with respect to this character was significant(Table 1).

The means of genotypes for first pod height trait ranged from 24.2 to 34.5 cm. Whereas the tallest first pod height was recorded from F97-28C, the shortest first pod height was recorded from F97-221C (Table 2). Similar findings were reported by Turk, (1999) and Turk *et al.* (1999). Furthermore, Yucel et al (2006) reported a high first pod height as 54.2 cm.The difference in first pod height may be attributed to genetic and climatic factors.

First pod height was exhibited high heritability with 0.85 (Table 3). It was found that the effect of phenotypic was higher than that of genotypic for this character.High estimates of heritability of the traits under study could be due to the greater genetic variability of the germplasm.

1000 Seed Weight (g)

Differences among genotypes and years with respect to 1000 seed weight were significant. The genotype x year interaction was no significant; this result revealed that environmental effect with respect to this character was no significant (Table 1).

The means of genotypes for 1000 seed weight trait ranged from 264.10 to 354.90 g. Whereas the highest 1000 seed weight was recorded from Diyar-95 cultivar, the lowest 1000 seed weight was recorded from ILC-482 (Table 2). Previously; ranging of 1000 seed weight trait for chickpea genotypes were reported by researchers from 130 to 390g (Khan *et al.* 2011,Yucel *et al* 2006, Akhtar *et al.* 2011).

This character showed high heritability with 0.89 (Table 3); this finding indicated that both effect of phenotypic and genotypic was significant on this character. The differences between genotypic and phenotypic coefficient of variability was very small indicating negligible role of environment. The results are in accordance with the findings of Iqbal *et al.* (1994). Khan *et al.* (2011), Saleem *et al*. (2008), Durga *et al*. (2007), Hakim *et al*. (2006), Ghafoor *et al*. (2004) found similar results and observed high heritability in chickpea for 1000 seed weight.High estimates of heritability of the traits under study could be due to the greater genetic variability of the germplasm.

Grain Yield (kg ha^{-1})

Differences among genotypes and years with respect to grain yield were significant. Genotype x year interaction was significant; this result indicated that grain yield affected not only by environment but yield performance of genotypes is important (Table 1).

The means of genotypes for grain yield trait ranged from 1316.00 to 1851.00 kg ha^{-1}. Whereas the highest grain yield was recorded from Diyar-95 cultivar, the lowest grain yieldwas recorded from ILC-482 (Table 2). Previously; ranging of grain yield trait for chickpea genotypes were reported by researchers from 495 to 2396 kg ha^{-1} (Akhtar *et al.* 2011, Turk, 1999, Turk *et al.*1999).

This character showed moderate heritability with 0.52 (Table 3). Khan *et al.* (2011), Saleem *et al*. (2008), Durga *et al*. (2007), Hakim *et al*. (2006), Ghafoor *et al*. (2004) found similar results and observed high heritability in chickpea yield plant^{-1}.

Variance	Plant Height	First Pod Height	1000 Seed Weight	Grain Yield
Genotype	10.18	4.76	302.29	78.24
Genotype x Year	0.69	1.10	19.29	118.17
Phenotype	11.25	5.58	337.06	151.87
Heritability	0.90	0.85	0.89	0.52

Conclusion

The present study concluded that there is a great amount of genetic diversity in the germplasm studied. Majority of traits revealed high heritability and low level of differences among PCV and GCV which indicate less environmental influence on these traits and showed that genotypes had more influential role in the expression of these traits. This suggests a great chance of genetic improvements of these traits in chickpea. Thus the variability found in the germplasm could be utilized successfully in different breeding programs for the betterment of existing genotypes and for the development of desirable genotypes through hybridization.

Abstract

Hexaconazole has been so far reported to show several properties in plant growth regulations. This study was conducted to evaluate the enhancement of hexaconazole on the growth, yield and quality of three purple sweet potato varieties (*Ipomoea batatas* (L.) Lam.) in Mekong Delta. The experiment layout was randomized completely block design, in factorial arrangement with three replications. Three purple sweet potato varieties used in the experiment were HL491 from Vietnam and two varieties imported from Japan (Lord) and Malaysia. Hexaconazole of 0, 10, 15, and 100 mg/L (farmers' practice) were spayed at 40, 55, and 70 days after planting (DAP). The results showed that the fresh vine biomass/m^2 and the anthocyanin content of the HL491 variety were the highest, but the number of marketable tuberous roots and total tuberous yield were lower than the two imported varieties. Hexaconazole application inhibited some agronomical characteristics such as the total leaf area, internodal and leaf petiole length at 60 DAP and reduced the fresh vine biomass (kg/m^2) at harvest. The highest marketable tuberous quantity, 21 tuberous roots/m^2, was achieved when spraying hexaconazole at 15 mg/L while the marketable tuberous yield and anthocyanin content were 26 tons/ha and 16.2 mg/100g fresh weight (FW) equivalent to CGE, respectively. These values were higher than those counterparts of the control: 15 tuberous roots/m^2; 8.05 tons/ha and 13.4 mg CGE/100 g FW.

Key words: *anthocyanin, hexaconazole, Ipomoea batatas (L.) Lam., tuberous quality, tuberous yield.*

Introduction

In Vietnam, sweet potato is a very important agricultural products and the area for cultivating it has been increasing in recent days with nearly 150 thousands of hectares in the year 2011 (Faostat, 2012). In the year 2015, Mekong Delta area accounted for about 15% of planted area and nearly 35% of sweet potato production in Vietnam (General statistics office of Viet Nam, 2016). Among some sweet potato varieties, purple sweet potato (PSP) variety HL491 is the most popular variety in this region. Purple sweet potato has large amount of flavonoids and anthocyanins which have antioxidant and radical-scavenging activity (Steed and Truong, 2008). A lot of experimental results indicated that nutrient can also affect the yield and the quality of tuberous roots of some sweet potato varieties; besides, some plant growth regulators could improve the yield and the athocyanins in many tuber crops (Jaleel *et al.*, 2007; Johnson *et al.*, 2008). According to Fletcher *et al.* (2000), hexaconazole, belongs triazole group of fungicides, has plant growth regulating properties. It has been widely accepted that hexaconazole has a strong influence on tuberous root growth and it may affect to produce a better quality, for example, protein, amino acid, the sucrose, carotenoids and starch contents of a tuberous root such as cassava, sweet potatoes... (Gomathinayagam *et al.*, 2008; Sivakumar *et al.*, 2009). Jaleel *et al.* (2007) found that, the application of triazole fungicides may be a useful tool to increase the tuber quality in yam plants by enhancing the accumulation of proline and total phenols in tubers. Similar results were reported by Gomathinayagam *et al.* (2008) that using 20 mg L^{-1} triadimefon and 15mg L^{-1} hexaconazole solution per plant on 25, 45, 65 and 100 days after planting (DAP) by soil drenching enhanced the chlorophyll, carotenoid, and anthocyanin contents of tapioca. Therefore, the objective of this study was designed to clarify the effect of hexaconazole on the growth, yield and quality of three purple sweet potato varieties (*Ipomoea batatas* (L.) Lam.) in Mekong Delta.

Materials and methods

The effect of hexaconazole application on three purple sweet potato (PSP) varieties was studied during the cropping season from 7/2016 to 11/2016 in the experiment field at Thanh Loi ward, Binh Tan district, Vinh Long province in Mekong Delta, Vietnam. The soil of the experimental field used was alluvial soil. Its agrochemical properties of top soil (0-20 cm depth) were: a pH (water:soil, 1:2.5) of 6,19, total N of 0.154%, total P of 0.09%, K exchangeable bases of 0.228 meq/100g, calcium exchangeable bases of 11.35 meq/100g and organic matter of 2.49%.

The experiment was laid out as a Randomized Complete Block Design (RCBD) in a factorial arrangement with three replications. The treatments consisted of three purple sweet potato varieties (PSP HL491 from Vietnam and two varieties imported from Japan and Malaysia (PSP Lord and PSP Malaysia)) combined with four hexaconazole application levels: 0, 10, 15, and 100 mg/L (as farmers' practice). There were 45 experimental units. The treatments were assigned to each plot randomly. Each was 5 m^2 of 5 m in length, 0.7 m in width and 0.3 m in space between plots. Plant density was 150.000 cutting plants/ha. Each plot had three rows, and 25 cutting vines (with sprout) of each variety which are 30 cm in length with 5-7 stem nodes were transplanted per row. Hexaconazole [2- (2, 4- dichlorophenyl)-(1 *H*-1,2,4-triazol-1-yl)-2-hexanol] ($C_{14}H_{17}Cl_2N_3O$) has been obtained from Hexaconazole PESTANAL® (Sigma Aldrich, 99,3%). The hexaconazole applications were sprayed at 40, 55, and 70 DAP. One liter of hexaconazole solution was used for each treatment per plot and one liter of irrigation water was treated for control at one time. The fertilizer was applied five times in the experiment at 1 day before planting, 7 DAP, 30 DAP, 60 DAP, 85 DAP and 110 DAP. Nitrogen (Urea 46%N), phosphorus (single super phosphate 18% P_2O_5) and potassium (KCl) at the rates of 100 kg N/ha, 80 kg P_2O_5/ha and 200 kg K_2O/ha were used for the plots. We didn't use systemic pesticide or fungicide during the experiment.

Three plants per plot from each treatment were collected randomly at 30, 60, 90 and 120 DAP for determining some growth parameters: the stem length (was measured from the soil level to the tip of the main shoot and expressed in cm), number of branches and fully developed leaves per each main stem (were counted and expressed as number per each plant). Five fully developed leaves (from the fifth node to ninth node) were chosen for measuring the total leaf area (expressed in cm^2 per plant by Leaf area metter, Japan), internodal length, stem diameter and leaf petiole length (by measuring the average length of five internodal stems and five leaf petioles).

Harvesting was done about 150 days after transplanting. All of the plots were harvested and analyzed the yield components: fresh weight of vines/m^2, number of marketable tuberous roots, total and marketable tuberous yield (whole tubers weighing at least 50 g). Storage roots were washed and cut fine before determining dry matter weight (were dried at 55^oC in hot air oven until the weight unchanged) and analyzed some quality characters: crude starch and total sugar was determined as glucose by colorimetric method (Dubois *et al.*, 1956), total anthocyanins was estimated by a pH differential method (Moor *et al.*, 2005).

Statistical analysis: statistical analysis was performed using one way analysis of variance (ANOVA) followed by Duncan's multiple range tests (at P< 0.05) and regression analysis were performed by using the SPSS program.

Results and discussion

Some growth characteristics of three PSP varieties were quiet resemblance at 30 DAP (Table 1). However, there was highly significant effect of hexaconazole upon the agronomical characteristics from 60 DAP. The mean values of the internodal length of three varieties treated with some hexaconazole treatments were lower than that of control values at 60, 90 and 120 DAP (Fig. 1).

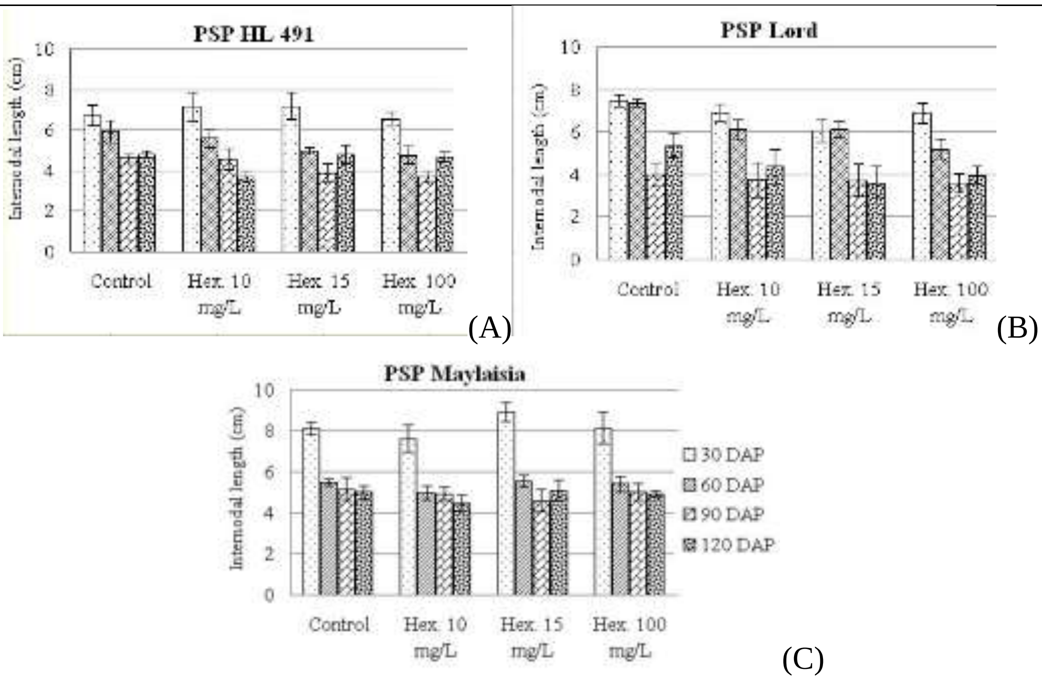

Fig. 1: Effect of hexaconazole on internodal length of three PSP varieties (PSP HL 491 (A), PSP Lord (B) and PSP Malaysia (C)) on different growth stages (DAP)

The leaf petiole length was highest at the early stage (30 DAP) and it gradually declined up to 120 DAP as shown in the Fig.2. During the period of tuber maturation (about 40 – 90 DAP), the agronomical characteristics such as shoot growth, stem length, number of branches, fully developed leaves, total leaf area, internodal length, stem diameter and leaf petiole length of all of the treatments declined (Fig.1, Fig. 2 and the data not shown).
This result confirms the results that were reported that hexaconazole inhibited some of the anatomical characteristics of plants including the retardation shoot growth, inhibition of gibberellins biosynthesis and enhancement of cytokinin and abscisic acid, increase the thickness of leaf, reduced stem elongation and plant height in some plants... (Fletcher *et al.*, 2000; Sivakumar *et al.*, 2010).

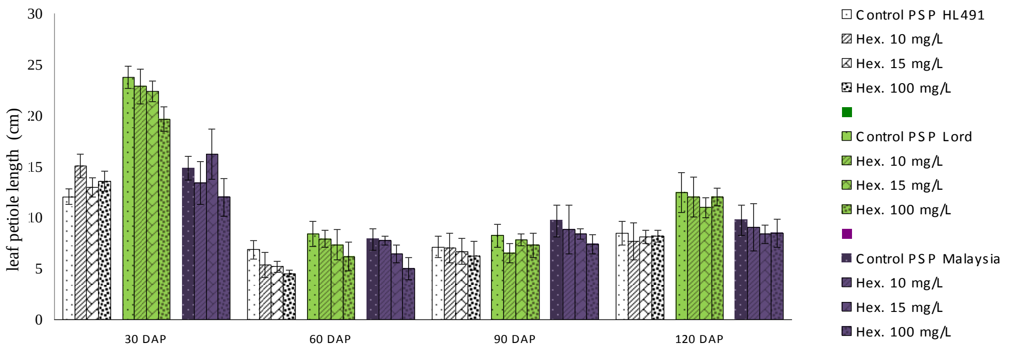

Fig. 2: Effect of hexaconazole (Hex.) on leaf petiole length of three PSP varieties (PSP HL 491 (white), PSP Lord (green) and PSP Malaysia (purple)) on different growth stages (DAP)

At harvest time, the highest fresh vine biomass was recorded from the variety PSP HL491 and it was 1.81 kg/m^2. The fresh vine biomass reduced under treatments with hexaconazole at 15 and 100 mg/L when compared to control treatment (Table 2). In three PSP varieties, PSP Malaysia had significantly higher number of unmarketable and marketable tuberous roots as well as marketable and total tuberous yield than the other varieties. The marketable tuberous yield of PSP Malaysia could reach to over 25 tons/ha while the others just reached 15.6 tons/ha (PSP HL491) and 17.7 tons/ha (PSP Lord).

Table 2: Effect of hexaconazole on some storage parameters of three PSP varieties at harvest time

From Table 2, the hexaconazole treatments could increase all of storage parameters recorded in this experiment. The more increase of number of roots was prominent in spraying hexaconazole at 10 and 15 mg/L and they were more than 20 roots when compared to control with under 20 roots. The highest marketable tuberous quantity, 21 tuberous roots/m^2, was achieved when spraying hexaconazole at 15 mg/L. Because of the higher number of roots, the application of hexaconazole at the concentration of 10, 15 and 100 mg/L could increase the yield over the zero application at harvest with the yield ranged from 21.5 to 26.0 tons/ha. There were highly significant effects of hexaconazole upon tuberous root yield. The result showed that, yield increased generally in three PSP varieties with different hexaconazole applications. Among the hexaconazole treatments, application of hexaconazole at 15 mg/L produced the highest marketable and total tuberous yield with 26 tons/ha and 31.6 tons/ha respectively over the control treatment. Some authors found that the cytokinin content induced by triazole may be the reason for increasing root growth because cytokinins are broadly used to induce bulb formation. A reduction in shoot growth related to the increase of root production so increase the yield (Fletcher *et al.*, 2000; Gomathinayagam *et al.*, 2008; Jaleel *et al.*, 2007; Sivakumar *et al.*, 2010).

The data presented in Table 3 are the results of some quality contents of tuberous roots at harvest time. In the field experiment involving four hexaconazole application concentrations, there was no significant variation in some quality characters of each PSP variety (Table 3). There was a slight increase in dry weight content from 36,5 to 37,5% over the control as a result of some hexaconaxole applications recorded from the PSP Lord variation but the dry weight of the other varieties were unchanged with the affection of hexaconazole (Table 3).

In terms of total sugar content, there was the interaction between three varieties and four hexaconazole applications. The total sugar contents when applying hexaconazole at 100 mg/L of PSP Lord and PSP Malaysia were higher than recorded from PSP HL 491. The crude starch content of PSP Lord and PSP Malaysia tended higher than the crude starch content of the control treatment of PSP HL 491, but there was no significant variation in comparison to the other hexaconazole applications of PSP HL 491. Without hexaconazole supply, the crude starch of PSP Lord was highly significantly lower than that of tuberous roots in hexaconazole supplied plots (Table 3). According to Jaleel *et al*. (2008) and Gomathinayagam *et al*. (2007), the higher chlorophyll content in the leaves, leading to higher photosynthesis might have increased total dry weight in affection of triazoles.

It can be seen from the Table 3 that the variation HL 491 contained the highest anthocyanin content. The anthocyanin contents of PSP HL491 variety tended to increase when spraying hexaconazole at 15 and 100 mg/L with the anthocyanin contents achieved over 25 mg CGE/100 g FW. This is in accordance with the previous reports that triazole compounds could increase the contents of anthocyanin, carotenoid, dry weight, total phenol of bean, yam, tapioca, sweet potatoes (Jaleel *et al*., 2007; Gomathinayagam *et al*., 2008; Sivakumar *et al*., 2009).

Conclusion

This research showed that hexaconazole application inhibited some agronomical characteristics during the time of tuberous root performance (from 40 to 90 DAP). Spraying hexaconazole at 40, 55, and 70 DAP improved the number of roots as well as the tuberous root yield of three PSP varieties. PSP Malaysia proved superior over the other varieties in improving the tuberous yield. Application hexaconazole could increase the dry weight of PSP Lord. Using the application of hexaconazole at 15 mg/L appeared appropriate for optimum yield in our study area. This concentration could also enhance the dry weight of PSP Lord, the crude starch and anthocyanin content of PSP HL 491. It is suggested that hexaconazole at 15 mg/L concentration could be used on these PSP varieties in Mekong Delta.

Abstract

Autochthonous cultures are an asset in the conservation, evaluation and use of native genetic resources. Especially for olive culture, where some of the native cultivars are regionalized and occupy entire masses, in thousands of acres, in areas different species of Albania, others are at risk of extinction due to genetic erosion. Many autochthonous olive populations retain special values that remain potential for exploitation by scientific research. These in general represent interest in research, biological, genetic and productive, to highlight their values. But its use, among other things, is related to the accelerated growth of forms that are of interest to either direct sowing or in the function of genetic improvement. This requires, among other things, the solution of some problems related to the addition, especially the use of phyto-hormones related to the rooting of vegetative fragments, in particular the use of IBA (Indole Butyric Acid). The use of plant hormones, which significantly increases the percentage of rooting and significantly shorten the time needed for the production of seedlings, provides healthy seedlings from phyto-sanitary side, etc. In the study are included 10 autochthonous cultivars which are the most widespread in Albania. The pieces obtained were treated with 4000 ppm solution of IBA (Indole Butyric Acid). These pieces are held in IBA (Indole Butyric Acid) solution for 5 seconds, 10 seconds, 15 seconds, and 20 seconds.

Key words: *cultivars, indole butyric acid, phyto-hormones, treatment, position*

Introduction

The production of olive seedlings is implemented in various forms: generative and vegetative forms. Olive vegetative multiplication is accomplished with new methods. The fastest production of olive shoots and the highest yield is achieved by the rooting method with indole butyric acid (IBA). This method has been the subject of study and seedlings production and is being presented in this article. For over 20 years, over 40,000 olive seedlings have been produced by specialist Rakip Iljazi. The plots planted with these seedlings are in wide production, successfully.

The IBA regenerator (Indole Butyric Acid) provides a greater and faster rooting of plant fragments, both sleepy and vegetation (Chiancone et al., 2012). In this framework we have undertaken a study related to the rooting of vegetative pieces, such as time of the treatment of the position of receiving the piece on the sprout, on the top, middle and on the basis of the sprout, the time of holding the piece in phyto-hormone etc. These studies are carried out for the first time in Albania, as these are done with native variants. Multiplication with leafy pieces is a modern and widespread way at the level of industrial seedlings for olive multiplication (Di Vaio et al., 2009). Consequently, the intensification of olive production is inseparably linked to the accelerated production of sowing and healthy material (Davison, 1997; Chaari et al., 2000).

Materials and Methods

In this reference two aspects related to the use of IBA (Indole Butyric Acid) for the rooting of pieces are discussed: this is the effect of the picking position on the sprouts and the holding time in the solution.
Installation of the rootstock position in the rootstock percentage (top, center, and bushes) treated with IBA 4000 ppm of the 10 variations of the site and a variation introduced (Table 1).

Table 1. Indigenous variety taken in the study

1.Kalinjot	6.Nisjoti
2. Kokërr madhi i Beratit	7.I holli i Himarës
3.I bardhi i Krujës	8.I bardhi Tiranës
4.Kripës i Elbasanit	9.Mixan
5.Ullastra	10.Leçino (var. I itroduktura).

Of the ten native autochthonous varieties were taken into one-year branches in three positions at the base, mid and top of the branch. After treatment with IBA phytonutrient with a dose of 4000 ppm the pieces were put on the rooting bar. Experiments were raised in three replications with 50 pieces taken in 50 randomly selected individuals. Experiment data is subjected to statistical variance analysis. The database has been updated accordingly.
2. Influence of holding time in the IBA solution of vegetative fragments at root rate. Cows of 10 autochthonous olive cultivars after IBA 4000 ppm solution treatment were held in solution for a time: 5 seconds, 10 seconds, 15 seconds, 20 seconds. After that, they were put on the roots. Experiments were raised for each variation in three replications with 50 pieces taken in 50 randomly selected individuals. Experiment data is subject to statistical variance analysis. The database has been updated.

Results and discussion

The results of the study of the impact of the stump position on the sprouts (tip, middle and base) in the percentage of rooting of vegetative fragments of native autochthonous cultivars.
The pieces for rooting can be in different parts of the branch, in its major part, in the middle of the branch or the base of the branch. It should be said that the emergence of adventive roots, which is at the root of the rooting capacity of a pile, is a complex phenomenon which is determined by four separate stages interdependent between them such as induction, differentiation, primordial neo-formation and emission of the roots (Chiari et al., 2000, Petrucelli et al., 2012, Ismaili, H., 2016, Rahman, N et al., 2014). Its success depends on a number of essential factors related to the vegetative state of the mother plant, the type of patch, the period of the patch preparation and the factors closely related to the effects of hormonal treatments, the temperature of the rooting ground, the intensity of the light, nebulization parameters, etc. According to Loret (2012) the rooting capacity varies between different cultivars based on the proportion of rootstocks (in the major, mid, or branch). But the variation observed in many studies does not allows above all to individualize the type of stalk that will be taken for rooting. In general, it can be assumed that, in line with vegetative growth, sub-major cuts are more susceptible to auxin treatments and have been equipped with a greater ability to root. Hartman H.Then.1975, Di Vaio C.etj. 2009. Di Vaivo, Nocerina and

Sorrentina in a 2014 study with Campanias olive cultivars observed changes where, according to them, the mid-sprouts and the tops had a higher rooting rate

But let's see how the percentage of rooting vegetative fragments of autochthonous varieties is presented, we refer to the average data of the experiments realized by us. From the data in Table 2 we note that the percentage of rooted pieces for the pieces obtained at the top of sprouts varies from 16.60 per cent to the variant of I Holli i Himarës in 90.60 of the Kalinjoti variant, with an average of 56.72 per cent. For the pieces taken from the middle of the sprout for this indicator varies from 14.60 per cent to the I Holli i Himarës variation at 82.60 per cent of the Kalinjoti variant, with an average of 55.08 percent. While for the pieces taken from the base of the branch range from 15.20 percent to the variety of I Holli i Himarës, to 80.6 percent of the Kalinjoti variety with an average of all varieties of 52.10 percent. As a conclusion, it is seen a decrease in the percentage of rooting by passing from the pieces obtained at the tip of the branch to these of the base of the branch. This is a general tendency since, if we refer to the average of all the varieties, we will see that the average of the pieces obtained at the tip of the branch has resulted 56.72%, whereas for the split pieces in the middle of the branch is 55.08% and the pieces obtained on the basis of the branch is 52.10%.

Table 2. Average data of the percentage of rooted vegetative fragments of 10 olive varieties. Pieces taken to the top, middle and base of the shoot after treatment with IBA 4000ppm.

Nr	Cultivars	Taken to the top, middle and base of the shoot		
		top	midle	base
1	Kalinjoti	90.6	82.6	80.6
2	KM Beratit	36	34	32
3	I bardhi i Krujes	38	35.4	32
4	Kripsi Elbasanit	52.6	50	48

10	Leçino	82	80.6	78
Average		56.72	55.08	52.1

Source of information: The experiment results

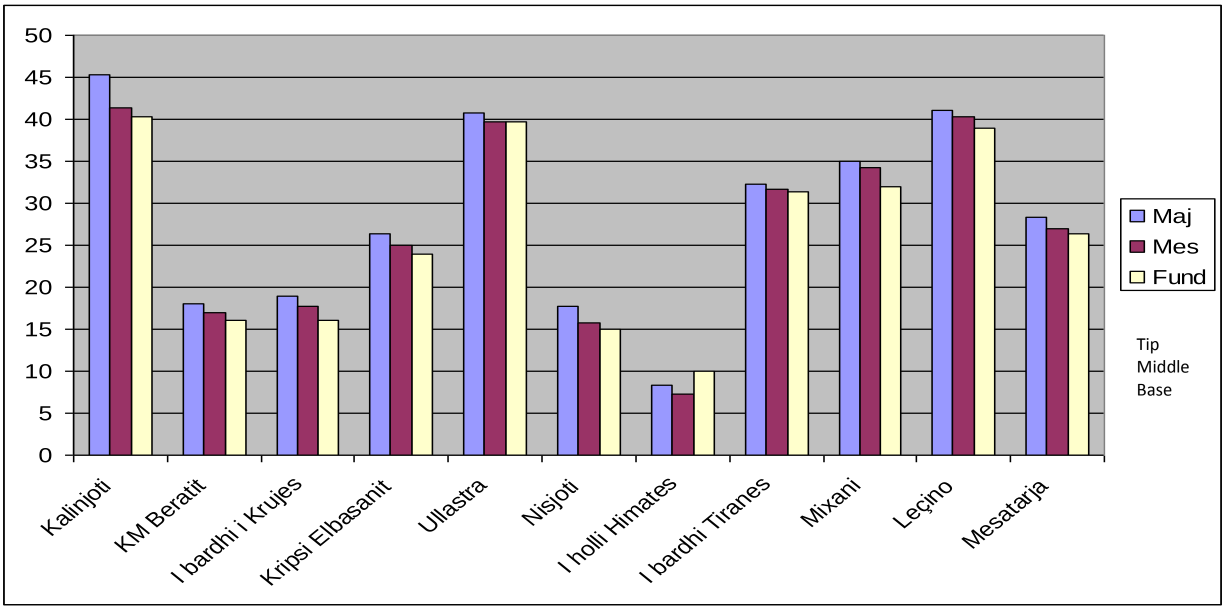

Figure 2**.** Graphical representation of the average number of roots, of the 10 olive varieties obtained (top, middle, and spinal base) after treatment with IBA 4000ppm.

Table 3 shows the variance analysis of the rootstocks data of 10 olive varieties obtained from the tip, the middle and the base of the seedlings after treatment with IBA 4000 ppm.
From the variance analysis data it can be seen that the variation on the percentage of vegetative rooting is significant for the variation coming from the varieties, and that from the position of the pieces picking to the spike is occasional.

Table 3: The variation analysis

Variation Source	**Square Sum**	Df*	**Mean Square**	**F. actual**	*P-value*	*F-kritike*
Cultivars	15908.86	9	1767.651	820.2134	1.20E-21	2.4563

Error	38.792	18	2.1551			
Total varation	16052.06	29				

*Df = Degree of freedom ** Significative at a level of 1% of probability (p < .01) * Significative at a level of 5% of probability (.01 =< p < .05) ns Non-significative (p >= .05)

In addition, two-factor analysis of the variance and interaction of the two variance factors and the position of receiving the part at their rooting was presented in Table 2. From the data of this table we see that the interaction between the factor variance and the position of the piece taken in the catch is random, that is not the same in all varieties.

Conclusions

From the experiment data regarding the picking position in the shoots performed in 10 olive varieties from which 9 local varieties and one introduced we reach the following conclusions: The mean rooting percentage of the pieces obtained in tip, middle and the base of the sprout after treatment with phyto-hormone indicates the highest ability in the major part, which comes down to the base of the sprout. This phenomenon is generally the case for studied addictions.
From the experimental data regarding the time of 10 olive cultivation solutions, differences between cultivators treated in terms of rooted pieces percentage are observed. The cultivar that provides a higher percentage of rooting is the cultivar Kalinjoti and the lower the I Holli i Himarës.
Data derived from these experiments can be used by specialized olive-seed producers when dealing with multiplication of these stages.

Abstract

The purpose of the present research is to study the significance and impact of factors: *variety* and *treatment options*, and their interaction on the structural elements of *Enola* and *Illico* common wheat varieties. For this purpose, an experiment was conducted in the period 2014-2016 in the training experimental field of Trakia University, Faculty of Agriculture, Stara Zagora, Bulgaria. The experiment was performed by the method of fraction plots, with a crop plot size of 10 m^2. It included two varieties of common wheat: *Enola* and *Illico*. The applied liquid fertilizer Lactifrost and Lactofol are special leaf fertilizers rich in macro and trace elements. The following test options were: 1. Control - zero fertilization; 2. Fertilization with N_{14}; 3. Fertilization with N_{14} + Lacticfrost; 4. Fertilization with N_{14} + Lacticfrost + Lactofol base; 5. Fertilization with N_{14} + Lactofol base. Foliar treatment was conducted in the morning hours at doses of Lactifrost - l/da and Lactofol base - 0.5 l/da. Results of a two-factor dispersion analysis proved that A factor - *variety* had a dominant impact on *ear grains weight* indicator in 2014. It was statistically proven at $p \leq 0.001$. The lowest and mathematically unproven was B factor - *treatment options* and the interaction of both factors. The individual effect of the studied factors is much more expressed at the formation of the structural indicator for the examined wheat varieties.

Keywords: *Common wheat, yield, foliar fertilizers, ANOVA, Bulgaria.*

Introduction

In the age of general globalization, agriculture must increase the yield of farming production because of the increasing demand and the reduced offer of food products. Yields increase can be obtained by agriculture intensification and soil fertility increase. One of the agro-technical measures leading to the increase of soil fertility is the application of fertilization with micro and macro-fertilizers. All fertility enhancers should be given a certain nutrient balance in the soil.

Yields, as well as their structural elements, are strongly influenced by the year conditions and the variety plasticity, Georgieva and co. (2004). Late germination leads to the formation of a smaller number of ear-bearing stems for the conditions of the Upper-Trakia Plain. Climate anomalies reduce the coefficient of productive tillering. The main agrotechnical factors for the formation of biological and economic characteristics of 14 winter common wheat varieties are the annual weather conditions. The main factors for grain`s yield is the norm of the mineral fertilization, according to Ivanova and co. (2009). Some authors` research shows that yield quantity is closely related to the variety, the level of applied agro-technology, and the soil and climatic conditions of the region (Cenov et all. 2009). Fertilization is a determining factor for obtaining high grain yields in the absence of another limiting factor, according to Gastol and Lemaize (2002). The unilateral application of mineral fertilizers leads to disturbance in the ecological equilibrium and lower production quality, according to Brzozowska I. (2008). An experiment has been conducted to study the effect of leaf zinc supply combined with nitrogen or phosphorus. It has been

established the element's availability in the grain at different levels of nitrogen supply (Meng et al., 2015).
The natural fertility of soils is not sufficient to ensure high and stable wheat yields. The main fertilization and foliar fertilization during the vegetation aim to obtain the maximum realization of the crop productive capacities and high quality production. Quality depends on the choice of variety and the applied cultivation technology. Qualitative indicators are external, physical, chemical, biochemical, technological, etc. It is important to explore and to distribute properly the nutrient macro and microelements, to create a strategy for yields increase without affecting nutritional qualities (Daniel and I. Ortiz-Monasterio, 2003, Ivanova, 2007, Yanchev, and K Ivanov, 2012; Valkova, E., 2015). The purpose of the present research is to study the significance and impact of the factors: A – “*variety”*and, B – “*treatment options”*, and their interaction (AxB) on the structural elements of *Enola* and *Illico* common wheat varieties.

Material and Methods

For this purpose, an experiment was conducted in the period 2014-2016 in the training experimental field of Trakia University, Faculty of Agriculture, Stara Zagora, Bulgaria. The experiment was performed by the method of fraction plots, with a crop plot size of 10 m^2. It included two varieties of common wheat: *Enola* and *Illico*. *Enola* is an early variety that is present in the official Bulgarian list of varieties. It is a fiery variety with red grains. Its advantages are: wide environmental plasticity, good cold resistance, tolerance to drought. *Illico* variety is implemented by Syngenta in Bulgaria. The introduced variety is a medium-sized, early-grain variety with large grains. It is well adapted due to its high plasticity in terms of climatic conditions; it gives high and stable grain yields (Dospatliev et al., 2015; Stoyanova et al., 2016). The Lafifrost and Lactofol base foliar fertilizers are the main specialized fertilizers of the company EcoFol. The applied liquid fertilizer Lactifrost and Lactofol base are special leaf fertilizers rich in macro and trace elements (table 1). The two formulations also contain physiologically active organic substances and natural binders.

Table 1. Composition of applied foliar fertilizers

Composition of the applied foliar fertilizers									
Foliar fertilizer	gram liter^{-1}				mg liter^{-1}				
	N*	P_2O_5	K_2O	SO_3	B	Cu	Mn	Mo	Zn
Lactofol base	101	29.4	50.9	1.36	305	203	226	23	452
Lactiftfrost	13.8	42.4	37.9	2.12	477	106	106	2120	64
* NO_3-N + NH_4-N + NH_2-N (g l^{-1}): 22.6 and 13.8 + 11.3 and 6.4 + 67.8 + 0, for Lactofol and Lactiftfrost, respectively									

The following test options were: 1. Control - zero fertilization; 2. Fertilization with N_{14}; 3. Fertilization with N_{14} + Lacticfrost; 4. Fertilization with N_{14} + Lacticfrost + Lactofol base; 5. Fertilization with N_{14} + Lactofol base. Foliar treatment was conducted in the morning hours at doses of Lactifrost - l/da and Lactofol base - 0.5 l/da.

Table 2. Organic and mineral content in the soil horizon 0-60 cm

Indicators	pH (KCi)	Humus %	Mineral nitrogen mg/1000g soil	N-NH_4, mg/1000g soil	N-NO_3, mg/100g soil	Assimilate P, mg/ 100g soil	Assimilate K, mg/ 100g soil
Experimental values	5.73	3.93	40.78	0.45	40.33	3.27	34.17

Soil conditions are of primary importance for wheat growth: the environment in which wheat develops its root system and draws the necessary nutrients. The experimental field is characterized with a typical meadow cinnamon soil. The profile power is 103-105 cm, with well-formed horizons. The humus horizon is clearly expressed and has a range of 0-50 cm. The mechanical composition of the soil is sandy-clayey. Conservation of organic and mineral substances in the soil layer 0-30 cm is presented in Table 2. Soil in the region is slightly acidic. It is medium with humus - 3.93%. Soil is medium supplied with mineral nitrogen - 40.78 mg/1000g, weakly supplied with active phosphorus - 3.27 mg/1000g and well supplied with absorptive potassium - 34.17 mg/1000g. The amount of mineral nitrogen (NH_4 + NO_3) was determined by the Parnas-Wagner apparatus; the mobile P_2O_5 by the spectrophotometric method, and the mobile K_2O-atomic absorption assay. The sowing was conducted in the optimum period for the region from 10 to 25 October. During the field survey, all the agro-technical requirements for a standard wheat breeding technology in Bulgaria were covered.
The mathematical processing of the results was performed by two-factor dispersion analysis (ANOVA).

Results and Discussion

When taking into account the climate, the region of the experimental field refers to the European continental climate region, the Trans-Continental Sub-region, which includes the area of Eastern Central Bulgaria and the Trakia Plain. Stara Planina Mountain from the north and the Rhodope Mountain range from the south affect the climatic conditions and protect from winds. The winter season is relatively mild and warm.
Taking into account the meteorological factors, the field experiment years are characterized with significant differences in the measured average daily temperatures by months compared to the multiannual period (1930-2014). The experimental field altitude is 160 m. The terrain slope is flat, with an incline of 3%.

Table 3. Meteorological characteristics, by months, for the period of common wheat vegetation, 2013-2016 for the region of St. Zagora

2015/2016	12.9	10.3	3.7	-0.1	7.8	8.8	14.6	16.2	23.0
1930/2014	*13.3*	*7.5*	*3.0*	*1.9*	*3.1*	*6.4*	*12.0*	*17.1*	*21.0*
1961/1990	12,9	7,4	2,9	1,7	3,1	6,5	12,0	17,1	20,7

The period of wheat growth was characterized by the three experimental years with uneven distribution of precipitation (Table 3). In March 2014, there was a peak in rainfall of 133.7 mm. Sufficient moisture storage with easily accessible moisture provided optimal crop growth conditions that year and compensated for the rainfall in February. Temperature values did not have large deviations from the average, measured during the period 1930-2014. In the third year of experience, low average daily temperatures were recorded in January (-0.1 C^o). Wheat survived successfully throughout the study period.

A two-factor dispersion analysis was performed to evaluate the significance and power of influence of the factors: A-variety, B-treatment variants and their interaction (AxB) on the structural elements of *Enola* and *Iliko* wheat. The obtained experimental data was processed statistically by MS Excel computer software. Impact evaluation of the factors was calculated with the Plocksky method (Lakin, 1990). It is defined as part of the intergroup variation in the overall variation. The squares sums were calculated by the formula: where - is the squares sum of the factor x, - the total sum of the squares (SS). The dispersion analysis for the impact of the factors: *variety*, *treatment options* and their interaction are presented in Tables 4, 5, 6, 7 and 8. The objective of the two-factor dispersion analysis is to assess the significance and the impact of the factors *variety*, *treatment options* and their interaction on the biometric indicators of the studied common wheat varieties. This is the reason that the presented analysis was made for two distinct years with different rainfall and temperatures. The climatic features of each region leads the selection of cultivated varieties. In each experimental year, with 20 varieties of soft wheat Samodova (2008), it was proven the impact of climate change and the coincidence of the phases of plant development with the current climate conditions. The dispersion assays for the influence of factors: A – “variety”, B - "treatment variants" and their interaction (AxB) on the biometric "plant height" indicator for the varieties under consideration are shown in Table 4. In this indicator, the 48% chance factors for the variability of the feature most affected the year 2014 and 67% in 2016, followed by species varieties and treatment variants. The interaction of the two factors is less pronounced.

The *ear length* indicator is statistically proven with a very high degree of confidence ($p \leq 0.001$) is the influence of the treatment variants and the variety, with a trend indicating the stronger influence of the variety, followed by the treatment options and the interaction of the Both factors. For the *number of spikes* in the first year of the study, the influence of factor A was greatest (39%), whereas the effect of treatment (factor B) was only 8%. In 2016, the impact of factor B is greater (19%). The results of the biometric indicator *number of spikes* are quite mixed. In 2014, the influence of the variety is dominated, followed by the unexplained impact due to random factors of 27% (Table 6). In 2016, the impact of random factors prevailed by 58%, followed by treatment options with an impact strength of 19%.

For the *number of ear grains*, the power factor A (*treatment options*) is 20% and 25%, respectively, in the first and third years. The impact of the interaction of the studied factors has the same values during the two years of the field study (Table 7). For the *number of ear grains* indicator, for both years under review, the unexplained impact of accidental factors of 70% is again most strongly followed, followed by fertilization options.

The A-variety factor is more expressed with a 69% and 39% of impact strength, respectively, in 2014 and 2016, with the ear grains` weight.

Results for the parameters: *ear grains weight*, *number of grains*, *plant height*, reliable options for Factor A - *variety* were recorded, with an impact of 69% (*ear grains weight*). The treatment options were statistically unproven; the interaction of the two factors was statistically less expressed (2014).

The variety factors, treatment options and their interaction were statistically unproven: *the plant height*, *the number of grains* and *the number of ear grains*.

According to the one-way ANOVA, as well as the conducted analysis for the impact of the two factors (variety and options of treatment) separately, and their interaction, the impact on grain-yield index was statistically proven at a very high degree of reliability ($p \leq 0.001$).

Conclusions

According to the two-way analysis of variance, and considering the impact of the two factors (variety and variants of treatment) separately, and their interaction, it was statistically proven a very high degree of reliability ($p \leq 0.001$) the impact of the variety on all the indicators under consideration. "Variety" had the greatest impact on the variation of the trait factor.

1) The results of a two-factor dispersion analysis proved that A factor - *variety* has a dominant impact on the *crop grains weight* indicator in 2014, which was statistically proven at $p \leq 0.001$.

2) The lowest and mathematically unproven was B factor - *treatment options*, as well as the interaction of both factors.

3) The individual effect of the studied factors was much more expressed in the formation of the structural indicator for the examined wheat varieties.

These data should be taken into account for their cultivation under different conditions.

Abstract

The present investigation was carried out at Giza Agricultural Experiments and Research Station, Faculty of Agriculture, Cairo University, (Egypt) during the two successive seasons 2015 and 2016 to determine productivity, water use efficiency (WUE), land equivalent ratio (LER) of intercropping soybean with corn in beds as compared with solid plantings in ridges. The experiment included eighteen treatments which were the combinations between three applied irrigation water (75, 100 and 125% of the recommended one,8092m^3/ha) and six cropping systems (intercropping 50% soybean + 100% corn and 100% soybean + 100% corn on beds, solid corn and soybean as 'mixed system', traditional solid soybean and corn on ridges). The experimental design was split plot design with four replications. The data indicated that soybean seed yields per plant and per ha were affected negatively by intercropping. Increasing soybean plant density per unit area in mixed culture from 50 to 100% of soybean increased soybean yield without reduction on corn grain yield. Soybean seed yield was not affected by water treatments; meanwhile the reverse was true for corn crop. LER was not affected by applied irrigation water treatments but it was affected significantly by cropping systems. LER ranged from 1.39 to 1.52. WUE was increased with decreasing applied irrigation water from 125 to 75% of the recommended one. High population densities of the intercrops with applied 100% water achieved the highest LER and WUE and could be recommended for Egyptian farmers.

Keywords: Intercropping, Soybean, Corn, WUE, LER.

Introduction

Population growth always requires an increase in the use of available environmental resources around the world. It is considerable pressure on available environmental resources especially water that is one of the major factors in arid and semiarid regions (Zadeh and Mousavi, 1996). Moreover; the limited water resources in Egypt are most pressing factors of water issues. However, increased cropping systems to meet world demands will require an increase of 40% in the area of harvest major crops by 2030, and that the amount of water allocated to irrigation must increase correspondingly by 14% (UNESCO, 2006). Accordingly, insufficient food supply in the near future encourages intensification of the search for more productive agricultural techniques by increasing water use efficiency (WUE). Improving WUE is necessary for securing environmental sustainability of food production in semiarid areas with respect to population growth (Medrano *et al*., 2015). The current population of Egypt is 94,779,988 based on the latest United Nations estimation.

Intercropping is one of the agricultural strategies for increasing water productivity to make maximum use of soil moisture (Alizadeh, 2001). In this concern, intercropping soybean with corn was the successful example to save irrigation water (Ouda *et al.*, 2007) and increase each of land and net equivalent ratios (Metwally *et al*., 2008;Metwally *et al*., 2012).

In Egypt, there is a modern trend for growing crops on beds (100 – 140 cm width) according to population densities of field crops (wheat, corn, cotton, soybean, --etc.) to save irrigation water by about 15% compared by traditional practice on ridges 60-70 cm in width (Ouda *et al.*, 2007). Therefore, the objective of this investigation was to determine productivity, WUE and LERs of intercropping soybean with corn in beds as compared with traditional solid plantings on ridges.

Materials and Methods

A two-year study was carried out at Giza Agricultural Experiments and Research Station, Faculty of Agriculture, Cairo University, Giza, Egypt during two successive summer seasons (2015 and 2016). The main factors were three levels of applied irrigation water (6069, 8092 and 10115 m^3/ha) and six cropping systems of solid and intercropping corn and soybean. Eighteen treatments were the combinations of the previous factors (Figure 1) as follows:

Intercropping systems

Corn plants were grown in both sides of beds 140 cm width by growing two plants/hill distanced 50 cm apart, meanwhile two rows of soybean were grown in middle of the bed (2 plants/hill distanced 15 cm apart). This pattern was expressed as 50% soybean + 100% corn plants as the previous pattern (Inter1).

Inter2, as that of pattern (Inter1) but four rows of soybean were grown in middle of the bed (2 plants /hill distanced 15 cm apart. This pattern was expressed as 100% soybean + 100% corn.

2. Solid systems:

a. Solid plantings of corn and soybean on beds as mixed (140cm).

b. Traditional solid plantings of both crops on ridges (70 cm).

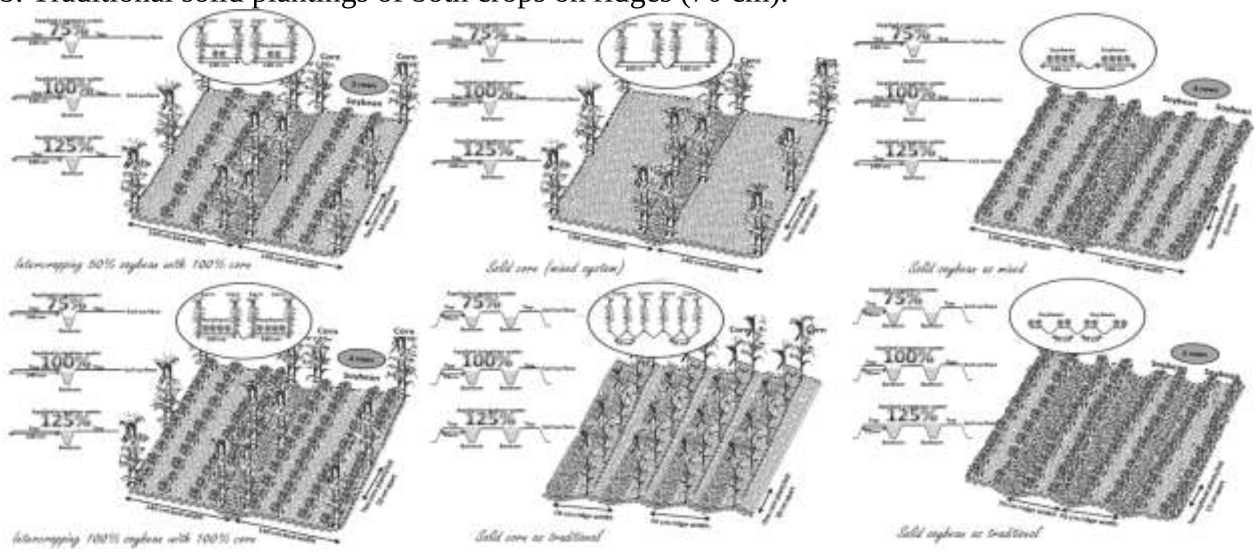

Figure 1. Intercropping soybean with corn and solid cultures of both crops.

Studied characters:

A. Corn characters:

Ten guarded corn plants were taken at random from each sub plot at harvest were taken at random from each sub plot to determine corn grain yield per plant (g).

Corn grain yield per ha (ton) were determined from grain weight of each sub plot and converted to ton per ha.

B. Soybean characters:

Ten guarded soybean plants were taken randomly from each sub plot plants at harvest were taken at random from each sub plot to determine soybean seed yield per plant (g).

Soybean seed yield per ha (ton) were determined from seed weight of each sub plot and converted to ton per ha.

C. Land equivalent ratio (LER): Land equivalent ratio (LER): It defines as the ratio of area needed under sole cropping to one of intercropping at the same management level to produce an equivalent yield (Mead and Willey, 1980). It is calculated as follows: LER = (Y_{ab} / Y_{aa}) + (Y_{ba}/ Y_{bb}); where Y_{aa} = Pure stand yield of crop a (corn), Y_{bb} = Pure stand yield of crop b (soybean), Y_{ab} = Intercrop yield of crop a (corn) and Y_{ba} = Intercrop yield of crop b (soybean).

D. Water relations: Irrigation water use efficiency (IWUE) values were calculated according to Bhattarai et al. (2006) as follow: IWUE = (Ey/ Ir). Where IWUE is irrigation water use efficiency (kg/m3), Ey is the economical yield (kg/ha) and Ir is the amount of applied irrigation water (m3).

Mean comparisons were done using least significant differences (L.S.D) method at 5 per cent level of probability to compare differences between the means (Gomez and Gomez, 1984).

Results and Discussion

Soybean seed yield:

Effect of applied irrigation water: Seed yields per plant and per ha were not affected significantly by levels of applied irrigation water (Table 1). These results could be attributed to canopy structure of soybean variety Giza 111 acclimated with the lowest applied irrigation water. In other words, shortage in applied irrigation water by 25% of recommended applied irrigation water did not reduce accumulation of dry matter in different organs of the plant during the early vegetative and development growth stages and consequently yield of the crop. These results are in accordance with those obtained by Aiken; Lamm (2012) who reported that the crop canopy shades soil and reduces evaporative water losses. Also, soybean have tap roots and tolerant to drought than corn. Increasing applied irrigation water to 25% over that of recommended applied irrigation water did not increase soybean yield. The highest applied irrigation water may have cooler canopy temperatures and retain moisture longer which increased the probability of foliage disease problems compared to others. Excessive irrigation water during the vegetative stage stimulates vegetative growth and dry matter and increase potentiality for lodging and may be increasing fungal diseases without an increase in yield (Kranz; Benham, 2003).

Effect of cropping systems: Seed yield per plant and per ha were affected significantly by cropping systems (Table 1). These differences depending on number of soybean plants per plot and shading effects by adjacent corn plants of intercropping systems. Traditional soybean solid culture had the highest values ($P \leq 0.05$) for seed yields per plant and per ha as compared to those of intercropping systems. In general, intercropping soybean with corn decreased ($P \leq 0.05$) seed yields per plant and per ha by about 47.94% and 55.76%, respectively, as compared with those of traditional solid system (Table 1). These results could be due to the adverse shading effects of adjacent corn plants which increase inter and intra-specific competition between plants as compared with those of traditional solid cultures, especially, during reproductive and seed filling stages (Metwally *et al*., 2012; Nagasuga *et al.*, 2014).

Also, soybean plants of intercropping system which have low density (Inter1-50% soy) achieved higher seed yield per plant than that of intercropping system (Inter2-100% soy); but the converse was true with soybean yield per ha. These results are in the same context of those obtained by Metwally *et al.* (2012); Abdel-Wahab; Abd El-Rahman (2016) who showed that soybean in solid planting had the highest seed yields per plant and per ha compared to those of intercropping.

The interaction between applied irrigation water levels and cropping systems did not affect significantly seed yields per plant and per ha (Table 1).

Corn grain yield

1. The highest applied irrigation water caused significant increments *($P \leq 0.05$)* in grain yields per plant and per ha as compared to those of the other treatments (Table 1). The highest applied irrigation water increased grain yields per plant and per ha by 11.82% and 14.26 %, respectively, as compared to those of the lowest applied irrigation water. this may be due to the excess irrigation water treatment (125%) enhanced efficiency of photosynthetic process of the plant especially corn which has high water requirements (Igbadun *et al*., 2008) and thereby more dry matter accumulation in the different organs of the plant.

2. Grain yields per plant and per ha were not affected significantly by cropping systems in the combined data (Table 1). These results could be attributed to corn which have high ability for acclimation more light intensity of intercropping systems (Metwally *et al*., 2012). These data suggest that corn plant had the same ability for convert more solar energy to chemical energy and more translocation of photosynthates metabolites to the ears under the studied cropping systems. These results are in agreement with those obtained by (Metwally, 1999; Undie *et al*. 2012) who indicated that intercropping soybean with corn had no significant reduction in grain yield of corn.

3. Applied irrigation water x cropping systems affected significantly grain yields per plant in the combined data (Table 1). Intercropping soybean with corn under application high level of water (125%) produced higher grain yield of corn per plant as compared with solid corn plantings. this may be attributed to wide spacing between corn plants in beds than those on traditional solid planting on ridges (70 cm). It is obvious that efficiency of photosynthetic process of the intercropped corn plant was enhanced with increasing applied irrigation water up to 125% of the recommended applied irrigation water. These results may be attributed to increase LA of the intercropped corn plant which increased surface absorbing sunlight and decreased evaporation rate from soil surface compared with the others (Andrade *et al*., 2002; Metwally *et al.*, 2012). Increasing irrigation water level from 6069 to 10115 m^3/ha had significant increments on grain yield per plant under intercropping systems more than that of traditional solid planting. Also, there were positive effects between corn plant and adjacent soybean plants due to beneficial effects of soybean residues under intercropping culture (Metwally *et al.*, 2008; El-Shamy *et al*., 2015). Accordingly, intercropping soybean with corn increased light intensity and CO_2 concentrations around corn canopy and thereby this biological situation reflected on the developing ears.

Land equivalent ratio (LER) Effect of applied irrigation water:

1. LER was not affected by levels of applied irrigation water (Figure 2). These data show that yielding ability of the intercropping was not (*$P > 0.05$*) likely to be much affected by applied irrigation water (Table 1) that contributed mainly in stability of the relative yield under intercropping with applied irrigation water.

2. LER was affected significantly by cropping systems in the combined data across the two seasons (Figure 2). Intercropping soybean with corn increased *($P \leq 0.05$)* LERs as compared to traditional solid cultures of both crops. The results showed that corn was superior in the intercrop pattern where relative yield increased; meanwhile, soybean was inferior companion crop where the relative yield was decreased in the combined analysis.

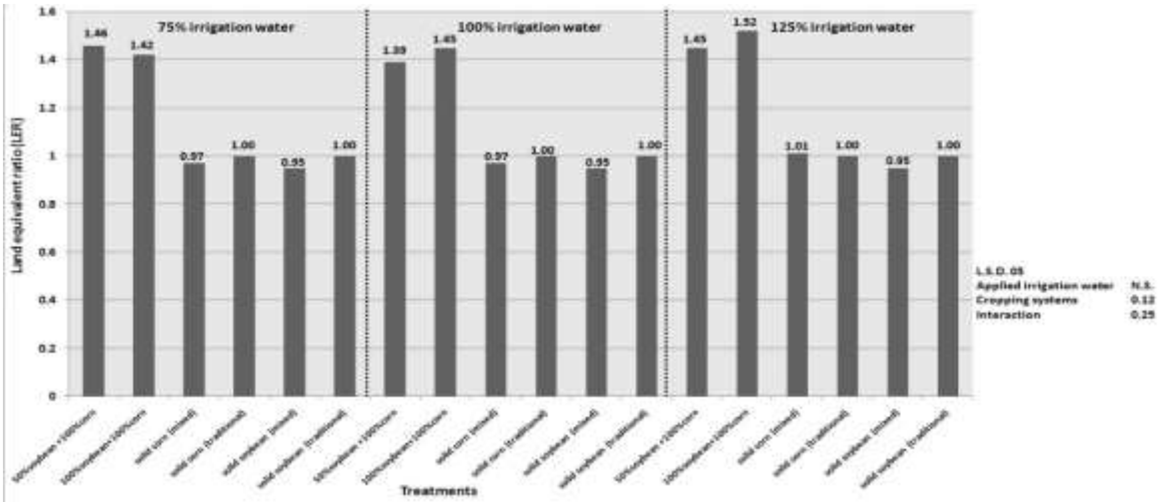

Figure 2. Effect of applied irrigation water, cropping systems and their interaction on LER, combined data across 2015 and 2016.

The advantage of the highest LER by intercropping soybean with corn over solid cultures of both crops could be due to their effects on intra-specific competition between plants of the same species for basic growth resources than those of traditional solid culture. These results are in accordance with those obtained by (Metwally *et al*. 2009) who found that intercropping patterns increased LERs as compared to solid cultures of both crops.

3. Applied irrigation water x cropping systems affected significantly LER (Figure 2). Intercropping soybean with corn (50% soybean + 100% corn) or (100% soybean + 100% corn) produced higher LER with regardless to applied irrigation water as compared with other treatments.

Water use efficiency (WUE):

1. WUE of economic yield was affected significantly by applied irrigation water, meanwhile WUE of biological yield was not affected (Figure 3). The lowest applied irrigation water caused significant increments *($P \leq 0.05$)* in WUE of economic yield as compared to those of the other treatments. However, there were no significant differences between 100% and 125% of applied irrigation water treatments. The highest applied irrigation water decreased WUE of economic yield by about 50% as compared to the lowest applied irrigation water.

2. Intercropping soybean with corn increased WUE of economic yield by 16.94% as compared to traditional solid plantings of corn (Figure 3). Also, intercropping soybean with corn increased WUE of biological yield by 9.33% as compared to traditional solid plantings of corn. With respect to intercropping patterns, increasing soybean plant density from 50% to 100% did not affect negatively WUE of economic yield (Figure 3). These results indicate that corn plants may grow larger and they may use more water and high CO_2 concentration as a result of intercropping with the C_3 plants. Despite WUE of C_4 crops often being higher than that of C_3 crops (Gowik; Westhoff, 2011), water availability still dictates the maximum yields achievable by the C_4 crop (Ings *et al*., 2013).

3. WUE of biological yield was affected significantly by the interaction between applied irrigation water and cropping systems, meanwhile WUE of economic yield was not affected (Figure 3). Intercropping soybean with corn with the application of 75% of recommended applied irrigation water achieved the highest WUE of biological yield than other solid plantings.

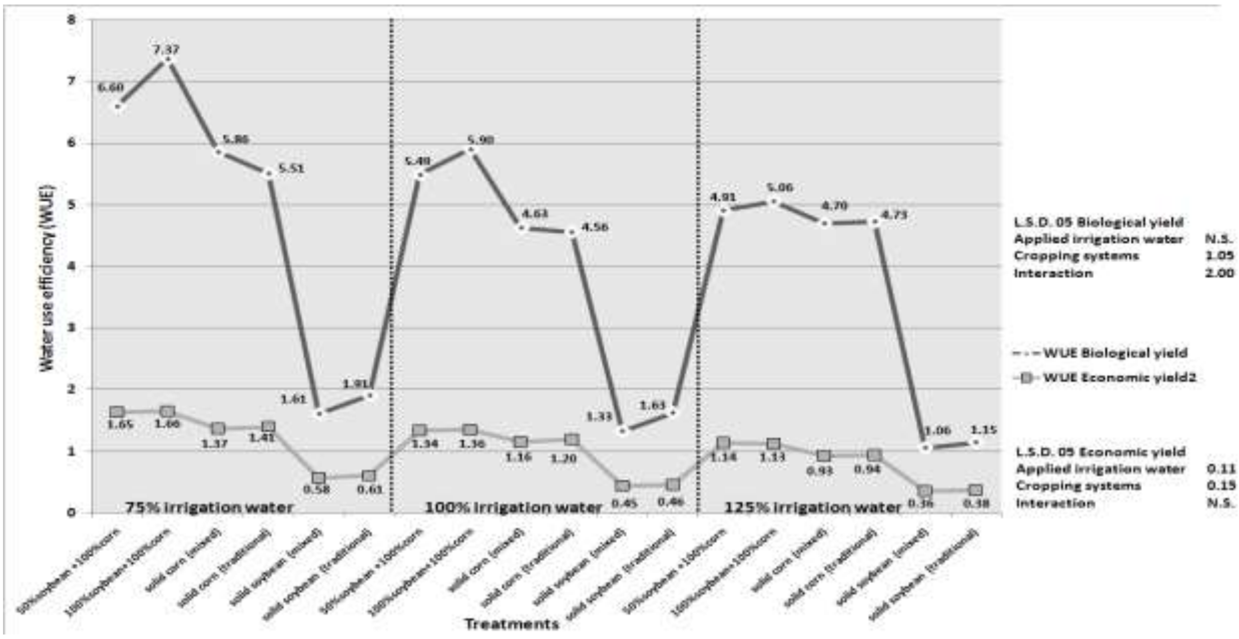

Figure 3. Effect of applied irrigation water, cropping systems and their interaction on water use efficiency (WUE), combined data across 2015 and 2016.

Table 1. Effect of applied irrigation water, cropping systems and their interactions on yield per plant and per ha for corn and soybean, (combined data across 2015 and 2016).

Cropping systems	Applied irrigation water(m^3/ha)	Soybean seed		Corn grain	
		yield/plant (g)	yield/ha (ton)	yield/plant (g)	yield/ha (ton)
Intercropping systems 50% soybean + 100% corn (Inter 1)	75% (6069)	7.6	1.14	205	6.83
	100% (8092)	9.1	1.41	215	7.36
	125% (10115)	10.4	1.36	241	7.76

L.S.D.0.05 Interaction		N.S.	N.S.	12.0	0.69

Note: * Average of solid corn and soybean

Conclusion

Productivity, land equivalent ratio (LER) and water use efficiency (WUE) were increased more under intercropping systems than those of solid ones. Also, the production of economic and biological yields, as well as, LER were increased more by increasing irrigation level of water from 75 to 125%, while the converse was true with WUE. It be concluded that applied irrigation water of 6069 and 8092 m^3/ha were suitable for economic yield under solid and intercropping cultures in beds 140 cm, respectively.

Abstract

The aim of this study was to determine variability of temperature sums for the occurrence of pheno-phases of silking, tasselling and pollination of seed maize. Nine maize inbred lines were tested in two production years. Compatibility and overlapping of silking, tasselling and pollination of parental components in a seed crop are important for achieving high yields. According to obtained data, the degree of accumulation of temperature sums was higher in the first year than in the second production year for all stages, except for the beginning of tasselling. The differences were statistically significant: the greatest and smallest differences were obtained for tasselling (t2 - 70.9^{o}C) and the beginning of silking (s1- 20.86^{o}C), respectively. The effect of genotypes on differences in temperature sums was the greatest for all pheno-phases, $p<0.005$. The effect of the production year on the number of temperature units necessary for silking and pollination was also high, but there was no high statistical effect on the beginning of tasselling. Since maize is a plant species that is grown in different regions, maize growing practices should be adjusted to the main aim of maize production, to achieving high and stable yields.

Key words: *grow degree units (GDU), maize, silking, tasselling, pollination*

Introduction

According to its morphological, physiological and other traits, maize belongs to the most variable crop. There are several classifications related to maize, and one of them is the classification according to the duration of the growing season. The decision on the introduction of vegetative groups in Europe was made as long ago as 1954 and was based on the FAO regulations with the US hybrids used as checks *(*Derieux and Bonhome, 1982*).*

The classification of maize into maturity groups, as well as, the determination of the duration of the growing season are done based on temperature sums as the most reliable method. The establishing of pheno-phases according to temperature sums has initially applied to peas (Katz, 1952), and afterwards to maize with the application of various methods for calculation of heat sums *(*Marton *et al.,* 2007). The temperature, humidity and mineral nutrition affect the length of the growing season. The information about temperature sums of developmental pheno-phases provides the appropriate planning of the production for achieving high yields. In order to get high yields in seed production it is necessary to achieve full pollination and kernel filling. The kernel number per plant and their size, i.e. their weight, determines the grain yield. The kernel number per plant is a trait that varies and is more strongly related to the yield than to the kernel size is (Peltonen-Sainio *et al.*, 2007). The kernel size has a significant role in modulating genetic and external control of the kernel number, Egli (2006).

Otegui *et al.* (1995) have established that the kernel number per plant also affected the water deficit in the period of tasselling and silking of maize.
High temperatures affect production and pollen viability. Dry and warm weather postpones the occurrence of silk and increases the number of days between tasselling and silking. According to results gained by Chassot (2000) and Stone *et al.* (1999) temperatures of soil and air are the principal physiological stress factor in the early development of maize plants.

Material and Methods

Nine maize inbred lines were used in the trail, which was set in the plots of the Maize Research Institute, Zemun Polje in the two production years (2013 and 2015). The plot size amounted to 0.09 ha. Each inbred was sown in three 50-m long rows with the inter-row distance of 70 cm. Standard growing practices for cultivating seed maize were applied during the growing season (the Regulation on control of the seed production, the content and the method of keeping records on production of seedlings of agricultural crops and the form on the report on the production of mycelia of edible and medicinal fungi, Oficial Gazette of RS 60/2006). Temperature sums were estimated based on meteorological data of the Maize Research Institute, Zemun Polje according to the GDU (Growing Degree Unit) method: mean daily temperature minus minimum maize growth rate (10^0C), extreme values below 10^0C and above 30^0C (maximum maize growth rate), were calculated as 10^0C and 30^0C (Shaw, 1975; McMaster and Wilhelm, 1997).

$$GDU = (T_{max} + T_{min}/2) - T_{base}$$

Where T_{max} is the daily maximum air temperature, T_{min} is the daily minimum air temperature and T_{base} is the minimum maize growth rate.
Based on visual observation, the dates of the beginning and ending of silking, tasselling and pollination were estimated. The first date was estimated when 5% of plants occurred in all three pheno-phases: beginning of silking (s1), beginning of tasselling (t1), and beginning of pollination (p1). The second date was when silk, tassels and anthers occurred on 100% of plants: end of pheno-phases of silking (s2), tasselling (t2) and pollination (p2).
Results were processed by the statistical program *IMB SPSS 2010*. The descriptive statistics was done for each parameter at the annual level; two factorial analysis of variance was performed to determine differences, while their significance was estimated by the t-test (Hadživuković, 1991).
Meteorological data in the trial period were equal regarding temperature sums and water regime. The average air temperatures during pollination (mid June - end of July) were approximately the same in both years of investigation (Table 1). Comparing with the official standard temperature period (1961-1990), we have an increase in temperature in both years of research, which is in line with climatic changes that move towards global warming.
Precipitation sums in 2015 were higher by 60.9 Lm^{-2} than in 2013. During pollination (June-July) precipitation sums were almost equal (31 L in June, while there were a bit more precipitation in July of 2013 - 16 L m^{-2}) (Table 1). As with temperature, changes in schedule and amount of precipitation were also determined. In the period of research, the amount of precipitation is less than the standard period (1961-1990) . The visible decrease was in the period June-July, ie at the time of the observed pheno-phases.

Table 1. Monthly values of precipitation and mean air temperature (weather station Zemun Polje)

	Monthly mean air temperature (^oC)							
Year	April	May	June	July	Aug.	Sept.	Oct	Average
2013	14.9	19.7	21.9	23.8	23.7	16.9	15.3	22.7
2015	12.9	19.1	22.1	26.4	25.7	20.2	12.4	23.1
61-90	12,3	17,1	20,0	21,7	21,3	17,6	12,4	20.4
	Monthly sum of growing degree units (GDU)							Sum
2013	147.0	300.7	357.0	427.8	424.7	207.0	164.3	2028.5
2015	87.0	282.1	363.0	508.4	486.7	306.0	74.4	2107.6
	Monthly sum of precipitation (mm)							
Year	April	May	June	July	Aug.	Sept.	Oct	Sum
2013	14.9	93.9	37.8	16.0	12.7	70.1	21.9	367.3
2015	19.7	97.8	31.1	7.2	56.0	73.6	65.1	350.5
61-90	57.6	69.3	89.3	70.0	54.3	51.3	41.0	433.0

*61-90 (1961-1990)-official standard period, GDU = (T_{max}+T_{min}/2)-T_b (extreme values below 10^0C and above 30^0C, were calculated as 10^0C and 30^0C)

Results and Discussion

Mean values of temperature sums were established over production years with the aim to observe variability of these sums. The lowest temperature sum was obtained in the first year (2013) at the time of tasselling, while the highest sum was detected also in the first year (2013) in the pheno-phase of pollination (p2) (Figure 1). In 2013, the temperature sums were higher for all pheno-phases. The exception was the beginning of tasselling in 2013, when values were a little bit lower than in 2015 (t1 in 2013 with GDU-621.23^oC, t2 in 2015 with GDU-627.73^oC). According to Çakir (2004), tasselling and ear formation were especially affected by soil water deficiency. A lower precipitation sum postponed tasselling in 2015. Tasselling (t1) expressed the greatest variability in performed trials, with the coefficient of variation of 7.04%. The smallest differences in means of coefficients of variation of temperature sums were detected in the pheno-phase of silking (s2 - CV 4.85%).

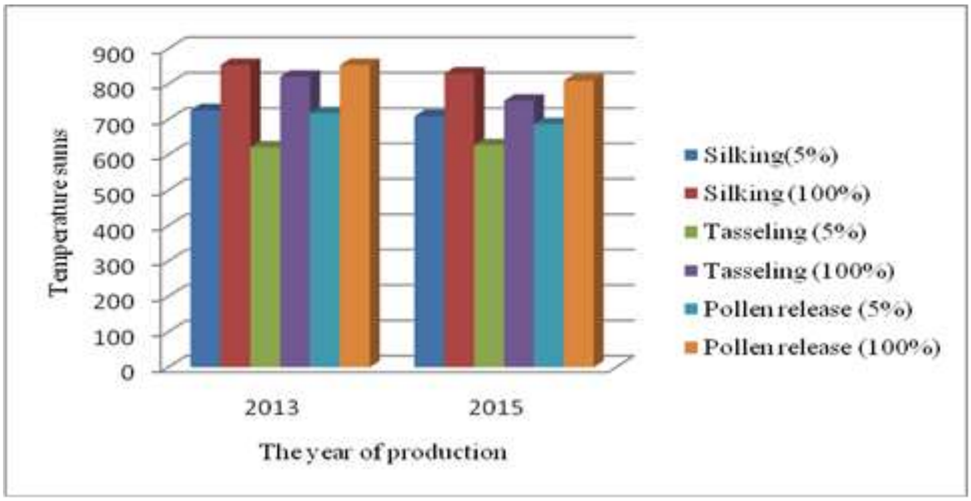

Figure 1. Temperature sums of phenol-phases over production years

According to the t-test, the differences in the time of the beginning of silking, tasselling and pollination over the two production years were significant (Table 2). The effect of the production year on the duration of the periods of silking (s2), tasselling (t2) and pollination p(2) was significant. The beginning of the stated pheno-phase differed in the two production years, but with no statistical significance. The amount and distribution of precipitation during flowering and kernel filling have a significant role in the expressing of plant potential (Bello et al., 2014).

Table 2. The t-test for the significance of differences in temperature sums over production years

	t-test for Equality of Means						
	t	df	Sig.	Mean Difference	Std. Error Difference	95% Confidence Interval of the Difference	
						Lower	Upper
s1	1.67	16.16	0.11	20.86	12.50	-5.62	47.34
s2	3.26*	27.00	0.00	35.95	11.02	13.34	58.56
m1	-0.31	27.00	0.76	-5.19	16.84	-39.74	29.35
m2	5.58*	27.00	0.00	65.78	11.78	41.61	89.95
p1	1.68	20.37	0.11	25.29	15.08	-6.12	56.70
p2	2.58*	27.00	0.02	48.48	18.79	9.94	87.03

The pollination period in maize inbreds is a very specific trait and is attributed to genotypic structure, $p<0.05$ (Table 3). Whether any particular pheno-phase will vary more or less also depends on environmental conditions. According to presented results, the production year was significant for all pheno-phases except for the beginning of tasselling. The beginning and the duration of the tasselling period were not statistically significant even in the genotype × production year interaction ($p>0.05$). On the other hand, silking and pollination depended on the interaction of both factors.

According to Kang (1998, 2004), the genotype by environment interaction implies the response of genotypes to conditions of the environment they are cultivated in. Since conditions under which the trials were carried out were similar, the effects of these two factors did not have any significant results for all studied traits.

Table 3. Two factorial analysis of variance

Source of variation	F					
	s1	s2	t1	t2	p1	p2
Genotype	35,03*	17,85*	4,06*	4,19*	3,51*	17,61*
Year	24,04*	35,82*	0,22	65,45*	5,99*	36,91*
Genotype × Year	19,82*	8,86*	0,88	2,01	1,2*	8,12*

Conclusions

The temperature sums for seed maize inbreds during the two production years similar in temperature and humidity conditions, pointed out variations in all of three observed pheno-phases. The influence of factors on occurense pheno- phasis was different which is also confirmed by coefficients of variation - the lowest (4.85%) and highest (7.04%) for silking and tasselling, respectively. Despite similar weather conditions over both production years, the year significantly affected only the beginning of tasselling (t1) $p>0.05$. It is necessary to know about the degree of variability in occurrences in stages during pollination, and conditions under which the production is planned, so the probability of incongruity between tasselling and pollination will be lower.

Since maize is a crop grown in various regions, the maize growing practices should be adjusted to conditions under which the seed production will be performed.

Abstract

Polyphenols, compounds included in the composition of plants, are products of secondary metabolism and a significant component of the cell wall structure of plants. These bioactive compounds are synthesized by plants as self-defense under conditions of oxidative stress, and studies have shown that they can be attributed to a very strong antioxidant effect. Regular use of food rich in polyphenols in human nutrition improves the general condition of the body and reduces the risk of chronic diseases such as cancer, Alzheimer's disease, heart disease. Numerous studies have been carried out on soybean seeds different color layer, as a very important plant species that is used for human consumption and as animal feed. Antioxidant capacity of soybean can be improved by treating the plant material with nonstandard fertilizers based on plant extracts and trace elements. In this study, three varieties of yellow soy Nena, ZP015 and Laura were treated with nonstandard fertilizers during two growing seasons. Total phenols, after the extraction of the plant material (milled grain) were determined by the Folin Ciocalteu method, and results were expressed as mg GAE/g d.m. (milligram equivalent of Gallic acid per gram of dry matter). Depending on the genotype and treatment values vary from 9.62 to 15.74 mg GAE/g d.m. The antioxidant activity was determined by DPPH method and the results were expressed as µmol TROLOX eq/g of dry matter. Values vary from 192.58 to 245 µmol TROLOX eq/g d.m. The total reducing capacity was determined by the FRAP assay, the results were expressed as µmol $FeSO_4$ x 7 H_2O eq/g d.m. Values vary from 83.62 to 208.61 µmol $FeSO_4$ x 7 H_2O eq/g d.m.

Key words: *polyphenols, soybean seeds, antioxidant capacity, foliar fertilizers.*

Introduction

Soybean (*Glycine max* (L) Merrill) has been known and used in the East-Asian countries for centuries, but in the last few decades it has become one of the five most widespread cultures in the world. The significance of soybean originates from extremely favorable chemical composition of the grain. The grains have protein content from 36 to 42% and oil from 15 to 23%, which makes soybean not only extremely useful, but also very economical plant species. Soybean proteins are rich in essential amino acids, which are not found in animal proteins. Soybean contains vitamin B complex, beta carotene, and minerals, mostly Ca, Fe and K, and also contains small amounts of vitamins C, D, E and K. These natural antioxidants prevent the oxidation of LDL cholesterol. The soybean seeds contain polyphenols, which are one of the largest, most widespread and biologically (physiologically and medically) most important groups of secondary plant metabolites. Phenols represent an integral part of the structure of cell walls, mainly in the form of polymeric materials (e.g. lignin), making mechanical support to plant cells and barrier to microorganisms (Wallace and Fry, 1994; Strack, 1997). Polyphenols participate in various biochemical processes related to photosynthesis, protect the plants from bacteria, fungi and viruses, as well as from mechanical damage. They are also important in the removal of oxygen radicals. The function of phenolic flavonoids, especially anthocyanins, flavones and flavonols, is also important as red, blue and purple pigments of fruits, leaves and petals of flowers (Harborne, 1994; Strack, 1997). The soybean seed contains high concentrations of phenolic compounds (Lee et al., 2011), phenolic acids and flavonoids, among them the most isoflavones. Soybean isoflavones can help reduce the risk of osteoporosis, heart disease and some types of cancer (e.g. breast, prostate, colon cancer, etc.) that are related to the level of human hormones (Potter et al., 1998). Soybean is one of the richest sources of the so-called phytoestrogens that interfere with estrogen receptors, induce the effects of true estrogen and reduce the symptoms of menopause (Potter et al., 1998). Soybean polyphenols increase the flexibility of blood vessels, lower triglyceride, reduce blood pressure (Sagara et al., 2004). Soybean is also a good source of protein and dietary fiber. The aim of this paper is to monitor changes in the total phenol content, antioxidant activity and antireducing capacity of soybean seed due to the treatment with nonstandard fertilizers.

Materials and methods

Experiments were conducted in 2013. and 2014. in field condition, in Zemun Polje (Belgrade). Three genotypes of yellow soybean Nena, Laura and ZP015 were used. In the first year of the experiment (2013), the soybean genotypes Nena and ZP015, were treated with two foliar fertilizers (Speedy-17% Mo and 1.7% Co, pH = 7.1; Wuxal Extra CoMo-16.5% Mo and 1.65% Co, pH = 5.5), and in the second year (2014) the soybean genotype Laura was treated with five foliar fertilizers: 1) Vegard- extract of some Chinese medicinal plants (1-2% C_{org}, 2-5% N_{org}, 5% humic acids, 10% fulvic acid, 1% K_2O, 1-2% amino acids); 2) Eco-Fus- algae fucus extract (*Fucus vesiculosus*), (1.8% N_{tot}; 1% P_2O_5 (water-soluble); 2% K_2O (water-soluble); 0.5% MgO; 1.8% Fe); 3) Calbit-C- plant extract (wood chips treated with H_2SO_4 and $CaCO_3$: 15% CaO (water -soluble in Ca-lignosulphonate); 4.5% C_{org}); 4) Cropmax- plant extract (sugar cane molasses and extract of other plants: 1.7% N_{tot}, 2% total amino acids, 2% C_{org}); 5) Zircon-extract of Echinacea (*Echinacea pallida*: 0,1 g/l polyphenolic acid: a) caffeic acid; b) chlorogenic and c) cichoric acid), twice in the season, initially at the beginning and during the flowering stage, in according to producers recommendation doses. After the harvest and yield assessments, soybean seeds from every genotype (100 g per treatment) were collected and stored in the freezer until analysis.

All samples were grounded and defatted in petrol ether before extraction. From each sample (0,5 g per sample) polyphenols were extracted with mixture of methanol and 10% HCl in a ratio of 85:15 v/v, for 30 minutes in ultrasound bath. Samples were centrifuged (15 min on 10 000 rpm). Compounds in supernatant are present in the soluble form ("free polyphenols"). Precipitate was subjected to alkaline hydrolysis (with 4M NaOH, 4h at 25°C), to separate polyphenols bound by ester bonds ("esterified polyphenols"). Separation of esterified polyphenols was carried out with the diethyl ether-ethyl acetate mixture (DE / EA = 1: 1). After centrifugation, DE / EA layer with isolated polyphenols is evaporated to dryness, then dissolved with 2 ml MeOH, and the lower aqueous layer is subjected to acid hydrolysis (with 6 M HCl, 30 min at 80°C), which aims to break the bonds and isolate the polyphenolic compounds bound to the cell wall structure ("bond polyphenols"). Separation of bound polyphenols was carried out with the diethyl ether-ethyl acetate mixture (DE / EA = 1: 1). After centrifugation, DE / EA layer with isolated polyphenols is evaporated to dryness, and then dissolved with 2 ml MeOH. From every fraction were analized total phenol content and antioxidant activity.

Total phenols content in grounded, defatted soybean seeds was determined by a Folin-Ciocalteu assay (Singleton and Rossi 1965; Singleton and Lamuela-Raventos 1999; Agbor et al., 2014) using gallic acid (GA) as the standard. The content of total phenols was expressed as mg GAE/g of d.m. Antioxidant activity was done by DPPH (2,2-difenyl-1-picrylhydrazyl) method of Chen and Ho (1995). The values were expressed as µmol TROLOX eq/g d.m. The FRAP (Ferric Ion Reducing Antioxidant Power Assay) was done by Benzie and Strain (1996) method. The results were expressed as µmol Fe^{2+} eq/g d.m.
Analyses were done in three repetitions and presented results represent their mean value.

Results and Discussion

The content of total phenols by fractions is shown in Figure 1. The content of the free fraction, depending on the genotype and treatment, is from 2.49 to 3.21 mg GAE / g d.m., which is in agreement with the results (Xu et al., 2007).
In genotype Laura there are small variations in the content of free polyphenols in the samples originating from treated plants compared to control. In contrast, content of the ester fraction of polyphenols in all samples originating from the treated plants is greater than that of control plants, except in the case of samples originating from plants treated with fertilizer Cropmax. In the case of content of bound polyphenol fractions do not have such regularity, except that their value is the highest in samples originating from plants treated with fertilizer Cropmax (Fig 1a).

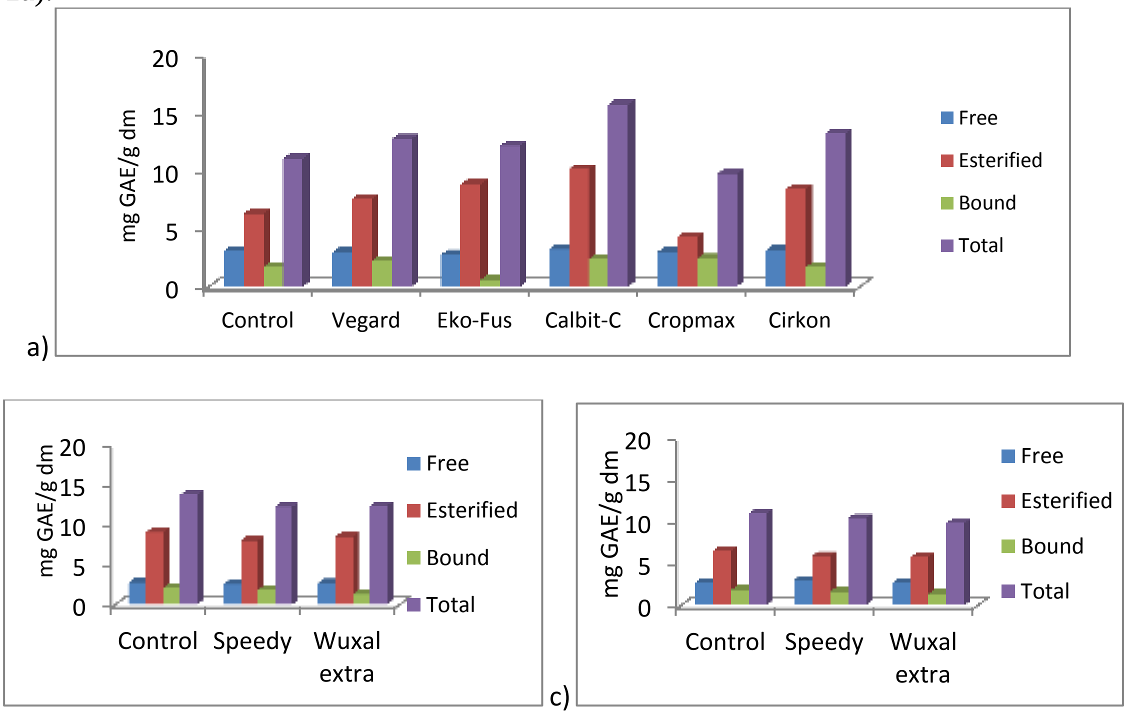

Figure 1: Content of polyphenols (mgGAE/g dm) per fractions: a) Laura, B) Nena, c) ZP 015

In total amount, content of polyphenols in all samples originating from the treated plants is greater than that of control plants, except in the case of samples originating from plants treated with fertilizer Cropmax (Fig 1a). Experiments done with plant extract and algae extract fertilizers (Kocira et al., 2016; Dragičević et al., 2015) show similar results. Depending of the treated culture, the content of polyphenols and other bioactive components can be affected by nonstandard fertilizers, but the crucial influence has genotype, climatic factors, soil type (Tawfeeq et al., 2016).

The content of total polyphenols for varieties Nena and ZP-015 is shown in Fig 1b, 1c. Although there is a certain influence of treatment with these two types of Mo-Co fertilizers, it is noticeable that the redistribution of polyphenol fractions is significantly more affected by the genotype of soybean plants.

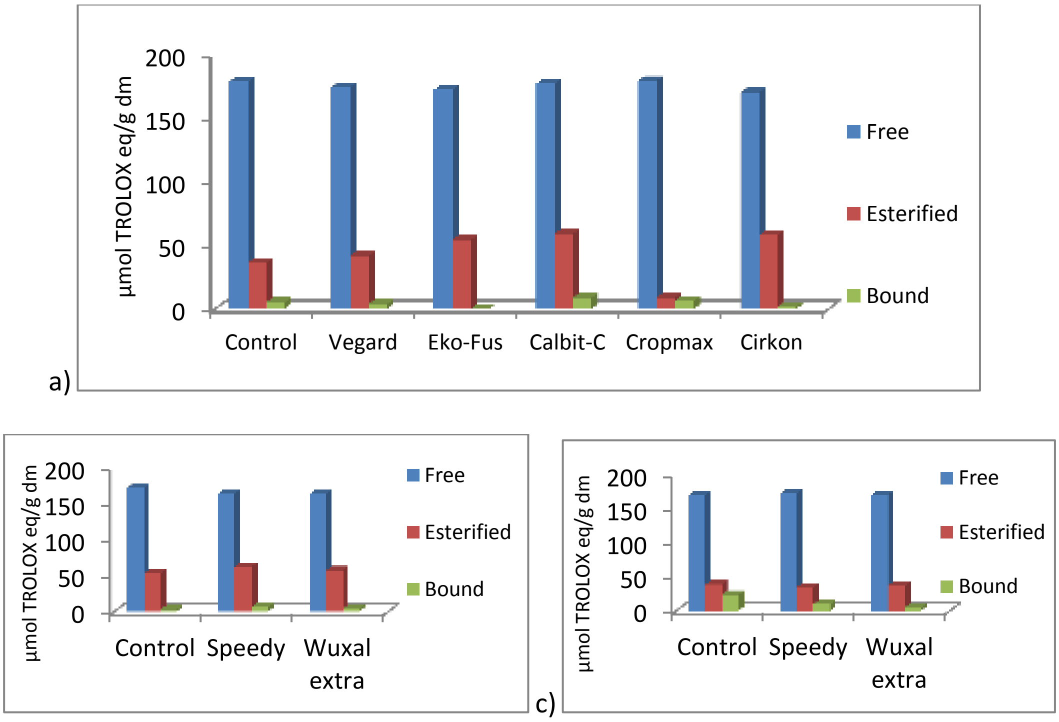

Figure 2: Antioxidant activity by DPPH (µmol TROLOX eq/g d.m.): a)Laura; b)Nena; c)ZP015

The total antioxidant activity of polyphenols via DPPH parameter, is given in Figures 2a,b and c. Results show that free polyphenol fraction most contributes to the antioxidant activity of total polyphenols, i.e. polyphenol fractions related to the vacuole (Nešković et al., 2003) contribute to the highest antioxidant activity of soybean seeds. In the soybean genotype Laura (Fig 2a), there is no regularity in treated samples, except that esterified polyphenol fraction from samples treated with fertilizer Cropmax show significantly less antioxidant activity comparing to control samples, what is consistent with the results for the total polyphenol content (Fig. 1a). In the soybean genotype Nena (Figure 2b), treatment of Mo-Co fertilizers reduces antioxidant activity of free soybean polyphenols relative to these values in control plants, while the treatment with the same fertilizers slightly increases antioxidant activity of free polyphenol fractions in genotype ZP015 (Figure 2c).
The reduction capacity via FRAP parameter, expressed in µmol equ Fe^{2+}/g d.m. is given in Figures 3a, b, c. For genotype Laura (Figure 3a) values of FRAP parameter for free polyphenol fraction are smaller in the treated samples compared to control, except in the samples originating from plants treated with fertilizer Cropmax. In contrast, the value of the FRAP parameter of esterified polyphenols of all samples originating from treated plants is similar or greater than those of control plants, except in the case of plants treated with fertilizer Cropmax. In the case of bound polyphenol fractions, there is no such regularity, except that their value is the highest in samples originating from plants treated with fertilizer Cropmax. For varieties Nena and ZP015 (Figure 3b and 3c), obtained results have no such regularity, which means that in this type of experiments with Mo-Co fertilizers on the FRAP

value, the predominant influence has a genetic factor. That is in line with results of World and Opstad (2007) and Abd El-Razek et al., (2011), but opposite from Wang and Lin (2003).

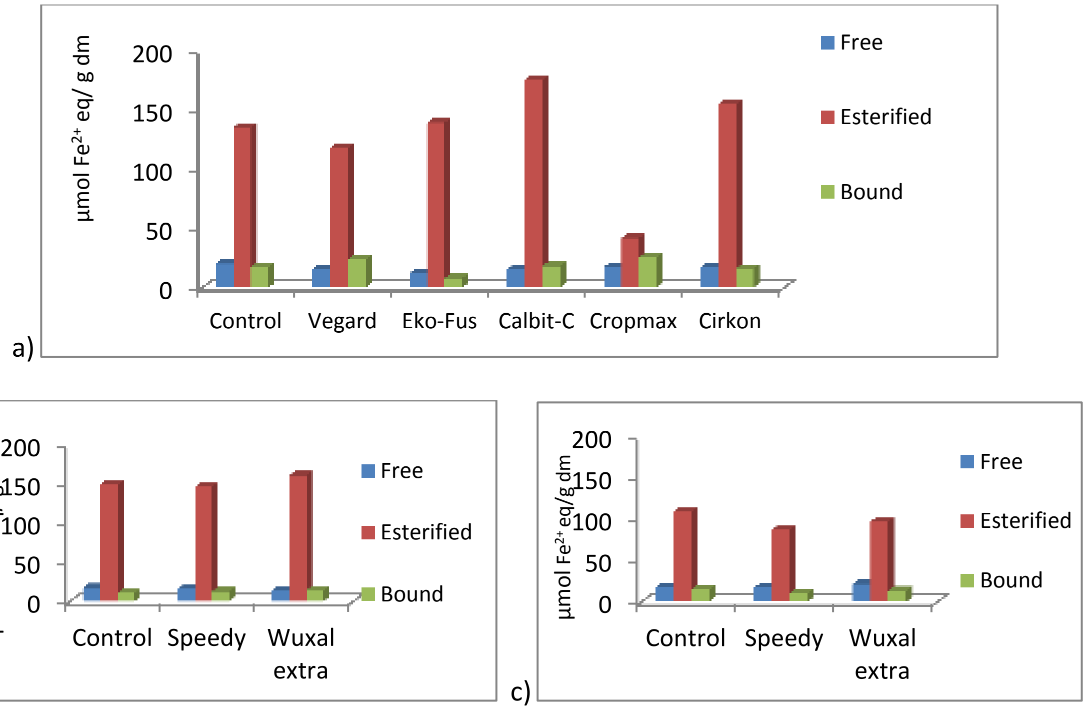

Figure 3. Reducing capacity (µmol Fe^{2+} eq/g d.m.) via FRAP parameter: a) Laura; b) Nena; c) ZP015.

Conclusions

According to the values of total phenols, DPPH and FRAP parameters we can conclude that various types of fertilizers can differently affect the amount, polyphenol distribution and antioxidant activity of soybean seeds. The results in this study show that foliar fertilizers based on plant extracts, have larger influence on polyphenol content and antioxidant activity than fertilizers based on trace elements. According to the values of control samples among different soybean genotypes, we can conclude that the soybean genotype has a greater impact than the treatment of the above mentioned fertilizers.

Abstract

Phacelia has been used for seed production and as a forage crops, either on its own or in a mix with peas or vetch to provide forage and honey production as a source of high quality nectar and pollen. The experiment was carried out in 2016, in the fields of the Institute of Field and Vegetable Crops in Bački Petrovac, in Serbia, with variety NS Priora. NS Priora had plant flowering continualy over 60 days and had high, good quality grain yield. NS Priora variety had average nitrogen content is 3.21%, protein content was 20.06% and the average thousand seeds weight was 1.42 g. Phacelia is presently very intensively used in organic agriculture and for sowing of arable land temporarily excluded from production which achieves high yields.

Keywords: *Phacelia, variety NS Priora, honey plant, seed quality, thousand seeds weight.*

Introduction

Phacelia is annual plant, native to the south western United States and northern Mexico, where it is used as a cover crop and as bee forage. There are about 200 species in the *Phacelia genera*, some perennial and some annual (Cazzola, 1987). As a commercial species *Phacelia tanacetifolia* Bent.has long been recognised by beekeepers as a preferred foraging plant for honeybees (Teittinen, 1980) with a high potential for honey yield (Orsi and Bionoi, 1987). Phacelia has also been used as a green manure crop in Europe for a number of years (Anon, 1989). When ploughed as a green manure, increases carbon and nitrogen content in soil to a depth of over 80 cm (Beckmann, 1977). The crop is also reported to have nematicidal properties (Cazzola, 1987; Anon., 1989; Booker Seeds, 1990) although it was not clear whether this is by means of a damaged crop or whether the root system was actively nematicidal. Phacelia has also been used as a forage crop, either on its own (Danial and Zobelt, 1986) or in a mix with peas or vetch to provide forage and honey production (Petkov, 1966). Phacelia has been found to have high energy and protein content, but some questions were raised about possible allele-chemical properties of the plant (Danial and Zobelt, 1986).
Excess production of basic agricultural plants determines growers to cultivate alternative crops, which become a next source of income and may enrich soil with organic matter as a green fertilizer or to feed animals in the form of mixtures with fodder plants with simultaneous low work expenditure (Brzezowska and Dreszczyk 2009). Tansy phacelia is one of them. It has not been popular up until recently. However, in the recent years slowly but successively it has gained numerous followers. Due to possibility of using it as an intercrop in the agro-environmental program, farmers obtain additional aid from the Agency for Restructuring and Modernisation of Agriculture. The crop itself is great for non-plough cultivation which on account of economics gives a great advantage over other post-crop plants (Leszczyńska, 2012). Tansy phacelia is presently very intensively used in organic agriculture

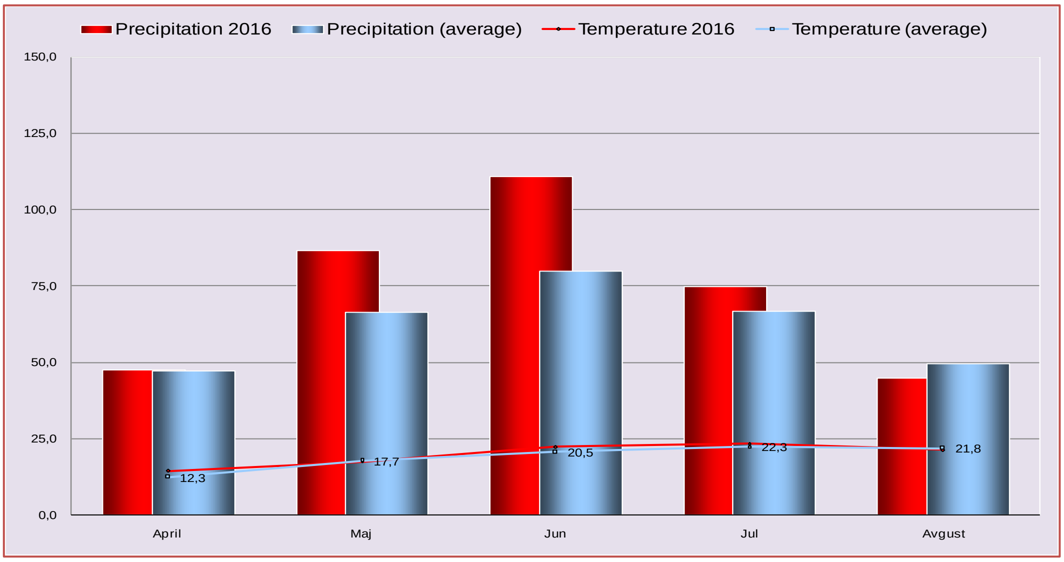
and for sowing of arable land temporarily excluded from production (Ramenda, 2003, Popovic et al, 2016, 2017a, 2017b).
Phacelia has been recorded as being a host plant for aphid predators in sugarbeet and wheat. *Syriphidae, Carabids, Coccinellids* and *Chrysopids* (all aphid predators) were all encouraged by the planting of *P. tanacetifolia* (Senegonca and Frings, 1988). Thus there may be some potential as a biological refuge for predatory insects. Phacelia has a long fibrous root system as well as a main tap root. It is claimed to benefit soil structure and also to have nematicidal properties (Cazzola, 1987; Anon., 1989). MAF Technology Lincoln have included Phacelia in trials evaluating the restorative properties of a number of crops (Francis, 1991). However, for seed production in New Zealand, it would seem unwise to sow the crop in depleted, poorly structured soils. The speed of growth of the crop indicates that optimum soil conditions are required. Soil of poor structure and bad compaction has to be avoid, because it may, in fact, create problems with damp seedlings (Krober and Beckrnann, 1975). Problem weeds, observed in the field, were fathen (*Chenopodium album*) and nightshade (*Solanum nigrum*) while wire weed (*Polygonum aviculare*) and willow weed (*Polygonum persicaria*) were seed dressing problems.Limited popularity of this plant depends on a low availability of its seeds on the market which results from difficulty in cultivation and price of seeds. Despite the fact that the plant has low soil, fertilization and climatic requirements, high yield may be obtained only with optimal moisture and thermal conditions. Plants which were negatively affected by weather may characterize with low yield and extension of flowering and seeds maturation. One of the grower's task should consist in maintaining high quality of seeds through their appropriate storage. The issue of the impact of long-term seeds storage on their sowing quality is very significant on account of economy and maintaining high germination ability of the investigated sowing material in the form of a specific species of crop. The indeterminate flowering, coupled with easily shattered pods, present a major harvesting problem with Phacelia.Aim of crop production is to establish uniform plant emergence, reasonably high plant populations and to attempt to compress the flowering as much as possible. The objective is to produce seed of even maturity. Pollination Bees are required for maximum seed set in Phacelia, however the crop is highly attractive to bees. About 2.5 hives per hectare should be provided if there is no bee source nearby (Ponichtera Piotr. 2016). According to Sulewska et al., (2005) during the so called farm storage of seeds, conditions and storage time should be absolutely considered, which affect germination ability, particularly when we plan the use of these seeds as sowing material.
The aim of this study was to examine the quality of seeds NS Priora grown in Serbia.

Material and metods

The aim of this study was to examine the quality of new variety NS Priora produced in 2016, the plots of the Institute of Field and Vegetable Crops Backi Petrovac (φN 45 ° 20 'λE 19 ° 40' 89 m.s.l.). The basic plot amounted to 10 m^2 in three replications. The experiment was conducted according to a split plot. Preceding crop was buckwheat. The standard technology for crop cultivation phacelia was applied. Autumn ploughing is carried out to a depth of 25 cm, when the present one 200 kg ha^{-1} of NPK nutrients. Sowing was done in late March 2016 at a depth of 2 cm. The general recommendation was to sow at a depth of 1-2 cm. It is recommended to use 8-10 kg ha^{-1} for phacelia seed sowing. Harvest was carried out at technological maturity of plants (Popović et al., 2016, 2017b). After the harvest, samples from all replicates were measured and quality of the seeds were evaluated.From chemical analysis, nitrogen content and protein content in the grain, were determined, by methods of Kjeldahl, *DM 05.10.03*. The analysis of the experimental data was performed using descriptive statistics and mediana using the statistical package STATISTICA for Windows 12 and all of the research results are presented in tables and graphs.

Meteorological conditions

Precipitation in 2016 (April-August, 364mm) were higher than for the long-term average 54 mm, while the average temperature was 19.64 °C, Graph. 1.



Graph 1. Precipitation and temperature in Bački Petrovac, 2016

In the vegetation period 2016 were observed abundant rainfall, and that in May 86.6 mm, 110.9 mm in June, July, 75 mm, 44.8 mm and in August, graph. 1.

Results and Discussion

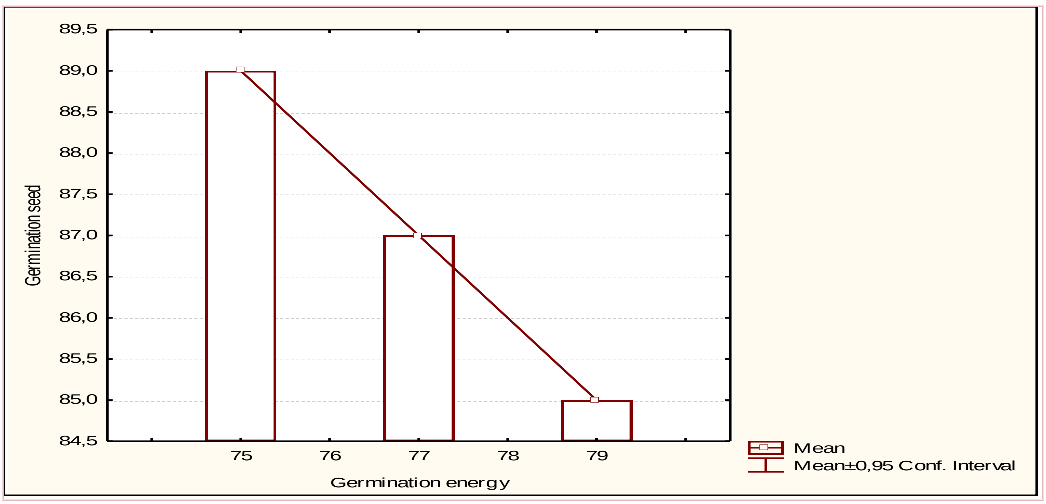
Phacelia is used in our country as a post-crop and honey plant. Genetic potential seed yields of variety NS Priora is 1000 - 1500 kg ha^{-1}, which would possibly be attainable if which would possibly be attainable if all seed could be harvested and losses through uneven maturity and/or shattering would be minimised. Grain yields of phacelia is 600-900 kg ha^{-1}. Phacelia flowering plant continues over 8 weeks (50-65 days) period (Popović et al, 2016a, 2017a, 2017b). Phacelia seed traits depend on many factors: genotype, the moisture content in physiologically mature seeds at harvest time, the technological maturation of seed, seed infection pathogens, the presence of pests and others. Seed characteristics are changed and due to different agro-ecological conditions.

NS Priora had high grain yield good quality. Flowering plant continues over 60 days. Grain yields of NS Priora in 2016 was 902 kg ha^{-1} (Popović et al, 2016, 2017a, 2017b). Average germination of seed, of NS Priora seeds harvested in 2016, was 87% and average germination energy was 77%, Table 1, Graph. 2.

The average thousand seeds weight was 1.42 g. The average cleanliness of seed, 98.28%, table 1. The standard error for thousand seeds mass was 0.02, Table 1, Graph. 3.

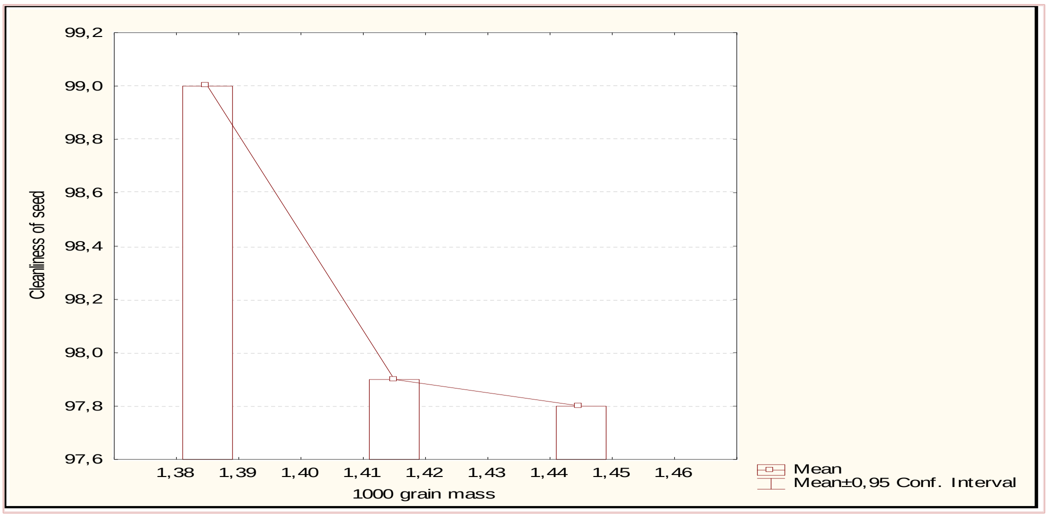
Table 1. The tested parameters of seed quality of variety NS Priora

Parameter	***Average***	***Minimum***	***Maximum***	***St. Dev.***	***St. Error***	***Variance***
Germination seed, %	87.01	86.00	88.02	2.00	1.15	4.00
Germination energy, %	77.01	75.05	79.00	2.01	1.16	4.00
Cleanliness of seed, %	98.23	97.8	99.00	0.66	0.38	0.44
Mass of 1000 seed,g	1.42	1.39	1.45	0.03	0.02	0.001
Nitrogen content, %	3.21	3.18	3.23	0.026	0.015	0.001
Protein content, %	20.06	19.85	20.19	0.18	0.11	0.04



Graph. 2. Germination seed and germination energy for seed NS Priora

Testing the quality of seeds shall be determined purity, germination, moisture, health, germination energy, 1000 seed weight and other properties. Determination of seed germination (viability of seed) presented the determination of maximum potential of germinated seeds of a single party. Filter paper can be used as a medium for testing the viability of seed. Inoculation is done is germination trays at a temperature of 20-30 ºC, or at a constant temperature of 25 ºC. After five days, reading is done of germination energy, and after 14 days viability is estimated, i.e., assessment of seedlings is performed. Germination energy represents the number of normal seedlings compared to the number of seed placed on germination determined after a expiry of time for the first assessment, i.e. the determining of germination energy. Germination energy and viability is expressed as a percentage of normal seedling, according to their number. Examination of the mass of 1000 of seed is carried out by taking a 1,000 seed from fractions "of pure seed" and their measurement determines 1000-seed weight average, expressed in grams. Length germination test was determined for each plant species. For phacelia smallest seed purity can be 94%, it can have up to 2% of other types, the lowest seed germination of 65,the maximum moisture content of 13% (Official Gazette of FRY 58/2002 - Rules on the quality of seed of agricultural plants).

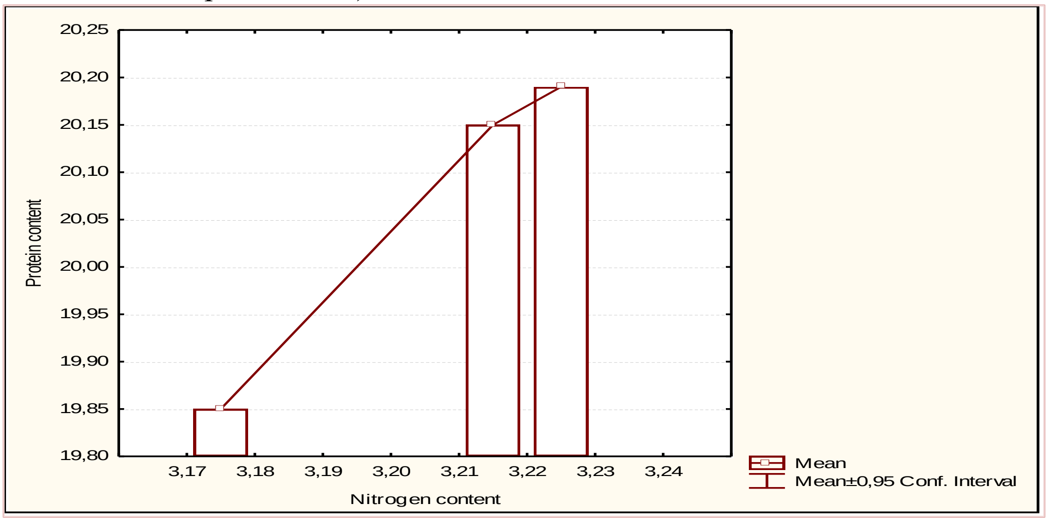


Graph. 3. Mass of thousand seeds and for cleanliness of seedv. NS Priora

NS Priora variety had average nitrogen content is 3.21% and protein content was 20.06%. The standard error for nitrogen content was 0.015, Table 1, Graph. 4.

One of the most important factors determining productivity is the photosynthesis process by which green plants accumulate organic matter and energy (Vasileva and Ilieva, 2017).

Agro ecological conditions depend on how many of the meteorological - edaphic conditions in an region of the same from the application agro-technical practices in the production of seed crops (Stevanovic et al., 2016). From above, it follows that properties of produced seed depend of procedures, totally controlled by human, from ecological conditions on which man can affects to some degree, on the genotype and on the interaction between all the above mentioned factors. By processing, seed materials eliminates the excess moisture and unwanted impurities and performes equalization of seed quality at condition suitable for sowing. During the processing procedures, properties of seed, in the natural seed material, are very important. Processing aim is to equalize usage characteristics of seed up to required agro-technology levels, regardless of production location and genotype (Popović, 2010; 2015; Glamočlija et al, 2015; Đekić et al., 2017; Terzić et al, 2016; Kresović et al, 2016; Živanović & Popović, 2016).



Graph. 4. Protein content and nitrogen content of seed for v. NS Priora

Phacelia is a hardy plant forage. It is grown for seed production, for obtaining green forage, silage, hay, as well as crop protection, crop of green fertilizers and as bee pasture (Popović et al., 2017a). In Europe, it is grown in many countries as a forage and ornamental plant. Phacelia is exploited in the green state or as silage and it is used for green manure and as pasture for bees.It is grown for reduction of nitrate in the soil and the recycling of the nitrogen (Hulin, 1993). Phacelia can be used as green manure. Most of the plants for green manure areplowed after flowering by fragmentation of overground mass and entering into the soil two or three days before sowing the main crop. Siderats enriches the soil in organic matter, improves the biological activity of the soil, increases the capacity of soil for water, affects the soil-hygiene and biological drainage, improves use of the hard available nutrients, lessens leaching of nutrients and the nitrate and reduces the evaporation of the water from the soil (cover crops) thatrepresents negative impact of drought. For the reason of better environmental adaptation and larger overhead and underground mass with more biologically-linking nitrogen may be combined in a mixture of legume and non-legume siderat. In the spring of a mixture of heartburn, phacelia and spring beans or in the autumn, vetch and peas in a mixture with oats or rye). Phacelia is useful for soil because with its good developed root system and a number of leaves that covers the soil and protect it from erosion. Spring sowing phacelia it is possible to suppress the competitive weeds such as ambrosia, sorrel etc. (Bogović, 2013, Popović, 2017b). The thick root of phacelia, who often penetrates soil to a depth of 70 cm improves soil structure (Čolaković, 2006). Phacelia population decreases cyst nematodes (Globodera) in soil (Šubic, 2016).

Beekeepers growing variety phacelia NS Priora will have a safe pasture and high quality honey yields, to over 1 t ha^{-1}. Honey of phacelia has healing properties: has antibacterial, antifungal and anti-inflammatory, for inflammation of the mouth and throat. It is good for intestinal diseases, jaundice, as a diuretic, helps convalescent after surgery and diseases, slows aging and extends the life (Yashmak, 1980). Puškadija et al. (2004) says that the phacelia seeds used in pharmaceutical in making of drugs.

Conclusion

Variety phacelia NS Priora, in 2016, achieved a high seed yield and excellent seed quality. The average protein content amounted of 20.06% while the nitrogen content of the grains was 3.21%.

Phacelia in Serbia it is grown as a forage and ornamental plant, are exploited in the green state or as silage. It is used for green manure, as cover crops and as bee pasture.

By growing of variety phacelia NS Priora, beeceepers will have a safe pasture and high yield of quality honey, of over 1 t.

Acknowledgments

The work was created as a result of projects TR 31025 and TR 31024 funded by the Ministry of Education, Science and Technological Development of Republic of Serbia.

Abstract

This research was conducted in order to determine the effects of different planting time and plant densities on some parameters of second crop sesame (*Sesamum indicum* L.) at the GAP Agricultural Research Institute Talat Demirören Research Station in 2015 and 2016 in Şanlıurfa province (Turkey). Trial was conducted according to randomized blocks split plots experimental design with 3 replicates. The main parcels planting times were 1 June, 15 June, 1 July, sub-parcels 2 different inter-row spaces were 35 cm, 70 cm, and 4 sub-sub plots 4 different intra-row spaces were 5 cm, 10 cm, 15 cm and 20 cm. In the conclusion of the two-year findings we found that; seed and oil yield were statistically significant in terms of planting time. Though seed and oil yield were found statistically significant in terms of different inter-row distances, the effect on the number of seeds per capsule was found insignificant. Seed and oil yield were found statistically significant in terms of intra-row distances as well. According to the results obtained from the study, the highest oil yield was obtained from the 35x5 cm planting density on June 15 with 60.64 kg/da, the lowest oil yield was obtained from the 70x20 cm planting density on July 1 with 28.79 kg/da. Interaction between planting times x inter-rows x intra-rows was found significant statistically at the level of 1% in terms of seed and oil yield.

Keywords: *Sesame, planting time, plant density, seed yield, oil yield*

Introduction

Sesame, a warm climate plant, is able to grow in tropical, subtropical and temperate climates (moderate climate) zone and in suitable temperature and precipitation conditions. Sesame exhibits its ideal growing between 25° of North and South parallel, reaching 42° in the North and 35° in the South. In this context, Turkey is located on the northern border of the world sesame growing area. The sesame total temperature requirement is 2500-2800 °C. Temperature can shorten the vegetation period as the temperature increases as until the temperature conditions do not affect the natural development of the plant. The temperature for germination should not fall below 12 °C. It is a good indication that average monthly temperatures do not fall below 20 °C during the 90-120 day vegetation period in Turkey conditions (Tan, 2007). The world's sesame planting area is 10.8 million hectares, production of 6.2 million tons and yield 576 kg/ha (Anonymous, 2014). The total cultivation area of oilseed plants in Turkey is 1.36 million hectares and the production 3 million 442 thousand tons (Anonymous, 2015). This research is to provide positive contribution to sesame farming which has been traditionally carried out in low productivity and limited areas in the GAP region, with the aim of determining the most appropriate sowing time and plant density for the second crop sesame growing in Harran Plain which is located in Southeastern Anatolia Region, which is experiencing semi-arid climatic conditions. It is aimed to improve yield and quality of sesame seeds only by changing certain habits of producers, without the necessity of using an additional input in the research. It is desirable to increase the producer income in parallel with the maximum yield that can be achieved per the unit area in terms of awareness and extension studies by medium and long term research results, application and transfer knowledge to the production. This will also contribute to the widespread and sustainability of oilseed crops at macro scale and sesame cultivation at micro scale. In addition, it is hoped that the results of the project will accelerate the production and reduce the dependency of our country on oilseed crops and the positive contribution to the economy of the country.

Material and Methods

The research was carried out in the Harran series, which is widely found in the red brown soil group of Harran Plain. The serial soils that are alluvial main material and are deep and shallow slopes. Typical red colored profiles have a clayey texture. Upper soil is mid-cornered block, then granular; the bottom soil is strong, large prismatic and then strong mid-cornered block. It contains low density secondary lime pavers to the bottom. The slip surfaces begin in the B-horizon and increase significantly in the downward direction. The whole profile is very calcareous, the organic matter content of the serial soils is low, and the Cation Exchange Capacity are high. Organic matter decreases from surface to inferior, ranging from 0.9 % to 0.3 %. Cation Exchange Capacity clay depending on the content, increases towards the lower layers (Dinç et al., 1988). Şanlıurfa province is affected by the Mediterranean climate as well as the terrestrial climate zone. The summers are arid and warm, and the winters are warm and relatively rainy. In summer, it is mostly affected by arid and warm tropical air mass, which is located in the Basra low pressure center, and it is affected by semi-arid climatic conditions. Daytime temperature is above 44 ^{o}C. The very low relative humidity increases evaporation (Atalay et al, 2006).
This research was conducted so as to determine the effects of different planting times and plant densities on yield and yield components of second crop sesame (*Sesamum indicum* L.) under Harran Plain semi-arid climate conditions at the GAP Agricultural Research Institute, Talat Demirören Research Station in Şanlıurfa province in 2015 and 2016. Arslanbey middle branched sesame variety which was bred for GAP Region used as material and the trial was carried out with respect to randomized blocks split split plots experimental design with 3 replications. In the trial, the main parcels were planting times (1 June, 15 June and 1 July), sub-parcels were 2 different inter-row spaces (35 and 70 cm), and 4 sub-sub plots were 4 different intra-row spaces (5, 10, 15 and 20 cm).

Results and Discussion

The second crop to be harvested in semi-arid climatic conditions in the light of the research findings will provide benefits to the following recommendations in sesame cultivation.

Excess seed use should be avoided,
In order to ensure the homogeneity of the seedlings, thinning must be done on time, pressurized irrigation systems should be used within the possibilities and soil preparation should be done properly.
Harvesting and threshing should be done at the most appropriate times and methods, not causing seed loss.
Planting must be done at the recommended date and density.

Also, when the research results are examined;

From the Table 1; in both years of the experiment, it is observed that the sowing time x inter row x intra row interaction was statistically effective at 1 % significance level for the number of seeds per capsule. The lowest number of seeds per capsule (36.00 pieces/capsule) from 35x10 cm planting density on June 15, the maximum number of seeds per capsule (55.33 pieces/capsule) were obtained from 35x15 cm on June 1 in the 2015 year, and the lowest number of seeds per capsule (37.00 pieces/capsule) from 35x20 cm planting density on June 15, the maximum number of seeds per capsule (59.33 pieces/capsule) were obtained from 35x20 cm on June 1 in the 2016 year. In both years of the experiment, close results for the number of seeds per capsule have been reached.

Table 2. Impact of Sowing Time x Inter Row x Intra Row Interaction on the Oil Yields for Sesame in 2015 and 2016 Years

LSD (İnt.)		3.16**				3.32**			

importance at the level of *:0.05, **:0.01 1: 1 June 2: 15 June 3: 1 July

From Table 2; in both years of the experiment, it was observed that the sowing time x inter row x intra row interaction was statistically effective at the 1 % significance level for the oil yield. The lowest oil yield (27.45 kg/da) from 70x20 cm planting density on July 1, the maximum oil yield (56.30 kg/da) were obtained from 35x5 cm on June 15 in the 2015 year, and the lowest oil yield (30.13 kg/da) from 70x20 cm plant density on July 1, the maximum oil yield (67.26 kg/da) were obtained from 35x10 cm on June 15 in the 2016 year. The highest oil yields in both years of the experiment were taken from 35 cm inter row space on June 15.

The findings collected were compliance with the findings of Rahnama et al., (2006), Tahir et al., (2012) and Noorka et al., (2011) researchers, incompatible with the findings of Aghili et al., (2015) and Sögüt et al., (2009).

Conclusions

According to the two-year average; the highest seed yield was obtained from the 35x5 cm planting density on June 15 with 143.42 kg/da, and the lowest seed yield was obtained from the 70x20 cm planting density on July 1 with 72.50 kg/da. According to the results obtained from the study; it is suggested that the most suitable sowing time as the second crop for medium-branched sesame variety with 3 flowers should be between 1-15 June and the most suitable planting density should be 35x5 and 35 x10 cm in GAP Region, which is located in semi-arid climatic conditions.

THE EFFECTS OF DIFFERENT DWARFING APPLICATIONS ON BURSA BLACK FIG (*FICUS CARICA* L.) TREES IN TERMS OF YIELD AND QUALITY

Halil Güner SEFEROĞLU*, Mehmet TOMAŞ

Adnan Menderes University, Faculty of Agriculture, Department of Horticulture, Aydin, Turkey
*Corresponding author: gseferoglu@adu.edu.tr

Abstract

The study to specify the effects of different applications for dwarfing, fruit quality and yield on Bursa Siyahı (Black Bursa) Fig Trees was performed between 2014-2015 in the parcel of Department of Horticulture, Faculty of Agriculture, Adnan Menderes University. In order to create artificial dwarfing on the fig nursery trees; Prohexadione-Calcium, a giberellin acid inhibitor, was used as 125 and 250 ppm. In addition, nursery trees were planted on 30° angle with ground level and were grown by strapping to galvanized wires. Two different dose applications of curving+Pro-cal were used and there have been 6 different applications in total including the control. The fig nursery trees were planted 1x1.5 m intrarow and above-row in parcels where branch bending applied and also 1x1 m intrarow and above-row in parcels where other applications made. Pro Ca applications were performed twice on vegetation period, by means of the period when new shoots are 5 cm tall on saplings. Morphological observations were performed to specify the effects of applications on dwarfing. Pomological observations were performed to specify the effects of applications on fruit quality and yield. Also, phenological effects of the application were observed. On Pro-Ca applications about the trunk development, node number increased while the trees with higher trunk length were obtained contrary to the expectations. On the applications where were not significant differences on the effects in fruit quality, the range of trunk cross-sectional area had the highest values in 125 ppm Pro-Ca application. Four old fig trees were observed phenologically and there were approximately a week delays in the development of trees with 30° sloping than standard trees.

Keywords: *Prohexadione Calcium, Pro-Ca, fig, dwarfing, fruit yield and quality, bending.*

Introduction

One of the most significant aspects in pomiculture is the excessive vegetative growth of fruit trees grown. Less penetration of light through the tree corollas results in decreased yield of quality of fruits as well as increased cost of agricultural disinfection together with the increased cost of cultivation activities such as pruning. As the shortening of youth infertility is quite substantial in dwarf fruit growing, vegetative growth is deliberately required be taken under control because yield can regularly be obtained from trees each year with the vegetative and generative balance established appropriately and accurately from the early ages. (Ağça, 2008, referring Faust). The state of pudginess in fruit trees is caused by artificially created pudginess and hereditary environmental conditions (Özçağıran, 1974). Dwarfing is commonly ensured by the utilization of dwarf rootstock. Dwarf rootstocks are the rootstocks that grow trees that are substantially smaller than the trees growing on their own roots (Webster, 1995). The purpose of researchers and arboriculturists is to grow rootstock with the characteristics of economically reproduction on wide fields and special adaptation. (Demirsoy and Macit, 2007, referring Cummins and Aldwinckle). Apart from this, selection of spur types can be performed (Tukey, 1964). Pinching, root pruning, ring removing, throttling, notching, tying tree branches by bending them down or obtaining wide angle branches instead of vertical growth help for dwarfing process. Apart from these methods, Benzyl Adenin, Paclobutrazol ve Prohexadione-calcium (Pro-Ca) are the most common used growth regulating agents assisting to the dwarfing can also be used (Ağca, 2008). It is not quite possible to mention about dwarf rootstock or hereditary dwarf fig growing related to the figs that are highly valuable and having strategic importance for our country. Cultivation is traditionally done in gardens constructed with 6x6 m distances. The increase in national and international transportation facilities within the recent years, technological advancements as well as developments reflecting on the chain after the harvest such as preparation for the market, packaging and warehousing has caused substantial increases in the demand for fresh fruits. 20%-25% of table figs produced in our country are exported and Bursa Black fig variety has the lion’s share in exportation with a ratio of around 90%. In this sense, all sorts of activities and endeavours for developing and improving the cultivation of Bursa Black figs that has a substantial role in our table fig production and exportation shall be highly important and noteworthy. From this viewpoint, it is considered that it is appropriate and convenient to develop modern fruit cultivation practices in the cultivation of Bursa Black fig, which is an important table fig variety. Therefore, determination of effects on various dwarfing applications for the purposes of increasing of plant number on the unit area which is among the essentials of dwarf fruit growing, obtaining yield in early ages, facilitation of care and yield processes, improving the fruit quality in plants such as Bursa Black fig variety that has a high habitus in terms of tree growing on dwarfing, fruit yield and quality is aimed in the thesis subject.

Material and Method

The research was conducted between the years of 2014-2015 on the field under the possession of Adnan Menderes University in Turkey, the Faculty of Agriculture, Department of Horticulture. The research was initiated after the performance of certain applications for 2 years upon the planting on Bursa Black fig saplings planted on February 17, 2012 on the field under the possession of Adnan Menderes University Faculty of Agriculture, Department of Horticulture.

Table-1. Applications performed on the materials used in the research pre and post-research period.

Application	2012	2013	2014	2015
U1 Group (Control)	Group with no applications performed			
U2 Group (125 ppm Pro-Ca)	125 ppm Pro-Ca (2 times)	125 ppm Pro-Ca (2 times)	125 ppm Pro-Ca (2 times)	125 ppm Pro-Ca (2 times)
U3 Group (250 ppm Pro-Ca)	250 ppm Pro-Ca (2 times)	250 ppm Pro-Ca (2 times)	250 ppm Pro-Ca (2 times)	250 ppm Pro-Ca (2 times)
U4 Group Pruning (30° bending)	Sapling within this group is secured by means of galvanized wires on August 6 after the planting with a pitch of 30° on March 26, 2012 and no further applications was performed accordingly.			
U5 Group Pruning (30° bending) + 125 ppm Pro-Ca	In addition to processes performed on U4 group saplings			
		125 ppm Pro-Ca (2 times)	125 ppm Pro-Ca (2 times)	125 ppm Pro-Ca (2 times)
U6 Group Pruning (30° bending) + 250 ppm Pro-Ca	In addition to processes performed on U4 group saplings			
		250 ppm Pro-Ca (2 times)	250 ppm Pro-Ca (2 times)	250 ppm Pro-Ca (2 times)

For the purpose of determination of the effects of the applications performed on the dwarfing process as well as the fruit quality and yield; phenological, pomological and biochemical data was collected during the period of vegetation and morphological data was obtained at the end of cultivation.

Table-2. Obtained data parameters

Pomological data	Phenological data	Morphological data
Fruit width	Foliation commencement date	Trunk length
Fruit length		Trunk diameter
Fruit height	Aftercrop generation date	Internode number
Ostiole	Full foliation date (Aftercrop generation date)	Length between internode
Neck length		Lateral branch number
Fruit length	Defoliation date	Longest lateral branch length
Brix, TA., pH and Hardness values		Length to the primary lateral branch

By means of applying TARİST statistical analysis program on the values obtained from the trial, variance analysis was made accordingly. LSD test with margin or error of 5% was applied for the purpose of revealing discrepancies upon comparing the means and the mean values are grouped based on the outcomes obtained from this.

Findings

Findings on Trunk Development, Fruit Yielding and Fruit Quality

Findings on Phenological Observations

Bud blistering was formed within U1-U2-U3 group applications on March 9, and on March 15 within U4-U5-U6 group applications. The differences among the applications are formed between the plants of vertical growing and the plants growing with a 30° inclination.

When the effect of various applications performed on fig leaves on the foliation commencement time, Control indicating vertical growth on March 13, 125 ppm Pro Ca, 250 ppm Pro Ca groups; 125 ppm Pro Ca+Branch bending, Branch bending applications were initiated to foliate.

The date for occurrence of full foliation on fig leaves as a consequence of applications performed was May 25 in the control and 125 ppm Pro Ca applications and May 26 for 250 ppm Pro Ca application.

The application in where the latest full foliation was occurred was 125 ppm Pro Ca+Branch bending and 250 ppm Pro Ca+Branch bending.

The defoliation was occurred on 16-17 December in the plants with vertical growing (U1-U2-U3) and on December 24-25 in the plants with growth of 30° inclination (U4-U5-U6). The difference of 8-9 days occurred between was resulted from the fact the plants displayed a vertical and inclined growth instead of the Pro-Ca application.

Results and Discussions

The morphological and pomological data obtained from the trial was subjected to variance analysis and the means were compared based on significance level for the purpose of determining the effect of the applications. When the findings obtained from Bursa Black fig trees related to lateral branch number and the longest lateral branch length were assessed, it was determined that Pro-Ca applications with the dosage of 125 and 250 ppm had the highest value. On another words, the effect of Pro-Ca is quite astonishing in terms of both lateral branch number and the longest lateral branch length. The fig trees having the most internodes were obtained from the applications of 125 and 250 ppm, whereas the lowest parameters of less distance between the internodes indicating weak growth were obtained from the control group fig trees. Hekimci (2013) stated with respect to Pro-Ca application realized for two years on the one year old fig trees that the lowest values were obtained for the distance between the internodes from the applications performed with the dosage of 125 and 250 ppm. It is observed that this situation ensured a decrease in the distances among the internodes as a consequence of application of Pro-Ca on elder saplings for the first two years; an increase of the distances among the internodes measured on the trees subject to the application of Pro-Ca upon the continuation of this application within the 3rd and the 4th year and even resulted in a situation in where the distance among the internodes were measured to be higher at the end of the 4th vegetation period.

Trunk diameter growth was determined to have the highest value on the trees with the application of 125 and 250 ppm Pro-Ca just like in the lateral branch number and longest lateral branch length. The application in where the trunk diameter growth was on the lowest value levels was obtained by combining the Pro-Ca with branch bending.

The values in where the distance up to the primary lateral branch was the lowest, just like in trunk diameter growth. It can be said that the primary lateral branching on the trees with low growth is an expected situation.

No yield could be obtained as a consequence of the applications in which 125 and 250 ppm Pro-Ca dosages were combined with branch bending on the fig trees with the age of 4 that were subject to certain applications. Comparisons of pomologic data obtained were performed among 4 applications as control, 125 and 250 ppm Pro-Ca and branch bending. According to the measurements conducted on the fruits obtained from Bursa Black fig trees; it was observed that no differences existed among the applications with respect to the parameters such as fruit width, fruit length, fruit height that determined the corpulence of the fruit. Smith et al. (2005), has stated that Pro-Ca applications has caused a decrease in fruit corpulence in pears whereas Gleen and Miller (2005) indicated that Pro-Ca applications has caused a decrease in fruit corpulence in apples. It was seen that the fruit corpulence, which is the most important factor of the quality criteria especially in table varieties has not caused a size reduction in Bursa Black fig fruits after the Pro-Ca application.

It was seen that no differences existed among the applications in terms of fruit weight, fruit length, fruit firmness, fruit Ph, brix amount and acid amount values that can be titrated.

When data for fruit weight per trunk cross-section area is analysed, the effect of Pro-Ca applied with the dose of 125 ppm is spectacular as the control and 250 ppm Pro-Ca applications produced approximate results, the highest values were obtained from Pro-Ca application applied with the dose of 125 ppm. In addition to this, it was observed that no apparent differences among the applications were formed in terms of istiole, yet slightly higher values were obtained from branch bending application when compared with other applications. When the phenological parameters such as bud blistering, foliation beginning, full foliation (aftercrop formation), defoliation timing are evaluated; it is seen that the differences among the applications are related to the vertical or inclined growth of the fig trees. In another words, Pro-Ca application has no effect on phenological differences. Because; it is seen that no apparent differences are observed between 125 and 250 ppm Pro-Ca applications, 125 and 250 ppm Pro-Ca application is combined with branch bending and similar situation exists among the applications in where only branch bending application is performed. It is further observed that there are delays of around 1 week between the 125 and 250 ppm Pro-Ca combined with branch bending and only branch bending application; control, 125 and 250 ppm Pro-Ca applications. Again by means of a different explanation, it is observed that there are delays of 1 week in the fig trees with inclined growth when compared with the ones with vertical growth. As a conclusion, attempting of Pro-Ca with frequent intervals with the doses ranging from 125 and 250 is important in terms of obtaining different results. In the event of planting the trees with the intrarow and above-row and distances among each other to be 1.5 and 2.0 meters in a manner not prevent each other in the following periods, scrutinizing the yield values per decares is benefited accordingly.

Abstract

This study was conducted in 2012 and 2013 at the newly established fruit collection garden belonging to Adnan Menderes University Department of Horticulture, in order to determine the earliness and development performances of four domestic and foreign apricot species in the ecological conditions of Aydin. In the study, in addition to evaluating the phenological observations and morphological measurements of the species, it was tried to determine the necessity of chilling of Zaza species. There were differences in the phenological observations in both trial years. When morphological measurements were evaluated, it was seen that Iğdır (Aprikoz) and Roxana gave positive outcomes in both years. The chilling durations of the Zaza species were determined to be 697 cold unit value in 2012 and 685 cold unit value in 2013. Zaza was the earliest blossomed species, and Roxana was the species that needs chilling most, so it was the latest coming up species. This study will shed light on the coming years in terms of adaptation of the species tested in the light of the obtained data.

Key words: Chilling, apricot, adaptation, phenology, morphology

Introduction

Fruit species can adapt to different ecological conditions. Particularly in countries and regions with similar ecologies, conducting of adaptation studies has been the primary research topic. This is even more important for apricots. Such that; the fact that the apricot, which has serious problems in terms of ecological adaptation ability among the fruit species, has only a few species that can completely adapt to every ecology and its other species cause serious problems was accepted as the most significant indicator of this situation (Gülcan, 1993).
It is reported that in the regions where spring frosts are rare or not seen at all, it is possible to cultivate early ripe apricots easily. Countries such as Spain, Italy, France and Greece, which are neighboring to the Mediterranean, can generate significant income by selling the apricots they harvested by the end of May to foreign countries, making good use of their ecological advantages (Asma, 2000). The Aegean Region is an appropriate region for growing early and table apricots. The most important problems in this region are that there is low need for chilling and the absence of quality species suitable for transportation (Özkarakaş and Ercan, 2004). Although our country has much bigger advantages, it is not in a good position to produce and sell table apricots. However, in recent years, many adaptation studies have been conducted with early table apricot species in Mediterranean and Aegean regions (Yarılgaç and Kazankaya, 2002). Despite the large number of apricot species adapted to different ecological characteristics, the fact that many of them are evaluated as dried fruits, the table species are not put on markets outside the cultivation regions, reasons such as problems of cold chain and transportation expenses causes the need for cultivating some species with high market value in different regions of the country. The average duration of chilling in Aydın province is 1180 hours. In general, when the apricot-chilling needs are examined, it is seen that this duration varied between 550 - 1600 hours depending on the species. Considering the need for chilling,

the species to be used in the study are shown in Table 1. In choosing the species to be tested, besides the need for chilling, attention was paid to the presence of the species with high economic value, which can be put on markets in different times (Asma, 2000).

Table 1. Species used in the study and the chilling needs

Species	Chilling Need (hour)
Tyrinthe	445 – 520
Roxana	790 – 1005
Iğdır	800 – 975
Zaza	to be determined in the study

In the study, Aydin, Roxana, Zaza and Tyrinthe species, some of the important table apricot species, were used and their adaptability to Aydin ecological conditions and development performances were tested using 2 aged seedlings over wild rootstocks. In addition, the chilling time of the Zaza species, the chilling need is not exactly known, has been tried to be determined.

Material and Method

The study was carried out at the fruit collection garden (37°45'44.7"N 27°45'27.0"E) of the Adnan Menderes University, the Faculty of Agriculture, Department of Horticulture.
In the study included 2 aged, Iğdır (Aprikoz), Zaza, Roxana and Prececo de Tyrinhte species with high table value, which were implanted on the wild apricot rootstock planted in the faculty collection garden in 2011-2012.
Onset Hobo data recorder device was used to record the meteorological data required for the calculation of the chilling requirement. The obtained meteorological data were evaluated by being processed with Onset Hobo Ware Pro software.
The climate chamber was used to determine the chilling needs of the Zaza species and to enable observation of the scions from the trees under controlled conditions. The climate chamber was kept constant at 24°C temperature and 80% humidity throughout the trial.
Accidental parcels were carried out according to the trial pattern. Each species included in the trial was set in a way to be 3 repetitions and 3 seedlings in each repetition.
In the trial, the seedling developments were investigated through the phenological and morphological observations. In addition, the need for chilling of the Zaza species, for which the need for cold weather is not known yet, has been tried to be determined by measurements made during 2 vegetation periods. The phenological observations of bud swell, bud bursting, flowering inception, full flowering, flowering end and defoliation were performed in the study. The phenological observations during the two vegetation periods in 2012-2013 were performed according to the criteria below stated by Özvardar et al. (1991).

Figure 1. Bud swell, coming up, flowering inception and full flowering in the phenolic observations of Zaza species
The shoot length and shoot diameter, stem diameter, petal height measurements and petal area calculations were made for each seedling included in the trial. The morphological

developments of the seedlings were determined by measurements made at the beginning and end of vegetation.

The vegetative period has been evaluated as the period from coming up of the buds to the defoliation (Guerriero and Watkins, 1984). For the Zaza species, the standard method and the Utah chilling unit (cold unit) method were used to calculate the chilling requirement.

The trial was established according to randomized trial pattern and carried out in 3 replications. In all species, the average of 3 trees was considered as a recurrence. The LSD values were used to compare the mean values of the data obtained at the trial.

Results and discussion

In the period of 2012-2013, the species began to rest on 25.11.2012, and the date of 13.02.2013 was determined as the cease of resting, when 50% of coming up was observed in scions kept under observation in the climate room. In the period of 2013-2014, the beginning of resting period was determined to be 08.12.2013 and the cease of the resting period was determined to be 05.02.2014. The resting in the period of 2012-2013 in scions planted to the perlite environment ceased on the date of 13.02.2014. The rest in the scions observed in 2013-2014 ceased in the scions taken on 05.02.2014, and 50% bud coming up among all scions was seen on 20.02.2014 in the scions in this group.

Table 9. Chilling periods calculated for the Zaza species

Measurement period	Standard Method	Utah Method
2012–2013	386 hours [25.12.2012 16.02.2013]	697 cold units [25.12.2012 13.02.2013]
2013–2014	677 hours [08.12.2013 14.02.2014]	685 cold units [08.12.2013 05.02.2014]

Conclusion

Based on the data obtained as a result of this adaptation study carried out in Aydın province for two years; it was determined as a result of the statistical analyses, that the development performance of the Precoce De Tyrinthe species was lower than the other species when they are analyzed in terms of morphological characteristics. According to the averages of the measurements of petal height, petal area and the stem diameter under first branch, the morphological measurement criteria, the petal width development brought up the rear in both trial years. In the second year of the trial, it was observed that no flowering observed in Precoce De Tyrinthe as mentioned above, while flowering and even fruit set are observed in other species. The Roxana species gave more positive results in terms of morphological criteria than Zaza and Precoce De Tyrinthe species. Roxana attained the highest values in both trials years in terms of shoot length development, shoot diameter development and petal area development compared to other species included in the trial and took place on the top. It was the species that got out of the resting period due to having the highest chilling period. It entered the resting period much earlier than the other species. The average flowering time is 11 days. Since the duration of the chilling is higher than the other species, it can be considered as an important species for the region in terms of continuity in the market due to the late harvesting time.As is the case with the Roxane species the morphological measurement results of the Iğdır (Aprikozu) species have yielded positive results. It took place on the top in terms of the he stem diameter under first branch, stem cross-sectional area and petal height in both years. Although it was in third place in the development of petal width during his first trial year, it took first place in the second trial year. The average flowering time is 9 days. Its coming up and flowering processes were more homogenous than other species. It is more likely than other species to reach the age of yield earlier and to be a valid species for our region due to the fact that its fruits are large, taste and high in attraction.The Zaza species, which has not yet been registered and about the characteristics of which no data has been obtained yet, has provided a great advantage to our region in terms of earliness. However, when examined from the point of view of morphological characteristics, it is thought that the results over which clear interpretations can be made could not be obtained in the data belonging to both years. It was the species that came up the earliest in both trial years. The flowering period was more gradual compared to other species. The average flowering time was 7-8 days. The fruits were ready for harvesting in the last week of May. As a result of the calculation of the chilling period, the values of 386 hours and 697 cold units were found for the first year for the first, and the values of 677 hours and 685 cold units were found for the second year. Comparing the two methods, it is thought that the cold unit method has reached a more accurate result. It can be said that it is a promising species for the region in terms of earliness. In a subject that requires long years of work, such as adaptation, the results of two years of data should not be viewed with certainty. For this reason, it seems that such studies should be carried out in a wider scope in terms of time. It attracts attention that this kind of studies are more important especially when our region is less affected by late spring frosts and this advantage is considered to be the potential of providing early table apricot products to the market.In conclusion, the data are open to discussion at a given point since the varieties used in the trial cover a period in which they do not undergo complete yield. Therefore, by expanding these types of studies, health and affordability of the species suitable for Aydın ecology will be examined.

Abstract

This research was carried out in order to determine the correlation (that resulted from the applications of different sowing time and plant densities) between yield and yield components of second crop sesame under semi-arid climate conditions at the GAP Agricultural Research Institute Talat Demirören Research Station in Şanlıurfa province in 2015-2016 growing seasons. The parameters examined were: the number of capsules per plant, number of branches per plant, number of seeds per capsule, plant height, first capsule height, seed yield, protein ratio, oil ratio, oil yield and thousand seed weight. According to the findings of combined correlation analysis of two year; positive and significant relationships were identified between the number of capsules per plant and number of branches per plant, between number of seeds per capsule and plant height, between first capsule height and plant height, between thousand seed weight and plant height, number of branches per plant, between seed yield and plant height, thousand seed weight, between protein ratio and number of capsules per plant, number of seeds per capsule, first capsule height, and between oil ratio and thousand seed weight, seed yield, respectively. Negative and significant relationships were identified between the number of capsules per plant and plant height, between number of seeds per capsule and number of branches per plant, between thousand seed weight and first capsule height, between seed yield and number of capsules per plant. On the other hand, no correlation was found between seed yield and number of seeds per capsule, between number of seeds per capsule and number of branches per plant. According to the results of two years, the highest seed yield was obtained from the 35x5 cm planting density on June 15 with 143.42 kg/da, and the lowest seed yield was obtained from the 70x20 cm planting density on July 1 with 72.50 kg/da.

Introduction

Sesame is an annual and herbaceous plant and can be grown easily in tropical-subtropical climate zones and micro-climate regions (2700-3500 ^{o}C). It can grow up to 80-180 cm in length, 40-50 cm in depth. The stems are flat and cornered. In the two carpels subspecies the stem is 4 corners, in the four carpels subspecies the stem is 6 or 8 corners. In normal sesame plant, the stem is angular, while in four carpel subspecies the stem is flattened at various grades and the flattening increases towards the tip of the stem (İlisulu, 1973). The world's sesame planting area is estimated 10.8 million hectares, production of 6.2 million tons and yield of 576 kg/ha (Anonymous, 2014). The total cultivation area of oilseed plants in Turkey is 1.36 million hectares and the production amount are 3 million 442 thousand tons (Anonymous, 2015). The reason for the low yields in sesame cultivation is that the necessary agricultural requirements (planting, cultural and chemical combat, certified seed use, irrigation, harvesting-threshing etc.) are not fulfilled and the agricultural characteristics of the grown seed are unknown. In order to make sesame growing more attractive, it is utmost importance to determine the important parameters that contribute to breeding work and to put them together in the new sesame varieties to be improved. At the same time, high yields can only be achieved of sesame species and ecotypes that are currently being cultivated by determining the parameters that make up the yield and by accessing the agricultural activities to be applied. In the second crop sesame cultivation, it is considered that the relations between the yield and some yield parameters are determined and that they contribute to the solution of the bottlenecks for sesame cultivation which are cultivated in limited areas.

Material and Methods

This research was planned and carried out in order to determine the effects of different planting times and plant densities on yield and yield components of second crop sesame (*Sesamum indicum* L.) under semi-arid climate conditions in Harran Plain at the Talat Demirören Research Station, which affiliated to GAP Agricultural Research Institute in Şanlıurfa province in 2015 and 2016 years. Arslanbey sesame variety which was bred for GAP Region in 2010 were used as material and the trial was carried out according to randomized blocks split split plots experimental design with 3 replications. In the trial, the main parcels were consisted of planting times (1 June, 15 June and 1 July), sub-parcels were divided into 2 different inter-row spaces (35 and 70 cm), and 4 sub-sub plots were divided into 4 different intra-row spaces (5, 10, 15 and 20 cm). The parcel area was arranged as 16.8 m^2 (6x0.7x4) for inter raw spaces of 70 cm, 8.4 m^2 (6x0.35x4) for inter raw spaces of 35 cm. The parcel lengths were 6 m. 3 m spaces between main parcels, 1 m between sub-parcels and 3 m between blocks were established. The research station where the experiment was conducted is at 36^o 42' North latitude, 38^o 58' East longitude and 410 m high from the sea level (Anonymous, 2003).

Soil specimens from 0-30, 30-60 and 60-90 cm deep were blended to represent the soil properties of the trial areas. The samples obtained were analyzed in the Soil Analysis Laboratory, which is located within the GAP Agricultural Research Institute (Turkey).

Table 1: Physical and chemical properties of experimental soil

Soil Depth (cm)	Structure	Volume weight (g/cm3)	Field Capacity (PW %)	Wilting Point (PW %)	Water Saturation (%)	EC (ds/m)	Lime (%)	pH	Phosphorus (kg/da)	Potassium (kg/da)	Organic Matter
0-30	Clayey	1.25	33.44	21.64	70	0.83	24.7	7.8	4.20	193.2	2.19
30-60	Clayey	1.30	32.34	21.99	64	0.99	24.7	7.8	3.13	180.6	1.78
60–90	Clayey	1.35	34.38	22.75	55	0.99	24.3	7.7	2.50	175.3	1.32

According to the analysis result; it was found that although the sample of the experimental site was taken from different depths, it was found to be the same in terms of lime and pH contents, and as the soil depth increases the phosphorus, potassium, organic matter and water saturation capacity decreased and EC value increased.

Mediterranean climate is dominant in the area where the experiment was conducted and drought was observed between June and October. In the second crop of sesame growing season; the highest temperature for 2015 was observed in July with 41.4 ºC and the average temperature in October with 10.2 ºC. The highest temperature for 2016 was measured in July with 40.2 ºC, the lowest temperature in October with 9.2 ºC. During the sesame growing season (June-October), it is understood that the monthly temperature values for year 2015 are relatively higher than the year 2016 (Table 2). Monthly average relative humidity values for year 2015 are relatively low in the sesame growing season (June-October) of 2016 (Table 3), while monthly average relative humidity values for long years are observed to be low compared to the years when the experiment was conducted. Almost no rainfall was detected during the sesame growing season (June-October) and the total rainfall amounts for the years 2015, 2016 and long years were 233.4, 268.7 and 459.4 mm, respectively. In recent years, precipitation has decreased by almost half compared to long years, that affecting agricultural production areas and causing yield reductions.

Results and Discussion

Relations (correlation) between the yield and yield components of the second crop sesame were identified. The various correlation between yield and yield parameters were studied are given in the following.

Table 5. Correlation between yield and yield parameters (Combined)

	1	2	3	4	5	6	7	8	9	10

1:Plant height 2:Number of branches per plant 3:Number of capsules per plant 4:Number of seeds per capsule 5:First capsule height 6:Thousand seed weight 7:Seed yield 8:Protein ratio 9:Oil ratio 10:Oil Yield

According to the correlation analysis, the relationships between yield and yield parameters were determined by Shim et al. (2006), Sumathi et al. (2007), Gnanasekaran et al. (2008), and Ramazani (2016) found to be parallel to the findings obtained from the research.

Conclusions

Increases in plant density and early planting can cause an increase in plant height, and thus appear to be a factor that increases the yield to a certain point. When Sesame is planted densely, the little branching appears. The Arslanbey sesame variety, which is forming 2-3 branches, is characterized as a medium branch, and it can also has branches 2 and 3 on side branches. The one thousand weight, one of the basic components of yield, may show an upward trend in early planting. Although the increases the plant density per the unit area decreases the number of capsules per plant but increases the total number of capsules and seeds per unit area. Thousand seed weight and total number of capsules and seeds per unit area were found to be an important factor in increasing yield. Positive and important relationships were determined between seed yield and plant height, thousand seed weight.

Abstract

During the period from 2000 to 2016 the corn yield in the Entity of Republic of Srpska (RS) in Bosnia and Herzegovina varied, both by years and by individual production regions. According to data from the Institute of Statistics of Republic of Srpska, the lowest yield was 1,96 tha^{-1} in the production area of Banja Luka in 2003, and the highest in 2016 in Novi Grad 6,76 tha^{-1}. Numerous factors have the influence on the maize grain yield. The maize producers can not affect the climate conditions, from which the achievement of yields greatly depends. It is particularly reflected in the drought years. By using data of the distribution and amount of rainfall for the six municipalities in RS, correlation coefficients of precipitation and maize grain yield were calculated by Hartung. It was found that the good and positive correlation value was manifested near Bijeljina for the period July-August (0,749), and in the average for all places in the same period (0,709) and production year (0,711). The maximum value of the correlation of monthly precipitation was recorded in August (0,683), which was manifested in the drought years (0,789). By a comparison of the obtained results, it was noted that in the dry years the coefficient was adequately lower for production-year and July-August rainfall and also higher in August and during the interval from January to March. It can be concluded that the precipitations before and during fertilization had the greatest impact on the achievement of maize grain yield, as well as on the formation and initial maize grain filling.

Keywords: *maize, yield, precipitation, correlation, Republic of Srpska.*

Introduction

During the period from 2000 to 2016 the maize yield in the Entity of Republic of Srpska (RS) in Bosnia and Herzegovina varied, both by years and by individual production regions. The lowest yields were 1,96 t/ha^{-1} in 2003 in the production area of Banja Luka and 1,97 t/ha^{-1} in 2000 in Bijeljina. The highest yield was in 2016 in Novi Grad and it amounted 6,76 t/ha^{-1} and 6,32 t/ha^{-1} in Bijeljina. Fertility of maize is affected by numerous factors, including climatic factors, because they represent a group of industrial risks that largely determine the size of the yield (Marković and Jovanović, 2011). After floods, droughts or storms always step up discussion on the provision of crops to compensate the production losses (Breustedt, 2003). Maize producers can not affect the climatic conditions, which greatly affect the realization of yield particularly in dry years. Based on the study of climate parameters in the RS, as a dry years were recorded: 2000, 2003, 2007, 2009, 2011, 2012, 2013 and 2015, when in average lower yields were realized compared to other production year. Some authors suggest the need for expansion of the insurance market of a number of risks and weather derivatives, which represent the more recent financial instruments for risk transfer and which compensation depends on adequate time indicators (Berg, 2002). With weather derivatives can be traded on the stock exchange or OTC, and of utmost importance is the provision of crops that have a leading part in the sowing structure and a higher level of yield per hectare (Marković and Jovanović, 2011), as is the case with maize in Republic of Srpska. The aim of this paper is to examine the impact of annual, vegetative and monthly precipitation on maize yield in the major production regions of Republic of Srpska with the application of the coefficient of correlation analysis. Of particular importance is evaluated correlation in the specific production years, such as extremely dry or wet years. Also, aim of this study was maize yield and mean month air-temperature (Kovačević et al, 2016). By knowing the value of this correlation, production basis risk decreases and increases the effect of eliminating risks with applying the time derivatives. Also, the knowledge on expression of certain climatic factors over many years in specific regions of the production has an effect on the application of the adequate growing technology (Araus et al, 2012).

Materials and methods

The basic data for this study were obtained from the Republic Hydrometeorological Institute in Banja Luka and refer to the schedule and the amount of rainfall for the six production regions in the RS, during the period 2000-2016. Also, data of the Institute for Statistics of RS on actual yield of maize grain during this period of Banja Luka, Prijedor, Novi Grad, Gradiška, Doboj and Bijeljina were used. The high degree of correlation between the total amount of precipitation and the resulting crop yield assume efficient application of the weather derivatives (Vedenov and Barnett, 2004). The weather derivatives are a product of the financial markets and are usually based on the amount of rainfall or an average temperature, and they need to determine the following parameters: type of derivative, the weather index, a weather station, the weather interval and the function of the payment, which involves determining the insurance premium, the threshold level and the monetary value of index (Mußhoff et al., 2005). Evidence of damage incurred as a result of adverse events such as drought, may not be needed at time derivatives, damage assessment does not carry out and producers are prevented that their actions affect the amount of damage and adverse selection at settling damages. In comparison to classical insurance, the biggest disadvantage is the distance of the production site and the reference meteorological station (more distance is greater and differences in the amount of rainfall). The relations between the meteorological conditions and the results of maize production are determined by correlation analysis using the assumption that the yield depends directly on the amount of precipitation in the growing season of the crop, so that each of the rainfall millimeters conditions the growth, development and yield of plants (Schmitz, 2007). The coefficients of correlation were calculated according to the appropriate mathematical form by Pearson (Hartung, 1998), using the software application Excel 2010. They are related to mentioned time interval from 2000 to 2016, as well as for drought years during this period. The degree of interdependence of the independent variable (the amount of precipitation) and the dependent variable (maize yield) is expressed by values from -1 to 1, so in the area from 0,1 to 1 is the positive correlation according to which with the increase of rainfall maize yield also increases. All of the values from 0,3 to 0,7 are considered for moderate correlation, while above 0,7 imply good or full correlation (0,9 to 1). In the case of a value of 0 there is no interdependence, a value of 0 to ± 0,3 show low interdependence (Kozak et al, 2012).

Results and discussion

The analysis of the interdependence of rainfall and grain yield is possible only on the basis of multiannual data. The results of the analysis in this study show that maize is the most common crop in Republic of Srpska (Ostić and Radanović, 2012) and that the yield is very variable, as is the case for the weather during the past 17 years. Average maize yield of six major regions in the RS was 4,05 tha^{-1}, with a range of 3,29 tha^{-1} in Banja Luka to 4,44 tha^{-1} in Gradiška. Highest yielding regions along Gradiška are Bijeljina (4,38 tha^{-1}) and Novi Grad (4,33 tha^{-1}), where they were registered the highest differences in the realization of yield during the studied years (tab. 1). In Bijeljina the grain yield of maize ranged from 1,97 tha^{-1} in 2000 to 6,32 tha^{-1} in 2016 (range of 4,35 ha^{-1}), in Novi Grad with the range of 4,13 tha^{-1}, and the smallest difference was recorded in Banja Luka (2,73 ha^{-1}) and Prijedor (2,84 ha^{-1}). On average, the highest maize grain yields in these regions were achieved in 2016 (5,56 tha^{-1}) and 2004 (5,29 tha^{-1}), and the lowest in 2000 (2,41 tha^{-1}) and 2012. (2,5 tha^{-1}). The lowest annual average temperature was in 2005, with the lowest of 10,4 °C in three regions, and the highest in Bijeljina (11,1°C). The highest temperatures were in 2014 and 2015, with the highest value for Gradiška (13,3°C) in 2015 and the lowest in Novi Grad (12,3°C) in 2014 (tab. 2). Except in Bijeljina, the largest total annual precipitation in all regions, were registered in 2014, when there were floods in Srpska (in Banja Luka 1.686,2 mm, then in Novi Grad 1.575,4 mm), and at least 2011, and the lowest in Gradiška (461,8 mm) and Bijeljina (467,4 mm). The average annual mean monthly temperature was 12,1°C and above this average are temperatures for Bjeljina, Gradiška (12,5°C) and Banja Luka (12,2°C), while the total annual average precipitation amounted to 911,9 mm and above average were in Novi Grad (1035,2 mm), Banja Luka (1030,3 mm) and Doboj (978 mm). The highest difference between the maximum and minimum total annual amount of rainfall during the seventeen-year interval was recorded in Banja Luka (1.098 mm) in 2014 and 2011, and minimum for Bijeljina (622,5 mm), in 2001 and 2011. Also, the study of the same climatological parameters for vegetation period of maize (tab. 3) can only confirm the kind of difference in the aridity of Bijeljina and Gradiska, in relation to, the most humid Novi Grad, then Doboj and Prijedor. Thus, the highest mean monthly temperature of the air in the growing period of maize was registered in Bjeljina (19,3°C) and Gradiška (19,2°C), which is 0,6°C or 0,5°C higher than the average for the six measurement points. The lowest average air temperature for the interval april-september was in Novi Grad (17,9°C) and Doboj (18,3°C). The least variation was occurred in Novi Grad (1,7°C), with a difference of 18,8°C to 2003 and 17,1°C in 2014. The highest difference was 2,5°C at Banja Luka, Prijedor and Gradiška, in which the highest recorded temperature was in 2012, and the lowest in 2004 (Gradiška in 2014). When one look at vegetation precipitation (Table 3) an extremely wet year 2014 can be noticed, as well as already mentioned dry year. In relatively moist year we included 2001 and 2010. The greatest precipitation on average during the growing period of maize were in Banjaluka (564,7 mm) and Doboj (562,1 mm), and the lowest precipitation in Bijeljina (434,9 mm), respectively Gradiška (430 mm), with a maximum difference of 134,7 mm. The differences are much more drastic per year for each of the studied areas. So we have the highest difference in Banja Luka (943,2 mm) and Doboj (852,2 mm), because of 1228,4 mm and 1115,2 mm in 2014 and 285,2 mm or 263 mm in 2011. The smallest differences were in Bijeljina (519,8 mm) and Gradiška (612,4 mm), which almost always have the lowest rainfall and at the same time the highest air temperatures. Such variations in climate parameters and yields indicate the need to examine the correlation amog the total amount and distribution of rainfall and grain yield per individual production locations. In simple interpretation of the obtained yields of maize per year and to production regions it can be seen that the higher yields were realized in arid Bijeljina and Gradiška, wherein not been investigated differences in the type and fertility of the soil, the applied agro-technical measures breeders, the intensity of cultivation and others. Because of the need that given correlation be precisely examined, the numerous accounting of correlation coefficient were implemented, separately for the calendar (I-XII) and the so-called production year (from October last year to September of the current year), before the vegetation period (October prior to March of the current year) and the growing period (IV-IX), as well as subperiods such as: January-Mart (I-III), April-May, April-Jun, Jun- July, July-August, July to September, August-September, and every month in the growing season (tab. 4). Good correlation value for the seventeen-year interval was manifested only in Bijeljina, in the period July-August (0,749) and in average for all places in the same period (0,709) and the production year (0,711). Apart from the abovementioned, in average the largest value of correlation was recorded for August (0,683), and the values greater than 0,5 were observed for: calendar year, vegetation period, April-May and May (tab. 4). The most significant values of the tested correlations were obtained for Doboj and for April (0,693), July-August (0,641) and the production year (0,611), this is of minor importance for the vegetation (0,548) and August (0,502), with the largest central correlations in Bijeljina. In Banja Luka, largest interdependence of rainfall and maize yields was for the production year (0,648), which is the case for Prijedor (0,604). In Gradiška this correlation coefficient was highest in July and August (0,612) and for August in Novi Grad (0,671). When one look at certain periods, the highest correlation coefficients were for the production year, July-August and August. On average, the highest values of this coefficient were obtained in Banja Luka (0,47) and Bjeljina (0,465), and the lowest for Gradiška (0,264) and Prijedor (0,357). Also, in tab. 4, one can see that in average of all six regions for dry years is very good positive correlation between rainfall and maize yield in August (0,789). Slightly lower values were obtained for the production year (0,652), the period of July-August (0,639) and from January- March (0,616). It should be noted that a very good correlation during dry years (0,842) was established in pre-vegetation period for Novi Grad, which is primarily due to precipitation in the period January-March (0,719), which is all together in a good interdependence with a total annual precipitation (0,703). On the other hand, other periods are of negligible correlation, except for August (0,594). Rainfall for January-March are the most important for achieving maize yield in almost all regions in the dry years. There are an integral part of pre-vegetation period and total annual rainfall. The period January-March is of particular importance (tab. 4) not only for Novi Grad, but also Doboj (0,758), Bijeljina (0,671) and Banja Luka (0,592).

Tab. 1. Multi-year average grain yield in maize production in six regions in RS

Year	Average grain yield (t/ha)						Average

Conclusion

By comparing the correlation coefficient value for the period from 2000 to 2016 and dry year during the seventeen-year interval, a certain similarity in the correlation of rainfall and corn yield was identified. It can be concluded that the greatest positive interdependence of these variables was in the period before and during hibridization, as well as in the formation and initial grain filling. The same can be applied to pre-sowing period and therefore production year, with an adequate schedule and amount at certain periods.

The difference is that in the dry years, compared to the entire seventeen-year period, the value of correlation coefficient for the production-year and the july-avgust period is somewhat lower, and slightly higher for August and January-March. The highest coincidence was expressed for the region Banja Luka, Doboj and Novi Grad, with somewhat higher values for dry years, when it comes to annual precipitation.

The highest values of positive interdependence between rainfall and maize yield were recorded for Novi Grad, in pre-vegetation period (0,842), and then to Doboj in the period January-March (0,758), also in dry years, while for the interval 2000-2016 in July-August (0,749) in Bijeljina. On average, for all production regions of maize in RS, greatest value of this coefficient was for August in dry years (0,789).

The obtained values of this correlation analysis can be of great importance in research about the possibilities of time derivatives in the production of maize, as in the Republic of Srpska, also in its specific production regions which differ in terms of humidity, the quality of soil resources and intensity of production and application of adequate agricultural practices and technologies for maize growing.

Abstract

In order to determine the effect of different sowing rates on yield and yield components of domestic winter wheat varieties used for the production of seed, the necessary research were conducted in 2015/16 on the experimental field of the Public Institution Agricultural Institute of Republic of Srpska, Banja Luka (in further text: Institute) in entity of Republic of Srpska, Bosnia and Herzegovina. The field trial has been conducted with the usual methodology inherent to the seed production in our agro-ecological conditions. The trial was designed in four replications and three seeding rates (500, 600 and 700 germinated seeds/m^2) for the wheat varieties Nova Bosanka and Jelena. Optimum utilization of the genetic potential of these varieties and production capacity of soil with adequate agricultural technology largely depends on the number of plants per m^2, as the main yield component. The optimum size of a vegetation area is the area that provides the highest yield per unit area. The different seeding rates have had different effects on the yield of the tested varieties, especially the yield components. This can be explained by the fact that this plant species has a great ability to compensate relationship among yield components and the yield. The highest average values of the number of productive spikes were implemented at the largest sowing rates. Neither one sowing rate showed significantly higher average values for grain weight per spike, mass of 1000 seeds, number of grains per spike and hectolitre weight. The highest average yield over 8 t/ha^{-1} was achieved with sowing rate of 600 germinated seeds.

Keywords: *Yield, Variety, Sowing rates, Yield components.*

Introduction

Wheat has a great influence on human life, so sometimes it is not realistic to see it as a common agricultural or commercial product. It is one of the basic food resources and has greatly influenced the development of man as a social being. Wheat is the most adaptable plant species. The existence of winter, facultative and spring varieties allows growing of this plant species in a significantly wide range, from the equator to near the Arctic Circle in the northern hemisphere and 40 degrees southern hemisphere. New varieties possess a significantly higher genetic potential from older varieties, or populations that have been grown long ago. The limiting factors are still agroecological conditions and the achieved level of technology. The potential number of grains/spike as a component of yield is formed 2 – 3 weeks before the blooming of which a relatively small number of initiated flower primordia survive and form a fertile flowers and grains (Kirby, 1988). The genetic potential of some of the world's wheat varieties is over 14 t/ha^{-1}, but the percentage of utilization of this potential is only about 20% because the average world yield is around 2.5 t/ha^{-1}. Breeders produce varieties targeted to specific areas of production with the particular production technology.

Multiannual yield analysis of several wheat varieties show different levels of variability among years, locations and varieties. Certain elements of production technology may have a decisive influence on the expression of genetic or production potential. Classic agrotechnic can reduce the variation to yield and yield components per year. Achieving extremely large yields, especially considerably higher than our multiannual averages, is the current trend of research among genotype – production technology – environmental factors. The most important elements of the production technology that are controlled by human (selection of varieties, sowing time, sowing rate, amount and type of mineral fertilizer) are designed to maximally adjust the environmental conditions to the genotype selected for production. Sowing rate, or the number of plants can not influence the increase of the yield in a significant percentage, if it is not in the corresponding correlations with other components of yield during the growing season (Tavčar, 1959, Đurić, 2001, Prodanović *et al*., 2009).
The aim of this study was to determine the influence of different sowing rates on yield and yield components of domestic wheat varieties.

Materials and methods

This paper analyzes the yield and some yield components of the domestic winter wheat varieties in the production (Nova Bosanka and Jelena) through field trials conducted on the experimental field of the Public Institution Agricultural Institute of Republic of Srpska (Bosnia and Herzegovina) during 2015/16. Trials were set up in four repetitions on brown - lowland soil. The land was cultivated in the traditional manner, the depth of plowing was about 20 to 25 cm, precrop was corn and sowing was carried out in 04.11.2015. In basic fertilization, 300 kg NPK 8:24:16 was incorporated into soil. Three sowing rates were tested, including 500, 600 and 700 germinating grains per m^2 for both wheat varieties.

Results and Discussion

The yield is a complex trait determined by more simple features, which are determined by complex genetic systems. The yield is controlled by the factors responsible for the adaptation or tolerance to the factors that limit the realization of yield for each plant species and the factors under which control is productivity. This shows the current yield which is a part of the existing potential for yield in a given agro-ecological conditions and with appropriate production technology. Potential for yield is the grain yield produced by the variety in conditions to which it is adapted without limitation for the necessary nutrients and water, with successful control of other factors that may reduce the yield.

Table 1. Realized yields t/ha^{-1} for the variety Jelena with different sowing rates

Repetition	Sowing rate, number of germinated seeds/m^2					
	500		600		700	
	$kg/5m^2$	t/ha^{-1}	$kg/5m^2$	t/ha^{-1}	$kg/5m^2$	t/ha^{-1}
I	4,69	9,38	4,94	9,28	4,75	9,59
II	3,95	7,90	4,10	8,20	4,00	8,10
III	4,15	8,30	4,00	8,00	3,97	7,94
IV	4,18	8,36	4,23	8,46	4,70	9,40
Average	**4,24**	**8,48**	**4,31**	**8,48**	**4,35**	**8,75**

Table 2. Realized yields t/ha^{-1} for the variety Nova Bosanka with different sowing rates

Repetition	Sowing rate, number of germinated grains/m^2					
	500		600		700	
	kg/5m^2	tha^{-1}	kg/5m^2	tha^{-1}	kg/5m^2	tha^{-1}
I	5,46	10,52	5,63	11,26	5,75	11,50
II	5,06	10,12	4,90	9,80	4,90	9,80
III	4,97	9,94	5,11	10,20	5,08	10,16
IV	5,93	11,86	5,80	11,60	5,68	11,36
Average	**5,35**	**10,61**	**5,36**	**10,71**	**5,35**	**10,70**

The highest absolute grain yield per hectare of 9,59 t/ha^{-1} had variety Jelena with a sowing rate of 700 germinated grains/m^2. The average yield for the tested variants was almost identical and ranged from 8.48 t/ha^{-1} to 8.71 t/ha^{-1}, and the overall average was 8.65 t/ha^{-1}, which is only about 0,9%, and it does not represent statistical significance. The lowest yield of variety Nova Bosanka of 9,80 t/ha^{-1} was achieved with two different levels of sowing rates, respectively with 600 and 700 germinated grains per m^2. The lowest yield of the variety Jelena of 7,90 t/ha^{-1} was achieved with two different levels of sowing rates, respectively with 500 and 600 plants per m^2 and the overall average for the variety was 10.71 t/ha^{-1}.

Nova Bosanka had the highest absolute yield per hectare of 11,86 t/ha^{-1} with the sowing rate of 500 germinated grains/m^2. The average yield for the tested variants was 10,71 t/ha^{-1}. Uniform yield may be the result of good compensation or redistribution of assimilates from photosynthetic organs to grain.

The yield difference between the tested varieties was evident and it amounted to 2.06 t/ha^{-1} with the same agrotechnic. Such significant difference under the same conditions of performing trials can certainly be attributed to the different genetic potential, primarily the current yields. One explanation may be that variety Jelena is significantly better than variety Nova Bosanka and for this reason the difference in yield is present. It is well known that, when it comes to a greater number of varieties, the quantity and quality have a negative correlation.

The effects of lower sowing rates are compensated by the formation of more large and productive spikes per plant, and also by the higher number of grains per spike. One of the consequences may be that the number of grains per spike determines the potential or actual yield. Agroecological conditions, which affect grain formation and grain yield have certainly played an important role in the formation of final yield in this variant. The number of spikes per unit area is usually in negative correlation with the number of grains in the spike and the yield. The variation in yield among different sowing rates is usually mitigated by various compensating relationships among the yield components.

The number of spikes per m^2 for three sowing densities fot variety Jelena ranged from 516 to 720, more exactly 546 to 664, representing a significant difference of 18 % in percentage. The number of spikes per m^2 for three sowing densities for variety Nova Bosanka ranged from 544 to 721, more exactly 567 to 663 spikes, representing a significant difference of 15 % in percentage.

Table 3. Harvested number of spikes/m^2 for variety Jelena with different sowing rates

Repetition	Sowing rate, number of spikes/m^2 and number of grains/spike					
	500		600		700	
	spike/m^2	number of grains/spike	spike/m^2	number of grains/spike	spike/m^2	number of grains/spike
I	562	41	608	34	622	33
II	528	36	636	36	720	34
III	580	38	680	33	667	28
IV	516	34	616	35	645	31
Average	**546**	**37,2**	**635**	**34,5**	**664**	**31,5**

The increased number of grains per spike or increased number of grains per unit area contributes to a positive correlation between the number of grains per unit area and yield (Shearman *et al.* 2005). Similar results have been obtained by other authors, who are dealing with the mentioned issue (Borojević 1992, Malešević 2004, Đurašinović 2009, Prodanović *et al.* 2009). Another important yield component is grain weight (1000 grains), and it is much more stable feature from the number of grains per unit area (Bingham *et al.* 2006, Peltonen *et al.* (2007).

Table 4. Harvested number of spikes/m^2 for variety Nova Bosanka with different sowing rates

Repetition	Sowing rate, number of spikes/m^2 and number of grains/spike					
	500		600		700	
	spike/m^2	number of grains/spike	spike/m^2	number of grains/spike	spike/m^2	number of grains/spike
I	544	70	609	60	623	48
II	568	65	635	55	721	55
III	556	64	680	57	665	54
IV	604	66	616	53	643	46
Average	**567**	**66,2**	**635**	**56,2**	**663**	**50,7**

On the basis of sample, the average weight of spike of 1.65 g was recorded in variety Jelena. The average grain weight was 1.31 g, while the spike index was 0,79 % with 37,2 grains per spike with the sowing rate of 500 germinated grains/m^2. Variety Nova Bosanka had spike weight 3.7 g, grain weight 2,55 g, harvest index 0,82 %, with an average of 66,2 grains per spike in the sowing rate of 500 grains/m^2. These values, especially for variety Nova Bosanka, indicate a high genetic potential of over 15 t/ha, which is obtained by multiplying the number of spikes per m^2 with the average spike weight.
It is important that with the increase in the sowing rate there is usually a decrease in the number of grains per spike which is recorded in both varieties. It is important that with the increase in the sowing rate there is usually a decrease in the number of grains per spike which is recorded in both varieties.

Conclusion

Based on the above, the following conclusions can be drawn:
The average lowest yield in the tested varieties was at the sowing rate of 500 germinated grains/m^2, but it is important that this difference is only 1.03% in relation to the highest yield. The highest yield for both varieties was achieved at the sowing rate of 700 germinated grains/m^2. For both tested varieties, the sowing rate of 600 – 700 germinated grains/m^2 should

be maintained, based on the parameters of seed quality, sowing time and soil preparation to determine the sowing rate.
From the research results can be seen how environment factors had a huge role in the formation of yield through the number of germinated grains or spikes as one of the main components of yield.
The expected differences in yield between the tested variants did not occur due to the favorable influence of agroecological factors throughout the year.

Abstract

Buckwheat is a plant which has been spreading in Bosnia and Herzegovina (BiH) in the last decade. Because of its brief vegetation period, this crop species is suitable for hilly-mountainous regions.

In 2015, the experiments were set in the three localities of Sarajevo – Romanija region (experimental field "Kula" of the Faculty of Agriculture, University of East Sarajevo; private economy "Sando" on the Nišići plateau; and private agricultural farm "Jugović" in Mokro village), and two variants of fertilization (control variant – without the use of organic and mineral fertilizers and the use of $N_{60}P_{60}K_{70}$. The Slovenian variety "Darja" was used for the experiments. The highest yield of buckwheat grains was at Nišići plateau (1.95 t ha^{-1}) and the lowest (1.24 t ha^{-1}) in East Sarajevo. The highest absolute mass of a buckwheat grain (25.68 g) was at Nišići, and the lowest (18.59 g) in at "Kula" of East Sarajevo. The buckwheat grain grown in at "Kula" East Sarajevo had the smallest hectolitre mass (51.8 kg), while at the localities of Mokro and Nišići the hectolitre masses were almost identical (55.5 kg and 55.7 kg). The average shell content for all these localities and fertilization variants was 24%.

Keywords: buckwheat, locality, fertilization, agro-ecological conditions, yield.

Introduction

Buckwheat is an old plant species native to mountain areas of Central and North Asia. Mongols brought it to Europe at the end of the 14^{th} century. Today, buckwheat is fostered worldwide on about 2.3 million hectares, with an average yield of approximately 1.0 t ha^{-1}.

After the World War II, the cultivation of buckwheat stops because of intensified production of other cereals grains, migration of rural population into industrial areas, but especially because of low yield and uneconomical production. Since 1995, buckwheat is fostered again on arable lands of BiH. The number of plots where the buckwheat is grown increases every year, and the reasons are: (i) buckwheat is suitable for growing in mountain areas that dominate in BiH, (ii) buckwheat has low need for fertilizers and pesticides; (iii) a significant number of producers that certify buckwheat as an organic. Because of its variety of use in nutrition and medical treatments, there is a great demand on the domestic and foreign markets for the buckwheat products. Thanks to simple agrotechnics which includes cultivating without the usage of chemical means, buckwheat can be cultivated as main or subsequent crop or as a part of eco-corridor between certain crops.

The objective of this work is to examine and compare the yield of buckwheat variety "Darja" in three different localities in Sarajevo-Romanija region (Bosnia and Herzegovina). These studies, although short-term, can contribute to spread the cultivation of buckwheat, and determin areas for production of high-quality buckwheat.

Material and methods

In 2015, , some studies have been conducted in Sarajevo-Romanija region to determine which locality is suitable for growing buckwheat, and whether mineral nutrition influences the yield and components of yield of buckwheat. Experiments had been set and conducted in three different localities and for sowing was used buckwheat variety “Darja”.

Darja was developed by crossing black buckwheat and Russian buckwheat genotypes The flowers are white, the seeds are dark-brown, with a higher percent of shell. This plant is diploid variety, its side flower branches end in flower buds, while the main flower branch has unlimited growth. It is resilient to drought and high temperatures as well as on lodging, but it is sensitive to low temperatures.

The extracts of soil were taken before the set of experiment with agrochemical probe that depth to 0-30 cm.

Chemical analysis has been made in the laboratory of the Faculty of Agriculture in East Sarajevo:

-pH value of soil: (I) in water (H_2O) or active reaction of soil, (II) in solution 1M KCl or substitutional reaction of soil, electrometrically.

-Determination of humus, bichromatic method by TUJURIN

-Determination of phosphorus (P_2O_5) spectrophotometrically, and potassium (K_2O), photometrically

-Determination of overall nitrogen according to the modified method by KJELDAHAL This difactorial experiment (locality and fertilization) was set by random block system with four repetitions.

<u>First factor - Locality (A):</u>

- Experimental field of the Faculty of Agriculture in East Sarajevo, approximately 500m above the sea level (A_1);
- Private agricultural farm “Jugovic”, in Mokro village, approximately 905m above the sea level (A_2);
- Private agricultural farm “Sando” in Nisici, approximately 1000m above the sea level. (A_3).

<u>Second factor- fertilization (B):</u>

- Control (B_0)
- $N_{60}P_{60}K_{70}$ (B_1)

The basic soil cultivation plowing was conducted in autumn to depth of 30 cm, and before sowing, during soil preparation, NPK fertilizer is added. The surface of elementary plot was 12 $m^{2.}$ Sowing was done manually to a depth of 4cm and a number of plants was 250 per m^2

In A_1 land the sowing of buckwheat was done manually on 08.05.2015, and the manual harvest took place on 18.09.2015. Experiment in A_2 was set on 25.05.2015 and harvest of14.09.2015. On A_3 land buckwheat is sowed on 1.06.2015 and harvested on 22.09.2015.

Meteorological data (temperature and precipitation) were followed at the two registered weather stations (Butmir and Sokolac).

Studies included: grain yield (t ha^{-1}), absolute mass (g), hectoliter mass (kg), percentage of shell.

Grain yield (t ha^{-1}) was calculated based on randomly picked 20 plants in each parcel and locality and by analyzing the average yield by plant, and then recalculated to yield per hectare.

The mass of 1.000 seeds (g) was determined from the fraction of pure seed obtained from the analysis of purity. Authors manually counted 800 seeds (100 seeds in 8 different chambers). Seeds from each chamber were especially measured on analytical scale. Given the values, it is calculated an average mass of 100 seeds which then multiplied by 10 and got the average mass of 100 seeds.

The volume mass of seeds (kg) was determined using the hectoliter scale.

Obtained data were statistically analysed and processed using the program Sigma Plot Windows 2000 (Jandel Scientific, Erkhart, Germany) and Statistica for Window.
The differences between the certain localities for each examined parameter, as well as differences between the fertilizers were tested using the LSD test.

Environmental conditions in 2015

Experimental field „Kula“ of the Faculty of Agriculture in East Ilidza. Experimental field „Kula“ is located 550m above the sea level. Climate in Sarajevo has strong influence of continental climate, with an average annual temperature of 12.5 ° C, and average precipitation amounts to about 900 mm. The highest temperatures are August, and the lowest is January.
In Sarajevo there are approximately 85 days per year with temperature above 30 °C.

Table 1. Meteorological conditions in 2015 and perennial averages for Sarajevo (Meteorological station in Sarajevo)

Month		I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII
Average (1961-1990)	Temp.(°C)	-0.8	1.7	5.5	10	14.8	17.7	19.7	19.4	15.9	10.9	5.6	0.4
	Pptn. (mm)	74	69	73	76	85	94	83	73	73	79	98	88
Year: 2015.	Temp.(°C)	0.9	1.7	5.3	9.2	16.1	17.8	23.2	21.8	17.6	11.1	6	-0.5
	Pptn. (mm)	112.6	56.6	80.4	43.6	52.9	91	9.4	57.4	60.2	124	75	12.5

Comparison of the meteorological conditions during the time of research in 2015 in experimental field in East Ilidza with perennial average, showed higher monthly averages of temperature and lower amount of precipitation. In July there was only 9.4 mm of rainfall while perennial average for this month is above 83 mm.
Experiment was set in an alluvial soil (fluvisoil). Chemical analysis is shown in Table 2.

Table 2. Chemical characteristics of soil in experimental field in East Ilidza.

Depth(cm)	pH/H_2O	pH/KCl	Humus	N	soluble mg/100g	
			%	%	P_2O_5	K_2O
0-30	7.16	6,39	4,12	0,27	>40	36,41

Private agricultural farm Jugovic (Mokro)

Experiment was set on private farm in Mokro village area. The average annual temperature amounts to 6.8°C, with absolute highest temperature 33.6°C and the lowest -30°C. According to Micevic (1979), Sarajevo-Romanija region has a harsh mountain climate with cold winters and cool summers. Vegetation starts on April 8th and lasts until October 22nd, or 197 days. This is the period of time when temperatures rise above 5°C and when the vegetation of woody plants starts. The vegetation growing season with temperatures above 10°C starts on May 6th and lasts until September 24th, or 141 day. Late spring frosts can appear by the end of May, but they’re most frequent in the first decade of May. The intensity of frosts is weak to moderately strong, with temperatures from -1°C to -4,2°C. Annual precipitation amounts to 800mm, and in period of time from April to September it amounts to 430mm. August is a ‘critical’ month because the temperatures are high and precipitation is low. Meteorological conditions and perennial average for the private farms “Jugovic” and “Sando” are shown in Table 3.

Table 3. Meteorological conditions in 2015 and perennial averages for Sokolac municipality (Meteorological station in Sokolac)

Month		I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII
Average (1961-1990)	Temp.(°C)	-4.2	-2.6	2.2	5.7	11.5	14.6	16	15.7	12.2	7.7	2.8	-1.8
	Pptn. (mm)	51	45	63	71	81	96	67	76	75	86	80	57
Year: 2015.	Temp.(°C)	-2.5	-1.3	2.1	6.2	13.4	15.3	19.8	18.9	14.5	8.4	3.2	-1.6
	Pptn. (mm)	89.9	56.1	74.7	53.2	75.4	113.3	25.2	85.7	84.3	106.9	71.2	0.3

Comparison of the meteorological conditions during the time of experiment in 2015 on private farms in Mokro and Nisici with perennial average showed higher monthly averages of temperature, while the amount and distribution of precipitation varied. Compared to perennial average, in May there was less rainfall, in June there was 17.3 mm more rain, in July 41.8 mm less rain, and in August 10 mm more rain. According to the soil map of BiH (Resulović et al., 2008) the most common type of soil in Mokro is acidic brown soil (Dystric Cambisol), which is also the type of soil where we conducted our experiment. Acidic brown soil (Dystric Cambisol) is a Ah-Bv-Cn type of soil, and it's mostly found in mountain areas, 450-1.000m above the sea level. Dystric Cambisol forms itself on quartz-silicate substrates, compact rocks and loose sediments. It has high acidity and low content of bases. They are suitable for growing potatoes and some kinds of grains. When determining the suitability of land for irrigation and agricultural production, mechanical composition is analyzed as one of the most important physical properties, because the mechanical composition influences other physical properties of the land. Analysis of soil is shown in Table 4.

Table 4. Chemical analysis of soil.

Depth of taking samples (cm)	pH/H_2O	pH/KCl	$CaCO_3$ (%)	Humus (%)	Overall N	P_2O_5 (mg/100 g)	K_2O (mg/100 g)
0-30	6,22	5,17	1,1	5,1	0,336	1,43	34,3

Chemical analysis of samples of acidic brown soil, taken at 0-30 cm depth, has shown that soil has acidic reactions, is well supplied with humus, well provided with potassium, but poor with Phosphorous. According to Resulović et al. (2008), this type of soil is poor in content with easily available phosphorus, and has very high scale of potassium, which author also recorded in analysis of acidic brown soil taken from two different depths.

Private farm Sando (Nisici)

Nisici plateau is located 950-1000m above the sea level. This area is dominated by continental and alpine climate, which are also characteristic for higher areas of Central Bosnia. The main characteristics of this type of climate are harsh winters with temperatures as low as -30°C and summers with temperatures rising above 35°C. Annual precipitation is around 1200 mm. The closest meteorological station is located in Sokolac municipality.

Table 5. Chemical analysis of soil

Depth of taking samples (cm)	pH/H_2O	pH/KCl	$CaCO_3$ (%)	Humus (%)	Overall N	P_2O_5 (mg/100 g)	K_2O (mg/100 g)
0-30	5,00	3,89	<1	6,68	0,34	2,32	23,03

Soil at this parcel had strong acidic reactions with high content of humus (6,68%), is well provided with nitrogen and potassium, and has low content of phosphorous.

Results and discussion

Grain yield of buckwheat. The grain yield of buckwheat is affected by environmental conditions, cultural practices and the genetic potential of varieties. According to *Bogadnovic* (1984) the most important components that affect the yield are number of plants per $m^{2,}$ number of grains per plant and the absolute mass of grain. Some authors consider that the yield is greatly affected by cultural practices (*Jevdjovic u cap*, 2012; *Popovic et al*., 2011; *Kasajima et al*., 2007) while others consider environmental conditions as the most influential factor (*Dolijanovic et al*., 2013; *Dolijanovic et al.*, 2014).

Average grain yield of buckwheat, regardless of locality or fertilizers was 1.61 t ha^{-1} (Tabel 6). Highest grain yield of buckwheat was at Nisici (1.95 t ha^{-1}) and the lowest in East Sarajevo (1,24 t ha^{-1}).

Determined differences were statistically highly important, as well as differences between localities in Mokro and Nisici. Grain yield of buckwheat in Mokro village had statistically higher yield compared to one in East Sarajevo. Similar results were found by *Vreva et al.*, (2012) *and Dolijanovic et al.*, (2013).

Table 6. The influence of locality and fertilization on grain yield of buckwheat **(**t ha^{-1}**)**

Locality	Fertilization		Average
	B_0	B_1	
A_1	1.15	1,32	1.24
A_2	1.44	1.86	1.65
A_3	1.74	2.15	1.95
Average	1.44	1.78	1.61
	A	B	AxB
LSD 5%	0.215	0.152	0.352
1%	0.296	0.241	0.428

In control variant, the yield of buckwheat was (1.44 t ha-1) and in variant where fertilization was done by mineral fertilizers (1.78 t ha-1). Identified differences were statistically highly significant.

In addition to the necessary assembly of plants, mineral nutrition of plants, good soil preparation, it was necessary to determine the optimal time of sowing for each parcel in order to avoid bad weather conditions (low or high temperatures, lack of moisture in soil and low relative humidity).

Mass of 1000 seeds. The mass of 1000 seeds highly depends on the external environment conditions and the ways of cultivation of buckwheat. It is the element of yield and along with number of seeds per plant it determines the productivity of the plant. Seeding date influences the mass of 1000 seeds. Most authors consider that the earlier the seeding takes place the higher the mass of 1000 seeds. (Demidenko and Lebedov, 1976; *Ovsejucuk*, 1980).

Average mass of 1000 seeds for all localities and variants of fertilization was 22.98 g (Tabel 7) . The biggest mass of buckwheat seeds was in Nisici (25.68 g), and the smallest in East Sarajevo (18.59 g). Determined differences, as well as differences in seed mass between Mokro and East Sarajevo, were statistically higher important, and the results were influenced by the lack of moisture in soil at the time of forming seeds and the temperature that was higher for 3,4°C compared to other two localities.

Tabel 7. The influence of locality and fertilization on mass of 1000 seeds of buckwheat **(**g**)**.

Locality	Fertilization		Average
	B_0	B_1	
A_1	17.54	19.65	18.59
A_2	23.74	25.61	24.68
A_3	24.63	26.72	25.68
Average	21.97	23.99	22.98
	A	B	AxB
LSD 5%	2.254	1.321	3.743
1%	3.043	2.154	4.538

The yield of buckwheat was (1.44 t ha-1) and in variant where fertilization was done by mineral fertilizers (1.78 t ha-1). In control variant, the mass od 1000 seeds was 21.97g and in variant with fertilizers 23.99 g. Identified differences were statistically highly significant, and are in accordance with other author's results (*Popović et al.,* 2013). In Dolijanovic et al., (2014) research, authors established statistically significant influence of locality on mass of 1000 seeds and fertilizer did not have statistical significance, while in our research both locality and mineral nutrition had great impact on the mass.

Hectoliter mass. Hectoliter mass has less importance in the evaluation of the quality, but is an important property in food industry, especially in the processing of grain. Lower hectoliter mass of grain indicates on lower quality. In less fertile years hectoliter mass is lower and it is an indicator of the STUROST of grains (*Bogdanović*, 1984).

Average hectoliter mass for tested localities and variants of fertilization was 54.3 kg (Tabel 8).The smallest hectoliter mass had buckwheat grains cultivated in East Sarajevo (51.6 kg), while hectoliter masses in Mokro and Nisici were almost identical (55.5 kg and 55.7 kg). Variant with the use of NPK (55.1 kg) compared to control variant (53.5 kg) had statistically higher hectoliter mass of grain.

Table 8. Influence of locality and fertilization on hectoliter mass of buckwheat grains (kg).

Locality	Fertilization		Average
	B_0	B_1	
A_1	50.8	52.4	51.6
A_2	54.7	56.2	55.5
A_3	54.9	56.5	55.7
Average	53.5	55.1	54.3
	A	B	AxB
LSD 5%	1.285	0.854	2.147
1%	1.964	1.582	2.946

Percent of shell. This property depends on hereditary characteristics of the variety. Better varieties have higher percentage of core and less percentage of shell. Percentage of shell is an important indicator of quality of grain, and it depends on grain size and the percentage of fulfillment of grain (Sahov, 1982), but also on the use of mineral fertilizers (Riznicenko, 1976), and average temperature from 19.4 to 20.8°C at the time of germination grain (Fesenko and Dragunova, 1972). Our results are in accordance with these results (Table 9).

Table 9. The influence of locality and fertilization on the percentage of shell **(%)**

Locality	Fertilization		Average
	B_0	B_1	
A_1	26.8	25.1	25.9
A_2	23.5	22.1	22.8
A_3	23.8	22.6	23.2
Average	24.7	23.3	24.0
	A	B	AxB
LSD 5%	0.529	0.431	0.753
1%	0.682	0.582	0.896

Average content of shell for all localities and variants of fertilization was 24%. Grains of buckwheat cultivated in East Sarajevo had statistically higher percentage of shell compared to grains in Mokro and Nisici. Compared to variants that used NPK fertilizers, variants without fertilization had significantly higher content of shell.

Conclusion

Based on data obtained from cultivating buckwheat at three different locations (East Sarajevo, Mokro and Nisici) and two variants of fertilization (Control variant and $N_{60}P_{60}K_{70}$(we have following conclusions:

- In our agro-ecological and soil conditions buckwheat has a high yield of grains, which are rich in overall proteins, mineral salts, oils and contains significant amounts of dietary carbohydrates and cellulose.
- Buckwheat cultivated in East Sarajevo had the highest percentage of shell, the lowest yield of grain, absolute mass and hectoliter mass, while buckwheat in Nisici had the highest yield and both, highest absolute mass and hectoliter mass.
- The usage of mineral ferilizers has positively influenced the most of tested quantitative characteristics of buckwheat.

Abstract

The consumption of *Brassica* spp. is quite high and it represents an important part of a well-balanced diet in the northwest of Spain. Seasonality and perishability cause that some of these vegetables are in the necessity of applying preservation technologies. Some of these technologies are frequently preceded by blanching. In general, the blanching limits the losses of nutritive and organoleptic qualities during processing. Peroxidase is one of the most heat-resistant of vegetable enzymes, which has led to it being used as an indicator of the adequateness of the blanching process. This enzyme has also been associated with losses in the colour, flavour and nutritional values of raw and processed foods. The inactivation of peroxidase depends on the temperature of the blanching water and the type and size of the vegetable. Galega kales (*Brassica oleracea* var. *acephala*) area popular vegetable among people from Northwest Spain, which are easy to find among local markets. Blanching was applied in this study in order to examine the inactivation of peroxidase in Galega kales. The objective was to obtain kinetic parameters of peroxidase inactivation that can be used in further analyses. Inactivation experiments were carried out at five different temperatures ranging 75–95ºC. The peroxidase activity was followed spectrophotometrically at 470 nm. Kinetic parameters, D and *z* values, were also determined. Fresh Galega kale had high initial peroxidase activity in this study. The enzyme inactivation was dependent on temperature and heating time. Peroxidase activity showed first-order kinetics with *z* values of 15.51ºC.

Keywords*: Peroxidase, Galega kales, Blanching, Inactivation, Kinetic parameters.*

Introduction

Brassica spp. are of great economic importance as vegetable crops. Their consumption is quite high and it represents an important part of a well-balanced diet in the northwest of Spain.

Kale (*Brassica oleracea* var. *acephala*) is a particular vegetable in this group, due to the presence of several beneficial compounds, such as vitamins, glucosinolates, phenolic compounds, carotenoids, etc.

The use of kale is limited by its seasonality and perishability; therefore, these vegetables are in the necessity of applying preservation technologies it is necessary. However, its industrial processing is until now low (mainly by freezing or canning).

Freezing or canning are frequently preceded by blanching. In general, the blanching limits the losses of nutritive and organoleptic qualities during processing. Peroxidase is one of the most heat-resistant of vegetable enzymes, which has led to it being used as an indicator of the adequateness of the blanching process (Goncalves *et al*., 2009; Arnnok *et al*., 2010).

Peroxidase has also been associated with losses in the colour, flavour and nutritional values of raw and processed foods (Fils *et al*., 1985; Yemenicioğlu *et al*., 1998; Polata *et al*., 2009).

The inactivation of peroxidase depends on the temperature of the blanching water and the type and size of the vegetable. Selecting an appropriate time-temperature combination (TTC) is important for enzyme inactivation processes and maintaining.
Galega kales (*Brassica oleracea* var. *acephala* cv. Galega) area popular vegetable among people from Northwest Spain, which is easy to find among local markets.
The objective was to obtain kinetic parameters of peroxidase inactivation that can be used in further analyses

Material and Methods

Fresh Galega kale plants were purchased at local markets supplied by different production areas in the province of Ourense (Galicia, northwest Spain). Samples were of uniform size, random appearance and defect free. The plants were transported to the laboratory, where they were washed with deionised water and inedible portions were discarded. Whole plants were analyzed (in this case, the ratio of leaves/stems was 75/25 [w/w]).
For heat treatments, kales were immersed in a thermostatic water-bath (±1ºC), at five temperatures (75, 80, 85, 90 and 95ºC), and collected after reaching pre-established time. After blanching, the samples were cooled in an iced water-bath for 2 min. Excess of moisture was removed before any further analysis.
A fresh sample was taken as a control.
Fresh and blanched samples (5 g) were homogenized with 25 mL Mili-Q water, and after they were centrifuged at 6,000 rpm for 15 min at 4 ºC. The mixture was filtered, and the supernatants were used for the determination of activity.
The filtrate was mixed with peroxidase (POD) substrate solution (0.1 mL guaiacol, 0.1 mL H_2O_2 (33%) and 99.8 mL potassium phosphate buffer (0.1 mol/L, pH=6.5). POD assays were conducted by pipetting 0.1 mL of enzyme extract and 2.9 mL of substrate solution in a quartz cuvette. POD activities were measured from the increase in absorbance at 470 nm using spectrophotometer (UV-1800-VIS, Shimadzu, Singapore). The reaction was monitored for 20 min. All the experiments were replicated thrice and average values were used in analysis.
One unit of peroxidase activity (U) was defined as the amount of enzyme that caused the oxidation of 1.0 μmole of guaiacol in 1 min. Total initial enzyme activities were expressed as specific activity (U/g)
The residual activity was determined as (A/A_0) where: A = mean enzyme activity (after blanching); A_0 = mean initial enzyme activity (before blanching).
First-order inactivation constant (*k*) was calculated from the slope of the natural logarithm (ln) of A/A_0 *vs.* time graph. Decimal reduction time (*D* value) was estimated from the relationship between *k* and *D* value: $D = \ln(10)/k$. The *z* value, which is the temperature increase required for a one-log10 reduction (90% decrease) in *D* value was determined from a plot of $\log_{10} D$ vs. temperature.

Results and Discussion

The fresh kales showed an initial peroxidase activity of 109.70 ± 17.86 U/g.
Figure 1 presents the residual activity (P/P_0) as a function of time for the different tested temperatures of blanching. The data was normalized in relation to the initial activity observed in the fresh product (A_0)
The enzyme inactivation was significantly affected ($P < 0.05$) by the blanching time and temperature (the higher the temperature, the more efficient is the blanching process).

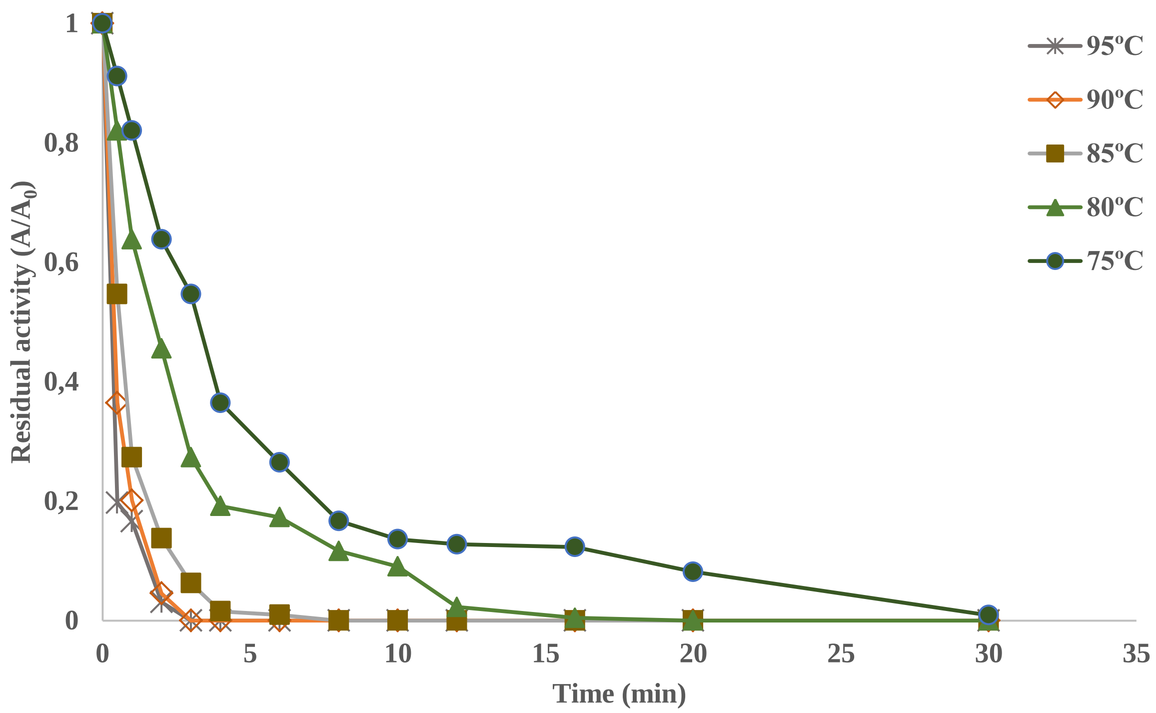

Figure 1.- Peroxidase activity of blanched Galega kale

The peroxidase residual activity at 6 min decreased a 73.54 % to 75 ºC, 82.7 % to 80 ºC and 99 % to 85 ºC. On the other hand, no activity of peroxidase was detected after 3 min of thermal treatment at 90 ºC, and after 2.5 min at 95 ºC.

The initial heat inactivation of peroxidase enzyme is rapid followed by a much slower inactivation period.

It has been pointed out that quality the quality of blanched food is superior even if some peroxidase activity remains because high time for complete inactivation can result in undesirable nutritive and sensorial qualities (Böttcher, 1975; Aamir *et al*., 2013). On the other hand, other problem associated with the complete inactivation of peroxidase is the presence of 1–10% of more heat-stable peroxidase isoenzymes in most vegetables, which are difficult to inactivate (Williams *et al*., 1986; Güneș *et al*., 1993).

An acceptable level of inactivation during blanching represents a 90% loss of original peroxidase activity (Williams *et al*., 1986). Table 1 presents different time–temperature combinations required to achieve this objective.

Table 1.- Time–temperature combinations required to achieve an acceptable level of inactivation of peroxidase activity during blanching.

Temperature (ºC)	Time (min)	% activity POD
75	16	10%
75	20	7%
75	30	2%
80	8	10%
80	10	8%
80	12	2%
80	16	0%
85	3	6%

85	4	1%
85	6	0%
90	2	4%
90	3	0%
90	5	0%
95	2	3%
95	3	0%
95	4	0%

An acceptable inactivation of kale peroxidase was accomplished at 75 °C with 16 min and at 80 º C with half the time (8 min). Complete inactivation of kale peroxidase required 16 min at 80ºC, 6 min at 85 ºC and less than 3 min at 90 and 95°C.

Mondragón-Portocarrero *et al*. (2006) reported that blanching of turnips for 2 min in steaming and boiling water. Gonçalves *et al*. (2009) observed that blanching of broccoli caused losses of 90% of peroxidase activity at 70, 75, 80, 85 and 90ºC for 6.5; 2.7; 1.2; 0.7 and 0.4 min, respectively. Okoli *et al*. (1988) also reported that blanching of spinach and amaranth at 95 ºC for 1 min was sufficient to inactivate the peroxidase.

Thermal resistance of enzymes is traditionally expressed in terms of *D*-values and *z*-values. The semi-logarithmic plot of the changes in peroxidase activity was presented in Figure 2.

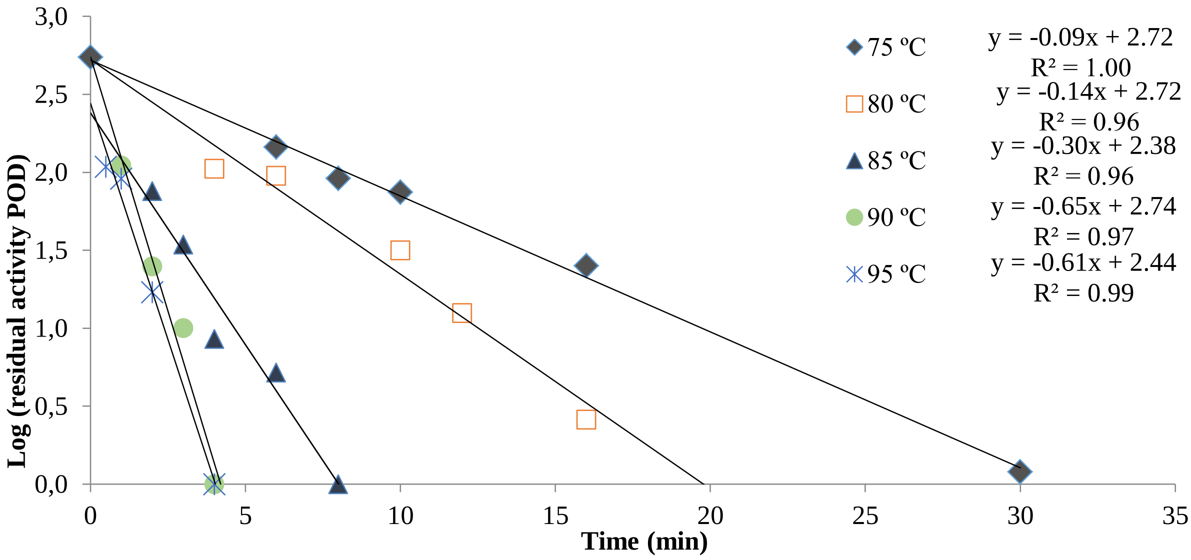

Figure 2.- Decimal reduction curve for peroxidase activity of kales.

Thermal degradation kinetic of peroxidase followed a first-order kinetics, with high R^2 values (0.96-1.0). D values ranged between 11.28 and 1.24 at the temperatures studied. *z* value for thermal inactivation of peroxidase was 15.51 ºC (R^2 = 0.97).This result was in agreement with those reported by Rayan et al. (2011), who found that *z* values for POD from cauliflower was 15.27 ºC, and it is in the range of those obtained for other vegetables, which ranged from 13.56 ºC for turnip puree to 37 ºC for corn-on the cub POD (Holdsworth, 1992).

The thermal sensitivity of an enzyme is affected by a number of different factors such as pH, ionic strength of the medium or type of vegetable.

Conclusions

Kales peroxidase enzyme inactivation due to water blanching treatments follows first-order model kinetics. Six min at 85 ºC and less than 3 min at 90 and 95°C are sufficient to inactivate 90% of the peroxidase activity. The kinetic parameters (*D* and *z*) could be used to optimize the blanching process in kales, reducing the process time and thus minimizing the loss of nutritional and sensory properties.

THE YIELD AND YIELD COMPONENTS OF SOME SILAGE MAIZE (ZEA MAYS L.) VARIETIES AS THE SECOND CROP

Bilal KESKİN*, Hakkı AKDENİZ , Süleyman TEMEL, Barış EREN

Igdır University, Agricultural Faculty, Department of Field Crops, Turkey
*Corresponding author: bilalkeskin66@yahoo.com

Abstract

The aim of this experiment was to assess yield and yield components of ten silage maize varieties (72 MAY 80, OSSK 644, TK 6063, OSSK 596, TK 6060, HİDO, RX 9292, 71 MAY 69, SHEMALL and OSSK 602) at the Agricultural Research and Extension Center, Igdır University from North East Turkey, in 2015. The experimental design was the completely randomized block with three replications on the soils of a clay silt loam. Results of experiments indicted that the yield and yield components of silage maize varieties as second growing crop were significantly different. It was reported that highest plant height (271.5 cm, OSSK 644), forage yields (99.47 t ha^{-1}, TK 6063), dry matter ratios (38.92%, HİDO), dry matter yields (31.49, 31.52 and 31.63 t ha^{-1}, TK 6063, HİDO, TK 6060 respectively), leaf ratios (24.92%, RX 9292), stem ratios (49.49%, HİDO), cob ratios (49.58%, TK 6063), leaf number (13.23 pieces, HİDO) and plant weights (1044.58 g, TK 6063) were found. It could be concluded that TK 6063 maize variety seemed to be the best suitable for silage between examined maize varieties and based on forage yield, dry matter yield, cob ratio and plant weight in the region conditions.

Keywords: *maize, varieties, yield, second crop*

Introduction

Maize (*Zea mays* L.) is one of the most important juices in animal feed, either green or as silage in the feed chain. The increase in the need for roughage in the livestock sector in recent years has naturally led to increased interest in silage maize varieties. Early maturing varieties are also very important so that they can be stored easily and do not create an extra drying cost (Vartanlı, 2006). Even though there is no serious hunger problem in our country today, an unbalanced feeding, especially based on cereals is seen. Most of the commonly used roughage feeds in our country constitute very low harvest residues in terms of animal feed known as straw. Maize has a great importance in terms of high yield from the unit area in summer grain types and especially in the short term because it is a product that can be grown in the year (Emeklier, 1990). As a result of the studies carried numerously, it has been emphasized that the identification of genotypes suitable for ecological conditions in the plant species with such a wide varieties is vital (Sade et al., 2005). This research was carried out to determine performances of some silage maize varieties regarding yield and yield components as the second crop in 2015.

Material and methods

The study was conducted on then maize hybrids (72 MAY 80, OSSK644, TK6063, OSSK 596, TK 6060, HİDO, RX 9292, 71MAY69, SHEMALL and OSSK 602) and all the maize cultivars were sown in the experimental soil with clay-loamy texture, pH 8.6, lightly salted (EC 1.37 dS/m), organic matter content (1.20%) and lime content ($CaCO_3$: 22.27%), (Erdogan, 2013) 24 June 2015 at the Agricultural Research and Extension Center, Igdır University from North East Turkey. The crop was sown in 3 replications using randomized complete block design. Ammonium sulphate half of the rate of 150 kg ha^{-1} and triple super phosphate at the rate of 10 kg P_2O_5 were applied for all plots as a fertilizer, and the rest of nitrogen were applied when the plants were reached to 40-50 cm height. The ten maize cultivars used for this research were chosen from the area with loam and sandy soil, in the texture of Agricultural Faculty of Igdır University in last week of June 2015. The experimental design was a randomized complete block with three replications (the soil lime 6.53%, soil pH 7.98, soil electrical conductivity 1.8 dS m-1). The plots size was 5 m x 3.5 m, having a row spacing of 0.70 m and space between plants of 0.20 m. Before planting, half of the total fertilizer with 15 kg pure N (ammonium sulphate with 21% N) and all phosphorus with 10 kg P_2O_5 were applied for all plots. The mean temperature from April to September was 22.8 ^oC, relatively moisture 43.2, mean precipitations 23.8 mm and the lowest precipitation was 4.7 and 5.0 mm (Anonym, 2015). Irrigations were applied by sprinkler system until the flowering, and then furrow irrigation were applied in all plots of the experiment according to the capacity of the soil. The two centered rows of each plot were harvested when the kernel was at the milk-dough stage for forage yield on 24 June 2015. The morphological fractions of the plant leaves (blade + sheath), cobs were separated from the stem from each plot manually.

Statistical analysis

The data of the research were subjected to a variance analysis using analysis technique, and Duncan's multiple comparison tests was applied to compare treatments means (SPSS, 1991).

Results and discissions

Plant height (cm). Forage plant height (cm), forage yield, dry matter ratio (%) and dry matter yield (t ha^{-1}) of silage maize varied significantly by variety (Table 2). Plant height is an important component which helps in the determination of grow attained during the growing period. Plant height ranged from 206.7 to 271.3 cm with the trial average being as a means of maize varieties. Plant height was highest in the OSSK 644 variety (271.3 cm), though did not statistically differ from other varieties except from OSSK 602 variety (Table 1). The present results fit with the findings of Keskin at al. (2017). The results of the plant height were found to be partially similar to plant height ranged 250.8-291.8 cm by Atakul at al. (2016). Akdeniz and Koç (2017) reported that the plant length was 273.6-316.9 cm, Tantekin et al. (2017) that height of the plants was 263.33–314.66 cm.

However, there was a relationship between forage yield and plant height (Fig. 1).

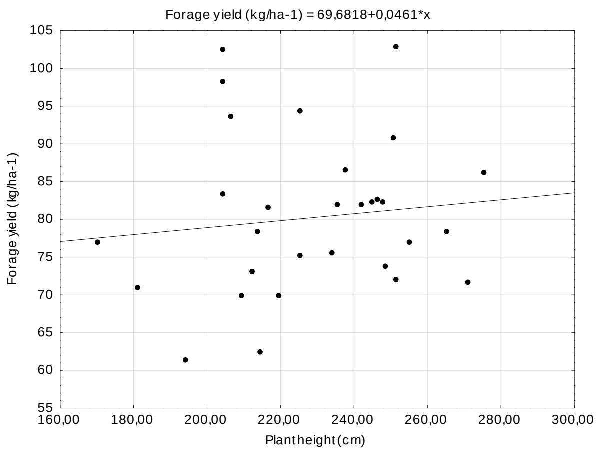

Figure 1. A relationship between forage yield and plant height

Forage yield (t ha^{-1}). As is presented in Table 1, forage yield ranged from 64.16 t ha^{-1} with OSSK 602 variety to 99.47 t ha^{-1} with TK 6063 variety. The highest forage yields were obtained from TK 6063 and TK 6060 varieties in the present trial in Figure 2. These findings of forage yields were quietly consisted with some varieties although forage yields are lower than finding by Keskin et al. (2017). Atakul at al. (2016) green herbage yields maize, (55.92-80.87 kg ha^{-1}), Akdeniz at al. 2004 found considerable differences among cultivars in green herbage 28.5-76.08 kg ha^{-1} and hay 7.4-14.6 kg/ha-1, Akdeniz and Koç (2017) suggested that average yields of maize cultivars with 45.6-58.9 kg ha^{-1} were higher than results of this trial. Also, Tantekin et al. (2017) cited that green herbage yield was 56.9-108.2 kg ha$^{-1.}$ These differences can be attributed agronomic, edaphic and environmental factors responsible for these differences yields

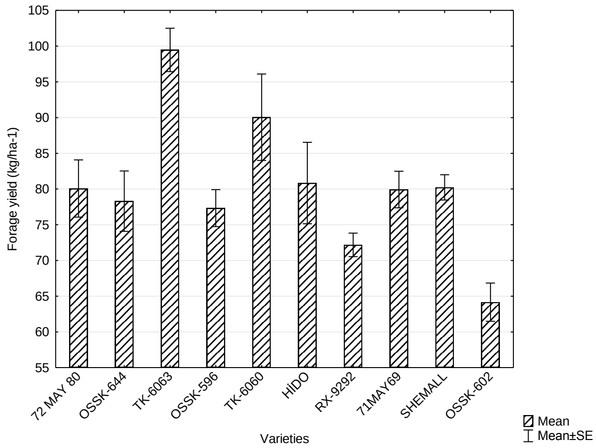

Figure 2. Forage yield of maize silage hybrids

Dry matter ratio (%). Whole-plant dry matter ratios (%) of hybrids had significant differences among maize hybrids. The highest and lowest dry matter content of maize varieties was obtained from the SHMALL variety with 31.12% and the HİDO with 38.92%, respectively. As all the varieties were harvested on the same date, the HİDO variety was the earliest growing variety. It may depend on the different stages of onset of these types. However, results of the investigation of present have also similar dry hay rates by Keskin et al. (2017). Akdeniz and Koç (2017) confirmed that according to the results of the trial, green silage yields were significant differences between of both maize varieties and localities.

Dry matter yield (kg/ha^{-1}). As the stand point of view of dry matter yield of maize are significant differences between varieties, the highest dry matter yields were 72 MAY 80, OSSK 644, TK 6063, OSSK 596, TK 6060 and HİDO are the same group in respect of dry matter yield. However, the values of maize hybrids range from 21.84 to 31.63 t ha^{-1}, OSSK 602 variety had the lowest value 21.84 (t ha^{-1}). It is seen that researchers by Keskin at al.(2017), who finds the average results of hay yields higher than this study and is quietly compliance with the kind of OSSK 602 in particular, however, with 31.49 t ha^{-1} of TK 6063 variety had the lowest yield. Coors et al. (1994) suggested that forage dry matter yield and quality traits are genetically variable in maize. Hybrids differences in dry matter yield have (Akdeniz at al. 2004; Atakul at al. 2016).

Table 2. Plant height, forage yield, dry matter ratio and dry matter yield of maize varieties

Variety	Plant height (cm)	Forage yield (t ha^{-1})	Dry Matter ratio (%)	Dry Matter yield (t ha^{-1})
72 MAY 80	223.0 bc	80.07 bc	37.83 ab	30.28 ab
OSSK 644	271.3 a	78.30 c	35.60 abc	27.88 ab
TK 6063	221.4 bc	99.47 a	31.66 d	31.49 a
OSSK 596	250.3 ab	77.33 c	34.42 bc	26.57 abc
TK 6060	214.9 bc	90.05 ab	35.06 abc	31.63 a
HİDO	223.1 bc	80.84 bc	38.92 a	31.52 a
RX 9292	235.9 abc	72.17 cd	34.22 bc	24.70 bc
71 MAY 69	226.6 bc	79.93 bc	37.75 ab	30.25 ab
SHEMALL	220.4 bc	80.23 bc	31.82 c	25.47 bc
OSSK 602	206.7 c	64.16 d	34.00 bc	21.84 c

* There were not significant differences in $P<0.05$ level among averages shown with same letter.

The leaf ratio (%). The leaf ratio of maize varieties in the study was statistically significant among the cultivar, and the highest ratio (24.92 %) and the lowest ratio (14.23 %) were obtained from RX 9292 and TK 6063 varieties among cultivars, respectively, Table 2. However, there was a negative relationship between forage yield and leaf ratio (Fig 3.). In addition to these findings were higher than the value of leaf rations cited by Keskin et al. (2017) and the leaf rations of these two varieties were found to be quite similar to results of the trial. That is why the varieties are stable in similar ecologies.

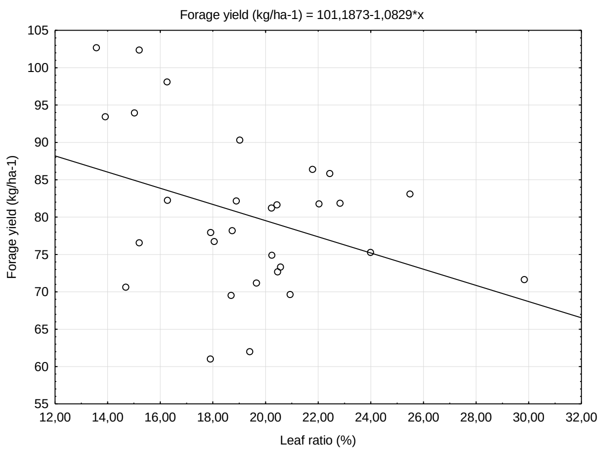

Figure 3. A relationship between forage yield and leaf ratio

Stem ratio (%). Stem rations of maize ranged from 31.90% with 71 MAY 69 and 49.49% with HİDO variety. Table 2. As a means of the stem, ration does not consist of results pointed out by Keskin at al. (2017). Tantekin et al. (2017) stated that the range of the ratio of stem plant with 41.93-58.50 % was higher than our present study. Some of the differences are due to the genetic structure of the varieties, as well as the environmental factor, sowing time, irrigation, fertilization, hoeing and so on. However, as was seen in Fig. 4, a relationship between forage yield and stem ratio has not been very clear.

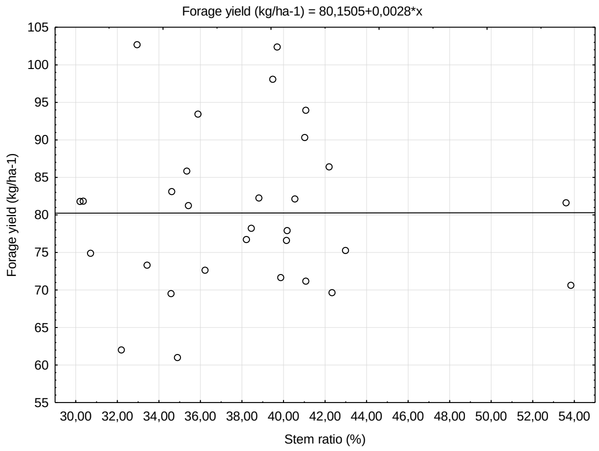

Figure 4. A relationship between forage yield and stem ratio

Cob ratio (%). The number of cobs per plant is a crucial yield parameter of maize. Cob ratio percentages had significant differences among maize hybrids. The highest cob ratio had 49.58% with TK 6063 variety. However, there were no differences between OSSK 596 and TK 6060. The lowest cob rations 32.45% and 33.34 5 were HİDO and RX 9292 varieties, respectively. In general, varieties with high stalk ratios were observed to have low cob of maize ratios. In both results of cob/plant was 20.37-38.50 % by Tantekin et al. (2017) and the results of cob rations (cob/plant (%27.3-%45.0) by Atakul at al. (2016) were higher than our values of cob percentages. These different results might be due to the changes in the genetic make-up of hybrid maizes. It is clearly seen that the cob (ear) ratio is positive on the herbage yield in figure 4, and that it is necessary to take into account the selection of varieties.

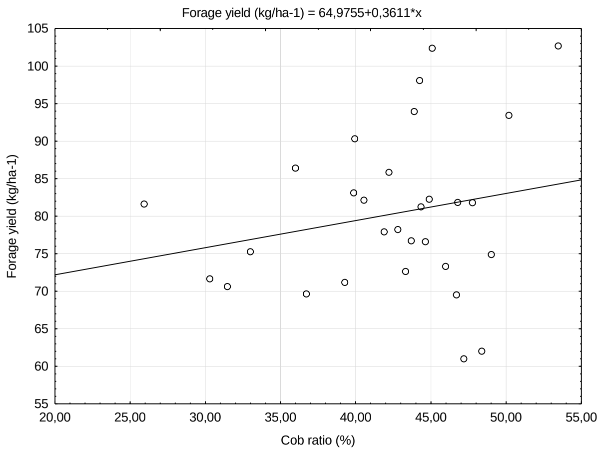

Figure 5. A relationship between forage yield and cob ratio

The number of leaves per plant. The number of leaves of silage maize ranged from 10.53 to 13.23, leaf numbers of HİDO and 71 MAY 69 varieties was counted, respectively. In both numbers of leaves and leaf ratio on a relationship between on forage yield was the negative relationship. However, there was a slightly negative relationship forage yield and number of leaves per plant in Fig. 6.

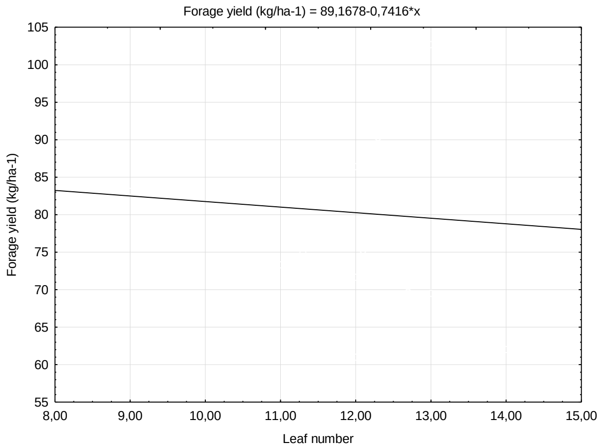

Figure 6. A relationship between forage yield and leaf number

Weight per plant (g). As regarded maize varieties showed in Table 2, plant weights (g) of maize hybrid had significant differences among maize hybrids, ranged form OSSK 602 with 673.80 g to TK 6063 variety with 1044.58 g. It is clear from the data the weight per plant was progressively increased wit in herbage yield (kg/ha^{-1}).

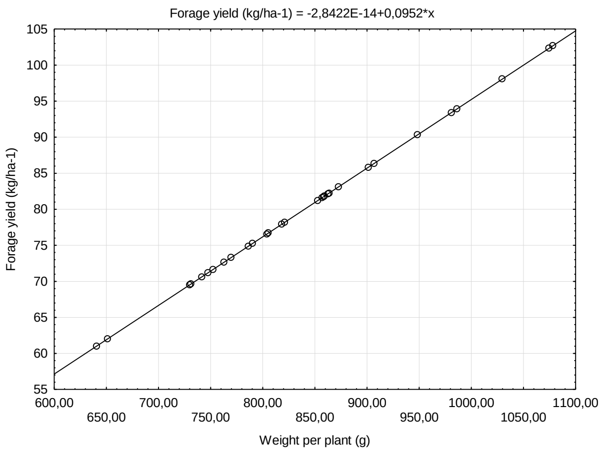

Figure 6. A relationship between forage yield and weight per plant

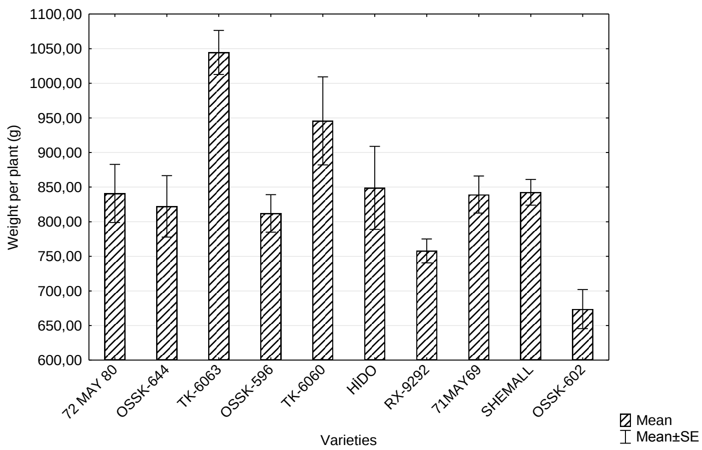

Figure 7. Weight per plant depends on maize varieties

Table 3. Leaf ratio, stem ratio, cob ratio, leaf number and plant weight of maize varieties

Variety	Leaf ratio (%)	Stem ratio (%)	Cob ratio (%)	Number of leaves per plant	Weight per plant (g)
72 MAY 80	20.82 abc	37.95 bcd	41.21 b	12.00 abc	840.80 bc
OSSK 644	20.00 bc	38.86 bc	41.12 b	12.43 ab	822.23 c
TK 6063	14.23 d	36.18 bcd	49.58 a	13.13 ab	1044.58 a
OSSK 596	18.22 bcd	38.04 bcd	43.73 ab	11.53 abc	812.06 c
TK 6060	16.67 cd	39.67 bc	43.66 ab	11.43 bc	945.64 ab

RX 9292	24.92 a	41.73 b	33.34 c	12.26 abc	757.94 cd
71 MAY 69	22.85 ab	31.90 d	45.23 ab	10.53 c	839.33 bc
SHEMALL	18.79 bcd	35.25 bcd	45.45 ab	10.56 c	842.53 bc
OSSK 602	18.67 bcd	33.90 cd	47.43 ab	13.00 ab	673.80 d

* There were not significant differences in P<0.05 level among averages shown with same letter.

Conclusion

It can be concluded that TK 6063 maize variety seemed to be the best suitable based on forage yield, dry matter yield, and cob ratio and plant weight between silage maize as a second crop in the local agro-ecological conditions. Yield and quality should be taken into consideration when selecting hybrids for forage. TK 6063 maize variety was the best suitable plant regarding the quality of the silage and green herbage.

THE EFFECT OF FERTILIZATION ON *LAVANDULA ANGUSTIFOLIA* L. YIELD IN NORTH GREECE

Elpiniki SKOUFOGIANNI, Kyriakos D. GIANNOULIS*, Dimitrios BARTZIALIS, Dimitra TZOUVARA, Nicholaos G. DANALATOS

Abstract

Lavandula angustifolia L. is a small orthodontic shrub with a dense branch. Spruces are of square cross-section, which quickly become woody. The leaves are about 5 cm long and linear. The color of the flowers is purple. Flowering shoots of this species contain 1.5-3% of essential oil. In this study we investigated the effect of four different fertilization types (F1: black, F2: organic, F3: 34.5-0-0 and F4: 10-20-0) on fresh and dry weight of the perennial *Lavandula angustifolia* L. during the establishment year and the 2nd year after establishment at an experimental farm at Kozani, North Greece in 2015 and 2016. It is well documented that the crop reaches its potential yield on the third-fourth year of cultivation and continues producing biomass for six to seven more years. Upon harvest (September 2015) during the establishment year, the crop reached a maximum dry yield of 0.22 tons per hectare and almost the double yield 0.74 t ha^{-1} for the treatment of the organic fertilization which produced the higher yield. Therefore, the above data show that *Lavandula* cultivation could be a promising alternative crop, especially in case of the consideration that average selling price of dry drogue in Greece is 3.5-5 € kg^{-1}, while the selling price of its essential oil is 100 € kg^{-1}.

Keywords: *Lavandula angustifolia L, fertilization, fresh yield, dry yield.*

Introduction

Lavender belongs to the family of the Lamiaceae (Order: Lamiales) and is mainly grown for essential oils. In the same family, there are also other crops such as basil, hyssop, marjoram, peppermint, oregano, rosemary, thyme etc., (Bruneton, 1999). The most well-known representatives of Lavandula are the genes *Lavandula angustifolia* (*L. officinalis*), *L. latifolia, L. stoechas, L. burnatii, L. dentata, L. canariensies, L. abrotanoides, L. lanata, L. multifida, L. pinnata, L. viridis, L. x Intermedia, L. luisierii. L. hybida* (sin. L. x intermedia) is common in Romania and has a high productivity (Silvia Robu et al., 2015).

Lavandula species exhibit a variety of antimicrobial activity and some species also exhibit antifungal activity as well as antioxidant activity. Lavandula species contain low levels of toxicity, since the essential oil is used in burns with therapeutic effect even in insoluble form, which has not been proved medical and pharmaceutical, although allergic dermatitis has been reported as a case (Balchin, 2002).

Lavender is a perennial low shrub. The aromatic leaves have a length of 5 cm and the flowers are distinguished by cross peaks and the sweet aroma (Curtis, 2005). There are many varieties in the wooden shrubs form and a height higher than one meter (Balchin, 2002).

The plantation can take place from spring till autumn. Researchers have found that autumn plantation produces more flowers in the coming year (Kimbrough & Swift, 2009). Lavender can be a long-standing crop with a typical productive life of about 10 years, although plants are known to live for 20 years.

Lavender requires well-drained soil, sandy soils and full sunshine, and therefore areas with high altitudes are preferred. Low fertility soils are still appropriate. The soil pH should range between 5.8 and 8.3. Very wet soils will cause poor plant growth, diseases or total destruction of the crop. English lavender varieties prefer alkaline soils, while levantine varieties require slightly more acidic soils (Directorate Plant Production in collaboration with SAEOPA and KARWIL Consultancy, 2009).

Lavender can tolerate moderate frost and drought, while long-lipped lavender cannot tolerate frost. All lavender varieties are sensitive to high humidity. High summer temperatures adversely affect the quality of the essential oil (Directorate Plant Production in collaboration with SAEOPA and KARWIL Consultancy, 2009). Whole flowering plants can be used to produce essential oil (Adam, 2006).

In its natural state, narrow-leaved lavender is cultivated at altitudes of up to 1.700 meters, while long-leaved lavender is grown only in the lower regions and is indigenous in areas from 200 to 700 meters from sea surface. The yields of essential oil increase as the altitude rises because the plant blossoming in cold areas is more abundant (Directorate Plant Production in collaboration with SAEOPA and KARWIL Consultancy, 2009).

Lavender can produce a well yield with an annual precipitation of 300 to 1400 mm. Soil should be able to dry well between irrigations and is not allowed the irrigation to an excessive extent (Directorate Plant Production in collaboration with SAEOPA and KARWIL Consultancy, 2009).

Trace elements affect the final yield and the quality of aromatic-medicinal plants. In an experiment conducted to determine the effects of nitrogen (N: 150-175-200-225-250 mg/L) and phosphorus (P: 30-40-50-60-70 mg/L) on the morphological and Biochemical characteristics of lavender under hydroponic status, showed that P levels mainly affected plant growth, while lower levels of N (150 mg/L) reduced chlorophyll content. Essential oil performance remained unaffected and independent of N and P levels (Chrysargyris et al., 2016).

This study was conducted in an attempt to enrich the relatively few data on plant growth and productivity of *Lavandula angustifolia* L. in Greece. For the purposes of the study the effect of four different fertilization types (F1: black, F2: organic, F3: 34.5-0-0 and F4: 10-20-0) on fresh and dry weight of the perennial *Lavandula angustifolia* L. during the establishment year and the 2^{nd} year after establishment at an experimental farm of Kozani, North Greece in 2015 and 2016 was investigated.

Materials and Methods

Lavandula angustifolia L. was established in a Kozani region (Greece). The transplanting took place on 3/5/2015, at a distance of 0.6m on the line and 0.6m between the lines. Plants were irrigated with 1 liter of water/plant during establishment. The effect of four different fertilization types (F1: black, F2: organic, F3: conventional 20-10-10 and F4: N-NO_3 46-0-0) on fresh and dry weight of the perennial *Lavandula angustifolia* L. was investigated during the establishment year and the 2^{nd} year after establishment at an experimental farm of Kozani, North Greece in 2015 and 2016.

The application of the fertilizers took place by hand, while the quantities of each fertilizer type were 0 gr/plant for the F1 (blanc treatment), 60 gr/plant for the F2 (organic fertilizer 6-0.5-0.3 and 85% O.M.), 10.46 gr/plant for the F3 (34,5-0-0) and 36.1 gr/plant for the F4 (10-20-0).

The experiment had a randomized block design (Graph 1) and each block had an area of 48 m^2, while 576 plants in total were planted. Flowers, leaves and shoots after harvesting were dried in a dark place at room temperature. The fresh and dry weight data were analyzed using the GenStat 7^{th} Edition statistical package.

Results and Discussion

Soil Analysis

The soil used for the cultivation was a semi-fertile as it is presented in the following Table 1.

Table 1. Chemical properties of the field experiment.

Property	Soil depth (0-30) cm	Soil depth (30-60) cm
	Before transplanting	After harvest
Texture	Clay-Loam	Clay-Loam
pH (1part soil:5parts H_2O)	7.6	7. 6
Organic matter (%)	1.8	1.8
Sand (%)	29	29
Clay (%)	33	29
Silt (%)	38	42
$CaCO_3$ (%)	22.0	20.5

Fresh Yield

In Figure 1 is illustrated the average fresh weight of lavender as it is affected from the four different used fertilizer types.

There was found statistical significant difference (Table 2) between the used fertilizer types and the zero fertilization (F1). It was found that the use of the F2 (organic) type produced almost higher fresh yield in both years (2 tha^{-1} and 3 tha^{-1} in 2015 and 2016 respectively). Specifically, the average yield for the F2 fertilizer type was higher than the double of the zero treatment.

Finally, as it was expected the total fresh yield increased in 2016 irrespective of treatment due to the perennial nature of the plant.

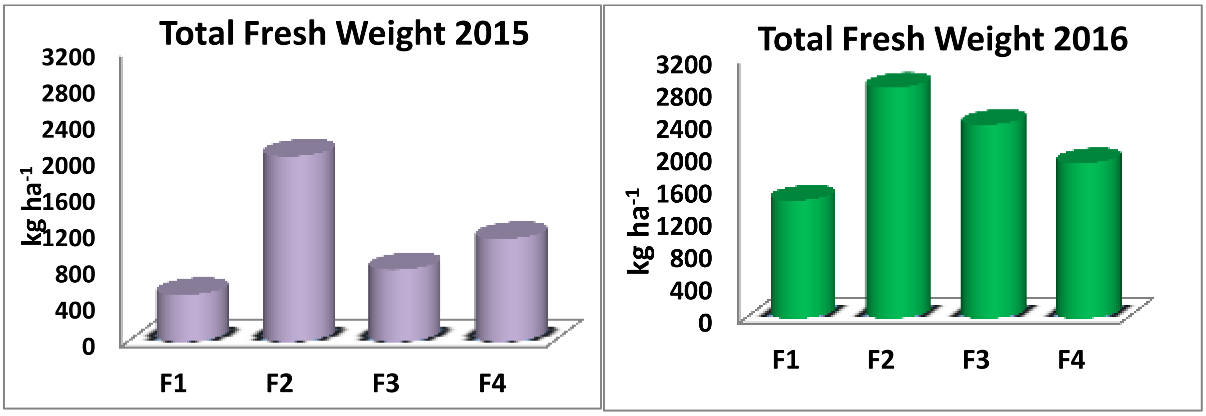

Figure 1. Total fresh weight of *Lavandula angustifolia* L. as affected by the four different fertilizer types (F1: Blanc, F2: organic, F3: 34.5-0-0 and F4: 10-20-0).

Table 2. Total fresh weight of *Lavandula angustifolia* L. under different fertilizer types.

Lavandula angustifolia L.	2015 (kg ha^{-1})	2016 (kg ha^{-1})
Fertilizer type		
F1: Blanc	519	1258
F2: organic	2048	2852
F3: conventional 20-10-10	797	2396
F4: N-NO_3 46-0-0	1138	1919
$LSD_{0.05}$	265.9	624.0
CV %	19,2	23,5

As it is is ilustrated in Figure 2 in both harvested years, the fertilizer type F2 prevails and produces a flower fresh weight greater than all the other treatments. Specifically, in 2015, the F2 treatment yields 372 kg ha^{-1}, while in 2016 almost triple the yield 1176 kg ha^{-1}. The above results are in agreement with experimental results carried out in Poland by testing flower productions with organic fertilization (Seidler-Łożykowska, et al., 2014).

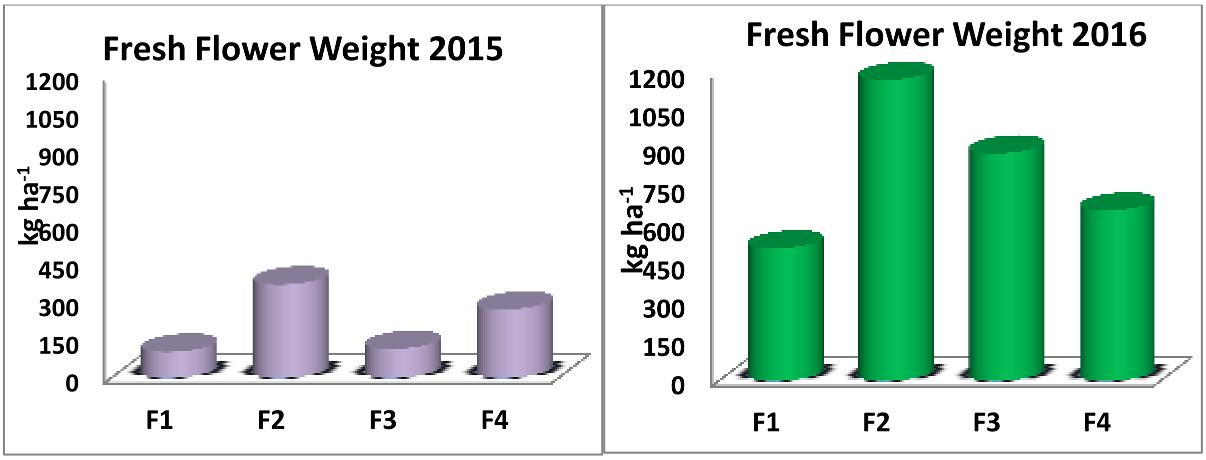

Figure 2. Fresh flower weight of *Lavandula angustifolia* L. as affected by the four different fertilizer types (F1: black, F2: organic, F3: 34.5-0-0 and F4: 10-20-0).

$LSD_{0.05}$	129.7	317.2
CV %	28.8	15,9

ns: non significant difference

Dry yield

It is clearly shown in Figure 3 that the F2 treatment reached the amount of 737 kg ha^{-1} total dry weight in the first year, yield which is almost the double comparing with the rest treatments. Similarly, in 2016 it is obvious that the organic fertilization (F2 treatment) maintains the higher total dry weight of 1227 kg ha^{-1}, followed by slight non significant differences (Table 3) in the yields of F4 and F3 with 1130 and 1171 kg ha^{-1} respectively. Finally, the zero fertilization (F1) produced 765 kg ha^{-1} total dry weight.

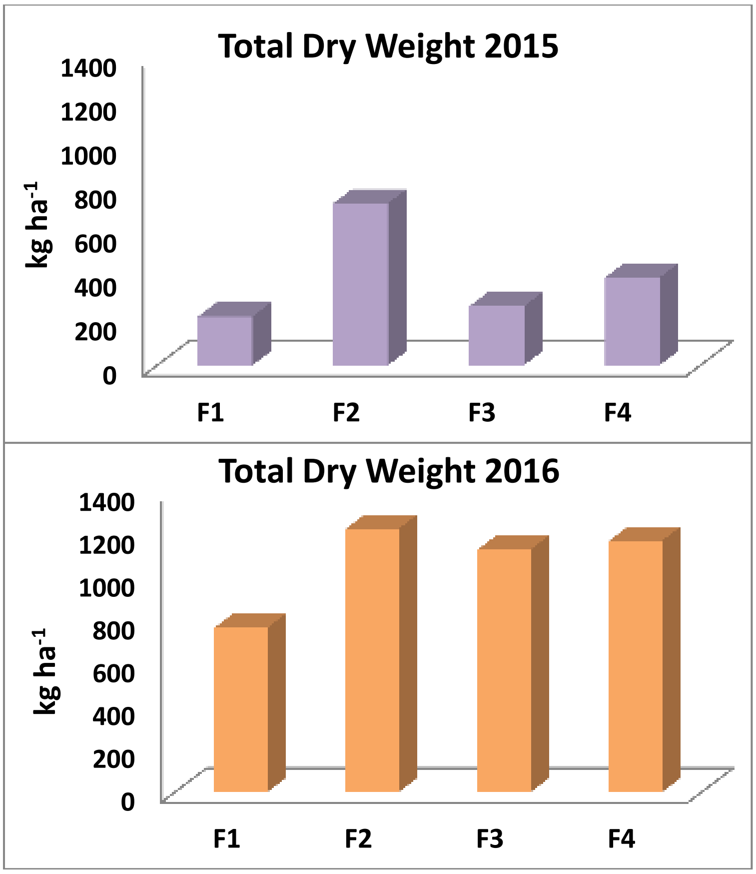

Figure 3. Total dry weight of *Lavandula angustifolia* L. as affected by the four different fertilizer types (F1: Blanc, F2: organic, F3: 34.5-0-0 and F4: 10-20-0).

Table 3. Total dry weight of *Lavandula angustifolia* L. under different fertilizer types.

Lavandula angustifolia L.	2015 (kg ha^{-1})	2016 (kg ha^{-1})
Fertilizer type		
F1: Blanc	221	765
F2: organic	737	1227
F3: conventional 20-10-10	268	1130
F4: N-NO_3 46-0-0	397	1171
$LSD_{0.05}$	108.3	ns*
CV %	21.7	15,0

ns: non significant difference

The fertilizer type F2 as shown in Figure 4 in both years 2015-2016 produced the higher yields of dry flower followed by F4 and F3. The commercial product of lavender is its flower and the essential oil. Therefore, it could be assumed that F2 type is delivering the best results, and lavender seems to be a plant of low nitrogen requirements.

Therefore, the above data show that lavender cultivation could be a promising alternative crop that could give to farmers an income of 1960-2800 € ha^{-1}, in case of the consideration that average selling price of dry flower in Greece is 3.5-5 € kg^{-1}.

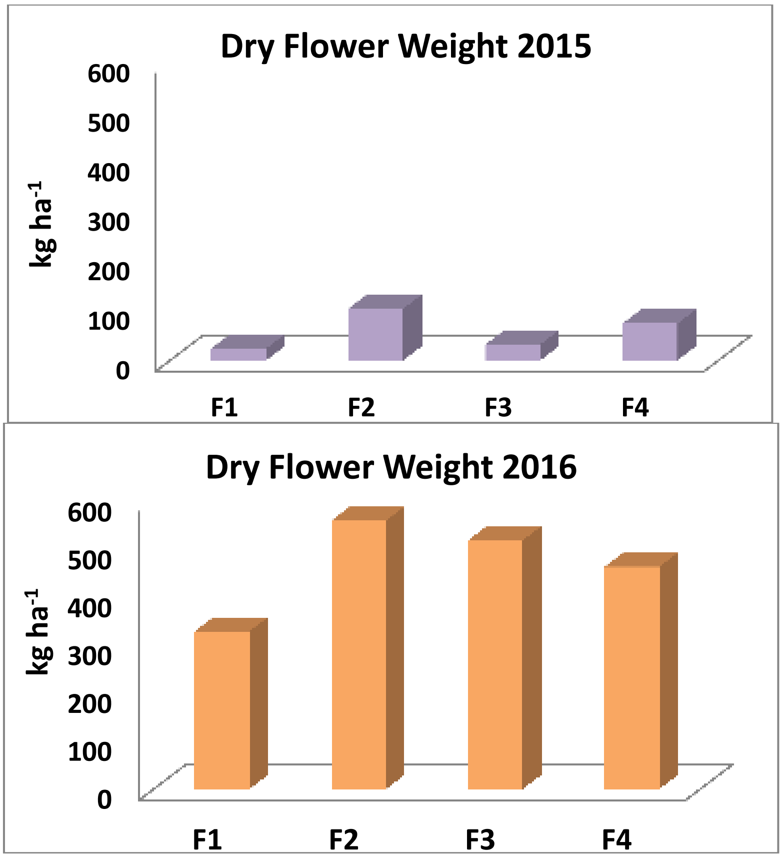

Figure 4. Dry flower weight of *Lavandula angustifolia* L. as affected by the four different fertilizer types (F1: Blanc, F2: organic, F3: 34.5-0-0 and F4: 10-20-0).

Table 4. Dry flower weight of *Lavandula angustifolia* L. under different fertilizer types.

Lavandula angustifolia L.	2015 (kg ha^{-1})	2016 (kg ha^{-1})
Fertilizer type		
F1: Blanc	24	329
F2: organic	104	560
F3: conventional 20-10-10	32	519
F4: N-NO_3 46-0-0	74	463
$LSD_{0.05}$	ns*	ns*
CV %	29,8	22,5

ns: non significant difference

Conclusions

The general conclusion that was found from this study is that *Lavandula angustifolia* L is a low nitrogen requirement crop, where the organic fertilization triples the yield in comparison with the zero fertilization. Moreover, the organic fertilizer observed constant voltage supremacy of each tested fertilizer type, but a further economical analysis to the fertilizer type is necessary in case to be able to be assumed that the organic fertilization is the most financially advantageous. The organic fertilizer produced 560 kg ha^{-1} dry flower setting this crop as a really attractive cultivation for farmers if someone will take in mind the selling price of the dry flower. Therefore, the above data show that lavender cultivation could be a promising alternative crop, but further investigation is necessary to be conducted as to be able to lead to safer conclusions.

Abstract

This study was conducted to determine the effects of Nitrogen and Phosphorus fertilizers on plant height and plants were Dry-forage yield ranged of intercropped common vetch and triticale in Şanlıurfa province in 2010 and 2012. The study was designed as split-plots where main plots were treated with different levels of phosphorous while split-plots (sub-plots) were treated with different levels of Nitrogen with three replications. 40 and 60% seed ratio for triticale and common vetch respectively was determined based on the available literature. Seed amount in the mixture of individual plants were determined as considering their sole crop seed amount which are 20 and 10 kg/da for triticale and common vetch respectively. Pure Nitrogen and Phosphorous were applied at rate of 0, 3, 6, 9 and 12 kg/da by using fertilizers in the forms of ammonium sulphate and triple super phosphate fertilizers. In the study, 5 different characteristics were investigated. Application of nitrogen and phosphorous fertilizers caused a significant increase in dry forage yields. The highest Tritacale 136.40 cm.. 6 kg/da Nitrogen and 6 kg/da phosphorous were applied. The highest common vetch 99.45 cm. 3 kg/da Nitrogen and 3 kg/da Phosphorous were applied. Dry-forage yield ranged from 762.81 to 1478.8 kg/da. The highest dry yields were 1545.3 kg/da when 9 kg/da Nitrogen and 6 kg/da Phosphorous were applied.

Key Words: *Common vetch, Triticale, Nitrogen, Phosphor, Fertilizing, Yield component.*

Introduction

Balanced and regular feeding is indispensable; vitamins, minerals and fiber-containing foods, as well as protein and carbohydrate diet. For this reason, it is important to feed on animal products if it is important to feed on plant products in terms of human nutrition and health. One of the most important criteria when determining the level of development of the countries is the amount of consumption of animal products per capita. Due to the fact that our country has not developed as much as its breeding capacity in animal husbandry, the animals are fed on grassland basis or the quality of animal products is low because the concentrated feeds used for animal feeding are not in sufficient quality. Our mines, which meet a significant portion of our roughage needs and cover 1/5 of our country's agricultural land, have become irregular and overgrained for decades and become ineffective. For this reason, it is necessary to improve the pastureland by breeding and preservation of pastureland areas and to graze to the extent of their capacities. In addition, the feed value and the digestibility of the hay used in animal feed are low, which causes significant loss of yield in animals. For this reason, while increasing crude yield as a precondition for roughage production, animals are twice as likely to feed on high quality feed even in farmer conditions. In our country, the cultivation of feed crops, which are 6.3% in field agriculture, to 25%. Especially in recent years, animal production enterprises established with government support have increased the amount of feed deficit which is present, and therefore the lack of feed plants in our region has made us more aware. Feed crops suitable for main and intermediate crops in field agriculture will be evaluated economically with the introduction of crop plants and plenty of good quality feed crops that our animals require. Wheatgrass and leguminous forage crops can be grown pure in agriculture for feed crops, and higher yields and quality crops can be obtained by cultivating these crops as a mixture. The characteristics of the mixtures to be formed should be such that at least one wheat and legume is arranged, the mixtures are suitable for weed or seed production, the ripening times of the plant species in the mixture are close to each other and soil and climate requirements are appropriate. The mixture of cereals such as triticale and barley, which contains vetch, can contribute to the improvement of the physical and chemical structure of the soil, while it can be used as a green fertilizer with grass and grains. In order to obtain the targeted high and high yield of herb by planting legumes and wheat as a mixture, it is necessary to determine the sowing rate of mixed species and the nitrogen and phosphorus fertilizers to be used.

Material and methods

Özeren Adi vetch and Tacettinbey triticale varieties were used as plant material in the experiment. Özveren vet is a new variety that has been successfully cultivated for dry hay production. The optimum harvesting time for weed is the start of formation of the lower fruits. Tacettinbey tritikale variety is resistant to winter, constancy and laying; the fertilizer reaction and the ability to blend well, is a moderately resistant and early varieties to cast the grain. When triticale is harvested as a green feed during the milking period, it contains 22-24% protein; yield is significantly higher than other grains; dry matter production is high. Ammonium sulphate containing 21% Nitrogen with physiological acid character and triple superphosphate containing 42% P2O5 as phosphorous fertilizer were used in consideration of regional soil. Sanliurfa is under the influence of the Mediterranean climate, including in the Southeast Anatolia climate region. The summers are hot and the arid winters are a mild climate. The experiment was carried out on 25 parcels with three replications according to the parcel trial design divided into random blocks with the phosphorus doses as the main parcel and the nitrogen doses as the sub parcels. In the lower parcels, the parcel size is set to 4 m, the parcel width is 2 m, and the distance between the blocks is 2.5 m. Fertilizer doses; Ammonium sulphate fertilizer at 0-3-6-9-12 kg / da pure N and TSP fertilizer at 0-3-6-9-12 kg / da pure P were used in the future. The total amount of P in the fertilizer and half of the amount of N were planted together with planting, while the other half was given in early seedling stage after emergence. The sides of the parcels were removed from the sides and the sides by 20 cm, and the remaining 5.6 m2 area was harvested during the full flowering period of the vetch.

The vertical distance between the soil surface and the extreme point was measured and the averages were taken in 10 vetch and Tritikale plants that were randomly selected before planting (cm) in each plot (Anlarsal and Gülcan, 1988). Dry grass yield (kg / da), dry weed samples randomly taken from each plot were found in the drying cabinet until the weights were fixed at 70oC, then the dry grass weights were found as%. The annual yield of each plot is calculated by multiplying dry hay yield by calculated hay yield (Anlarsal and Gülcan, 1989). The results obtained from the experiments were subjected to analysis of variance according to the split plot design of random blocks and the differences between the experimental subjects were checked by F and LSD tests.

Graph 1. An overview of the experiment.

Results and discussion

Triticale plant height

In the first year of the experiment, the lowest triticale plant height value was obtained from the N0P0 plot with 88.13 cm, while the lowest value was obtained from the N6P0 plot with the lowest value of 97.58 cm. The highest triticale plant height values were obtained from N6P6 plots with 136.40 cm in the second year of experiment, while they were obtained in N9P6 plots with 132.64 cm in the first year, depending on years and fertilizer applications.

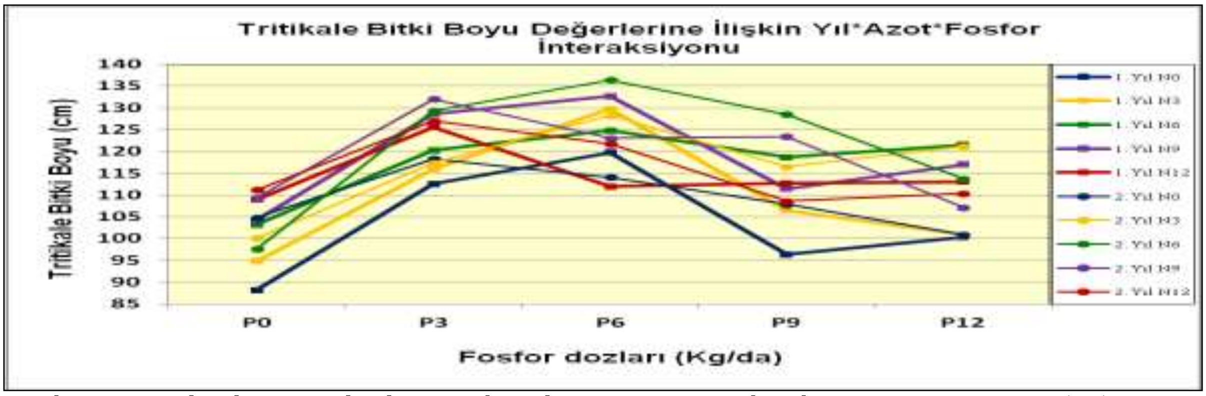
1) The averages indicated by similar letters are not statistically different within the 5% error limits according to the F and LSD test.

According to the results of F and LSD tests, it was determined that the plant height in the N0P0 control plot in the planting of 40% tritical to 60% vetch mixture was found to be statistically significantly lower than the plant height in 5 different nitrogen and phosphorus applied fractions. Alp (2009); in his work on different triticale varieties he reported that the plant length changed between 98.12-116.35 cm and that the production of Tacettinbey variety for this region would be suitable. The findings are in parallel with our plant height values.



Graph 2. Year Related to Triticale Plant Height Values * Nitrogen * Phosphorus Doses Interaction (cm)

Reductions in Triticale plant height were observed in more phosphorous fertilizers at 6 kg / da phosphorous doses, but these reductions were found to vary according to years and applied nitrogen doses. In the parasites where the highest dose of phosphorus is applied, triticale is observed to decrease in a similar tendency according to the previous phosphor dose every two years, but there is also a small increase in contrary to the decrease in the first year of testing in the N3 fertilized parcels. Thus, different effects of different doses of nitrogen and phosphorus on the triticide are caused by different dosages and years of reaction depending on the interactions.

Vetch Plant height

Nitrogen and phosphorus fertilizers were used to determine the total vetch plant height values between 50.93 cm and 99.45 cm for two years and the highest vet plant height value was obtained from 3 kg / da nitrogen and 3 kg / da phosphorous fertilizer application. In higher N and P fertilization applications, the shortening of the vetch neck was observed.

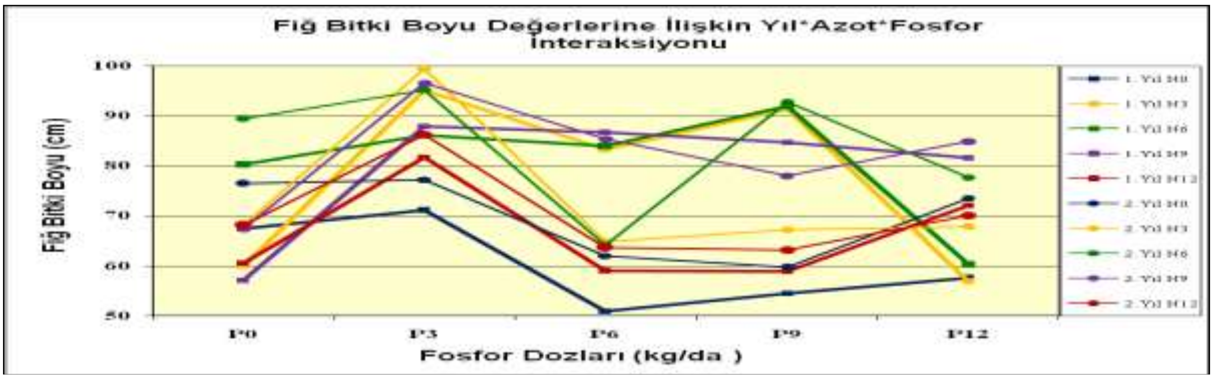
1) The averages indicated by similar letters are not statistically different within the 5% error limits according to the F and LSD test.,

Karaca and Çimrin (2002); reported that phosphorous fertilizer applied at increasing doses did not have a significant effect on the plant height of Adi vetch plant, while nitrogen fertilizer increased the length of the common vetch plant statistically significantly. It was reported that the average length of the common vetch plant was 23.50 cm in the parcel without nitrogen fertilizer (N0) and 28.48 cm in the 6 kg nitrogen application (N6), and this value was statistically significant (P <0.01). Arslan and Gülcan (l996) reported that they obtained the longest vetch plant with 75% vetch + 25% barley mixture in vetch + barley mixtures to be grown as winter crops in Southeastern Anatolia Region. Lithourgidis and Dordas (2010); they were found to be higher when compared to the pure planting of legumes in mixed sowing. Tan (1991); found that the nitrogenous fertilizer increased the plant height significantly. Keskin et al. (1996) reported that nitrogen tolerance and phosphorous fertilizer effect on the plant length has a positive effect in the vineyard conditions, in vineyard varieties and for three years. 4 kg N and 8 kg P2O5 were applied in the experiment and they reported that the average length of the plant was 30.8 cm for the Adi vet D-120 line used in the experiment.



Graph 3. Year Related to Vetch Plant Height Values * Nitrogen * Phosphorus Doses Interaction (cm)

When examining Figure 3 for veterinary plant height values, in other applications, except for high nitrogen doses such as N9 and N12 in P12 application, veterinary plant height values showed an unstable result compared with years. This situation is thought to be caused by differences in climate conditions between years. In the case of high phosphorus dosimetry, higher values of vetch height were reached in the second year of the study, but only in the first year in which the highest nitrogen application N12 dose vet plant values were tested in all other nitrogen doses except for N12 dox. Different responses of vetch plant depending on years and applied fertilizer doses, Year * Nitrogen * Phosphorus doses caused interaction.

Triticale Dry Grass Yields The values of dry weaning values for tritical averages for two years are varied between 802.32 kg / da and 1226.2 kg / da in different nitrogen applications and between 1004.8 kg / da and 1193.6 kg / da in phosphorus applications. The highest tritical rate was taken from the N9P6 plot, which was applied at 1400.7 kg / da nitrogen at 9 kg / da and phosphorous at 6 kg / da. The obtained triticale yield values support the research findings of Öztürk ve Serin (1996), Bedir (2010), Çil (1998) and Karaca and Çimrin (2002). It has also been reported by many researchers that nitrogen and phosphorus fertilizer in the vetch + barley mixture increases green and dry yield (Sobkowicz and Sniady 1999).

Vetch Dry grass yield

The average values of nitrogen and phosphorus application were found to be between 36.38-77.23 kg / da in the first year and 48.74-92.51 kg / da in the second year when the two years average values and groups in the vet hay yield in Table 5 were examined respectively.

1) The averages indicated by similar letters are not statistically different within the 5% error limits according to the F and LSD test.

The vetch yield values for the two years ranged from 46.31 to 70.73 kg / da depending on the nitrogen application and the highest vetch yield was obtained from N9P6 plot with 9 kg / da nitrogen and 6 kg / da phosphorus, the lowest vetch yield were taken from the N12P9 parcels, which were treated with 12 kg / da nitrogen and 9 kg / da phosphorus. Girenko et al. (1986) found that 8 kg of nitrogen, 8 kg of phosphorus fertilizer could be given in the experiment to determine the need for fertilizer. Keskin et al. (1996) reported that some of the common vetch varieties were fed with 4 kg / da N and 8 kg / da P2O5 and 98.1 kg / d of dry hay, respectively, and these values supported the results of our research. Yagodina and Trepachev (1989) reported that fertilization and nitrogen binding capacity of the vaginal vetch and vetch + oat mixture increased to 9.7 mg phosphorus and 18.7 mg phosphorus (18.7 mg), respectively. Panciera and Sparrow (1994) found that the nitrogen fertilizer increased the weed yield from 404 kg to 547 kg, while the amount of nitrogen removed from soil increased from 10.6 kg to 15.5 kg. Vigor hay yield values; Bedir (2010), Çil (1998) and Karaca and Çimrin (2002).

Dry grass yield

When the nitrogen and phosphorus values are plotted in Table 6, where the groups are composed of years with hay yield and two-year values, the lowest yield is 734.36 kg / da in N0P0 parcel without fertilizer in the second year, the highest yield is 9 kg / kg / da phosphorus-treated N9P6 plot at 1545.3 kg / da.

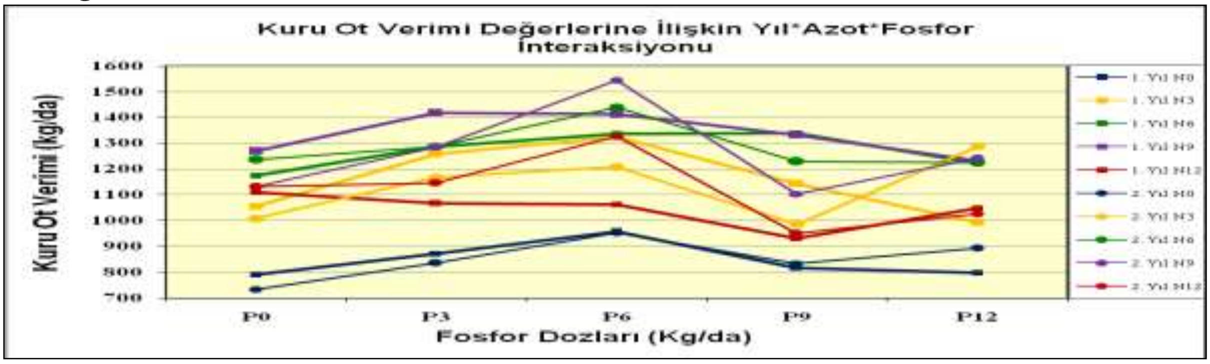
	Ort	1048.2	1144.5	1295.1	1020.6	1134.9	1128.6

1) The averages indicated by similar letters are not statistically different within the 5% error limits according to the F and LSD test.

The highest total dry forage yield was obtained from the N9P6 plot with 1478.8 kg / da with 9 kg nitrogen and 6 kg phosphorus and the lowest total dry weight yield was taken from N0P0 plot with 762.81 kg / da without nitrogen and phosphorus. Aydin and Tosun (1961) reported that the blend of blend of 80% vetch and 20% triticza yielded a low value of hay yield of 221.0 kg / da, due to the high legume ratio in the mixture. In addition, Aydın and Tosun (1993) reported that the average hay yield was 245.4 kg and 271.5 kg, respectively, with 0 and 6 kg P2O5 phosphorous fertilization in vetch and barley mixture, respectively, and phosphorus hay yield effect was realized in the presence of nitrogen. Kılıç (1999) found that the mixture ratio of 25% vetch + 75% tritikale was the most suitable mix ratio in terms of dry weed yield, whereas Damage and Tukel (1994) had the highest hay yield (846.4 kg / da), 25% vetch + 75% triticale from the mixture. The results support our research results. Arslan and Gülcan (1996) found that the highest dry matter yield was obtained from pure barley cultivation while the lowest dry matter yield was obtained from pure Adi vet cultivation in vetch + barley mixtures to be grown as winter intermediate crops in Southeastern Anatolia. Öztürk and Serin (1996); (0, 4, 8, 12 kg N / da) and phosphorous (0, 3, 6, 9 kg P2O5 / da) in vetch + barley mixtures in the study they conducted; the highest dry weed yields were 4-12 kg N / da and 3-9 kg P2O5 / da, Karaca and Çimrin (2002); Yaktubay (1998) found that the highest fertilizer yield was 6 kg N / da and 8-12 kg P2O5 / da, the highest dry weed yield was 6 kg N at the reservoir and 291 kg / ha at the 12 kg P2O5 doses. dry hay yield was found to be between 708-908 kg / da and total hay yield was higher in late sowing. Çil (1998) concluded that the highest yield of dry hay was obtained from a mixture of 40% vetch and 60% triticale, Vasilakoglu et al. (2008); the yield of dry hay in mixed sowing was reduced compared to pure sowing.



Graph 4. Year Related to Dry Matter Yield Values * Nitrogen * Phosphorus Doses Interaction (kg / da)

When Figure 4 is examined in which the interactions of the hay yield values are given, it is seen that the applications of the N0 doses are generally excluded from the interaction. However, with increasing nitrogen doses, it has been observed that there are differences in phosphorus doses and years, leading to significant changes in hay yield. As a matter of fact, stable doses of P0, P3, P6 and P9 were observed every two years in the N3 dose, but it was observed that there were differences in the dosage of P12 according to years. However, at doses of N6, N9 and N12, the interaction appeared even at the dose of P6 and appears to continue at higher doses of phosphorus. Different reactions depending on years of dry hay yield and applied fertilizer doses caused interactions.

Conclusions

The nitrogen and phosphorus fertilizer doses applied to the mixture of 60% vetch and 40% triticale, triticale and vet plant length, total dry matter the effect on the yield of grass was found statistically significant. When the two year average values are examined; Triticale plant height, 124.23 cm, vet plant height, 87.64 cm were taken. The highest value was obtained at 1400.7 kg / ha, while the vetch yield was 70.73 kg / da, total dry matter yield was 1478.8 kg / da. The lowest values were obtained from N9P6 fertilizer doses and the lowest values were N0P0 with no fertilizer It has been determined that it is taken from the control parcels. It has been determined that the most suitable fertilizer combination is 9 kg / da nitrogen (N) and 6 kg / da phosphorus (P), provided that at least 10 kg / ha of phosphorus is found in the soil in the mixed growing system to be built. It is thought that the amount of phosphorus to be applied and half of the amount of nitrogen should be given together with planting, while the other half of nitrogen is given in the early seedling stage of the plant after the emergence.

Abstract

Plant breeders continually generate ever-higher yielding cultivars, but also want to improveseed constituent value, which is mainly protein and oil, in soybean. But in the same time another works still continue in plant production period systems. The soybean (Glycine max (L.) Merrill) is an annual legume that is primarily produced as a source of edible oil for human consumption. Generating higher yielding soybean cultivars is an important issue, as well as improving the value of seed ingredients, which is mainly consisted of protein and oil. Therefore, soybean production plays an important role. The objective of this study was to determine the influence of various tillage practices on the oil yield of soybeans (Glycine max L.). The tillage treatments were conventional tillage with residues incorporated in soil (CT1), conventional tillage with residues burned (CT2), reduced tillage with a heavy tandem disc-harrow (RT1), reduced tillage with a rotary tiller (RT2), reduced tillage with a heavy tandem disc harrow fallowed by no-tillage (RNT), and no tillage (NT). The tillage plots were of 12 m width and 40 m length (480 m^2). The applied treatments resulted in the soybean oil yield of 0.16; 0.18; 0.19; 0.18; 0.6 and 0.17, respectively.

Key words; Soybean, tillage, oil yield.

Introduction

Soybean (*Glycine max (L.) Merrill*) is an annual legume that is primarily produced as a source of edible oil for human consumption. The protein and oil content of soybean makes it a major source in human and animal nutrition source for biofuels as an alternative of fossil fuels. Soybean seed quality is often determined by seed protein, oil, fatty acid, and mineral content. Soybean seed protein concentration ranges from 341 to 568 g kg^{-1} of total seed weight, with a mean of 421 g kg^{-1}. Oil concentration ranges from 83 g kg^{-1} to 279 g kg^{-1} with a mean of 195 g kg^{-1} (Bellaloui et al., 2010). The composition of soybean oil comprises of 50-57% linoleic acid, 18-26% oleic acid, 7-14% palmitic acid, 6-10% linolenic acid, 3-6% stearic acid and trace amount of meristic acid, palmitoleic acid[2].

Materials and method

Experimental site

The study was performed in 2014 at the Çukurova University Research Farm (Turkey) located between 37°00’54’’N and 35°21’27’’E on elevation ranging from 32 m above mean sea level. The experiment was carried out on the Arik clay soil series with a slope about 1%, and soils were classified as fine, smectitic, active, mesic TypicHaploxererts (Soil Survey Staff, 1999). The soil structures of the study area were 18% sand, 32% silt, 50% clay at the depth of 0-30 cm, pH 7.82 and organic carbon content 0.9%. The soil humidity was 13.45% ± 1.71.Study area has a Mediterranean climate characteristic. Summers are hot and dry, and winters are mild and rainy. The annual average precipitation is 625 mm, temperatures differ between -8.1°C and +45.6°C.

Experimental design and tillage systems

Soybean is cultivated as second crop between June 2014 and October 2014 following the harvest of winter wheat. The experiment was conducted on a randomized complete block design with three replications of conventional tillage with residue incorporated in the soil (CT1), conventional tillage with residue burned (CT2), reduced tillage with heavy tandem disc-harrow (RT1), reduced tillage with rotary tiller (RT2), reduced tillage with heavy tandem disc harrow fallowed by no-tillage (RNT), and no tillage (NT). The tillage plots were of 12 m width and 40 m length (480 m^2). Details for tillage practices, order of the treatments within each practice and sowing methods were given in Table 1.

Table 1. Tillage practice of the treatments

Threat-ments	Winter wheat (November 2013)	Second crop soybean (June 2014)
	Conventional tillage with residue incorporated in the soil (CT1)	
CT1	Stover chopping of second crop Mouldboard plough(30-33 cm)[a] Disc harrow (2 passes, 13-15 cm) Float (2 passes) Drill (4 cm) Stover burning of second crop	Stubble chopping of wheat Heavy tandem disc harrow (18-20 cm) Disc harrow (2 passes, 13-15 cm) Float (2 passes) Planter (8 cm) Stubble burning of wheat
	Conventional tillage with residue burned (CT2)	
CT2	Mouldboard plough (30-33 cm) Disc harrow (2 passes, 13-15 cm) Float (2 passes) Drill (4 cm) Stover chopping of second crop	Chisel plow (35-38 cm) Disc harrow (2 passes, 13-15 cm) Float (2 passes) Planter (8 cm) Stubble chopping of wheat
	Reduced tillage with heavy tandem discharrow (RT1)	
RT1	Heavy tandem disc harrow (2 passes, 18-20 cm) Float (2 passes) Drill (4 cm)	Rotary tiller (13-15 cm) Float (2 passes) Planter (8 cm)
	Reduced tillage with rotary tiller (RT2)	
RT2	Rotary tiller (13-15 cm) Float (2 passes) Drill (4 cm)	Stubble chopping of wheat Rotary tiller (13-15 cm) Float (2 passes) Planter (8 cm)
	Reduced tillage with heavy tandem discharrow fallowed by notillage (RNT) for the second crop	
RNT	Stover chopping of second crop Heavy tandem disc harrow (18-20 cm) Float (2 passes) Drill (4 cm)	Stubble chopping of wheat Herbicide application No-till planter (8 cm)
	No tillage (NT)	
NT	Stover chopping of second crop Herbicide treatment No-till drill (4 cm)	Stubble chopping of wheat Herbicide treatment No-till planter (8 cm)

[a]Figures in parenthesisareaverageworkingdepths of theequipment.

In the conventional tillage methods (CT1 and CT2), following wheat harvest, farmers burn the residues, and plough the soil to save time for the second crop soybean. In CT2, crop residues were burnt after the wheat harvest. In the CTI, RT1 and RT2 practices, the soil was tilled after

the first and second crop residues shredded on the plots. The residues of firstand second crops were shredded and left on the soil surface in NT system. Whereas, the stover of the second crop were shredded, and soil was tilled in RNT where the stubble of the first crop were only chopped (Table 1). RT1,RT2, RNT and NT methods are thought to be possible alternatives to the conventional methods used in the region for a long time.
Two weeks prior to sowing, the total herbicide (500 g ha^{-1} Glyphosate) was used to control weeds in the NT and RNT treatments. Compound NP fertilizers were applied in the seedbed at the rates of 172 kg N ha^{-1} and 55 kg P_2O_5 ha^{-1} for wheat and 120kg N ha^{-1} and 40 kg P_2O_5 ha^{-1} for soybean.Theseeding rate of soybean was23.6 plants per m^2 and nine times irrigated by sprinklers in 13 day intervals. The amount of water applied each irrigation was identical for all treatments and no irrigation water was applied to the wheat.

Results and discussion

The oil yield of soybean under different tillage systems is shown in Table 2. Comparing oil extracts in graphs below in each group max. oil yield was found at Reduced tillage system with 19.06 % of oil. This oil yield is nearly close to reported oil yield by Linda [4] at the condition of 4.5% moisture content extraction duration of 22 h (Isopropylalcoholand Petroleumether). She reported that total oil yield of soybean is 22%. The cold press extracted oil from our experiment seems very high while the industrial application gets from the soybean seeds. Cold press application of oil remains some oil in cakes. It depends on oil extractor and application condition. In our experiment the screw rotation speed was 23 rpm.

Table 2. Oil yield and cake amounts of soybean seed as affected by tillage treatments

Sample ID	AppliedAmount (g)	OilYield (g)	CakesAmount (g)	AverageOilYield (%)
CT1	350	61,88	183,43	0,174704762
	350	58,15	183,58	
	350	53,75	183,47	
CT2	350	56,95	189,84	
	350	70,44	180,97	
	350	65,71	188,12	
RT1	350	67,68	186,91	0,190319048
	350	59,73	183,73	
	350	73,1	183,14	
RT2	350	65,48	192,64	
	350	77,08	181,18	
	350	56,6	184,02	
RNT	350	59,24	188,89	0,170795238
	350	57,13	183,73	
	350	57,69	188,93	
NT	350	55,48	184,7	
	350	69,53	186,67	
	350	59,6	191,57	

On the other hand, the decrease in the oil yield observed at CT and NT systems were below 1.5 and 1.9%. These results give some idea about the tillage systems and it effects of one year application on oil yield. From the data it could be concluded that RT systems increases the oil yield of soybean by means of 1.7%.

Conclusion

The obtained datum form our experiment was one year application. So that it is so hard to say tillage systems effect the oil yield of soybean. But here we see some results which lead us to study on different tillage systems on production and oil yield of soybean.

Abstract

In Bejaia , the vegetable crop takes fourth place after the arboricultures, oleicultures, and the great cultures ; Tomato, pepper, pepper, bean and cucumber the crops most grown by farmers in the region to obtain and improve their income. Many factors contribute to low yields, diseases, nematodes, mites and insect pests.The thrips is the insect that caused more damage to thevegetable cropsin Bejaia's region and the farmers find many difficultiesto control and combat them.In the present study, in order to know this problematic, surveys were carried out on a farm on a peppery crop in 2014 due to a discharge by 15 days for 8 months, Two sampling methods were used, Trap and direct counting of number of the thrips. The Thrips were put in a flask containing an alcoholic solution at 70 %.Thrips were sampled and identified under a microscope using morphological characteristics. To estimate the damage caused by the thrips, we take 60 plants randomly, they will be examined visually observed; And then the attack rate was calculated using the following formula:
Attack rate = (number of plants attacked and damaged / total number of plants examined) X100.The damage caused by thrips was estimated for the different stages of crop development, he majority of the thrips were foudedin the flowering stage.We observed significant declines in yield, In view of this situation, farmers use unchecked chemical control to stop this threat.

Keywords: *Thrips,damage,pepper, Bejaia.*

Introduction

The vegetable crops of open field and under shelters occupied in Algeria an average of 88000000 ha. The areas under cover crops shelter (shelter greenhouses, greenhouses, multi-tunnel greenhouses and small tunnels) account for 30% of this area, so 16650 ha divided into ; 2250 ha under unheated greenhouses : The tomato remains the main species grown under unheated greenhouse with 56% of the area, Followed by pepper which takes on average 26% of the area (Anonymea, 2013). Pepper is a group of cultivars of the species Capsicum annuum, These are the mild varieties from this species by selection. The Mediterranean climate suits him well..Many factors contribute to low yields, diseases, nematodes, mites and insect pests. Thrips is the insect that caused more damage to the study site where farmers find enormous difficulties in controlling.Thysanoptera or thrips are insects that live in groups as their name always indicates in the plural (Duval, 1993). They are among the insects that have the smallest size often on the order of a millimeter.More than 50 species of thrips are harmful to crops and 10 species of tospovirus are transmitted worldwide (Mound, 2004). Among these species, thrips californi in Frankliniella occidentalis and thrips from tobacco and onion Thrips tobacco are the most capable of transmitting TSWV (Tomato Spotted Wilt Virus or the Tomato Spotted Tomato Spot Virus)And the Impatiens Necrotic Spot Virus (Impatiens Necrosis Virus). The TSWV mainly affects vegetable crops (tomatoes, peppers) (Lambert, 1999).Some species are polyphagous: Frankliniella occidentalis (Alford, 1998) Contrary to what is observed in most biting insects, Thrips do not eat sap. The insect bites the plant with buccal styling and then injects its saliva, which produces an initial lysis of cell contents, then sucks the product with its powerful pharyngeal pump (Bournier, 1983).Lambert (1999), mentioned that the damage caused are of several types of thrips.. The main damage is due to the injection of saliva, the latter injected; Diffuses through the cell walls and destroys neighboring cells .The dead cells become dehydrated, lose their coloring, become silvered and then white pearly. Breeding also causes damage, especially on young fruits. The insertion of the eggs by the female in the plant causes the appearance of pits first clear that become progressively necrosed. The consequences of Thrips attacks vary according to the nature and the vegetative state of the affected organs (Moreau and Le teinturier, 1997).In fact thrips by their biting cause a reaction of the plant result in the induction of blistering and corky beaches of brownish gray color on the leaves, flowers, fruits, this depreciates strongly commercial value and can lead to falls Yields up to 30% of production (Hanafi and Lacham, 1999). Among the indirect damage, several species of thrips are involved in the transmission of the TSWV "Tomato Spot Ted Wild Virus". The species Thrips tabaci is the only Palaearctic species, the clear forms of summer as well as the dark forms of winter are vectors of this virus.According to Lambert (1999), the thrips of the small fruits Frankliniela occidentalis and Thrips tabaci are able to transmit the Tomato Spotted Wilt Virus (TSWV) viruses and the INSV (Impatiens Necrotic Spot Virus) Impatiens necrosis virus.The TSWV can be very dangerous on several vegetable and floral species (tomato, sweet pepper, lettuce, chrysanthemum, anemone, impatiens, etc), some weeds can also harbor this virus, Symptoms of TSWV are very variable such as Necroses,Mosaic, etc., according to host plants, (Moreau and Le teinturier, 1997).Despite their economic importance, thrips are not well known in Algeria. However, fragmentary studies have been carried out recently on ornamental plants in Algiers by (Benmessoud et al., 2010), also on Mitidja vineyardswith Bounaceur*et al.*,(2010)and on the Biskra region on vegetable crops its doing by Houame (2013). For all these reasons, we considered it useful to undertake an exhaustive study of the main thysanoptera that are dependent on vegetable crops using an approach to study their damage.

Material and Method

In order to study the damage caused by thrips, a study station was selected on a farmer's farmstead; This farm is located in the region of Baccaro which belongs to the littoral part of the wilaya of Béjaïa (36 ° 45 'N, 5 ° 04' E.). The latter is located in northern Algeria, in the region of Kabylie on its Mediterranean coast 241 km from Algiers. It extends over an area of 120, 22 km2. The station belong to the sub-humid bioclimatic stage in mild winter. The average annual of the temperature is 26.5 to 28.2 ° C. and theprecipitation is between 600 and 900 mm all year round . .

Fig.1. Study site

Within the farm, a 400 m2 greenhouse has been delineated, peppers are grown underground planting in January 6, 2014 at a density of 2.7 plants / m2, the trial lasted eight month.To track the flight of the Thrips, four blue slabs were stuck in a greenhouse. Every fifteen days, from planting to harvesting, the blue patches were changed and analyzed under a binocular microscope to note the presence of thrips.For monitoring the evolution the number of thrips, 20 to 30 plants, are taken at random, a count of thrips was made directly and each plant underwent a shaking over Japanese umbrella, in which fall adults and larvae . The Thrips are recovered in a flask containing 70% alcoholic solution,. This technique was performed once every 15 days. Sampled thrips were mounted and identified under a microscope using morphological characteristics. To estimate the damage caused by the thrips based on the method described by Arpaia et al., (1991), 60 plants were randomly taken, visually observed, and the attack rate was calculated using The following formula:
Attack rate = (number of plants attacked and damaged / total number of plants examined) X100.

Results and discussion

F. occidentalis feeds on more than 250 plant species, but prefers those that favor its development. (Rahman et al .,2010). According to Hanafi and Lacham (1999) in Morocco, this pest is causing serious damage to greenhouse pepper crops. This phenomenon has spread to other horticultural crops, mainly cucumber and floral crops.
The damage of the thrips is direct, by the taking of food on all the plant organs, or indirectly by the transmission of viruses. Giving our study we are interested in the attic organs and the damage caused by these little insects.

1-Attack of thrips :

The attacks are variable depending on the vegetative stage of the plant on leaves, flowers and fruits.The first flights of thrips were recorded on the blue trap engulfing (06/03/2014), and this insect on the plant. The observations of the period (06/04/014) found the presence of the thrips on leaf and flower but it is the most attacked flower has 3 to 5 thrips per flower.
The attack peak was recorded at the end of June and beginning of July more than 60 thrips on plant. The greenhouse is completely affected by 70% plant growth.

Fig.2.Thrips of the thrips on the flower of sweet pepper.(original. 2014)

In 1985, *Frankliniella occidentalis* was responsible for a 20% yield loss on greenhouse cucumbers in Canada (EPPO, 2002). According to the author, this thrips is the main vector of tomatospottedwilt virus (TSWV) on tomatoes in Canada. In the United States of America, TSWV is responsible for 50-90% of losses on lettuce.

2-Damage of thrips :

Damage of the thrips causes several damage to the various organs of the plant.

Thrips of small fruits are the most common thrips on greenhouse cucumbers across Canada(ANONYMOUS, 2013)..*Frankliniella occidentalis* has aseveral host plants. Young and adult feed on leaves and fruits, piercing the surface and sucking the contents of the cells of plants. This results are manifested in the formation of silver-white spots or strips on the surface of the leaves and fruits. In surface of leaves or flowers we can also found the excrement of this insect. Excessive infestation of *Frankliniella occidentalis*reduces the yield of the plant and may cause severe deformation or twisting of the fruit. Onion thrips usually occur in the lower stratum of cucumber crops and rarely cause fruit twisting or direct fruit depredation (ANONYMOUS, 2013).

2.1- Damage to plant growth:

The plant generally had a low growth, as the majority of the leaf is wound and dried. It has also been found that the distance between knots is short for the plants attacked.

2.2.- Damage on leaf:

The thrips feed on the epidermis of the leaf, this if leads to lesions of the leaf, the leaves overlap with silvered points and then brown beaches dried out what influences the reduction of photosynthesis and then the weakening of the plant.

Fig.3. Thrips damage on pepper leaves (original, 2014)

Larvae, like adults, feed on the underside of leaves, as well as on flowers, buds and fruits, penetrating the surface and sucking the contents of the plant cells. This activity creates streaks or silver-white spots on the leaf or fruit. The feeding behavior of thrips on growing young shoots causes deformation of the leaves. Berry thrips is a vector of the Impatiens Necrotic Spot (INSV) virus, and the Tomato Tan Spot (TSWV) virus in peppers and tomatoes. Young and adults also feed on pollen. (ANONYMOUS,2013).

2.3. - Damage to the flowers:

Thrips cause damage to different parts of the flower, in our study it has been noticed that either the larvae or the adults feed on pollen that cause to cause the fall of the flowers.

Fig.4. Damage of thrips on the flowers and flower bud of pepper(original, 2014)

Young and adults of thrips also feed on pollen (ANONYMOUS, 2013). for example 10 thrips per flower cause moderate damage to stamens;higher densities at early flower development may lead to dieback of the stamens before maturation and release of Pollen (Steiner and Medhurst, 2003). Heavy infestations can destroy buds and flowers (Hore, 2004).

II.2.3. - Observable damage to the fruit:

For our test the thrips cause remarkable deformations for the fruit to the point that it becomes unsaleable.

Fig.5 - Thrips damage on pepper fruits (original, 2014)

The phytophagous thrips, larvae and adults, pierce the plant tissues to suck the sap. The presence of air bubbles and desiccation of the cells are responsible for the tanning and cracking of the fruits; Breeding also causes damage, especially to young fruits. The insertion of the eggs by the female into the vegetal, leads to the appearance of punctuation first clear that progressively necrosis (Moreau et al., 1997).

Egg laying and the trophic activity of larvae on young fruits change color and shape, making fruit unsaleable. The nymphs feed under the eye of the fruit. We can see black debris mixed with excrement (ANONYMOUS, 2013).

Conclusion

Thrips are particularly important pests of vegetable crops because they are also vectors of viruses. Several damage is caused by this pest for the cultivation of sweet pepper on the different organs of the plant, which reduces the commercial value of the fruits; To deal with this pest a specific integrated control is recommended, monitoring the first thrip of thrips with the installation of blue sticky tape is advised.

Abstract

Field observation in citrus orchards in Chlef valley showed many cases of decline and other typical symptoms of tristeza disease mostly in plants grafted on sour orange which is the dominant rootstock in the valley. A survey of *citrus tristeza virus* (CTV) was carried out during the spring of 2016 to evaluate its current situation and to identify the potential aphid's vectors. Total of 1680 samples collected from 93 orchards located in 21 communes were tested by DTBIA/DAS-ELISA. The analyses have confirmed the presence of CTV in 54 samples through the study area on citrus trees of different species, varieties, ages and origins, whereas the inventory of citrus aphids species carried out during the same period highlighted the presence of two important CTV vectors which are *Aphis gossypii* (Glover) and *A spiraecola* (Patch). However, there was no evidence of the presence of the major vector *Toxoptera citricidus* (Kirkaldy).

Keywords: *Citrus, CTV, Aphids, vector, Chlef valley.*

Introduction

For several decades, citriculture has been considered as the most important fruit crop sector in Algeria and part of its traditional agriculture. Before the French colonization (1830), more than 22 000 citrus trees, mainly orange trees, were already grown in the Mitidja area (near Algiers). Currently, citrus orchards cover an area of 45,040 ha, or 0.6% of the agricultural land, and 11% of lands reserved to fruit trees crops , 90% of this crop is located along the coastal zones in 13 different regions, four of them represent 55% of the total area (Bilda, Chlef, Mascara and Relizane). Chlef valley is the second most important in Algeria, and citriculture is covering about 6000 hectares, however the crop is facing to serious issues, among them salinity and drought. To face these two obstacles, growers use the sour orange rootstock (*Citrus aurantium*), which is very adequate for such soil (salty and alkaline) and dry weather, furthermore the sour orange is tolerant to gummosis which was the major disease of citrus in the past, whereas the emergence of new diseases as Tristeza in the valley since 2010 (Ali Arous *et al*, 2016), which induced several cases of decline on sweet orange grafted on sour orange, had oblige the citrus industry in the valley to start thinking to an alternative rootstock which is adequate both to the new biotic and abiotic conditions. The current study contribute to understand better the current status of this epidemic disease and its epidemiology by monitoring CTV and its vectors in the main citrus growing areas of the valley. The work may help authorities to set up strategy to protect citrus industry from the serious threat of Tristeza citrus disease.

Material and methods

II.1. Citrus aphids monitoring

Thirteen (13) citrus orchards situated in eight different locations in Chlef valley were chosen to carry out the sampling from March to May 2016. On each of the ten trees per orchard ten shoots were weekly observed (100 shoot per orchard) choosing them randomly at different height and orientation and collecting ten young shoots per tree. Collected shoots have been put in polyethylene bags and examined in the laboratory where infestation rate and aphid's identification were performed by using the universal dichotomy identification key Blackman R.L. and Eastop V.F. (2000**)**.

Since valuable documents for studying ecological characteristics of the aphids can be obtained by taking photographs from aphid colonies and their closest environment, a lot of photos were made in the studied citrus orchards.

II.2. CTV survey

In order to investigate the presence and the incidence of CTV in the Chlef valley citrus groves a second survey was carried out during the blossom period in March and April 2016.

A total of 93 groves, representative of the main citrus growing areas in Chlef valley were chosen for monitoring. About 25% of the trees were sampled from each selected grove according to the hierarchic method of Gottwald and Hughes (2000) or randomly on the diagonals of the fields. Most of the visited groves were homogenous in terms of age, rootstocks, density and variety. Age of surveyed trees ranged between 1 to over 40 years. Each sample was made by 10-15 closed flowers, leaves and petioles taken from each site of the canopy of the selected trees. Samples were put in plastic bags, labeled and stored in a refrigerator box containing ice pads. Fresh flowers were printed on the CTV membranes in the laboratory. A total of 1680 samples were collected.

All collected samples were analyzed by DTBIA for the detection of CTV using stems and leaf petioles (Bar Joseph *et al*., 1979; Cambra *et al*., 2000). Positive samples have been confirmed by DAS-ELISA tests.

Results and discussion

III.1. Results of Citrus Tristeza Virus (CTV) survey

As shown in table 1, a total of 54 infected trees of different categories were detected by DTBIA test, which represent around 3.21% as infection rate, in term of citrus surface, 8.07% of the total area prospected were contaminated, whereas the survey has revealed that 16% of citrus groves are infected by CTV (Tab 1).

Table 1. Results of the CTV survey in the study area

	Total (N)	infected	% of infection
Orchard	93	15	16 %
Surface (ha)	660	53.3	8.07 %
Trees	1680	54	3.21 %

III.2. Study of some epidemiological parameters of Tristeza disease.

III.2.1. Citrus species

Majority of CTV infected trees were sweet oranges (41trees) out of 1296 trees tested; sweet orange was the widest group on this study, because it is the most important cultivated group in Chlef valley (DSA, 2016). The second important group is mandarin with 13 infected trees out of 336 tested trees, whereas no grapefruit or lemon positive cases have been recorded. According to the survey, most positive cases were detected on sweet orange species.

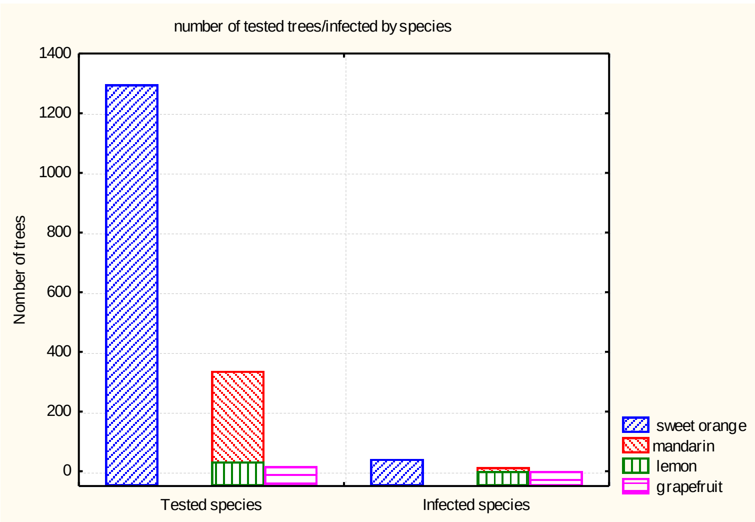

Figure. 1. Infected trees by species

Even though 13 only mandarin were contaminated by Tristeza virus, the infection rate (3.86%) was higher than in sweet oranges (3.16%); the survey highlighted that the occurrence of citrus tristeza virus was significant, with about 24% of mandarin orchards and 14.5% of sweet orange groves CTV infected (Fig 1). According to Kitajima *et al* (1974) et Muller *et al* (1974), *Citrus sinensis* (L), *Citrus reticulata* (Blanco) et *Citrus paradisi* (Macf) are the principal host of CTV.

III.2.2. Age of orchards

The survey shown that CTV were present in all categories of citrus orchards regardless their age, unless the youngest plantations of less than 7 years. Prospection allowed the assessment of CTV status in function of age of trees, the lowest infection rate (1.7%) was recorded in the oldest trees (more than 40 years old), which were planted during the French colonial period, followed by the groves aged between 18 and 39 years old (3.7%). However, the highest infection rate was found in the tree of 8 to 17 years old, whereas no positive case was recorded in trees aged less than 7 years. In 2011 the first CTV infection case in Chlef valley was detected, the tree was 6 years old, another case has been detected a year after, the tree was 62 years old (Ali arous *et al*, 2016)

According to Rebours (1950), till the second world war, Algerian citrus industry was one of the most important in the Mediterranean basin, at that time bud-woods groves already exist, they were under rigorous varietal assessment and pests investigation. Thus it is difficult to know the origin of CTV infection found in old orchards, we think that natural dissemination by aphids and illegal grafting were probably associated to this situation, the first quick decline were detected since 1948, CTV has been mentioned associated to these cases. Infected vegetal material imported from overseas into Mediterranean countries including Algeria is the cause if these first contaminations (Bové, 1966).

III.2.3. Origin of plant materials

The study has focused on the origin of plantation, Analysis shown that the incidence rate of the disease in orchard planted with plant material brought from Mitidja region were the highest, we recorded 11 contaminated orchard out of 48 tested; whereas , from two orchard created with plant material imported from Spain, one was infected (Tab 2)

Table 2. Situation of CTV/origin of plants

Origin/Plants	orchard (N)	Infected orchard	%
Mitidja	48	11	22.9
Unkown	39	03	7.6
Spain	02	01	50
Ain Defla	01	00	00
Bir safsaf(Chlef)	02	00	00

In old groves with unknown origin, the survey came out 3 contaminated orchards out of 39 analyzed. We stressed that trees produced locally were completely free of CTV.
Result of investigation highlights that 36 plants came from different nurseries of Mitidja have been diseased plus 7 imported plant from Spain, all plants were 8 to 17years old. This report excludes thus the role of aphid vectors; more likely, contamination took place in nurseries, since natural dissemination take long time to become significant (Gambra *et al*, 1988).

III.2.4. Rootstocks

The survey has supported that sour orange rootstock *Citrus aurantium* (L) is dominant in Chlef valley: 85.7% of tested tree were grafted on it, only 12.3% were grafted on citrange *Poncirus trifoliata* (L), furthermore 14.2% of infected groves had trees with combination *C. sinensis* or *C. reticulata*/*C. aurantium* (Tab 3). Sour orange is well adapted to calcareous soils, which are widely present in the valley; it is also tolerant to gummosis and drought. but very sensible to Tristeza, the most destructive disease of citrus (Lacirignola and D'onghia, 2009; D'onghia *et al*, 2009; Roistacher, 1991).

Table 3. Situation of CTV/ rootstocks

rootstocks	orchards (N)	Infected orchards	Tested trees	Infected trees	% infection (trees)
sourorange	84	12	1440	44	3

citrange	07	03	208	10	4.8
volkameriana	02	00	32	00	00

Even though the resistance of citrange and volkameriana *Citrus volkamerana* (Ten and Pasq) rootstocks to decline due to CTV, their use must consider other crucial biotic and abiotic parameters like (salinity, freeze, gummosis…), to ensure the future of citrus industry in any region (Yokomi, 2009).

IV. CTV Aphid vectors monitoring in the study area

A survey of frequency, abundance and infestation rate of aphid vectors population was done from March to May 2016 in 13 orchards located in 8 different areas.
Dichotomy identification of aphid populations encountered during the monitoring has revealed only two species among about fourteen related to citrus (Blackman et Eastop, 2000; Remaudière, 1996). Both species belong to the genus of Aphis, *Aphis gossypii* (Glover 1877), *Aphis spiraecola* (Patch 1934) (Homoptera: Aphidoidea) (Remaudière, 1996).

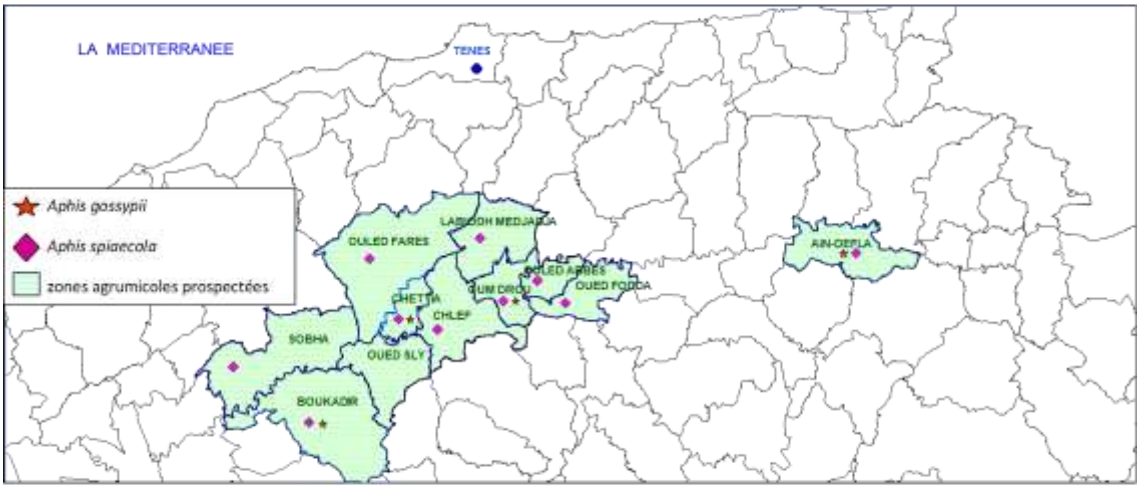

Figure 2. Repartition of *A gossypii* and *A spiraecola* in the study area.

A spiraecola was the dominant species during the survey, the green citrus aphid is strongly related to rutaceae family (Blackman and Eastop, 2000) it is the dominant species in many Mediterranean countries (Abou Kubaa *et al*, 2009; Baloglu and Birisik, 2009 and Delkhosh and Tousi, 2009), whereas *Aphis gossypii* (Glover) was less frequent than *A spiraecola* (Fig 2), the average of infestation rate was 2.8%, its occurrence frequency was around (23.8%), the infestation rate of the melon aphid during a survey carried out in 2010 in the valley recorded around 43% (Ali Arous *et al*, 2016). However, there was no evidence of the presence of the major vector *Toxoptera citricidus* (Kirkaldy).

Conclusion

The survey has shown the rapid dissemination of tristeza virus through citrus groves of Chlef valley, its status is changing constantly. Investigation has revealed very important technical information and confirmed the role of nurseries and informal propagation materiel movement in the high incidence of the virus. Natural dissemination by aphids in the spread of the disease is not clearly established for which more studies are required. Management policy and strategies for disease control and quarantine should be taken in order to limit the spread of the disease through citrus orchards of the region.

Abstract

The consumption of low-quality dairy products can endanger consumers' health and even cause serious food poisoning. The implementation of the quality policy in dairy units is therefore a priority in terms of consumer protection. To assess the implementation of hygiene in dairies in the Ghardaia region in Algeria, a field survey of 7 dairies and a literature research were conducted across the province. Members of staff play a vital role in determining food quality; being trained in hygiene practices remains a quality determinant. Conversely, if poorly trained or careless, staff can be a major source of contamination with their own health, their clothing or their work practices. Also, at the farm level, the incorrect maintenance of the milking equipment and the insufficient level of hygiene in the building proved to be a source of bacterial contamination. In this context, our work has focused on the evaluation of hygiene practices applied by dairies staff.

Keywords: *Aerobic plate count, Dairy, Hygienic Practice, Personal, Saharan Region, Safety*.

Introduction

Micro-environments that promote the growth and proliferation of different microbial strains are created in different stages of milk processing lines. That affects the quality of milk; in other word affects the customer's health. This encourages the dairies managers to take all the necessary preventions for protect their products, such as the hygiene practices. The food safety should be compulsory in every phase of the production chain, and the primary level of production is the first step which means that the dairy quality is closely connected to the activities that take part in the production process that happens on the farm itself (Vilar *et al.,* 2012).

The purpose of our study is to investigate the effect of hygiene practices, especially the staff practices on the milk microbiological quality. By the use of a field survey of seven dairies in the province of Ghardaïa, which recently knows a revolution in milk and its derivatives industry and also by a literature research were conducted across the province.

We have focused on staff in this work; because we thought that they are in directly contact with the product from the first step of preparation until the last stage of storage. We also believe that their conscience with their professionalism play a very important role in their hygiene practices as the respect of security rules, wearing the correct uniform (blouse, cap, boots and gloves) and their own personal hygiene. We found when these practices are not respected the dairy products are poor in the microbiological content. The implementation of hygiene practices by staff gave significant effect to milk quality.

The population growth and the evolution of their standard of living assert the use of modern technology to need of the high level of consumption of food products. This can clearly be seen when we know "UHT milk is consumed extensively throughout the world" (Pujol et *al.,* 2013). That’s why many governments devoted their interest in food industry, which have one of the most important challenges which is the microbial quality and the upkeep of sanitary conditions as the high availability of nutrients and oxygen favor microbial growth (Cleto *et al.,* 2012). UHT processing is responsible for 95% of total fluid milk consumed in Algeria (MADR, 2012).The dairy industry depends on proper disinfection by regular sanitization procedures because the milking procedure, shipping and storage of milk load faces risks of further contamination from man, the environment, or from growth of inherent pathogens (Pandey *et al.,* 2011). One of the most important precautions is taking hygiene practices in consideration, specially the staff practices.

Algeria, like other countries seeking self-sufficiency in milk production and its derivatives has created many dairies, and is the case in the Ghardaia region. The enthusiasm for milk production in the M’zab valley led to the creation of many cattle farms (Bensaha *et al.,* 2014a). And because the number never substitute for quality, therefore, the implementation of monitoring the correct hygiene of milk and dairy products throughout the supply chain is essential to ensure the safety and suitability of these products for their intended use (Pandey *et al.,* 2011). Sporulated bacteria pertaining to the genera *Bacillus* and *Paenibacillus* are the main micro-organisms identified as being limiting factors for fluid milk quality, due to inadequate hygienic condition (Huck *et al*., 2007; Ivy *et al.*, 2012). It's the responsibility of the food producer (Dairy) to identify these points and implement control measures to protect the milk from contamination (Vignola, 2002).

The objective of this study is to investigate the effects of staff hygiene practices on the quality of milk produced by the dairies in M'zab valley. To appreciate the implementation of hygiene in dairies in the Ghardaia region, a field survey on 07 dairies, based on the findings and bibliographical research was conducted across the province, followed by microbiological analyzes of the final product for each dairy concerning the total aerobic mesophilic flora. The notion of good hygiene practices in Algeria remains to be introduced (Plan national de salubrité des aliments, 2006).

Material and methods

Survey of dairies studied

This study is based on a detailed survey of 7 dairies in region of M’zab in the province of Ghardaïa (located 600 Km south of Algiers) **(Figure.1)**, The survey was conducted during three month, from September to November 2016.

The approach of the study was focused on surveys and interviews with the processing units in order to characterize the daily staff hygiene practices of milk processing and dairy products. This survey was performed to determine within each dairy, the worker’s instruction level, the clothes worn (blouse, cap, boots and gloves), the medical periodical survey and safe and hygienic measures (Table 1).

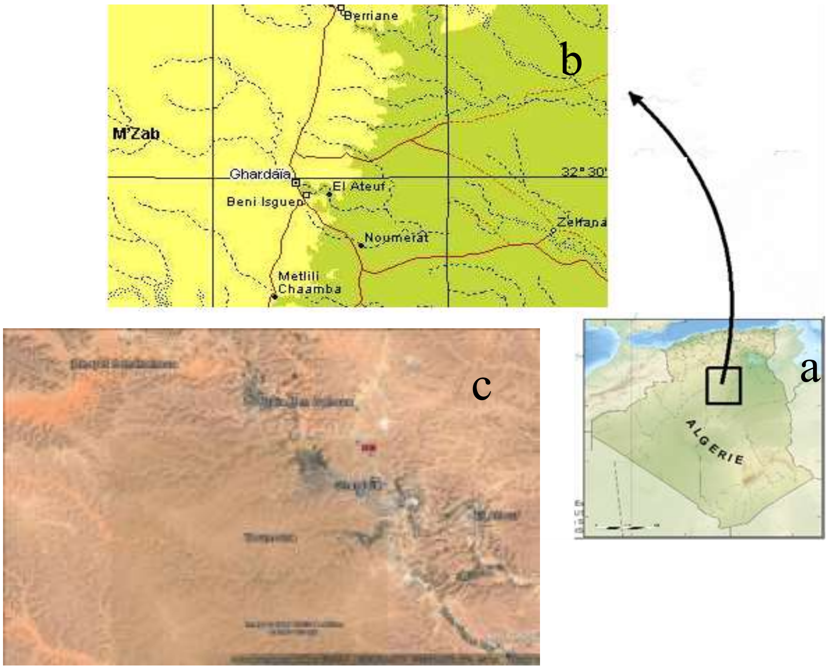

Figure 1: **The geographical location of the study area.**

A set of maps showing the study area location, map of Algeria, which shows the location of the province of Ghardaïa (**a**), the geographical location of the areas concerned (**b**), the geographical location of the areas concerned taken by Google Earth site at an altitude of 30.64 km on 08/02/2016 (**c**).

Table 1: The data of staff hygiene practices collected.

Dairies	Instruction level	Gloves	Blouse	Blouse color	Boots	Cap	Safe & hygienic rules board	Frequency of medical visits
LA Ghardaia	Secondary	No	Rare	Blue	No	No	No	06 months
LC Gerrara	Medium	No	Yes	White	No	No	No	Every year
LkGerrara	Ts+ Secondary	Yes	Yes	Brown	Yes	No	No	Every year
LM Gerrara	Ts+ Secondary	No	Yes	White	No	No	No	Every year

LA Metlili	Ts+ Medium	No	Rare	White	No	No	No	Every year
LS Daya ben dahoa	Medium	No	Rare	White	No	No	No	Every year

Sampling procedure and laboratory analysis

Milk samples were collected immediately after the packaging (the final step of production), which were transported directly to the laboratory of Algerian central of quality control and packaging in Ghardaia for microbiological analyzes.

Total aerobic mesophilic flora: dilutions (10^{-1} to 10^{-5}) of each sample are made. The Petri dish is inoculated with one ml of each dilution which is added to the PCA agar (Table 2). After 72 hours of incubation, all the colonies are counted and the results expressed in units CFU per ml of milk (CFU / ml). (**Federation Internationale de Laiterie, 1991**)

Table 2: Microbiological analyzes of aerobic mesophilic total flora analysis of each dairy.

Dairies	TPC
LA Ghardaia	5×10^5
LC Gerrara	7×10^2
LkGerrara	8×10^3
LM Gerrara	7×10^3
LW Berrieane	6×10^3
LA Metlili	4×10^2
LS Daya ben dahoa	7×10^3

Data Analysis and Statistics

We have two types of studied parameters, qualitative parameters (parameters are studying by surveys) and quantitative parameters (microbiological analysis) and to analyze these parameters, we choose to go through two methods.

The first method is to quantify and standardize the values of these parameters in binary system, which represents the parameters values using two different symbols: typically 0 (zero) and 1 (one).

The second method is based on statistical multivariate tools such as Multiple Factorial Analyses (Factor analysis of mixed data), which were used to determine the main factors which describe the variability of milk hygienic quality

The results of the study (Table 03) show that the level of education of the personnel of these processing units is medium or even modest.

Table 3: Standardized parameter values in binary system.

Dairies	Instruction level	Gloves	Blouse	Blouse color	Boots	Cap	Safe & hygienic rules board	Frequency of medical visits	TPC
LA Ghardaia	0	0	0	0	0	0	0	0	0
LC Gerrara	0	0	1	1	0	0	0	1	1
LkGerrara	1	1	1	1	0	0	0	1	1
LM Gerrara	1	0	1	0	0	0	0	1	1
LW Berrieane	0	0	1	1	0	0	0	1	1
LA Metlili	0	0	0	1	0	0	0	1	1
LS Daya ben dahoa	0	0	0	1	0	0	0	1	0

Their low level of education is a handicap for the adoption of newly introduced practices in dairy processing and requiring technical mastery. According to (Bensaha, 2009) the level of training of this staff, their skills in animation and their good knowledge of the specificities of their areas of intervention constitute a non-negligible capital in the development of the production unit. Indeed, we have recorded that these people are poorly recruited, poorly adapted to their jobs and, even worse they received little training on the tools, methods and practices that fall under their responsibility. The training and development of the dairy staff contributes significantly to improving the quality of intervention of these people (Bensaha *et al.,* 2013). Nevertheless, with regard to the availability of labor power, we find that more than half of the dairies face difficulties for its availability in due time, because it is made up of a young workforce, without any experience and with a low professional qualification. This experience remains based on empirical knowledge with very little scientific knowledge. This situation is incompatible with good hygiene practice because the low-tech worker is often incapable of rapidly preventing situations that may affect the milk processing chain.

The initiative should also encourage processors to play their full role and assume their responsibilities in the search for efficient recruitment systems.
The uniform must conform to good hygiene practices, namely: a clean, short-sleeved blouse, clean rubber boots and short nails, no jewelry (wristwatches, gourmet, rings ...), a bucco-nasal mask for Sensitive workstations, gloves, shoes and work boots (Vignola, 2002). The study shows that 80% of milk handlers do not wear headgear, gloves, or bucco-nasal mask and rarely blouses and boots.
Therefore, the cleanliness of body and clothing is not satisfactory. The agents assigned to the various work stations all have a single work wear and boots. According to Bensaha *et al* (2012), cleanliness of staff is essential in the food industries especially for perishable foodstuffs such as milk (Bensaha *et al.,* 2012). Nevertheless, 20% of the manipulators are dressed in a clean white coat and take care of their body and clothing cleanliness (Burbuddhe *et al.,* 2008). Generally, staff must ensure a high degree of body cleanliness, a hair must be well maintained, nail cleanliness and it must have two to several work clothes, preferably light colored. All staff must have clean hands, wear clean clothes and perform clean practices (Pandey *et al.,* 2011). A manipulator must be designated for each task, this reduces the risk of contamination of people coming from contaminated areas (Bensaha *et al.,* 2014b). According to Olechnowics *et al*., (2012), at the farm level, microbial contamination of milk occurs via the surface of the milking equipment.
The study shows that in 90% of dairies, toilets are far from all other premises. In 20%, the soap is absent at the entrance to the sanitary facilities, which favors poorly washed hands. Cleanliness in the bathroom is not satisfactory (Bensaha *et al.,* 2014a). Noted that bad design of buildings can generate health concerns with significant negative economic repercussions as well as the work of the manipulators. At 90% of the times, dairy equipment and rooms are manually cleaned at regular frequencies. Thus, adequate hand washing facilities and a hygienic hand drying method should be available in the vicinity of the handling area (DSP, 2012). A routine program to check the effectiveness of cleaning should be put in place (Varnam *et al.,* 2001).
Human diseases can be transmitted via milk. The Staff engaged in the handling of foodstuffs and milk in particular must undergo a health examination (Varnam *et al.*, 2001). All dairies (100%) report receiving, once or twice a year, a visit from the working doctor and having their workers vaccinated. It is worth highlighting the positive character of the periodic (bi-annual) health action associated with epidemiological surveys initiated locally to maintain all the epidemiological indices at a satisfactory threshold. This is reflected in visits to the processing units carried out periodically to sensitize the dairy managers to the many aspects of their activity: hygiene, good practice (Bensaha *et al.,* 2014b). It is recommended that people involved in the handling of food should be subjected to health regular checks (Burbuddhe *et al.,* 2008). Only 03 of the dairies surveyed possess plates of safe and hygienic rules. Thus, it is understandable that it is almost impossible for these people to hold a reading of these distinctive emblems. Indeed, it is possible to operate the transformation units according to modern organizational methods. But there must be an agreement to start with on diagnoses and make proper investments as the economic profitability is already enormous (Plan national de salubrité des aliments, 2006).

Conclusion

Through the presentation of theoretical notions of good practice, the success of the dairy industry depends on the promotion of knowledge, examination, continuous study of the performances acquired and practices that have affected positively the safety of food hygiene. This confirms the importance of hygiene training for food handlers.

The adoption of good hygienic practices is an operational approach to tackle the many challenges in food safety and safe and healthy agri-food products. This finding can have important economic consequences; as such contamination can increase the probability of consumers purchasing a product that may have problems related to appearance and flavor. In the end, the debate remains open and the concept of good hygienic practices deserves careful reflection and popularization, both in terms of management and the agricultural profession.

Abstract

The phytopathogenic bacteria affect several vegetable crops. *Streptomyces scabies* is the causal agent of common scab, the toxin involved in this pathology is the thaxtomin A. Among genes encoding this toxin, there is the *nos* gene. The objective of this work was focused on the screening of potential biocontrol agents against *S. scabies*. Thus, six strains of Actinobacteria (*S. griseus* Lac1, *S. rochei* Lac3, *S. anulatus* Pru14, *S. champavatii* Pru16, *Nocardiopsis dassonvillei* Vic8 and *N. alba* Pin10) were isolated from Algerian rhizospheric soil. The evaluation of the antagonist capacity of these strains was tested. The *in planta* antagonism test was conducted on radish seedlings in growth pouches. Root growth was estimated by analysis of data with the Winrhizo software. The promising Lac1 antagonist strain was selected to study its effect on *nos* gene expression (qRT -PCR) and thaxtomin A production (HPLC). The Results of antagonism test against *S. scabies* indicated that Pru16, Vic8 and Lac3 strains showed no inhibitor activity *in vitro*. However, *in planta*, these same stains could reduce the pathogenic effect on radish seedlings, which resulted in the disappearance of necrosis. These strains appear to be PGPR. The Lac1 proved active both *in vitro* and *in planta*. Compared to all isolates, the Lac1 isolate acting by antibiosis showed the most significant antagonism. Also, this isolate had effect on *nos* gene expression and production of thaxtomin A. In addition to the widely studied *Streptomyces* sp., this study showed promising new candidate for biological control belonging to the genus *Nocardiopsis*.

Keywords: *Common scab, biological control, Streptomyces, Nocardiopsis.*

Introduction

Common scab of potato is a disease that causes economic losses. The disease can also affect other types of vegetables such as radish. Common scab is associated with four main species of Streptomycetes: *Streptomyces scabies, S. acidiscabies, S. caviscabies* and *S. turgidiscabies.* Common scab is mainly caused by species *S. scabies*. This organism inhibits the growth of young seedlings. The taxonomic studies on plant pathogenic *Streptomyces* showed a high genetic diversity within this group. A common characteristic of these organisms is their ability to synthesize phytotoxins, called the thaxtomins (King *et al.*, 1991).
The thaxtomins are nitrated peptides which inhibit the synthesis of the cellulose during the development of plant tissue. Thaxtomin A is the major toxin produced by *S. scabies*. Its biosynthesis involved a conserved non-ribosomal peptide synthetase (NRPS), P450 monooxygenases and a nitric oxide synthase, encoded by the *nos* gene, which is required for the nitration of the toxin **(**Loria *et al.*, 2008**)**. The nitric oxide synthase is also responsible for the release of nitric oxide causing scab in host-pathogen interface. This suggests that nitric oxide may play an additional role during the infection process **(**Healy *et al.*, 2002**)**. Thaxtomin A plays a central role in the induction of lesions formation on the tubers. Studies have shown

that all pathogenic strains of *S. scabies* tested produce thaxtomin A **(**King *et al.*, 1991**)**. They have demonstrated a correlation between the production of thaxtomin A and pathogenicity.
The investigation focused on the *in vitro* and *in planta* antagonism of six actinomycetes strains against *S. scabies* .Also, the study of the culture supernatant effect of the representative strain *S. griseus* Lac1 (active against *S. scabies in vitro* and *in planta*) on *nos* gene expression, involved in thaxtomin A biosynthesis by *S. scabies*.

Material and methods

Microoganisms

S. scabies was isolated from the potato affected by common scab, cultivated in Quebec. The antagonists actinomycetes strains (*S. griseus* Lac1, *S. rochei* Lac3, *S. annulatus* Pru14, *S. champavatii* Pru16, *N. dassonvillei* subsp. *dassonvillei* Vic8 and *N.* alba Pin10) were isolated and identified in Laboratory of Applied Biochemistry and Microbiology University of Constantine (Aouar *et al.,* 2012). The strains were designated: Lac1, Lac3, Pru16, Pru14, Vic8 and Pin10.

In vitro Antagonism against *S. scabies*

Determination of antagonism activity of stains against *S. scabies* was carried out by four different techniques: the vertical stripe (Selvin *et al.*, 2009), agar cylinders (Bauer *et al.*, 1966), the wells technique **(**Kutzner, 1981) and diffusion disk technique (Wu *et al.*, 2007).

In planta antagonism of actinomycetes against *S. scabies*

Radish germination

Radish seeds (*Raphanus sativus* 'Cherrybelle') were sterilized, and then washed with sterile water. They were distributed on Petri dishes containing agar-water medium, and incubated in darkness for germination at 30 °C for 48 h.

Subcultures of antagonistic actinomycetes and *S. scabies*

For all strains, tryptic soy broth (TSB) medium was inoculated with 10 µl of a spore suspension (10^8 UFC/ml). The medium was incubated at 30 °C in a rotary shaker (190 rpm) for 48 hours. The culture was then centrifuged at 4000 *g* for 10 minutes; each pellet was re suspended in five volumes of fresh TSB **(**Legault *et al.,* 2011**)**.

Growth pouches

Six radish seeds were placed in each growth pouch previously sterilized (125 X 75 mm, Mega International) and filled with 18 ml of sterile distilled water. Radish seeds were grown in the presence of 1 ml of antagonist actinomycete suspension and 1 ml of physiological saline, in order to test their eventual effect on radish growth **(**Legault *et al.,* 2011**)**.To evaluate the antagonistic effect, the radish seeds were inoculated with 1 ml of *S. scabies* suspension and 1 ml of antagonistic strain suspension. The positive control was inoculated with 1 ml of saline and 1 ml of *S. scabies* suspension. Four repetitions were performed for each treatment. Growth pouches packed in aluminum foil and incubated for 6 days at 21°C and 68% humidity, in the plantarium.

Effect of Lac1 supernatant on *nos* gene expression

Culture of *S. scabies* strain

Subcultures of 48 hours were used to inoculate the minimum starch medium (MSM). This medium was amended with (0.1% W/ V) suberin and (0 5% W/V) cellobiose as inducers of thaxtomin A production. The incubation period was 5 days at 30 ° C under agitation (180 rpm). The cultures were supplemented with the methanolic extract of the Lac1 strain at concentration 4 µg/ml (Wu *et al.*, 2007). A randomization of three repetitions was performed for each treatment.

Total RNA extraction

Cultures were stopped and the mixture was centrifuged. The pellets containing the total RNA were harvested and supplemented with 1 ml of lysozyme prepared in buffer Tris / EDTA and β-mercaptoethanol (β-ME). After sonication, phenol-chloroform was added, followed by centrifugation. The supernatant was recovered; this step was repeated three times. Finally, a volume of 600 µl of ethanol was added to supernatant containing the RNA. The remaining steps are those of a commercial preparation of RNA "kit" extraction 'Rneasy MiniKit Protocol' (Qiagen, Mississauga, ON, Canada) **(**Legault *et al.*, 2011**)**

Synthesis and amplification of cDNA

An amount of RNA (20 µl) was dissolved in DEPC water, denatured by heating at 65° C for 7 min. The first strand synthesis is carried out with a commercial preparation 'kit' (GE Healthcare, Baie d'Urfé, QC, Canada). Two target genes were amplified *nos* and *gyr* A. The pair of primers was obtained from Integrated DNA Technologies (IDT, USA). The reference *gyr* A gene 2457 bp (forward primer ggacatccagacgcagtaca; reverse primer ctcggtgttgagcttctcct). The *nos* gene 1173 bp (forward primer gagctggtcttggaggtccctatc; reverse primer cgcatgttggagatgacgggtacg). Amplification is performed in a thermocycleir type Biometra. The amplification cycles are the following: pre-denaturation 95° C (5 min); denaturation 95° C (1 min); association 60° C (1 min); elongation 72° C (2 min); end amplification 72° C (2 min).

Genomic DNA extraction from *S. scabies*

S. scabies strain was cultured in TSB medium for 5 days. After centrifugation, the DNA contained in pellet was extracted (Pospiech and Neuman, 1995) . This genomic DNA will be amplified together with the cDNA, it will serve as a control for both *nos* and *gyr* genes.

Gene expression (qRT-PCR)

The q RT-PCR analysis of transcripts gene was conducted on the Stratagene Mx3000P with SYBRGreen. Thresholds amplification (Ct) for both *nos* and *gyr* genes were translated into relative expression **(**Legault *et al.*, 2011**)**.

Effect of Lac1 supernatant on thaxtomin A production

Thaxtomin A production and extraction

The MSM amended with suberin and cellobiose was inoculated with *S. scabies*. A Lac1 methanol extract was prepared and added to the culture medium at a concentration of 4µg/ ml. The cultures were incubated at 30° C for one week on a rotary shaker (200 rpm). Four repetitions were performed for both assays and controls (Lauzier *et al.*, 2002).

After centrifugation, the supernatant was harvested. The pellet was used to determine dry weight biomass. Thaxtomin A contained in the supernatant was extracted with ethyl acetate.

Once concentrated, it was separated by preparative thin layer chromatography. The mobile phase was chloroform: methanol (9:1). After migration the yellow spot with Rf equal to 0.27 corresponding to thaxtomin A, was scraped and eluted with methanol: chloroform (Beauséjour *et al.*, 1999).

Quantification of thaxtomin A by HPLC

Purified thaxtomin A was dissolved in acetonitrile then quantified by reverse phase HPLC using an Agilent 1260 Series (Agilent Technologies, Santa Clara, CA, USA) with the column: Zorbax SB-C18 (Agilent Technologies). Elution was carried out with a 25-75% acetonitrile linear gradient and detected at 249 nm with a diode array detector (DAD) (160-620 nm).

Statistical study

The SAS 9.1 (Statistical Analysis System) program with the GLM (General Linear Model) was used to increase the precision of ANOVA procedures.

Results and discussion

Results

In vitro antagonism against *S. scabies*

Results of the vertical stripe technique showed that among the six strains only Lac1 and Pru14 inhibited *S. scabies* growth. The inhibition zones recorded were 20 mm for the both strains. The same strains were positive with the agar cylinders technique, where Lac1 and Pru14 exhibited inhibitions of 38 and 16 mm, respectively. However, disk diffusion and wells technique showed that only Lac1 was active, and the inhibition zone was 30 mm. With all the techniques employed, the strains Lac3, Vic8 and Pin10 showed no activities. *In vitro,* the Lac1 strain presented the best inhibition against *S. scabies*.

Antagonistic actinomycetes effect on radish growth

After the incubation period, the pouches were scanned. The antagonistic actinomycetes strains showed no pathogenic effect on growth seedling, where the plant showed a good rhizogenesis and the absence of necrosis (Figure 1).

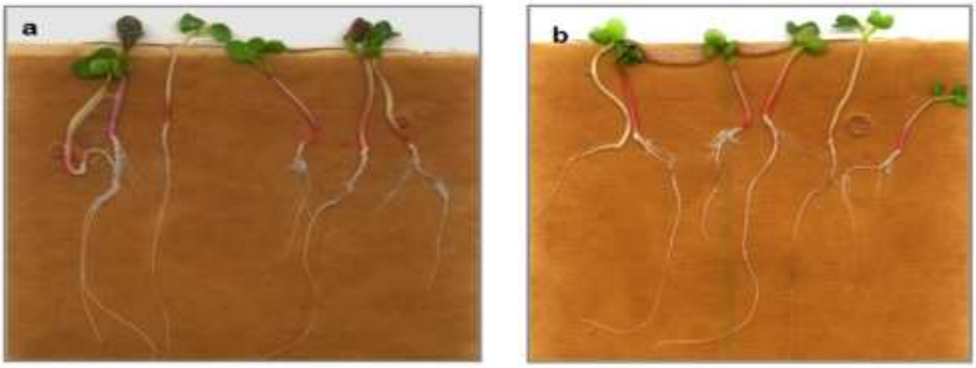

Figure 1: antagonism on radish growth: (a) negative control, (b) Lac1 strain effect.

In planta antagonism against *S. scabies*

Results analysis by the software WinRhizo followed by ANOVA statistical analysis consolidated with LSD test ($P < 0.05$), indicated that radish seedlings inoculated only with *S. scabies* were affected by common scab, the root surface was 3.44 cm^2. The surfaces of root seedlings inoculated with *S. scabies* and antagonists strains varied between 5.66 and 8.06 cm^2 (Table 1).

Table 1: Effect of antagonistic strains on the growth of roots radish inoculated with *S. scabies.*

Roots Surface (cm^2)	Negative control	6.36 ± 0.99 **ab**
	Positive control	3.44 ± 0.33 **c**
Roots Surface of inoculated seeds with *S. scabies* and antagonists (cm^2)	Lac1	8.06 ± 1.64 **a**
	Lac3	6.80 ± 1.81 **ab**
	Vic8	5.96 ± 0.99 **b**
	Pin10	5.76 ± 1.28 **b**
	Pru14	5.66 ± 1.76 **b**
	Pru16	5.57 ± 1.16 **b**

Statistical analysis revealed no significant differences between root surfaces of the negative control and those of seedlings inoculated simultaneously with the antagonist strains (Figure 2). Compared to the other strains Lac1 presented the most significant antagonistic activity (Table 1).

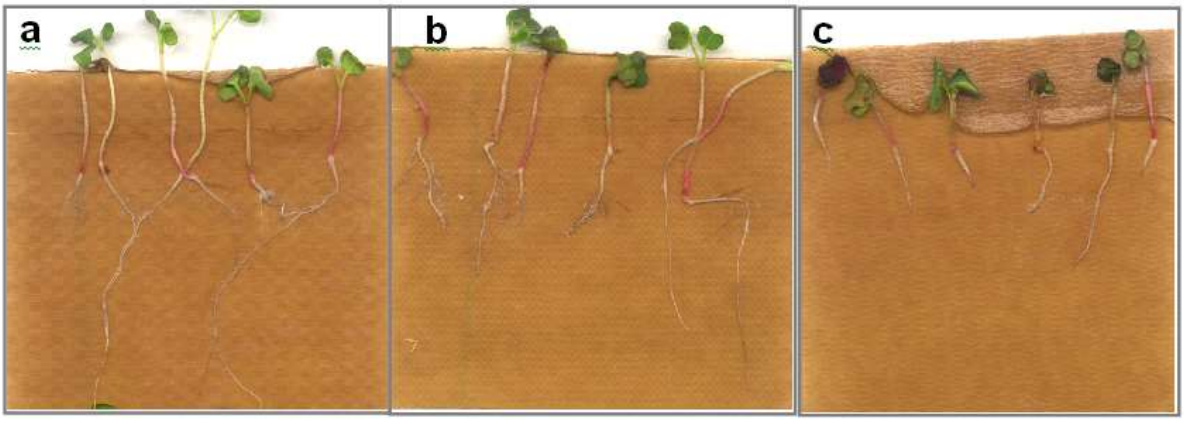

Figure 2: Effect of the antagonists on the roots growth of radish inoculated with *S. scabies*
(a): Lac1; (b): Pru14; (c) positive control.

Gene expression

The dissociation curve showed two peaks corresponding to two amplicons formed *nos* and *gyr*. This result showed the absence of dimers primers. The dissociation temperature (Tm) was equal to 89.9° C for *gyr* gene and at 92° C for *nos* gene. Ct values obtained were significant and varied between 23.2 and 31. The highest value (23.2) corresponding to the genomic DNA. The Ct of the reference gene *gyr* was 27 for both controls and assays. This is the reason why the gyr gene was chosen as reference gene. The Ct for the target *nos* gene varied from 28 to 31. Analysis of results achieved by the RESET program (Table 2) showed that at 24, 48 and 72 hours significant differences were recorded between controls and the assays. This means the presence of supernatant effect of Lac1 on *nos* gene expression. The expression of the *nos* gene coding for the production of thaxtomine A decreases in the presence of the extract of the Lac1 strain after 48 h of incubation (Figure 3).

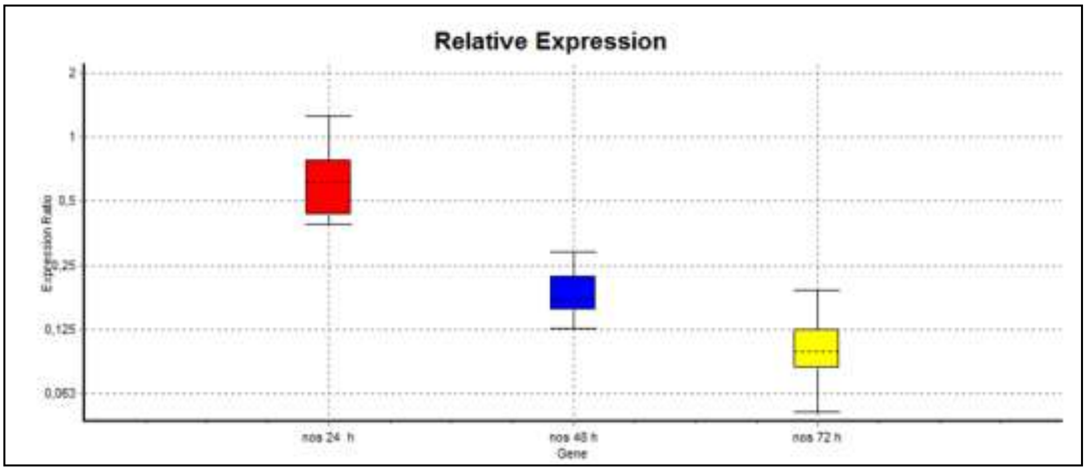

Figure 3: Relative expression of *nos* gene in the presence of Lac1 extract

Extraction and quantification of thaxtomin A

The minimum starch medium supplemented with suberine and cellobiose, amended or not with the Lac1 methanolic extract, induced thaxtomin A production by *S. scabies*. The HPLC analysis was carried out with commercial thaxtomin A as standard, which was eluted at 4.90 minutes. Its peak presented a typical absorption spectrum from 150 to 500 nm with a maximum at 249 nm. The chromatogram of the organic extract obtained from *S. scabies*, revealed a peak at 4.91 minutes which has the same absorption spectrum as commercial thaxtomin A.

Quantification of dry weight of the purified thaxtomin A by HPLC in the absence of Lac1 extract was 2543.39±248.47 µg/mg/ DW and 1752.87±152.59 µg/mg/ DW in the presence of Lac1 extract. Statistical analysis by the Student test ($\alpha = 0.05$) showed a significant difference ($P = 0.0014$) between the amounts of thaxtomin A produced in the absence and in the presence of the Lac1 extract. There is a significant decrease in the production of thaxtomin which confirmed the gene expression results.

Discussion

The strain Pru14 showed inhibitory activity with the agar cylinders technique. However, its activity with disks technique diffusion was only partial. This could be explained by the fact that the bioactive molecule was not produced in a liquid medium or it was produced but was not extracted with ethyl acetate. In the case of actinomycetes, the solid medium is the suitable medium for bioactive molecules production (Anibou *et al.*, 2008). Some metabolites are produced during maturation because aerial mycelium of actinomycetes have morphogenesis program colony coordinated with bioactive molecules excretion (Thompson *et al.*, 2002). In addition, the Pru14 aqueous solution deposited in the wells showed no inhibitory activity in contrast to the agar cylinders technique. It is possible that the molecule diffused poorly in agar medium or is not soluble in water. Common scab caused by *S. scabies*, affect not only potatoes, but also other vegetables like radish. In this study, the radish seedlings were chosen to perform this test *in planta* for two reasons: their susceptibility to *S. scabies* and their rapid growth in the planetarium. The rhizospheric Lac3, Pru16, Pin10 and Vic8 strains showed no *in vitro* activity against *S. scabies*. However, *in planta* these same isolates have minimized the pathogenic effects on radishes; which were translated by the appearance of secondary roots. It is possible that the antibiotic molecule does not diffuse into the agar, or the inadequacy of the fermentation medium and/or extraction solvent. This is in agreement with the results obtained by Selvin *et al.* (2009), who found that the bioactive molecules of the strain *N. dassonvillei* MAD08 extracted by organic solvents inhibited *in vitro* the growth of Gram positive and

Gram negative bacteria, whereas the soluble phase in the water, inhibited *Candida albicans*. According to the literature, about 5% rhizobacteria promote growth and protect plant against pathogens, including bacteria and fungi (Beauchamp *et al.*, 1993). Thus, antibiosis is not the only mechanism used by rhizobacteria to antagonize pathogenic microorganisms. Rhizospheric actinomycetes can also compete with *S. scabies* and thereby reduce its pathogenic effect on seedlings, or produce plant hormones. It appears that Lac3, Pru16, Pin10 and Vic8 strains act either by competion and/or siderophore production. Biological control or biocontrol against *S. scabies* has already been the subject of several studies. A strain of *Streptomyces albidoflavus* CH33 was used as biofertilizers for the control against *S. scabies* (Hayashida *et al.*, 1988). This biological control agent acts by antibiosis, it has been reported that strains belonging to the *S. diastatochromogenes* and *S. albogriseolus* species inhibited the growth of *S. scabies* (Liu *et al.*, 1995). Thaxtomin A synthesis requires the presence of two genes encoding two key enzymes, *txtA* encodes a peptide synthetase involved in cyclization, while *nos* encodes a nitric oxide synthase involved in the nitration of tryptophanyl **(**Legault *et al.*, 2011**)**. The isolate Lac1, was the most antagonist of *S. scabies* on radishes, was selected to test the effect of its methanolic extract on *nos* gene expression. To extract the total RNA used for the quantification of *nos* gene expression, the culture medium employed was a minimal starch medium amended with suberin and cellobiose. This medium was recommended by Lerat *et al.* (2010) who demonstrated that suberin and cellobiose are inducers of thaxtomin A production in *S. scabies*. Our results confirm those of Lerat *et al.* (2010). In fact, the combination of minimal starch medium with suberin and cellobiose has activateted the production of a significant amount of thaxtomin A. The amount of RNA was maximal at 24 hours; this can be explained by the intensity of protein synthesis during the exponential phase of bacterial growth. Our study indicated that thaxtomin A production was not inhibited with 4 mg/ml of methanolic extract of Lac1 strain. Quantification of expression level of *nos* gene by q RT-PCR showed a lower expression level in the presence of the methanolic extract of Lac1. Also, Legault *et al.* (2011) founded that in a culture of *S. scabies* tryptophan addition leaded to a significant decrease in *nos* gene expression. The proteomic result concorded with that of genomic, because the quantification of thaxtomin, A produced in liquid media by HPLC confirmed the results obtained by the q RT-PCR. Also, studies conducted by Legault *et al.* (2011) on the regulation of thaxtomin A production were confirmed by HPLC and by q RT-PCR. Thaxtomin A biosynthesis is modulated by several factors such as development stage of bacteria, plant compounds, glucose and other aromatic amino acids (Beauséjour *et al.*, 1999).

Conclusion

The Lac1 strain was active against *S. scabies* with all the antagonism methods used. However, the antagonism of strain Pru14 was found positive only with the agar cylinders technique. This results show their antibiosis action. However, the *in planta* experiments on radish seedlings showed that all strains reduced disease symptoms (root necrosis, etc.). The best results were obtained with the Lac1 strain both *in vitro* and *in planta*. Although the strains Pru16, Lac3, Vic8 and Pin10 showed no activity *in vitro*, but *in planta* they were active because they have reduced the effects of the pathogen. The six strains tested antagonists appear to stimulate the growth of radish seedlings. This stimulation action is certainly involved in the biocontrol process (Kleopper *et al.*, 1980). These strains may be affiliated to PGPR (Plant Growth Promoting Rhizobacteria). It has been reported that some of these rhizobacteria (PGPR) may also protect plants against phytopathogenic infections by inducing their defense system (Gamalero *et al.*, 2005). These isolates are interesting for biological control because they produced antifungal molecules, and showed chitinolytic activities (Aouar *et al.*, 2012). It is confirmed that the Lac1 strain acted by antibiosis, also it has an effect on the *nos* gene expression. Among the six strains, two of them belong to the genus *Nocardiopsis*. According to El-Tarabily and Sivasithamparam (2006), *Streptomyces* sp. have been widely studied because of their abundance in the soil and their antibiotics production, which have commercial importance. Commercial biocontrol products containing *Streptomyces* living cells as active ingredients are available for farmers (Mycostop, Actinovate and Actino-Iron) (Tahvonen and Avikainen, 1987; Cross and Polonenko, 1996; Crawford *et al.*, 2005). However, the biological control of plant pathogens by non-*Streptomyces* actinomycetes is rarely reported in the literature (El-Tarabily and Sivasithamparam, 2006). Members of the genus *Nocardiopsis*, obtained in this study, could be good candidates.

Abstract

Carob moth *Ectomyelois ceratoniae* Zeller control requires knowledge of biological parameters in relation with different diets; these data will represent a fundamental tool allowing mechanisms interpretation of variation in abundance of this pest. The biological parameters of *E. ceratoniae* were studied in a controlled breeding chamber within a temperature of 27 ± 2 ° C, relative humidity of 65 ± 10% and a photoperiod of 16 hours light and 8 hours of darkness on the dates of Deglet Noor, Mech Degla and Ghars varieties. The results showed that the net reproductive rate (R_0), intrinsic rate of increase (rm) and the finite rate of increase (λ) of the carob moth on the three considered varieties dates are significantly different. These latest parameters were lower on the dates of Mech Degla and Ghars and higher on Deglet Noor (respectively 29.05 ± 6.84, 0.162 ± 0.05 and 1.18 ± 0.05). The mean generation time (T) and the doubling time (DT) were significantly longer on the dates of Mech Degla with respectively, 32.66 ± 7.74 and 8.37 ± 1.35 days. On the contrary of fecundity rate and fertility, the development duration of various stages of *E. ceratoniae* showed highly significant differences where, the longest time was recorded in individuals fed by Ghars dates. Our results showed that the fruit nutritional quality of the three varieties influence greatly on the development and the growth of *Ectomyelois ceratoniae.*

Keywords: *Ectomyelois ceratoniae, date, development, growth, reproduction*

Introduction

The *Ectomyelois ceratoniae* Zeller is a well-known pest of date in Algeria (Lepigre, 1963 and Wertheimer, 1958), it remains among the most dreaded pest of the Algerian palm groves. The carob moth poses a serious economic threat to the date Industry (Norouzi and *al*., 2008).
The study of the mechanisms responsible of the organism populations' regulation is essential for a better understanding of the structure of biological communities and their evolution forces in nature (Alyokhin and *al*., 2011).The quality and quantity of food offered by the host plant are major factors controlling the population dynamics of phytophagous insects (Klingauf, 1987). Thus, nutrition provides for the insect the necessary chemical compounds for its growth, development, reproduction, defense, displacement and survival (Slansky and Rodriguez 1987).The host plant as a food source plays a key role in population dynamics with its nutritional and allelochemicals components (Ohgushi 1992).
Insect nutritional needs changes in function of time, depending on the destination of growth, reproduction, diapauses and migration. In general, the nutrients needs of young larvae are higher than the older ones (Kumbasli, 2005).In order to control this polyphagous pest, it is important to clearly define its feeding behavior with a variety of food sources. What makes the study of various biological parameters under the effect of different diets, a fundamental

information allowing the comprehension and the interpretation of variation mechanisms in abundance of this pest.
For that, our work aim is to study the impact of the nutritional quality of three diets dates of Deglet Noor (semi-soft), Mech Degla (dry) and Ghars (soft) on parameters development, reproduction and growth of *E. ceratoniae*.

Material and Methods

To determine the life table parameters of *E. ceratoniae* it needs rearing of carob moth on dates of Deglet Noor, Mech Degla and Ghars varieties. This experiment was conducted in the laboratory in rearing chamber at a temperature of 27 ± 2 ° C, relative humidity 65 ± 10% and a photoperiod of 16: 8 (L: D) hours.
To facilitate the observation and monitoring of each larval stage, we introduced freshly laid eggs (same age) into dates, an egg for each date, after being cut in two parts by using secateurs and eliminating the core. Dates are then sealed and placed separately in small plastic boxes on which establishment date, the individual's number and the name of the variety were indicated. After removal of no fertile eggs, measurements were performed on only 25 individuals of each development stage, from egg incubation until adult emergence.
The development stages were verified each day with a binocular microscope and periods of development, mortality of eggs, larvae, pupae and adults, and sex ratio were recorded. This experiment was continued until the death of all individuals in the cohort.
To calculate the demographics parameters of carob moth, the same number of males and females was selected at random from the newly emerged adults respectively Deglet Noor, Degla and Mech Ghars variety for the separated couple placed in Petri dishes in the rearing room. The number of eggs laid by each female and the number of fertile eggs were recorded daily until the death of the last female. The essential factors allowing population parameters calculation were female age in days (x), number of live females at age x (lx) and mean number of female eggs laid per female per day (mx).
Demographic parameters were calculated from daily records of mortality, females' fecundity and fertility of *E. ceratoniae* cohorts. Reproductive (gross rates of fecundity and fertility, net fecundity and fertility, the mean number of eggs and the mean number of fertile eggs per female per day) and growth parameters [Intrinsic rate of increase (r_m), net reproductive rate (R_0), mean time of a generation (T), finished rate of increase (λ) and doubling time (D_T)] were calculated using the formulas proposed by Carey (1993) et Maia and *al.*, (2000).The various calculated parameters were subjected to an analysis of variance (ANOVA) and the mean comparison is made by the Fisher's multiple comparison tests at 5% level using XLSTAT software 2013.

Results and Discussion

Developmental time and life table

Monitoring development cycle of *E. ceratoniae* spawning until adult emergence in dates varieties Ghars, Deglet Noor and Mech Degla (Table 1) showed that the duration of larval period development (1st instar larvae from to 5th instar larvae) of *Ectomyelois ceratoniae* was significantly different (Table 1). The duration of the various instars longest was recorded on variety Ghars compared to Deglet Noor dates and Mech Degla. Our results showed that the duration of carob moth larval development obtained in our study on three varieties of dates was shorter than that recorded by Norouzi and *al*. (2008) on Zahedi date. Conversely, no significant difference (P = 0.5322) was observed between the eggs incubation period (from

3.76 to 3.88 days) between the three varieties. These results were partly in agreement with Norouzi and *al*. (2008); Al Rubeai (1987).

Table 1. mean developmental time (day) of *E. ceratoniae* on dates of three varieties

Stages of development	Mean duration ± standard deviation (days)			P
	Deglet Noor	Mech Degla	Ghars	
Eggs incubation period	3.88 ± 0.33 **a**	3.76 ± 0.44 **a**	3.84 ± 0.37 **a**	0.5322
1st instar larvae	6.28 ± 0.46 **a**	4.32 ± 1.15 **b**	6.12 ± 0.73 **a**	< 0.0001
2nd instar larvae	6.04 ± 0.68 **b**	4.88 ± 0.53 **c**	7.52 ± 1.01 **a**	< 0.0001
3rd instar larvae	5.04 ± 0.74 **b**	5.44 ± 1.29 **b**	6.04 ± 0.68 **a**	0.0015
4th instar larvae	4.08 ± 1.04 **b**	5.84 ± 1.60 **a**	5.92 ± 1.00 **a**	< 0.0001
5th instar larvae	6.40 ± 2.42 **b**	6.80 ± 1.63 **b**	8.96 ± 3.60 **a**	0.0023
Larvaldevelopment time	31.72 ± 3.12**b**	31.04 ± 3.01**b**	38.40 ± 4.13 **a**	< 0.0001
Pupalperiod	6.28 ± 1.95 **b**	7.16 ± 1.63**ab**	7.96 ± 2.87 **a**	0.0318
Adultlongevity	4.30 ± 1.13 **a**	3.40± 0.69 **b**	4.65 ± 1.23 **a**	0.0192
Life cycle	42.60 ± 4.06**b**	42.20 ± 3.65**b**	51.40 ± 5.73 **a**	< 0.0001

Different letters in the rows indicate significant ($P < 0.05$) differences within various dates.

However, significant differences were recorded between development time chrysalis stage (P = 0.0318), and adults (P = 0.0192) on the three varieties of fruit, with a longer duration for pupae Ghars dates (7 96 days) and a shorter one for Deglet Noor dates (6.28 days).Emerged adults of Ghars and Deglet Noor dates had a longer life marked with 4.65 and 4.30 days respectively compared to adults emerged of the Mech Degla dates with 3.40 days (Table 1). The duration of the pupal stage of *E. ceratoniae* on different dates was similar to that found by Norouzi and *al*, (2008); Zare and *al*. (2013). Also, emerged adults on Deglet Noor and Ghars had scored a close longevity that observed by Norouzi and *al*. (2008) on the Zahedi.
A highly significant difference was also observed between the life cycle duration of carob moth made on the dates of the three varieties (P <0.0001), it ended in a long period of 50.50 days in the variety Ghars compared to the other two varieties. The life cycle of *Ectomyelois ceratoniae* on different varieties was comparable to that recorded by Zare and *al*., (2013) on three pomegranate varieties. However, it was shorter than that obtained by Norouzi and *al*., (2008). It appears that the duration of the different development stages of *E. ceratoniae* is affected by the food quality. The work of Nay (2006) showed that the mortality rate and development time carob moth may be affected by dates humidity.

Reproductive parameters

The gross rate of females fecundity and fertility of carob moth was higher among females emerged from Deglet Noor dates (respectively 129.70 and 111.90 eggs) followed by the females of dates Mech Degla (respectively 128.80 eggs and 101.00 eggs), whereas it was low in emerged females of Ghars variety with 112.80 and 91.70 eggs respectively (Table 2).
For net fecundity and fertility, they were lower on the Mech Degla dates (respectively 41.22 and 32.32 eggs) compared to other varieties. However, analysis of the variance in gross and net rates of fecundity and fertility of *Ectomyelois ceratoniae* on the three varieties of dates, showed no significant difference (Table 2).

Table 2. Population reproductive parameters of *E. ceratoniae* on dates of three varieties of dates.

Parameter	Dates Varieties			P
	Deglet Noor	**Mech Degla**	**Ghars**	
Gross fecundity rate	129.70 ± 9.66 **a**	128.80 ± 12.65 **a**	112.80± 14.75 **a**	0.5658
Gross fertility rate	111.90 ± 10.13 **a**	101.00± 7.35 **a**	91.70 ± 14.39 **a**	0.4726
Net fecundity rate	51.88 ± 3.86 **a**	41.22± 4.05 **a**	45.12± 5.90 **a**	0.3807
Net fertility rate	44.76 ± 4.05 **a**	32.32± 2.35 **a**	36.68 ± 5.76 **a**	0.2530
Mean Daily eggs per female	27.76 ± 2.09 **ab**	36.41± 6.82 **a**	21.99 ± 2.95 **b**	0.0432
Mean Daily fertile eggs per female	23.83 ± 2.15 **a**	28.04± 4.19 **a**	17.91 ± 2.77 **a**	0.0777

Different letters in the rows indicate significant ($P < 0.05$) differences within various dates.

The Mean number of eggs per female per day for females emerged from different dates was significantly different (P = 0.0432). This parameter was higher on Mech Degla with 36.41 eggs and lowers on Ghars with 21.99 eggs (Table 2). In addition, the fertile eggs number per female per day was not significantly influenced by the difference in dates varieties consistence (P <0.0777).This variation in reproductive parameters of carob moth on different varieties could be the result of differences in host plant quality, translating a difference of nutrients required by the pest or differences in the levels of secondary compounds (Naseri et *al*., 2011).

Growth parameters

In this study, we noted that the net reproductive rate (R_0), intrinsic rate of increase (r_m) and the finite rate of increase (λ) were significantly higher on Deglet Noor dates in comparison to the two other varieties, respectively 29,05 females per female per generation, 0,162 females per female per day and 1.18 (Table 3).
According to Dajoz, (1974) the intrinsic rate of natural increase (r_m) is a parameter that can predict the population growth rate because it includes values such as development time, fecundity and mortality which condition the reproductive capacity of the species.
The parameters of life table, especially the intrinsic rate of natural increase (r_m), are the most important parameters that can be used to evaluate the level of plant resistance to insects (Razmjou and *al*., 2006; Goodarzi and *al*., 2015; Mahmoudi and *al*., 2015). The host plants with lower values of rm are relatively stronger than plants with higher values of r_m (Zare and *al*., 2013). Indicating that the variety Deglet Noor is a suitable food source for the growth of carob moth population in comparison with other varieties of dates.

Table 3. The population Growth parameters of *E. ceratoniae* on fruit of three varieties of dates.

Parameter	Varieties of dates			P
	DegletNoor	**MechDegla**	**Ghars**	
Net reproductive rate (*Ro*)	29.05 ± 6.84 **a**	14.84 ± 3.26 **b**	21.66 ± 8.95 **b**	0.0055
Intrinsic rate of increase (*rm*)	0.162 ± 0.05 **a**	0.085 ± 0.01 **b**	0.125 ± 0.03 **b**	0.0027
Finite rate of increase (λ)	1.18 ± 0.05 **a**	1.09 ± 0.02 **b**	1.13 ± 0.04 **b**	0.0029
Doubling time (D_T)	4.68 ± 1.60 **b**	8.37 ± 1.35 **a**	5.92 ± 1.53 **b**	0.0010
Mean generation time (*T*)	22.20 ± 6.45 **b**	32.66 ± 7.74 **a**	24.45 ± 5.00 **b**	0.0174

Different letters in the rows indicate significant ($P < 0.05$) differences within various dates.

The doubling time (D_T) of the population of E. ceratoniae is longer on the Mech Degla (8.37 ± 1.35 days) and very short on Deglet Noor (4.68 ± 1.60), the doubling time of the dates of the three varieties are significantly different (P = 0.0010).Doubling time (D_T) calculated on Deglet Noor and Mech Degla is partly consistent with Nay (2006) on artificial diet, dates Kimri, dates Khalal, and dates Ripe. The same author has also determined that the doubling time of carob moth is strongly influenced by the dates' humidity.
The mean generation time (*T*) of the *E. ceratoniae* showed a significant difference in the three cultivars (P = 0.0174) (Table 3). The maximum and minimum of the mean generation time was calculated on the Mech Degla and Deglet Noor respectively 32.66 ± 7.74 and 22.20 ± 6.45 days (Table 3).
Vegetal species differ greatly in their pertinence as hosts for specific insects when measured in terms of survival, development and reproduction rates (Naseri and *al*., 2009 and 2011). A shorter time of development and greater insect reproduction on a host plant indicates greater relevance of this plant (Van Lenteren and Noldus, 1990). The quality and quantity of food ingested by an insect can directly affect the survival and reproduction (Van Steenis and El - Khawass, 1995; Du and *al.*, 2004). So the fitness of phytophagous insects depends on the nutrients in their host plant (Naseri and *al*., 2009). In fact, the date Deglet Noor seems response to the nutritional requirements of larvae's better than other varieties.

Conclusions

The independent nutrition parameters, which are the mean incubation period of eggs and fecundity and fertility rates and the number of fertile eggs laid per female per day that does not seem to be affected by the nutritional quality of three varieties of dates. For dependent parameters of nutrition, we identified the growth parameters and development parameters.
This work demonstrated that the heterogeneity in the nutrient quality of food influences on the biological performance and feeding behavior of the carob moth. This showed that the dates of the variety Deglet Noor provided the best conditions for the development and growth of the population of the carob moth in comparison with Mech Degla and Ghars dates. It appeared that Deglet Noor is more sensible to attack by this pest compared to other cultivars.

Abstract

This work is a study on the insecticidal effect of aqueous extracts of seeds and leaves of Harmal *Peganumharmala* and essential oils of mint *Menthapulegium* on both of two larvae L2 and L3 of barbarian locust *Calliptamusbarbarus* (Orthoptera: Acrididae). Treatments on *C. barbarus* have been performed by two ways: contact and ingestion. Contact allowed us to obtain a cumulative mortality rate (after 3 days of treatments) which was 90% for a highest dose (2.4 g/l) with an LD 50 of 0.67 g /l for *P. harmala*EAq seeds and 50% of mortality with 3.01g / l for leaves of the same plant. For the HEs of *M. pulegium*, with the highest dose (48 µl/ml) we recorded a cumulative mortality of 100%. The LD50 is 12.58 µl/ ml. By ingestion and after 6 days of treatments, the cumulative mortality rate for the dose of 2.4 g/l and the LD 50 of EAq seeds were respectively 90% and 0.45 g /l. For leaves of the same plant, these were 70% and 0.85 g /l. For the HEs of *M. pulegium*, the yield of mortality was 80% with a dose of 48µl/ml for an LD50 of 23.98 µl/ ml. Finally authors concluded that the results were very satisfactory.

Introduction

Food safety is mainly based on the protection of crops against bio-aggressors, including Orthoptera. Among the Calliptaminae, *C. barbarus* is the most polymorphous species. It has a chromatic and geographical polymorphism (Clement et al.,1987; Benzara, 2004; Larrosa et al., 2004; Rouibah et al, 2016). In addition, it is a dangerous species causing a lot of damage in Algeria. In agriculture, the protection of crops against pests, weeds and diseases is generally achieved through chemical control. This is based on the application of various phytosanitary products of synthesis (Regnault-Roger et al., 2002). Unfortunately, these chemicals cause health and environmental problems. The cause is the contamination of natural environments by non-degradable polluting molecules. For these reasons, it is therefore urgent to propose alternative solutions such as the use of natural pesticides. These pesticides are based on the extraction of bioactive substances from plants. Currently, this use is very widespread in the world hence the interest of this study. In order to control the larvae of *C. barbarus*, the choice was made on two plant species known for their therapeutic virtues. It is the Harmal: *Peganum harmala* (Zygophyllaceae) and the mint pouliot: *Mentha pulegium* (Labiae). Some works has already been successfully carried out on the harmal but against the larvae of the Desert Locust: *Schistocerca gregaria* (Idrissi Hasani et al, 1998; Benzara et al, 2010). Concerning mint, the works are rare, but this plant is known for these therapeutic virtues (Karousou et al., 2007). The aim of this study is to test the effect of the aqueous extracts and essential oils of the grains and leaves of these two plants on the larva of *C. barbarus* the locust by two methods: the direct contact and their effect by ingestion.

Material and methods

For Harmal, the bioactive substances tested are the aqueous extracts (EAq) of grains and leaves. For the Mint, the bioactive substances tested are the essential oils (HEs) of the leaves. Two processes were required for the extraction of the active ingredients. For Harmal, the method of maceration was chosen with a view to obtaining the extracts (mainly the alkaloids). For mint, the method of hydro distillation has been adopted for the extraction of these essential oils. Once the substances are obtained, their yield is calculated and their chemical composition analyzed before testing their acridicidal effect.

Preparation of extracts based on grains and leaves of *Peganum harmala*: Maceration protocol

The grains of *P. harmala* were cleaned of impurities, washed with tap water and dried in the dark for a few days. They are then ground (using an electric mixer) into a moderately fine powder, from which the various extracts have been prepared. The aqueous extract (EAq) is obtained according to the method described by Mbiantcha et al. (2011), with some modifications. Maceration is done with 100g of the grain powder in 1000 ml of warm distilled water for 3 days. Filtration on hydrophilic cotton and then on Wattman paper was carried out. For the evaporation of distilled water, the filtrate is placed in an oven at 45 ° C. until an extract is obtained which is subsequently stored at -4 ° C. in a freezer until it reaches its use. The brute extraction (EBr) was carried out with 80% methanol (10 g of grain powder / 100 ml) for 24 hours at ambient temperature and protected from light. A second maceration is carried out after filtration on hydrophilic cotton and then through Wattman paper. The filtrates are recombined and then evaporated (by a rotary evaporator) almost dry. The final residues are dried in an oven as described previously (Mbiantcha et al., 2011).

Extraction of essential oils from Mint: hydrodistillation protocol

Once collected, the leaves were first rinsed with distilled water and then dried in the shade for 8 days. The essential oils of Mint are obtained by hydro distillation. It is a method based on the use of a Clevenger, using dried leaves with distilled water. The experimental hydro-distillation protocol employed here is that proposed by Pavida et al. (1976), with some modifications: 50 g instead of 100 and 700 ml of distilled water instead of 1400. According to El Haib (2011) the duration of a hydro-distillation can vary considerably. It can reach several hours depending on the material used and the plant material to be treated. It can influence not only the yield but also the composition of the extract. This operation was carried out for 3 hours by boiling a mixture of 100 g of plant material and 1400 ml of distilled water. The separation of essential oils is made in the Florentine vase by means of the difference in density with distilled water. The oils thus obtained are stored at 4 ° C in hermetically sealed tubes covered with aluminum foil. The yield of essential oil is expressed as a percentage relative to the dry matter (Pavida et al., 1976).

Efficacy tests

Prior to testing the effectiveness of bioactive substances, *C. barbarus* larvae were placed in rearing cages. They should be fed with wheat seedlings supplemented with bran (Benzara et al., 2010). To perform the tests, the larvae were isolated in batches of 10 individuals in insect boxes. The experimental conditions in the laboratory are almost the same as those in the field (temperature, photoperiod and relative humidity). The treatments were carried out by direct spraying on insects in captivity or mixed with food. In the case of Harmal, four doses of active ingredient were used per liter of distilled water: 0.3, 0.6, 1.2 and 2.4 g / l. Two methods of treatment are used: contact and ingestion. Contact treatment involves spraying the product directly onto the larvae. The second method is based on the treatment of insect foods. Note to confirm the biological tests, two controls are used. One negative (distilled water) and the other positive, an insecticide (ACEPLAN 20). To do this, 16 boxes of insects in total are used, one box per dose. For the essential oil of mint, the following doses were prepared: 6, 12, 24 and 48 µl of active substance per ml of diluent (distilled water and acetone). The experimental device of this test is the same as that described above. For contact treatment, the results (counts of dead individuals) were read 1, 2 and 3 days after spraying the product. For treatment by ingestion, and in order to allow the product to act against insects, the reading was done 2, 4 and 6 days after the application of the product.

Results and discussion

Effect by contact of the EAq of grains of *P. harmala* and essential oils of *M. pulegium*

Figure 1 shows that the population treated with the EAq recorded progressive mortality according to dose and duration of treatment. The highest mortality rate (90%) was recorded on the 3rd day, with the highest dose (2.4 g / l). This is the same result obtained with the positive control (Aceplan). On the other hand, the lowest dose (0.3 g / l) had no effect on the larvae during the first day and caused only 30% mortality on the 3rd day of treatment. The other doses (0.6 and 1.2 g / l) had an average effect on the larvae of *C. barbarus* (between 40% and 60%). It should be noted that all these results are compared with the negative control (distilled water).

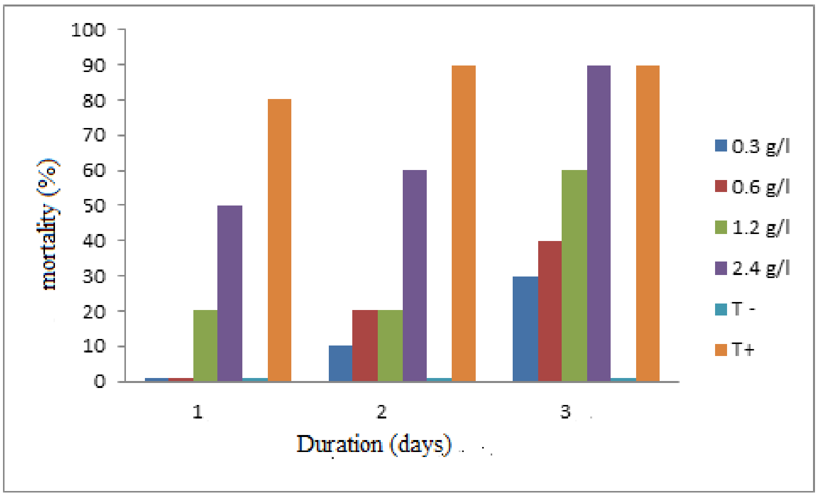

Figure1. Effect by contact of the EAq of the grains of *P. harmala*
(T: negative control, T +: positive control)

The following regression equation can be obtained by adjusting the cumulative mortality percentages (mortality after three days of treatment) as a function of the doses: y = 28.406x +

23.043 (r = 0.9942 = 99.42%). The correlation coefficient (r) is equal to 99.42% (very strong correlation between dose and mortality). Thus, 99.42% of the mortality variation in the *C. barbarus* population is due to the EAq treatment effect of *P. harmala* grains by contact. Similarly, analysis of variance (ANOVA) revealed a significant difference between doses (P equal to 0.024, therefore less than 0.05). In consquence, the higher the dose and the higher the mortality. To calculate LD 50 (letal dose to kill 50% of the population), doses are converted to log doses and cumulative mortality in Probit. The calculation of the LD 50 from the equation of the regression line y = 1.97x + 5.33 shows that the dose of 0.67 g / l caused a mortality of 50%.

Compared to EAq, *M. pulegium* HEs resulted in a total mortality of 100% (more than the chemical insecticide), (Fig.2).This mortality is obtained from the first day of treatment but with a very high dose (48 µl /ml). The linear equation of dose-specific mortality rates is: y = 1.9275x +9.1304. The correlation coefficient is 99.24 (r = 0.9924). There is therefore a strong correlation between the different doses on one side and the mortality rates on the other side. For its part, the ANOVA test showed that there was a significant difference between the two (P = 0.041 <0.05). A dose of 12.58 µl / ml is obtained with a mortality rate of 50%.

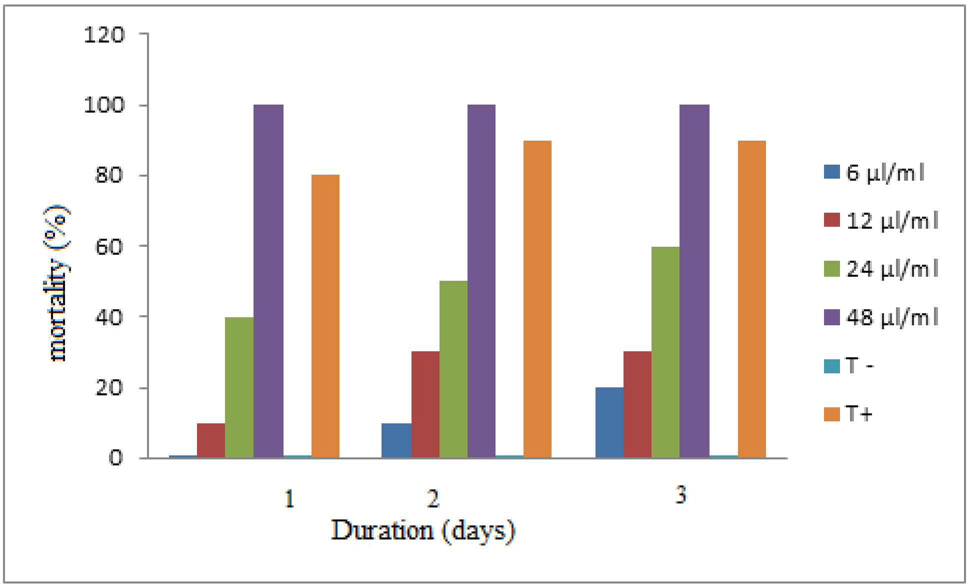

Figure2. Contact effect of *M. pulegium* essential oil

By studying the toxic effect of the EAq of the grains of *P. harmala* by contact on the L5 of the Locust locust: *Schistocerca gregaria*, Benzara et al. (2010) first obtained a low mortality rate, less than 26% at doses of 0.3 and 0.6 g / l. Then this rate increased to 50% with the doses 1,2 and 2,4 g / l. These extracts are therefore more effective on the L2 and L3 of *C. barbarus* than on the L5 of *S. gregaria*. This may be due to the difference in developmental stages, with L2 and L3 having a higher sensitivity than L5 which are more resistant. Idrissi Hassani et al. (2002) recorded a mortality rate of 55% in Desert Locust L4 for a dose of 3 ml / l. Against *S. gregaria*, the action of these extracts led to a decrease in food intake, a reduction in motility and perturbations in the reproductive function (Abbassi et al., 2005). This action also caused blockage of ovarian development in females (Idrissi Hassani et al., 1998). Furthermore, Benzara et al. (2013) by contacting the effect of the Harmal grains on the L5 of *Locusta migratoria*, obtained a low mortality rate estimated at 30% for doses 0.3 and 0.6 g / l. On the other hand, this mortality increased markedly with doses 1,2 and 2,4 g / l, for which this rate reached 60% and 80% respectively. These results are quite close to a few 10%. In the case of

Mint, according to Benayad (2008), essential oils of *M. pulegium* proved very effective against two Coleoptera species: *Sitophilus oryzae* and *Rhyzopertha dominica*. Insect mortality was total, as early as 24 h after treatment, but at low doses (3 and 12 µl / ml). The two experiments seem to be similar, except that to reach this 100%, the concentration used for the present work is higher (48 µl / ml). In all cases, these studies show that the HEs of this plant have an excellent insecticidal power both on the Coleoptera and on the Orthoptera.

Effect by ingestion of the EAq of grains of *P. harmala* and HEs of *M. pulegium*

The results obtained for the ingestion efficacy tests are summarized in Figures 3. The EAq of the grains of *P. harmala* did not start to act until the 4th day. The mortality rate then evolved according to the concentration gradient (from the lowest to the highest concentration). On day 6, the mortality rate reached the peak of 90% obtained with the dose of 2.4 g / l, as the positive control (Fig.3).

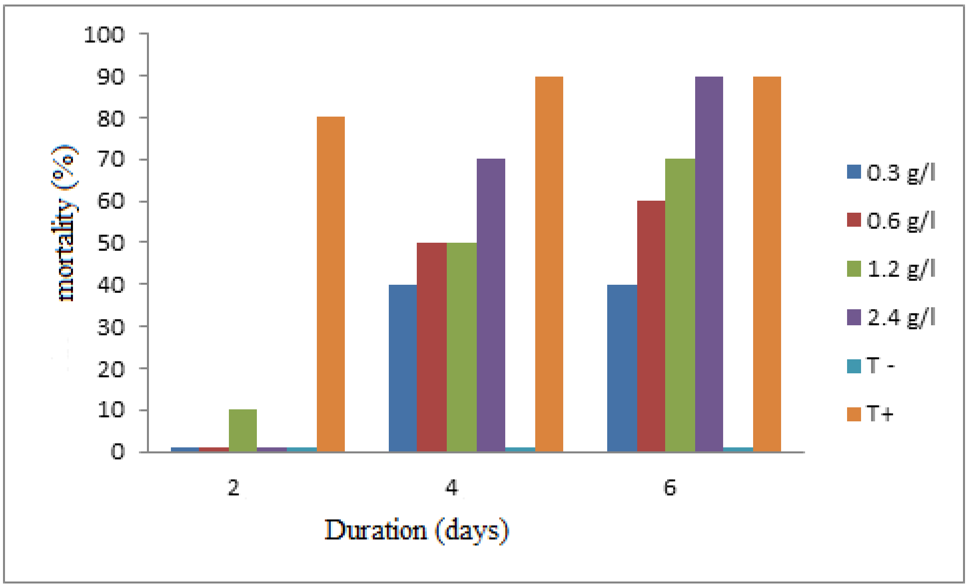

Figure3. Effect by ingestion of EAq of grains of *P. harmala*

For statistical analyzes, the correlation coefficient is calculated from the linear regression line of mortality rates as a function of doses: y = 21.449x + 40.87 with a correlation coefficient of 91.57% (r = 0.9157). The latter shows that 91.54% of the variation in the effect of the extracts of the grains of *P. harmala* is due to the variation of the doses. In addition, the ANOVA test indicated that there is a very significant difference between doses and mortality rates (P = 0.007, therefore less than 0.01).Thus, the higher the dose, the greater the mortality. The linear regression line is calculated: y = 1.6169 x +5.5648. This yielded a LD 50 of 0.45 g / l.

Regarding the HEs, and whatever the doses used, the mode of action by ingestion of the latter gave no results on the 2nd day. It produced a rate between 10 and 20% on the 4th day of treatment. Then, mortality changed significantly on day 6, from 10% for the lowest dose to 80% for the highest dose (Fig. 4). For the M. pulegium HEs test, the equation of the linear regression line is: y = 1.4928x + 13.913 with a correlation coefficient r = 0.8622. The latter showed a mean correlation between mortality and doses. Note that the ANOVA test revealed a probability P = 0.04 <0.05. There is therefore a significant difference between the two (the higher the dose, the greater the mortality rate). In addition, the LD 50 is 24µl/ml.

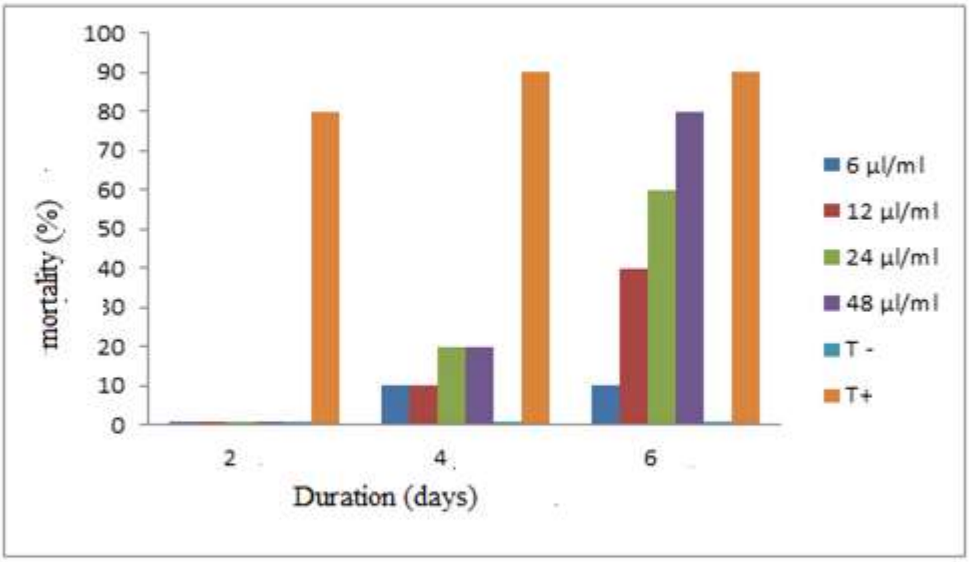

Figure 4. Ingestion Effect of HEs of *M. pulegium*

For the treatment of *P. harmala* by ingestion, Benzara et al. (2013) reported mortality rates of 30 and 40%. The latter are obtained by doses of 0.03 and 0.06 mg / ml. By increasing these concentrations to 0.12 and 0.24 mg / ml, the mortalities reached 70 and 90% respectively. For the present work, approximately similar results are obtained, but with doses 10 times greater (1.2 and 2.4 g / l). By testing the ingestion activity of EAq *P. harmala* during the flowering period on the L4 of the Desert Locust (*S. gregaria*), Abbassi et al. (2005) recorded a mortality rate of 75%. It should be noted from this information that the EAq of the "harmal" have proved, to varying proportions, their effectiveness against locusts. This efficacy is justified by a histological study in the middle intestine of *S. gregaria* (Idrissi Hassani and Hermas, 2008). In this study, it is shown that the Desert Locust has a reduction in external circular musculature. The latter led to a relaxation of the intestine and atrophy of the intestinal mucosa with reduced striated epithelium. The mesenteric epithelium in turn exhibits a granular appearance, an altered brush border, and typical signs of cellular necrosis (Idrissi Hassani and Hermas, 2008). These results may be explained in the work on extracts of *P. harmala*, which showed that alkaloids (alkane for the present case) are responsible for toxicity in insects. These alkaloids act through harmalol and harmol (Idrissi Hassani and El Hadek, 1999). But, they act mostly through harmine and harmaline. These are two substances present at all the phenological stages of the plant and more particularly at the maturation stage of the grains and roots. During this last stage, the rate varies from 2 to 7% compared to the foliage where only 0.5% is recorded (Tahri et al., 2004, Benzara et al., 2010).

Comparison between the two modes of action (by contact and ingestion)

After 3 days of contact treatment, a result (90%) similar to that recorded 6 days after ingestion treatment is obtained for the Harmal grains. This difference in mortality time is interpreted by the difference between the modes of penetration faster by contact than by ingestion. Concerning the HE of *M. pulegium*, the action by contact is also greater than that by ingestion.

Idrissi Hassani and Hermas (2008) believe that in *S. gregaria*, fed by ingestion through *P. harmala*, there was a direct effect on epithelial cells and thus an inhibition of absorption and assimilation. In addition, there was an indirect effect with absorption of the metabolites but without assimilation. On the other hand, for Benzara et al. (2013), the bio-pesticide effect induced by the *P. harmala* grains is lesser compared to the ingestion treatment, despite the fragility of the cuticle of the larvae. Finally, it should be noted that the effectiveness effect by contact is stronger than by ingestion. This can be explained by the direct action of these oils on the cuticle of insects and other soft-body Arthropods (Chiasson and Beloin, 2007). It remains, however, to determine the mechanism by which these HEs degrade the external cuticle of certain insects and mites. The lipophilic nature of the essential oil can degrade the waxy layer and cause water losses (Chiasson and Beloin, 2007). As regards ingestion, most of the time, the action of bioactive substances in HEs is generally due to inhibition of growth regulators in the treated insect (Ketoh et al., 1998).

Conclusion

In order to combat this potential pest of crops, bioactive substances have been extracted from different parts of the two well-known medicinal plants. These are the grains of *P. harmala* and the leaves of *M. pulegium*. These substances have been applied as bioacridicides by contact and by ingestion with juveniles of *C. barbarus*. The results recorded after the biological tests were carried out were very satisfactory. After treatment of the larvae, the best efficacy was obtained using *M. pulegium* HEs used by contact at the dose of 48 µl / ml (total mortality after 3 days of treatment). This has even exceeded that of the chemical insecticide (Aceplan), with which the mortality rate is 90%. It should be noted that for all bioactive substances, the highest mortality rates are recorded with the highest doses either by ingestion (6 days) or by contact (3 days). For example, the grain EAq caused 90% mortality with the dose 2.4 g / l, whereas with the dose 0.3 g / l, this rate is only 30 to 40%. The insecticidal effect by contact of the Harmal EAq grains is evaluated by a DL 50 of 0.67 g / l. Regarding the effect by ingestion, the LD50 recorded is 0.45. Whereas for the HEs of *M. pulegium*, it is to register a LD 50 of 12.58 µl / ml by contact and 23.98 µl / ml by ingestion. It should also be noted that these results are obtained with only the active ingredients without any adjuvant. It will be interesting to know what their effect will be by adding substances such as stabilizers, surfactants or other antioxidants and synergists.

POPULATIONS OF APHIDS ON TWO MANDARIN VARIETIES AND THEIR CORRELATION WITH SOME LEAF CHARACTERISTICS

Salim LEBBAL[1,2]*

Abstract

Mandarin is an important fruit crop in the world. It confronts many diseases and pests such as aphids. The use of resistant cultivars is an alternative control method that may limit the negative impact of pesticides. In the present study, the level of aphid populations on two mandarin varieties (Carvalhal and Ortanique) were investigated in an orchard situated in the region of Skikda (northeast Algeria), from January to June 2014, by sampling 16 leaves/variety monthly. Furthermore, the relation between the infestation degree and some leaf morphological and chemical characteristics are evaluated. We identified one aphid species on Carvalhal (*Aphis spiraecola*) and two species on Ortanique (*A. spiraecola* and *A. gossypii*).Concerning the fluctuations of aphid populations, ANOVA did not show a significant difference of infestation levels between the two varieties although we noticed that Ortanique was the most infested reaching its peak in April. In addition, during this month, Ortanique presented higher amount of total flavonoids and lower quantity of total phenols than Carvalhal. On the other hand, the comparison between the two examined cultivars revealed some differences in the leaf morphological characteristics such as its width and the intensity of its green color. These differences in leaf chemical and morphological traits of mandarin varieties might explain the variations in the infestation degree between them.

Keywords: *Aphids, Citrus, Ortanique, Carvalhal, phenols, flavonoids*

Introduction

Citrus is the most economically important fruit crop in the world (Tadeo *et al*., 2008). They contain vitamin C and numerous other vitamins and minerals**.** Because of their nutritional and organoleptic qualities, citrus fruits contribute to nutritional balance for both Northern and Southern populations (Lacirignola and D'Onghia, 2009). Mandarins are among the species belonging to this group. They are soft-skinned and easy to peel varieties compared to other citrus types (Skaria, 2004).The production of mandarins, tangerines, clementines and satsumas in the world was more than 30 million tonnes in 2014 (FAOstat, 2017).

Numerous biotic and abiotic factors limit mandarin production, of which the aphids constitute real dangerous pests to this culture. There are more than 4000 species of aphids in the world. They are important pest insects in the agriculture of temperate regions (Hong and Boo, 1998).They affect plant growth and crop production either directly, such as leaf and/or fruit deformation, or indirectly through the development of sooty moulds on honeydew excretion and phytovirus transmission (Bonnemain, 2010).

The main method used to control these pests was chemical pesticides that are effective, but some of them showed negative effects. Sullivan (2008) mentioned that evidence from field studies demonstrated that pesticide residues persisted in the ecosystem, and accumulated in the food chain causing unexpected dangers to non-target organisms. To confront these undesirable effects, the selection of resistant cultivars represents one of the most interesting alternative methods to control plant enemies. Adoption of insect-resistant cultivars has been considered as the most economic and eco-friendly strategy for pest management (Bhatia *et al*., 2011). Knowledge about the population of a pest on different host plants gives us an idea about the resistance or susceptibility of hosts (Özgökçe and Atlihan, 2005). In the present research, we studied the level of aphid populations on two mandarin varieties in the field, as well as their relation with some leaf morphological and chemical characteristics.

Materials and Methods

Aphid infestation on Ortanique and Carvalhal mandarin varieties

The study was conducted in the Skikda citrus region located 500 km east of the capital Algiers. The studied orchard (36° 42’ N, 6° 47’ E, 200 m altitude) is situated at the level of the Technical Institute of Fruit Arboriculture of Emjez Edchich extends over 10 ha of area.

Two mandarin varieties were considered in this paper, Ortanique and Carvalhal. From January to June 2014, sampling was conducted at approximately monthly intervals. Four leaves were collected from different orientations of the tree canopy at each of the four randomly selected trees per variety, for a total of 16 leaves per variety per sampling date.

All aphids installed on each sampled leaf are counted. Afterwards, these pests were conserved in ethanol and then identified in the laboratory basing on two identification keys (Stoetzel, 1994; Blackman and Eastop, 2000).

Total phenols and total flavonoids

Leaf analysis for phenols and flavonoids was carried out using leaves collected in April 2014, that correspond to the highest level of infestation by aphids on the two varieties.

Total phenols are measured spectrophotometrically by the Folin-Ciocalteu method (Makkar *et al*., 2007), while total flavonoids were quantified using aluminum chloride method (Zhishen *et al*., 1999).

Leaf morphological characteristics

Several authors have reported that some leaf characters have a role in plant resistance to aphids (Stipanovic, 1983; Gregory *et al*., 1986). In our case, on each variety of mandarin, 5 morphological characters relative to the leaves were studied. The green color, the emargination, the length of the petiole, the length and width the leaves were measured. The young leaves used for this assessment were collected from 4 trees representing each variety. They were located at man's height and at the outer surface of the canopy.

Statistical analysis

Means of infestation degrees, quantity of phenols and flavonoids is compared by ANOVA followed by Student-Newman-Keuls test. These statistical procedures were carried out using the software SPSS (10^{th} version), while the graphs were created using MS Excel 2007.

Results and Discussion

Aphid infestation on Ortanique and Carvalhal mandarin varieties

On Carvalhal variety only one species (*Aphis spiraecola* Patch) was identified , whereas this species and *A. gossypii*(Glover) are identified on Ortanique variety. In other regions, different aphid species are identified. For instance in Turkey, Yoldaş *et al*. (2011) found five species of aphids in satsuma mandarin orchards and the most common species observed were *A. gossypii*

and *A. spiraecola*. While, *Toxoptera aurantii*, *A. craccivora* and *A. gossypii* found infesting mandarinin Greece (Kavallieratos *et al*., 2007).
Concerning the fluctuations of aphid populations, ANOVA did not show a significant difference of infestation levels between the two varieties although we remarked that Ortanique variety was the most infested reaching its peak in April (Figure 1). Smith (2005) mentioned that individuals surviving the direct effects of antibiosis may suffer the debilitating effects of reduced fecundity.
It is noticed also that the level of infestation was higher in the spring than those in winter for the examined varieties (Figure 1). The peak of infestation in April was followed by a decrease in the number of aphids. The spring season is characterized generally by the production of new shoots and a pertinent temperature to the development of aphids. Kindlmann and Dixon (2010) indicated that an initial dramatic increase in population size in spring is typically followed by a steep decline in abundance during summer. Furthermore, Wang and Tsai (2000) highlighted the influence of temperature on biological parameters of *A. spiraecola*.

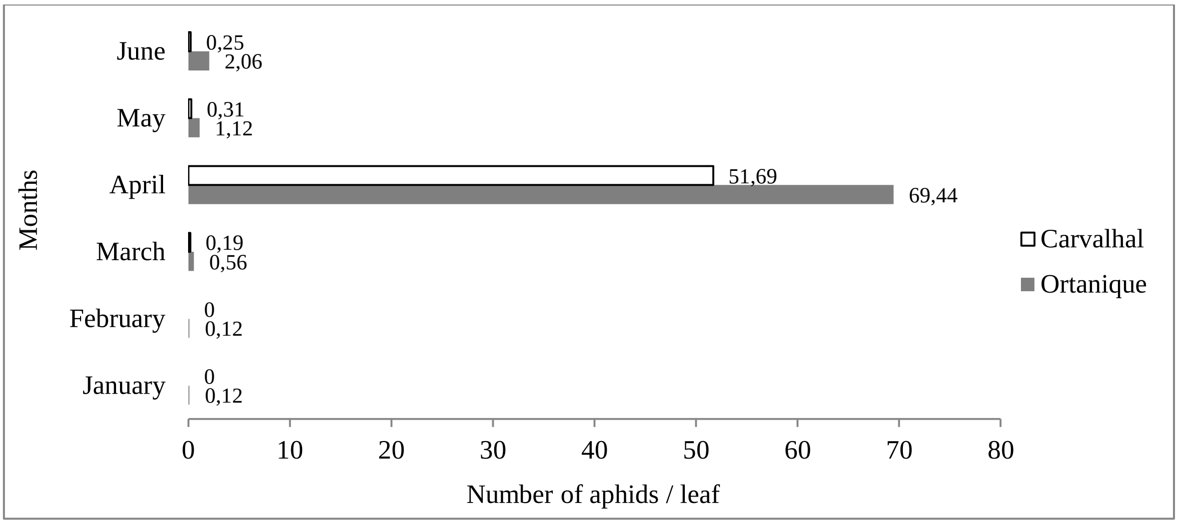

Figure 1. Mean number of aphids/leaf on two mandarin varieties.

Total phenols and total flavonoids

ANOVA showed significant difference of total phenols ($P < 0.05$), and no significant difference of total flavonoids between Ortanique and Carvalhal varieties.
Ortanique variety presented higher infestation level and lower quantity of total phenols, than Carvalhal variety (Table 1). Plant phenolics are involved in the defense mechanisms of plants against insect herbivores (Lattanzio *et al*., 2006). Polyphenols produced in relatively large quantities are among the most effective repellents against herbivores (Mooney *et al*., 1983). Several studies found that plants containing higher phenolic levels had some resistance against different aphid species (Eleftherianos *et al*., 2006; Kamel and El-Gengaihi, 2009; Wójcicka, 2010). Moreover, Chrzanowski *et al*. (2009) demonstrated that plant phenolic compounds act by reducing the enzymatic activity of aphids. In addition, tannins, which are a group of polyphenols, have the ability to precipitate proteins (Peng, 1991). Nevertheless, Bastide *et al*. (1988) mentioned that some phenolic compounds or their derivatives in the peach resistant hybrid to *Myzus persicae*, seem to be more important than the higher overall level of phenolics in the susceptible hybrid.

Table 1. Infestation level and total phenols and flavonoids of leaves collected in April 2014.

Mandarin variety	Number of aphids/leaf	Phenols (Mg/g)	Flavonoids (µg/g)
Ortanique	69,44 a	4,60 a	65,53 a
Carvalhal	51,69 a	5,95 b	63,63 a

* Values indicated with different letters are significantly different at P<0,05

On the other side, we found that Carvalhal variety presented lower infestation level and lower quantity of total flavonoids, than Ortanique variety (Table 1). Similarly, the results of Goławska *et al*. (2008 and 2012) suggested that lower level of flavonoids of an alfalfa (*Medicago sativa*) cultivar was less attacked by the pea aphid (*Acyrthosiphon pisum*). Furthermore, Kamel and El-Gengaihi (2009) reported a positive correlation between the population density of *A. gossypii* and the content of the cucumber in flavonoids. The role of flavonoids in plant resistance may be the result of some of its types and not by the total amount. Flavonoids are known to have important physiological functions in plants by protecting them from biotic stresses (Goławska *et al*., 2010). Lattanzio *et al*. (2000) demonstrated a direct involvement of quercetin or isorhamnetin in the resistance mechanism of *Vigna* species to aphids.

Leaf morphological characteristics

The results of the morphological characters of the leaves revealed differences in the intensity of the green color, emargination, leaf and petiole dimensions (Table 2). The leaves of the Ortanique variety, which seems to be the most susceptible to attacks by aphids, have been distinguished by long petioles and broad leaves, compared to the Carvalhal. Apparently, the large area of the leaves of the Ortanique allowed the aphids to develop denser colonies. Similarly, Whitham (1978) observed in his study a positive correlation between leaf size of *Populus angustifolia* and the biotic potential of the aphid *Pemphigus betae*.

Table 2. Description of the mandarin leaves.

Morphological characters / Variety	Carvalhal	Ortanique
Length of leaves(cm)	6	5,76
Width of leaves (cm)	2,87	3,04
Length of petioles(cm)	0,7	1,2
Green color	dark	light
Emargination	present	absent

In addition, the variety Ortanique, presented leaves of light green color. It seems that this color is the most attractive to citrus aphids compared to the dark color that characterized Carvalhal. According to Sadasivam and Thayumanavan (2003), most aphids express a particular preference for leaves that reflect colors in the range of 500 to 600 nm (yellow-green).

Conclusion

Our study showed that Carvalhal variety was slightly more resistant than Ortanique. This may contribute in reducing pesticide sprayings and thus producing healthy mandarins with low cost. On the other hand, although it is remarked that the increased number of aphids was associated with high amount of flavonoids and low amount of phenols, further studies should be conducted to better understanding the relation between mandarin varieties composition in primary and secondary metabolites, and their susceptibility to aphids.

Acknowledgments

I would like to thank Aicha HALIS, Adel LEKBIR and the workers of the Technical Institute of Fruit Arboriculture of Emjez Edchich (Skikda) for their help.

Abstract

Tomato occupies a strategic place in the national and global economy. The objective of this study was to find out the entomofauneqtique procession associated to the culture of Tavera variety of tomato (*Lycopersicon esculentum* Mill). This study was conducted in a multispan greenhouse using the colorful pots traps sampling technique. A total of 45 colored pots are placed alternately: 9 traps at the ends of the culture and 5 between rows of tomatoes.
The total number of species recorded shows the presence of 1736 individuals belonging to 146 insect species, distributed in 12 orders. The most abundant order was the Diptera with 44 species (34%) and with a predominance in red traps. In addition to Insects, 8% of the total number of individuals captured belongs to the Aranea, Acari and Collembola orders. Depending on the color of the traps, the overall rate of captured species was highest in yellow pots (41%), followed by reds (32%) and lastly the green pots (27%). The distribution of the different trophic categories revealed the existence of 5 large groups with the predominance of phytophagous species (34%).
The values of (S) are between 48 species and 97 ($48 \leq S \leq 97$). The lowest total wealth was recorded in April with only 48 species, although the number of individuals captured was higher than in March (N = 537). The values of the Shannon-Weaver diversity index of species counted in colored traps, were from 4.20 to 4.89 bits. For the values of fairness, they varied according to the month from 0.47 to 0.81. The graph of factorial correspondence analysis highlights the presence of each season in a separate quadrant.

Keywords: *Lycopersicon esculentum Mill., Tavira, colorful pots traps, Diptera, parasites*

Introduction

The tomato(*Lycopersicum esclentum Mill.*, *Solanaceae*) is one of the 40 most important vegetable species in the world, and ranks second after potatoes, as well as in production and consumption (Trichpoulou and Lagio, 1997). Despite an extension of the vegetable areas, the yields remain moderate. However, greenhouse cultivation offers great possibilities for improving vegetable yields. In Algeria, work on the entomofauna of the tomato under greenhouse is rare. Among them, at most, it is possible to cite those of Chennouf (2011), who studied the faunal diversity associated with tomatoes in the Ouargla region, and it is to try to complete this work that we decided to study the faunistic diversity of the tomato in a multispan greenhouse using the technique of colored traps. In fact, the study of the entomofauna of the tomato in greenhouse offers a great ecological importance. The aim of this work is to make a contribution on the knowledge of the faunistic species associated with the cultivation of the tomato under multispan greenhouse.

Material and Methods

The faunistic inventory is carried out in the National Specialized Institute for Professional Training in Bougara (L'I.N.S.F.P), located at 25 km from the capital of the Blida district (La wilaya de Blida), at an altitude of 114 m and coordinates 36 ° 32 'N, 3 ° 05' E in a hemicylindrical multispan, with a north-facing. The choice of this site is motivated by the appropriate experimental conditions (controlled temperature, aeration, irrigation). The climate of this region is typically Mediterranean, characterized by a mild, rainy winter, and a warm, dry summer.
The preparation of the soil and the cultivation of the tomato (Tavira variety) involve several operations: plowing, disking, sowing, planting, pitching, pruning, leaf removing and weeding. In order to control the temperature, considered as an important factor for the growth and development of the culture, the greenhouse is equipped with a digital thermometer, as well as two large ventilation systems.
The daily temperature of the greenhouse is measured 3 times per day (9 am, 1 pm, 4 pm). The sampling method used is the technique of colored traps; 45 colored plastic containers of which 15 yellows, 15 greens and 16 reds were placed alternately early in the morning. 09 traps placed at the ends of the culture, and 5 traps in the middle of the rows. The traps were filled two-thirds of their height with soapy water and a few drops of white vinegar (Fig1). Collection is carried out every 48 hours, the contents of the traps were poured into a filter and the insects were collected with a fine brush and stored in 70% alcohol, into marked test-tubes (date and color of trap) until their identification. The sampling is carried out once every 15 days during the period of our study.

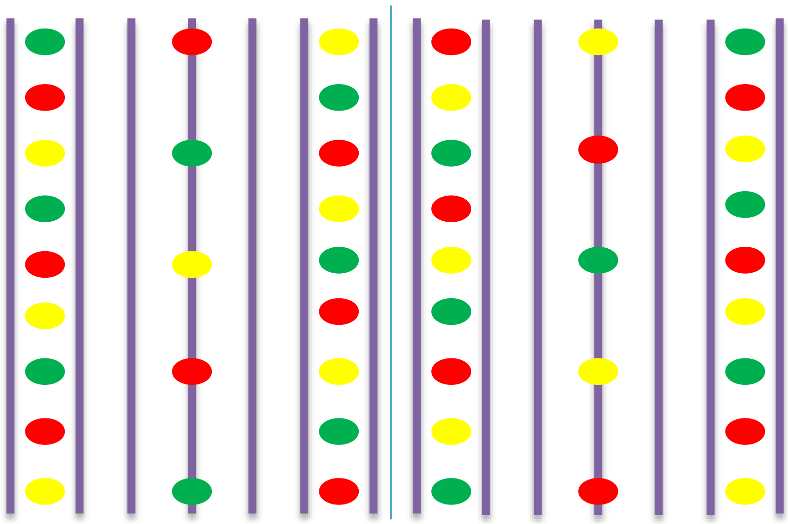

Figure.1. Trapping device

Results and Discussion

The study of the entomofauna using colored traps allowed to inventory 1.736 invertebrates distributed among 3 classes, those of Arachnida, Collembola and Insecta. Our results corroborate those of Belatra (2010) which in a potato field in Maalba and Moudjbra stations,

captured in yellow traps 140 invertebrate species distributed among 71 families, 13 order and 3 classes. Within these classes, the Insecta dominates both in number of individuals and in number of species. Indeed, in term of richness, Insecta are rated with 128 species (92%) and it is the same in term of numbers with N=1.598 (97.1%). The month of May contributes with a total of 97 species, and a greater number of individuals, or 891 individuals. In March the total richness (S) is 67 species represented by 307 individuals. The lowest total richness is recorded in April with only 48 species, but with a higher number of individuals than in March (N = 537). The average richness (Sm) varies between 24 and 49 species.
The present results confirm those of several authors who used the same sampling technique Belatra (2010) in a potato field using the same sampling technique reported 121 species in Maalba, and 91 species in Moudjbara. Like Remini (2007), in a wasteland of the Zoological Park in Ben Aknoun, reported 117 species. Moreover, in other types of environment, from an author to another the number of species is variable, in fact N'doye (1975) in Bondy in France, mentioned in its study on the altitudinal distribution of an entomological fauna above a meadow, 35 species divided between two classes. Whereas, Moussa (2005) in the plots of greenhouse culture in Staoueli records 87 species. Among the class of Insecta, the Diptera are best represented with 44 species with a rate of 34%. For relative abundances (RA %) of invertebrate species trapped in colored traps, the highest frequency was 39.80% recorded for *Myzus sp*. (Homoptera, Aphididae). Apart from Insects, the invertebrates sampled belong to the Arachnida and Collembola classes and together account for 8% of all the caught species (Fig2).
The present results confirm those of several authors who used the same sampling technique. In fact, in the highlands southwest of Madagascar, Hautier et *al*., (2003) noted the abundance of the Diptera with 24.80%, followed by Hymenoptera. And even Boussad and Doumandji (2004) at Oued Smar have noted the predominance of the Diptera order with 33 species, followed by Hymenoptera with 23 species. Hamiche (2005) reports that Diptera are dominant with a rate of 27.4%, followed by Coleptera with 25 species (23.6%) and lastly Hymenoptera with a rate of 20.8%. But Belatra (2010) in a field of potato mentioned the presence of Diptera with a rate of 15.5% lower than what found in the present study. Similarly Berchiche (2004) reported the presence of Diptera with a percentage of 24.80% followed, Homoptera and Orthoptera with dominance of the order Hymenoptera (33.33%).

The diversity values of Shannon-Weaver applied to the species captured using the color traps technique, range from 4.20 to 4.89 bits indicating that diversity was important in the months of May and March. The calculated value of H' exceeds that mentioned by Moussa (2005), in Staoueli which records a value of 3.48 bits. In a bean culture, Boussad (2003), noted a value ranging from 3.43 to 4.77 bits depending on the stations considered, while in the farm of Alia, Boussad (2006) noted a higher value of 6.22 bits on the same cultures. For Belatra (2010) the value found was 5 bits in the station of Maalba and of 5.07 bits in Moudjbara in different pear orchards. In the wasteland of the Zoological Park in Ben Aknoun, Remini (2007), reports a value of 5.33 bits. Similarly, Alili (2008) reports values of 5.09 bits in Birtouta station, 5.34 bits in Eucalyptus, and 4.89 bits in Réghaia.
In the present work, the fairness values found are 0.81 for the month of March; 0.63 for the month of May; and 0.47 for the month of April, which indicates an imbalance between species numbers characterized by the presence of a dominant species such as *Myzus* sp. Value of the same order of magnitude as that of Berchiche (2004) noted at Oued Smar (0.60). However, several authors report higher values. Indeed, Remini (2007), in studies carried out in the wasteland, maquis, and in the forest of the Zoological Park in Ben Aknoun, reported equitability values respectively equal to 0.78, 0.71, and 0.82. Similarly, Hamiche (2005), in the olive groves of Boudjima, mentioned a fairness equal to 0.75 and 0.84 in the Maatkas station.

The distribution of the different trophic categories revealed the existence of 05 large groups among the 292 species of insects inventoried with the dominance of phytophagous species (34%), followed by a massive presence of auxiliaries (33%) represented by the predators (16%), parasites and parasitoids (17%) (Fig3). The presence of these two categories of species is more often reported in yellow traps. Polyphagous species represented by fungivores, necrophages, omnivores, and acrophages are present with a percentage of 29%, most of which are trapped in red pots. Lastly, the saprophagous or coprophagous species are poorly rated with a rate of 04% (Fig4). However, the comparison with the authors mentioned above is not possible because they did not study the distribution according to the categories.
The factorial analysis of the correspondences highlights a resemblance between 4 groups for each month; each group is placed in a separate quadrant. For the trophic distribution of the species we note the presence of 5 groups. This analysis revealed the presence of one ubiquitous species (*Scatopse sp.*) during the three months of the study, with a frequency occurrence of 100% and an abundance of 0.35%.

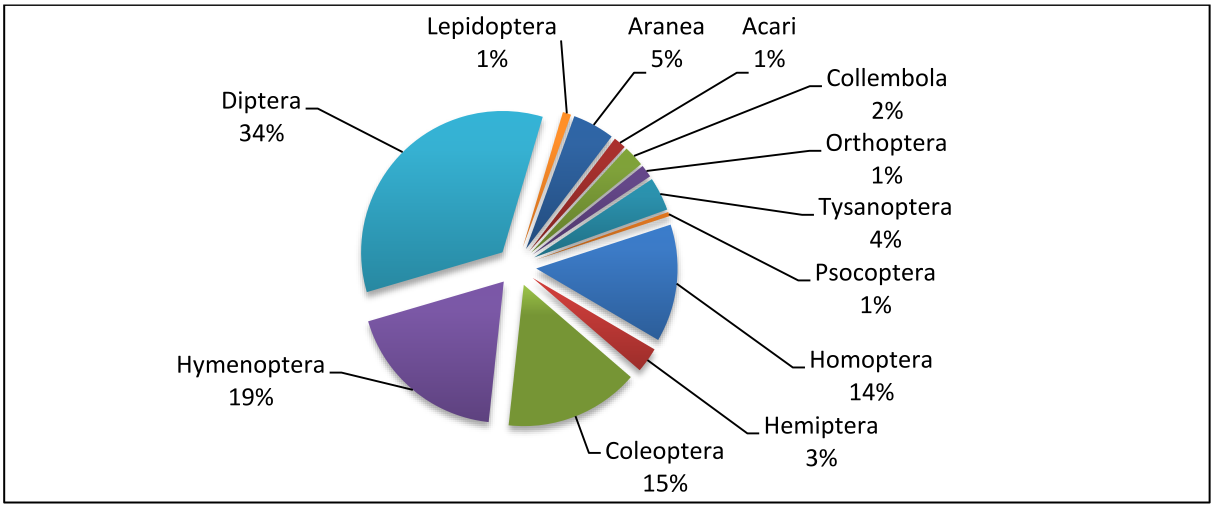

Figure.2. Total number of species trapped according to orders

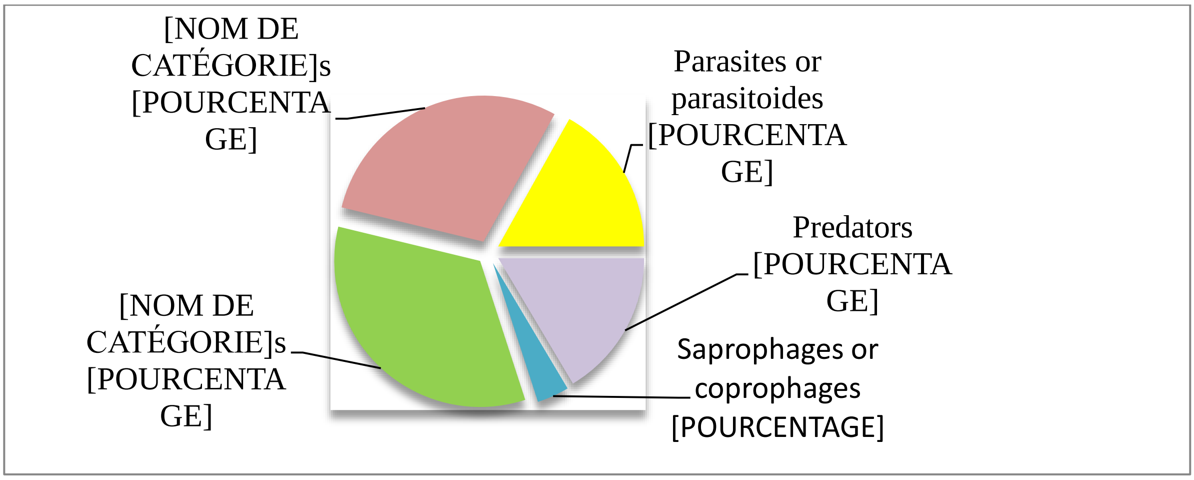

Fig3. Trophic distribution of entomofauna recorded on greenhouse tomato

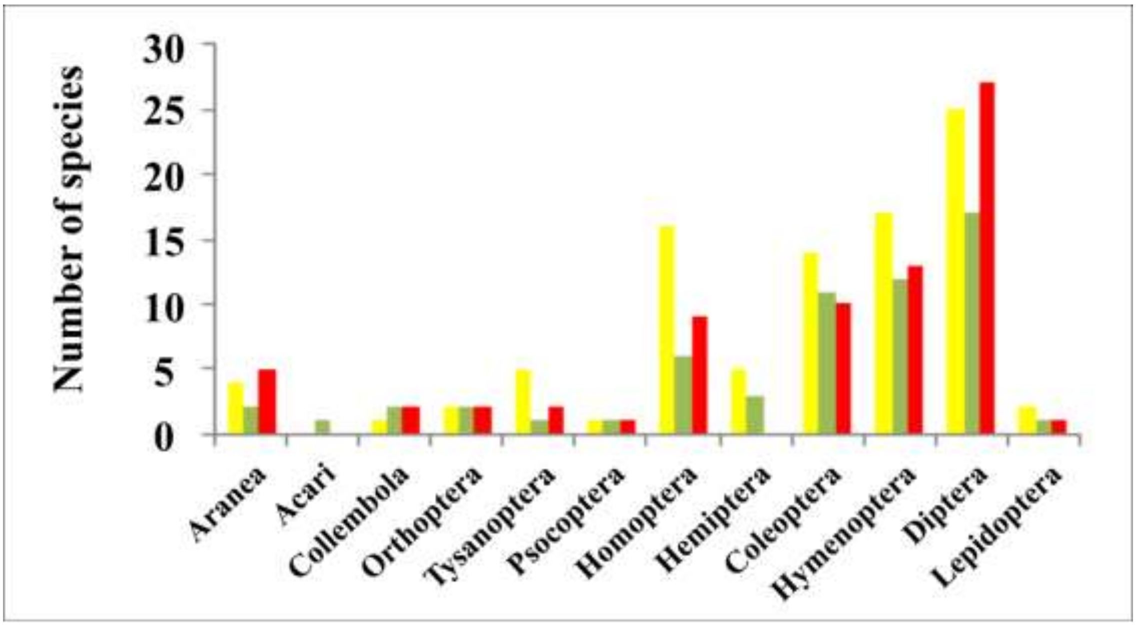

Figure.4. Total number of trapped species according to the color of the trap

Conclusion

To further this study, it would be desirable to consider other sampling techniques by increasing the frequency of sampling. Consideration could be given to extending the scope to other regions belonging to other geographical entities, phytocenotic or simply bioclimatic such as the humid, subhumid, semi-arid, arid and Saharan levels. It would be interesting to follow several cultures of the same family of Solanaceae in different biotopes. Similarly, it would be instructive to examine the biological cycles of species and their phenological stages.

THE MAIN CITRUS APHID SPECIES AND THEIR PARASITOIDS IN NORTHWESTERN ALGERIA. WHY IS APHID CONTROL NOT ALWAYS SUCCESSFUL?

Zine Eddine LABDAOUI*, Yamina GUENAOUI

Department of Agronomy, University Ibn Badis of Mostaganem, Algeria
*Corresponding author: zineddine.labdaoui@univ-mosta.dz

Abstract

Aphids are an important problem in the Algerian citrus groves with very high densities during spring seasons. During the last years, the aphid *Aphis spiraecola* Patch has displaced *Aphis gossypii* Glover and *Toxoptera aurantii* Boyer de Fonscolombe (Hemiptera: Aphididae) in most citrus groves located in the region of Mostaganem (northwestern Algeria). This research was conducted in order to develop the control of the main Citrus aphid species. We have to record parasitoid populations able to destroy the aphid populations in 2 localities in order to determine the main parasitoids associated with the dominant aphid species and to evaluate the impact of pesticides on the parasitism rate. Samples of infested young leaves were recorded weekly from the beginning of the flush period until the end of spring. Aphid densities reached 153 aphids/leaf equivalents to 10 aphids.cm^{-2}. The parasitoid species *Lysiphlebus testaceipes* Cresson and *Binodoxys angelicae* Haliday (Hymenoptera: Braconidae: Aphiinae) were associated with both *A. spiraecola*, *A. gossypii* and *T. aurantii*, but the parasitism rate remains very low in both situations varying between 0.76 and 2.66. We tried to give some factors to explain why parasitoids were unsuitable for use in biological control of *A. spiraecola*.

Keywords: *Citrus, aphids, natural enemies, integrated control, Northwestern Algeria.*

Introduction

Among several pests attacking *Citrus* trees, aphids are considered as the most damaging insects causing economic losses both in nurseries and Citrus groves. Feeding on young foliage, they produce leaf curling and are also able to transmit the most damaging disease due to *Citrus Tristeza Virus* (CTV) (Hermoso de Mendoza, 2001; Addante and *al*., 2009). The damage is more important in spring (Hermoso de Mandoza et *al.*, 2001, 2006). In Algeria, the first work on aphid on *Citrus* spp. was started in 1985 (Aroun, 1985). Some works on aphids and their natural enemies, especially parasitoids were done in most growing *Citrus* spp. regions located in the north; in the centre (Benoufella-kitous and *al*., 2014), in the northeast (Lebbal and Laamari, 2015) and in the northwest (Labdaoui and Guenaoui, 2015) but these studies were not deepened. Only 6 aphid species were found in the northwest of Algeria: *Aphis spiraecola* (Patch.), *Aphis gossypii* (Glover), *Aphis craccivora* (Koch), *Aphis fabae* (Scopoli), *Toxoptera aurantii* (Boyer de Fonscolombe) and *Myzus persicae* (Sulzer), with always a predominance of *A. spiraecola* (Labdaoui and Guenaoui, 2015). The European producing countries of *Citrus* spp. fruit usually try to control aphids by natural enemies associated to *Citrus* spp. (Stary *et al.*, 1988a; Jacas and Urbaneja, 2010; Gómez-Marco *et al.*, 2016). Indeed, in Algeria, chemical control is the only issue for the farmers, and it is very hard to guide the farms towards sustainability, promoting ecological principles with the conservation of resources. The objective of this study was to evaluate the importance of parasitoids attacking aphids in 2 situations: in a Citrus orchard, free of pesticides and in a plantation currently sprayed with insecticides against aphids, and the leaf miner *Phyllocnistis citrella* (Lepidoptera: Gracillaridae).

Material and methods

Sites of study:

This study was conducted in the spring of 2016 on two *Citrus* orchards named site “A” at Mazaghran (35°53' 30.49"N - 0° 5'7.94"E, 1.12 ha) and site “B” at Sirat (35°43' 34.8"N 0°12' 25.5"E, 2.10 ha) in the Mostaganem region. “A” is a mixed orchard with a dominant variety *(Citrus clementina*) which is 30 years old. The orchard “B” (15 years old) is only constituted of *Cirus sinensis* var. Thomson; both were flood irrigated. The orchard “A” was free of pesticides and B was treated with Acetamiprid at the dose of 12 gr/ hl. The sampling dates started on 14th April and stopped on 23rd May in orchard “A” and from on 29th March to 14th May in orchard “B”.

Field sampling

Colonies of aphids were marked at the beginning of spring leaf-flushing period and tracked weekly over the flush duration. One hundred young leaves from ten trees (10 leaves/ tree) were randomly collected on each sampling date. Samples placed separately in a labelled plastic bag were taken to the laboratory for the monitoring of aphids and their enemies.

Aphid complex:

Samples were observed under a stereo-microscope. Healthy aphids were counted and parasitized aphids were left until mummification. New mummies were added to the total number.

Parasitoid complex:

Mummies were separately placed in a gelatin capsule until the emergence of parasitoids.
Emerged adults were immediately placed in 95% ethanol and stored at 4°C. The percentage of parasitization was estimated by calculating the number of mummified aphids to the total number of aphids. Parasitoids were observed and morphologically identified using different identification keys (Kavallieratos *et al*., 2005; Rakhshani *et al.* , 2012, 2015; Tomanović *et al* ., 2012; Stary *et al.* , 2014; Petrović *et al* ., 2015).When needed European specialists were asked for confirmation.

Statistical analysis

We used the software IBM SPSS Statistics v.23.

Results and discussion

Aphid complex:

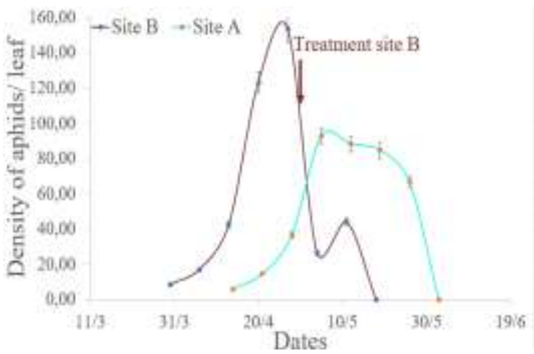

Figure 1: Total density of aphids/ leaf in site A and B

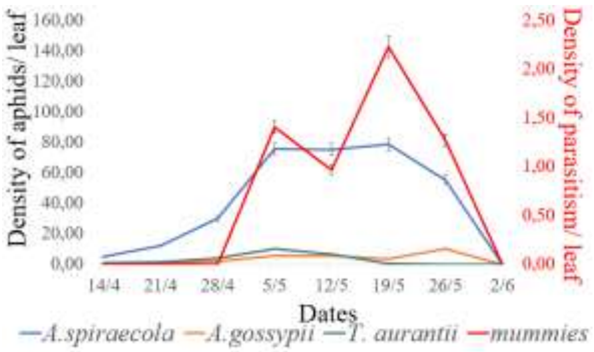
Density of aphids reached a peak of 92.75 ± 22.44 aphids/leaf which represent 6.90 ± 1.06 aphids. Cm^{-2} on 19th May in site “A” and 153.24 ± 35.88 which represent 10.46 ± 4.66 aphids.cm^{-2} on 27th April in site “B” (Figure 1).

Three aphid species were identified: *A. spiraecola* , *A. gossypii* and *T. aurantii* . The latter was found only in “A” with the dominance of *A. spiraecola* in all cases (Figure 2 and 3) with a presence in 90% of infested leaves. In Spain, it is also the most prevalent, especially on *C. clementina* (Hermoso de Mendoza *et al.*, 2006; Gomez Marco, 2015).



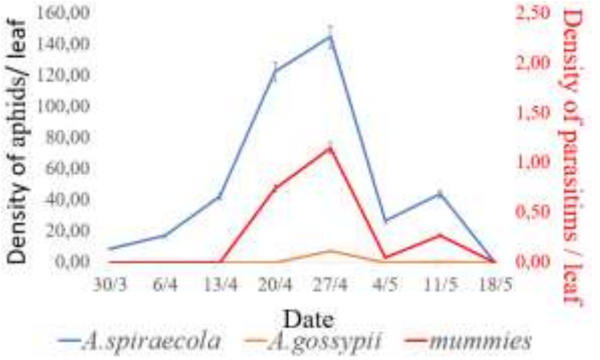


Figure.2: Density of aphids/ leaf in site “A” Figure.3: Density of aphids/ leaf in site “B”

To control the infestation in site B, the *Citrus* spp. plantation was sprayed with a systemic insecticide (Acetamiprid) on 29th April (Figure 1). After treatment, aphid population decreased to 26.49 ± 10.90 individuals/ leaf which represent 1.81 ± 1.80 individuals.cm^{-2} on 04th May with 64% of leaves infested. Of course, the aphid infestation decreased but its density was still remained high, exceeding 25% of shoots infested by *A.spiraecola* and as a threshold used the same number of aphids in Spain for chemical control (Hermoso de Mendoza *et al.* , 2001 and 2006).

Parasitoid complex:

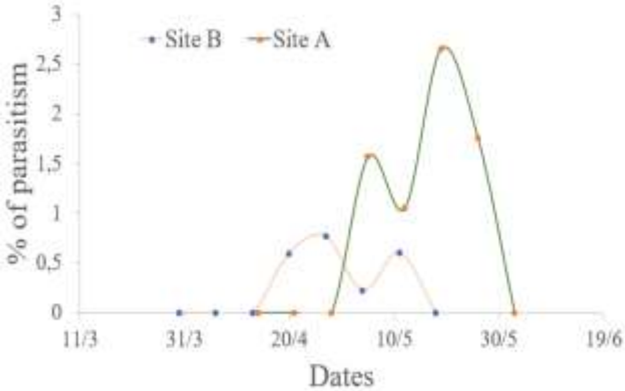

Figure 4: Rate of parasitism in site A and B

The first mummies were recorded on 04th May in “A” and on 20th April in “B”. The parasitism rate had been very low in both sites not exceeding 0.76% in the sprayed orchard and 2.66% in “A” without chemicals (Figure 4). In site “A” (Figure 5), between 05th May and 26th May, the rate of *A.spiraecola* mummies ranged from 60% to 86% with 13.51% of mummies on *A. gossypii*. On 12th May, we also noted that 28.57% of mummies on *T. aurantii*. On the last week of sampling (19th -26th May) the number of *A. spiraecola* mummies was always high (82 and 86%).

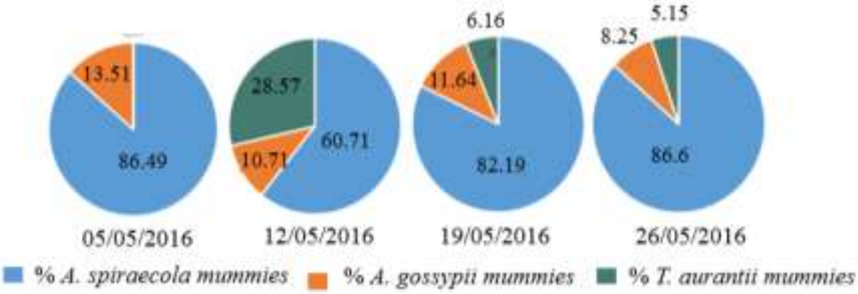

Fig.5: Rate of parasitism in site "A"

In site "B", we found only *A. spiraecola* mummies because of the predominance of this species (95 and 100% of total aphids during all sampling).
Emergence of adults from *A. spiraecola* mummies had been limited with 26.57 % in A (Figure 6) and 10% in B (Figure 7) and statistically insignificant (P=0.442) in "A" and (P= 0.118) in "B". We recorded only 2 primary parasitoids species: *Lysiphlebus testaceipes* Cresson and *Binodoxys angelicae* Haliday (Hymenoptera: Braconidae: Aphiinae) and 4 hyperparasitoids species (secondary parasitoids) with a new species recorded on *A.spiraecola* (Ferrer-Suay *et al.*, 2017). In Spain, only *B. angelicae* was found parasitizing *A. spiraecola* (Gomez Marco, 2016). In Tunisia 4 parasitoids were inventoried on *A. spiraecola* (Sellami *et al*., 2013). Until now, the causes of the low efficacy of parasitoids on *A. spiraecola* have not been well understood (Costa and Stary, 1988; Stary *et al.*, 1988; Gomez-Marco, 2016). According to Stary *et al.* (1988), *L. testaceipes* is not able to have a complete development on *A. spiraecola*. Malausa *et al*., 2008 noted that mummies have emerged rarely. In our study, *L. testaceipes* represent until 31.58% (Site A) of the total emerged mummies on 05th April.
We found 4 Hyperparasitoids species: *Asaphes vulgaris* Walker, *Pachyneuron aphidis* Bouché, *Phaenoglyphis villosa* Hartig, *Phaenoglyphis heterocera* Hartig. The latter was recorded for the first time in Algeria in site "A" (Ferrer-Suay *et al*., 2017).
Hyperparasitism can also contribute to the mortality and low abundance of primary parasitoids (Sullivan et Völkl, 1999; Rosenheim, 1998). In our case, the rate of parasitism has reached 17% in site "A" (Figure 6) and 30% in site "B" (Figure7). In Spain, the diversity and the abundance of hyperparasidoids from the beginning of spring were the cause of the low rate of parasitism (Gomez-Marco *et al.*, 2015).

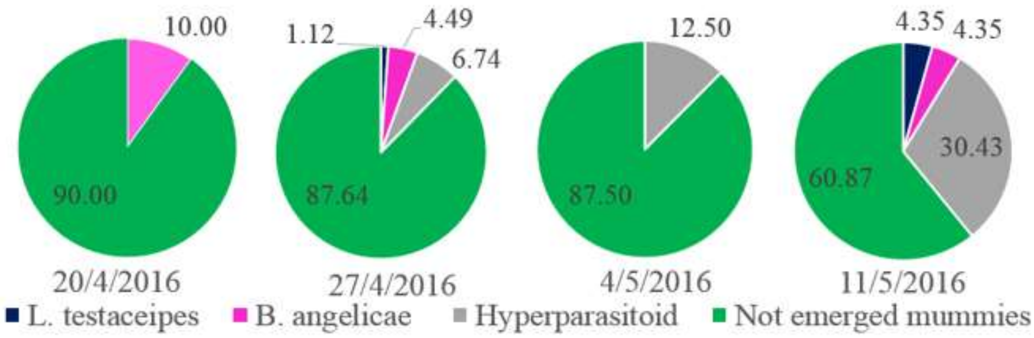

Fig.6: Rate of parasitism on *A. spiraecola* in site "A"

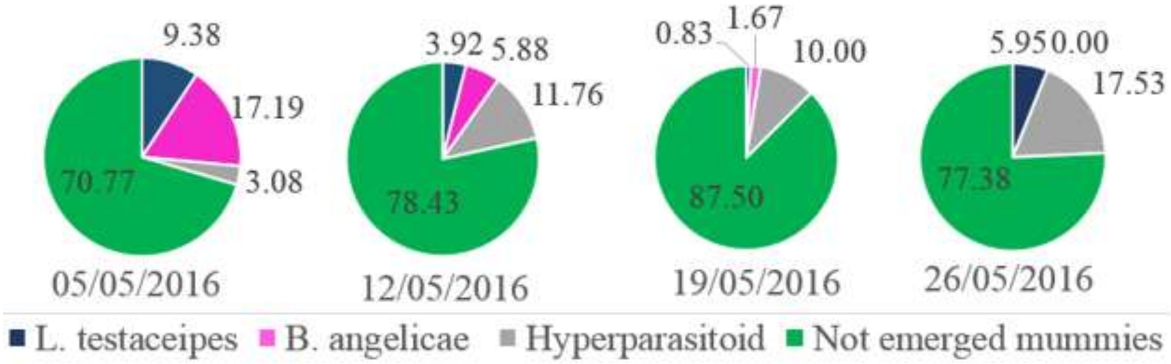

Fig.7: Rate of parasitism on *A. spiraecola* in site "B"

Conclusion

In this study, only 3 aphids were recorded: *A. spiraecola, A. gossypii* and *T. aurantii*.
The most dangerous one, *Toxoptera citricidus* have not been found until now. *A. spiraecola* was the dominant species during the sampling period. Despite chemical control, the aphid density was still important. Only 2 parasitoids were found: *L. testaceipes* and *B. angelica* with a limited rate even in free pesticides plantation (under 3 %). The presence of the 4 hyperparasitoids recorded could have disturbed the efficacy of these primary parasitoids. Within the framework of integrated protection management, other measures can underpromote the development of specific weeds to attract more natural enemies. This research could help *Citrus* spp. growers in the adoption of sustainable practices and could provide answers to some questions related to frequent high aphid infestations even in free pesticide orchards.

Abstract

One of the basic raw materials in the production of vanilla crescents is vegetable fats, which affect the product taste, consistency, texture and other properties. Greater content of vegetable fat gives the product a lighter structure, increased volume, better solubility and softness during consumption; however, at the same time, it may have a negative effect on the product taste and smell. The purpose of this paper is to examine the effect of application of the different types and quantities of vegetable fats on the quality of vanilla crescents produced at the *Klas Sarajevo* Company plant. The vegetable fats used in this paper were products of companies *Zvijezda* and *Dijamant.* Directly after the production and two months after the preservation, all the samples of vanilla crescents were subjected to sensory evaluation in order to examine the extent to which the change in the type and quantity of vegetable fats affected the quality parameters of the basic product, specifically, the product shape, upper and lower surface, breakage, structure and crispiness, solubility, and smell and taste of vanilla crescents. Sensory evaluation was done by a ten member evaluation team, who applied a unified evaluation form. The evaluated, quality parameters were rated from 1 to 5, multiplied by a corresponding significance coefficient (SC), specifically 0.3 for shape, 0.5 for upper surface, 0.4 for lower surface and breakage, 0.6 for structure, and 1 point for taste and smell. The values, thus obtained were then added up, the maximum sum of points being 20.The tea cookie samples where *Zvijezda* fats were used on average scored higher compared to the samples with *Dijamant* fats and it is recommended in further production.

Key words: *vegetable fats, vanilla crescents, melting point, fat, water, sensory evaluation*

Introduction

In confectionery industry, natural vegetable fats are used (cocoa butter), as well as hydrogenated vegetable fats, individually or in combination with animal fats (Corbo, 2008; Stanimirovic, 1987). In the technology of confectionery products specific purpose fats are used, namely vegetable butters, special and bakeable fats. Vegetable butters consist of simple mixture of triglycerides, which melt within a narrow temperature interval, are crispy and display the property of polymorphism. They regulate the behavior of dough through their qualities of plasticity and the ability to absorb air bubbles. Special fats have functional properties adapted to achieving appropriate physical qualities of a confectionery product. Preference is given to special fats which do not contain lauric acid, sensitive to hydrolytic and enzyme spoilage. Depending on the composition of a confectionery product, changes in the product smell and taste may occur as a result of chemical changes in fats, leading to shorter product durability. Bakeable fats need to be resistant to the effect of the dough pH value and baking temperature (Gavrilovic, 2011). Being one of the basic ingredients of confectionery products, fats affect their taste, consistency, texture and physical properties. Vegetable fat (cocoa butter) contains 60 % of saturated fat acids, stearic and palmitic acid. Additionally, it contains non-saturated fatty acids. When consumed, it melts softly within a narrow temperature range between 29 and 33°C and significantly determines the product sensory properties. Other vegetable fats have a lower portion of saturated fatty acids but melt within a broader temperature range between 35 and 40°C and still contain a high proportion of unmelted fraction (Schunemann and Treu, 2012.). Depending on the product type, 30 to 40% is added, which significantly affects the physical and sensory properties of the product (Gavrilovic, 2000). Higher proportion of fat gives the product a lighter structure, more volume, better solubility and softness when consumed (Kramar, 2004; Corbo *et al.*, 2006). Tea cookies take up a significant place in the overall confectionary production and consumption (Pajin *et al.*, 2005; Oluwamukomi et al., 2011; Galla *et al.*, 2017). There are four groups of tea cookies: pressed, formed, cut and dressed. They differ in their shape, upper surface, size, aromatic properties and decoration. Their common characteristic is that their top is smooth to rather rough, shiny or without shine, with clear mold prints, more or less damaged bottom, weary looking cross-section, crunchy and crispy breakage. Fats give these products plastic-elastic and grainy structure, their middle is softer, dry, with round, unevenly placed holes. When broken and chewed, they are extremely crunchy and gently sandy due to large granules of pastry flour. Depending on their type, these products are decorated and coated with chocolate or sugar coating (Beslagic, 1999; Beslagic, 2005).

Material and methods

Physical and chemical analyses were performed on different fats (margarine, vegetable butter and vegetable ghee) used in the production of vanilla crescents. In the production process, fats were added in accordance with the original recipes, ± 5 % in respect to the original recipe (Table 1). In addition to the fats, in the preparation of raw materials, all-purpose wheat flour Type 500 was used, along with powdered sugar, fresh eggs, confectioners sugar, salt, water and flavors. After the production, the packed products were kept in storage at 15ºC and air humidity of 60%.

After the preparation, scaling was done, which was followed by the mixing in two phases. In phase one, fast mixing was applied for 8 minutes, while in phase two the mixing lasted for 2 minutes. The raw materials were mixed in a mixer with an installed spiral hook (Universal Mixer V 250-V1600 Diosna). The dough was formed by pressing it through molds and cutting by wire to a specified height. The cutting device (Hecrona-Hass type) consists of a dough bowl, underneath which are two ribbed rolls spinning one against the other. This way they accept the dough and push it through the mold openings arranged in two rows and located below the rolls. The shaped dough falls down to a conveyor belt, where the shaped pieces are cut. After the shaping, the dough goes to the industrial tunnel baking chamber. In zone one, the initial baking temperature was 150 to 200ºC, which was then gradually increased to 220 and up to 240ºC. The baking time was 7 to 15 minutes. When the product left the oven, it was cooled naturally on open conveyer belts at air temperature between 3 and 10ºC. After cooling, the final products were packed in PS polystyrene pads and PP polypropylene and PS polystyrene printed foil. Before packing, the top of the tea cookies was sprinkled with hazelnuts. The cookies were then packed in cellophane and the packaging for transportation. The raw materials were prepared and vanilla crescents were produced at the confectionery factory *Klas Ltd Sarajevo.*

Table 1. Names and markings of the samples examined

Tea cookies/sample marking	Fats/sample marking	Quantity of fats added and with a lower portion during the production (fats produced according to the manufacturer's recipe)
Vanilla crescents (DVZ)	*Zvijezda* vegetable fat (BMZ^-)	- 5% vegetable fat
Standard sample – vanilla crescents (DVS)	*Zvijezda* vegetable fat (BMZ)	Recipe known to the manufacturer
Vanilla crescents with hazelnut (DVLJ)	*Zvijezda* vegetable fat (BMZ^+)	+ 5% vegetable fat
Standard sample – (DVLJS)	*Zvijezda* vegetable fat (BMZ)	Recipe known to the manufacturer
Vanilla crescents (DVD1)	*Dijamant* vegetable fat (BMD^-)	-5% vegetable fat
Standard sample – (DVSD)	*Dijamant* vegetable fat (BMD)	Recipe known to the manufacturer
Vanilla crescents with hazelnut (DLJD)	*Dijamant* vegetable fat (BMD^+)	+5% vegetable fat
Standard sample – (DLJS)	*Dijamant* vegetable fat (BMD)	Recipe known to the manufacturer

Fat analyses were done prior to their adding into the products, that is, prior to the production. In terms of the physical analyses, the fat melting point was determined by open capillary method *(HRN EN ISO 6321:2004).* In terms of the chemical analyses, the fat content was determined by the Soxhlet extraction method *(HRN EN ISO 659:2004)*, while the water content was determined by drying method at 105ºC (HRN EN ISO 662:2004).
The sensory analysis was done for two samples of vanilla crescents (with and without the addition of hazelnuts), produced with the same dough composition, to which different fats had been added. Sensory evaluation was done by 10 professional evaluators according to standard and common practice in factory. After the production and two months of storage, the final product was subjected to sensory evaluation. The following quality factors were evaluated: shape, upper surface, lower surface, breakage, structure and crispiness, solubility, smell and taste. The descriptive quality indicators were rated on a scale from 1 to 5, multiplied by the corresponding coefficient (CC). All products evaluated as *excellent* and *very well* may be placed on the market (Kaludjerski and Filipovic, 1998).
The standard mathematical-statistical method was applied, which implied the variance analysis and evaluation of the significance of the differences obtained by applying the appropriate Tukey's test ($W_{0,05}$ test) and using Microsoft Excel 2003.

Results and discussion

Individual values of the melting point, fat and water content for all the samples of vegetable fats, vegetable ghee and margarine are shown in Table 2.

Table 2. Melting point, fat and water content **o**f the examined fat samples

Samples	Melting point (ºC)	Fat (%)	Water (%)
BMRZ	34.00 ± 1.63	97.32 ± 1.30	0.23 ± 0.02
BMZ	32.00 ± 1.63	95.17 ± 11.19	0.18 ± 0.08
MGZ	39.33 ± 2.49	77.67 ± 0.46	8.17 ± 0.37
BMRD	34.00 ± 2.00	97.75 ± 1.19	0.79 ± 0.02
BMD	29.33 ± 1.15	97.71 ± 2.68	0.20 ± 0.01
MGD	40.00 ± 2.00	77.68 ± 3.63	15.11 ± 1.15

Vegetable fats have different melting points. This is the temperature at which a matter, fat included, melts and is transformed from solid to liquid state (Rade *et al.,* 2009). In the winter period it is 30 to 32ºC and in the summer it is between 34 and 36ºC (Official Gazette of RB&H 2/92). The fat containing 15-30% of solid phase at the temperature interval between 10-30ºC possesses the properties of plasticity (Beslagic, 2005). The melting point in fat samples was in range from 29.33 (BMD) to 40 ºC (MGD). There are no statistically significant differences in the melting point between the examined fat samples produced by two different manufacturers. The results obtained are in accordance with the Rulebook values (Official Gazette of RB&H 2/92).

The content of fat ranged from the lowest value in the case of margarine sample (MGD) and was 77.68 % to the maximum value in the case of the vegetable ghee (BMRD) and was 97.75 %. The results were in accordance with the results of authors Lambasa-Belak *et al.* (2005) and Kramar (2004), who indicate the fat content in the vegetable ghee of up to 95 %. The values of the results for water content did not deviate from the values prescribed by the Rulebook (Official Gazette of RB&H 2/92) of up to 1.5% for vegetable ghee, where in the case of the vegetable ghee sample (BMRZ) it was 0.23 %. There are no differences in the fat and water content among the examined fat samples produced by different manufacturers.

Table 3 presents the results of the examination of the vanilla crescents quality parameters depending on the type and quantity of added vegetable fats directly after the production.

Table 3. Average sensory values of the examined vanilla crescent quality parameters depending on the type and quantity of added vegetable fats observed directly after the production*

Type and quantity of added vegetable fat	shape	upper surface	lower surface	breakage	structure	solubility	smell and taste	score sum
Variation 1. (BMZ)	1.5a	2.5a	2a	2a	3a	4a	5a	20a
Variation 2. (BMZ^{+})	1.44b	2.35a	2a	1.92b	3a	4a	5a	19.71b
Variation 3. (BMZ^{-})	1.5a	2.30b	1.84b	1.88b	2.76c	3.92b	5a	19.2c
Variation 4. (BMD)	1.5a	2.50a	2a	1.92b	3a	4a	5a	19.92a
Variation 5. (BMD^{+})	1.47a	2.25b	2a	1.92b	2.82b	3.84c	4.80b	19.1 c
Variation 6. (BMD^{-})	1.44b	2.35a	1.88b	1.92b	2.70d	3.76d	5a	19.05c

* Different letters in columns from a to d for each parameter indicate signifiantly different values among varations at $P< 0.05$

The results presented in Table 3 indicate that the overall quality of vanilla crescents, at the time directly after the production, significantly depended on the type and quantity of added vegetable fat. The highest sum of scores for the overall product quality was observed in the variation 1, where *Zvijezda* vegetable fat was added in the production in accordance with the recipe, and in the variation 4, where *Dijamant* vegetable fat was used also in accordance with the recipe.

Observed within the same quantities of added vegetable fats, almost all examined vanilla crescent quality parameters had significantly higher values in the varieties where *Zvijezda* vegetable fat was used to compare to the varieties where *Dijamant* vegetable fat was used. This leads to a conclusion that certain chemical properties of vegetable fat also have a significant effect on the quality of vanilla crescents.

Table 4 presents the results of examination of vanilla crescent quality parameters depending on the type and quantity of added vegetable fats, however, observed two months after the production.

Table 4. Average sensory values of the examined vanilla crescent quality parameters depending on the type and quantity of added vegetable fats, observed two months after the production*

Type and quantity of added vegetable fat	shape	upper surface	lower surface	breakage	structure	solubility	smell and taste	score sum
Variation 1. (BMZ)	1.47b	2.35bc	1.88c	1.84c	2.70c	3.76c	4.9a	18.9c
Variation 2. (BMZ^{+})	1.50a	2.40b	1.88c	1.92b	2.76b	3.84b	5a	19.3b
Variation 3. (BMZ^{-})	1.47b	2.35bc	1.92b	1.84c	2.70c	3.76c	4.9a	18.94c
Variation 4. (BMD)	1.50a	2.50a	2a	2a	3a	4a	5a	20a
Variation 5. (BMD^{+})	1.50a	2.30c	1.88c	1.88bc	2.64d	3.76c	5a	18.96c
Variation 6. (BMD^{-})	1.47b	2.35bc	2a	1.92b	2.58e	3.52d	4.7b	18.54d

* Different letters in columns from a to e for each parameter indicate signifiantly different values among varations at *P*< 0.05

Two months after product storage, all samples were evaluated as *excellent*. The presented results also suggest that within each examined type of vegetable fat, the overall quality of vanilla crescents statistically significantly drops if the vegetable fat content in them is lower. If one compares the results presented in tables 3 and 4, one can see that the overall quality of vanilla rolls was significantly lower two months after the production, particularly in the case of the product structure and solubility as the quality parameters. The results obtained could be realistically expected if one takes into account the fact that with time vegetable fats degrade.

Conclusions

During sensory evaluation, all of the tea cookie samples were descriptively evaluated as *excellent*, and as such they can be placed on the market. It is important to mention that the samples where *Zvijezda* fats were used on average scored higher compared to the samples with *Dijamant* fats. It is therefore recommended that *Zvijezda* fats be used in further production and that *Dijamant* fats be placed on the list of raw materials as an alternative. This research has given a contribution and a recommendation for maintenance and possibly improvement of quality of tea cookies produced by *Klas Sarajevo*.

Abstract

The aim of this work is a comparative analysis, microbiological and chemical characteristics of the pomegranate juice from area Mostar city, Bosnia and Herzegovina. Sampling of juice was randomly selected, selecting from area Mostar city: Podgorani, Vrapčići i Bijelo Polje. Microbiological analysis were: *Salmonella types* in 25 g (ml), *Coagul.pos.staphilococae* in 0.1 (ml), *Sulph.red. clostridiae* u 0.1 g (ml), *Proteus species* in 0.1 g (ml), *Escherichia coli* in 0.1 g (ml) and total number of bacteria in 1 g (ml). Chemical analyses were: determination of soluble dry matter (manual refractometer), determination of the total dry matter (gravimetric), determination of total sugars (method by Luff-Schorl), determination of Vitamin C, the presence of artificial paints by the chromatographic method of color induration. The samples tested according to the provisions of the Ordinance on conditions in terms of chemical, microbiological correctness, which must comply with foodstuffs in the market, Official Gazette R BiH 2/92, rulebook on refreshing non-alcoholic beverages and similar products (Official Gazette of BiH No. 85/08, 54/11), as well as the Ordinance on microbiological criteria for food (Official Gazette of BiH No. 11/13).The results obtained indicate that all three analyzed juice samples deviate from the prescribed values, the microbiological correctness in terms of the total number of bacteria1 g (ml), as well as the dry matter content, while the high values of vitamin "C" in each of the tested samples determined, indicates a significant nutritive value of pomegranate juice and its significance in our diet, especially from the aspect of human health.

Keywords: *juice, pomegranate, microbiological and chemical analysis, quality*.

Introduction

Fruit juice is a non-alcoholic drink usually made from fruit, but also some types of vegetables, and is obtained by squeezing of their liquid. Juices, together with their related products, represent the most important group of fruit products from the food and economic point of view. They differ in physical and chemical characteristics, as well as the technological process of production itself. Sugar content can be corrected by adding it in the production process. Pomegranate juice (especially from wild pomegranate) is distinguished by its potability and beneficial effect. Juice from the pomegranate fruit of Herzegovina and Montenegrin varieties mainly contains water (62.8-73.6%) which is sterile and healthy. For the production of juice wild pomegranate that grows freely in spontaneous vegetation without the influence of man is used. Also, for the production of pomegranate juice, the most important is the harmonious relationship between sugar and acids. Domestic pomegranate juice due to chemical composition, primarily because of dry matter content and method of production (cooking process), belongs to fruit syrups. Fruit syrup is a product with a high percentage of dry matter, syrup consistency, obtained from freshly squeezed or semi-processed clear or blurry juice with the addition of sugar. Dry matter is from 65 to 67%

(Niketić, Aleksić, 1982). Syrup is produced primarily from aromatic fruits. For the quality syrup, in addition to aromaticity, very important is intense color, in order for the diluted product to have a certain intensity of the characteristic color of the fruit from which the syrup was obtained. Because of that, the syrup is produced by mixing fruits, wherein aromatic and intensively colored types - i.e. varieties are combined. Adding artificial colors is not allowed according to the valid Rule book. Natural colors can be added in the form of concentrated fruit juices up to 5% of the amount of juice. Technological process of syrup production consists of two phases (Omanovic, 2008): The first phase is to obtain a clear or blurry juice, i.e. semi-processed, chemically preserved juice, and the second phase is cooking the juice with the addition of sweetening agents. It can rightly be said that the pomegranate juice belongs to functional food. Pomegranate juice not only provides enough nutrients for the body, but it has been proven that its consumption has a good impact on health, positively influences some body functions and affects the prevention of disease. Pomegranate juice (especially from wild pomegranate) is distinguished by its potability and beneficial effect. especially in cases of mild stomach problems and urinary tract inflammation. Properties of juice have been known since the early centuries where it was used to treat diabetes, asthma, heart disease and arteriosclerosis. Pomegranate juice is used in many ways in nutrition and drinks. The aim of this work was to examine the microbiological and chemical characteristics of three pomegranate juices from three different independent producers from the area of Mostar, compare the results with the parameters of the current Rule book, and give an assessment of the acceptability of the products for future potential consumers in the free market with the presentation of the results of chemical analyzes.

Material and Methods

Sampling was carried out in 2015 in the Mostar area by random selection of three different independent producers of pomegranate juice: sample number 1, Independent manufacturer: Tipura Elvina, Podgorani-Mostar, sample number 2, Independent producer: Kubić Alija, Vrapčići-Mostar and sample number 3, Independent manufacturer: Zaklan Emina, Bijelo Polje. Samples were submitted to analyzes made at the Federal Institute for Agriculture in Sarajevo and the Agromediterranean Faculty in Mostar.

The aim of the chemical analysis is based on the determination of the nutritive values: % of dry matter (gravimetric technique) ,% of total sugar (titrimetric determination technique), total acid content(titrimetric technique) , pH value (electrochemical determination technique), presence of artificial colors (chromatography methods) and content of vitamin C(oxidation-reduction method).

The microbiological analysis of all three samples included the analysis on *Salmonella* and *Escherichia coli*, *Coagul.pos.Staphilococae, Sulph.red. Clostridiae*, Proteus species and total number of bacteria, which was made in accordance with food safety criteria for cut fruits and vegetables.

Results and Discussion

The obtained results of the microbiological analysis for all three samples are shown in Table 1 and compared with the parameters of the rule book Official Gazette of BIH 2/92, thus obtaining the overall picture of the quality of the product in terms of health and hygiene correctness of the product.

Table 1. Microbiological analysis of samples

Parameter	Sample 1	Sample 2	Sample 3
Salmonella types in 25 g (ml)	negative	negative	negative
Coagul.pos.Staphilococae in 0,1 (ml)	negative	negative	negative
Sulph.red. Clostridiae in 0,1 g (ml)	negative	negative	negative
Proteus species in 0,1 g (ml)	negative	negative	negative
Escherichia Coli in 0,1 g (ml)	negative	negative	negative
Total number of bacteria in 1 g (ml)	$1{,}0 \times 10^3$	5,0 x 102	4×10^2

OPINION: Tested samples do not meet the requirements of the Rulebook on conditions in terms of microbiological correctness which must comply sustaining food (rations) in traffic, due to an increase in the total number of bacteria in 1 g (ml), Official Gazette of BIH 2/92.

The results of the chemical analysis are shown in Table 2:

Table 2. Results of chemical analysis:

Parameter	sample 1	sample 2	sample 3
Dry matter content %	59,10	64,33	63,76
Total sugar content %	57,10	62,05	60,40
Total acidity content %	1,764	1,652	1,652
pH value	3,16	3,06	3,09
Presence of artificial colors	Not present	Not present	Not present
Vitamin „C¨ content %	935,66	1046,46	1056,73
Degree of sweetness mg/100g	32,36	37,56	36,56

The dry matter content of all three of these samples was carried out with a drying technique (gravimetric). This method is based on the drying of samples in various types of dryers, under ordinary or reduced pressure to constant mass. In order to ensure proper drying, care must be taken of the preparation of the samples, the temperature and the drying time, the quantity of samples, and so on. The highest dry matter content has a sample number 2. (64.33), while the smallest content has a sample number 1. (59.10). According to the literature (Niketić, Aleksić, 1982) the dry matter content in fruit syrups should be from 65 to 67%, and one can conclude that all three samples are slightly below these values. From the tabular display the content of total sugar in the samples it can be concluded that the sample no. 2 (62.05) has the highest value of sugar content. The smallest sugar content has sample no. 1 (8.5). The highest content of total acidity has sample no. 1 (1,764), while samples no. 2 and no. 3 have the same acidity content (1.652). The obtained pH values are also the highest in sample 1 (3.16), while the other two analyzed samples have approximate values and these are 3.06 and 3.09. From the tabular display it can be concluded that none of analyzed sample contains any artificial colors which is in accordance with the applicable Rule book. Data obtained in terms of vitamin C content are very important, given that its positive effect on human health is known, some literature quotes mention the fact that content vitamin "C" in pomegranate is immediately behind the lemon (Džubur, 1999). The degree of sweetness is the relationship between sugar and acid and which participates in the final formation of the taste of the juice that should be acceptable for targeted consumers. The value of the degree of sweetness should not be less than 30, otherwise correction should be made in that direction (Niketić, Aleksić, 1982). Based on the above, all three analyzed samples are acceptable for consumption.

Statistical analysis

We used a one-way analysis of variance (ANOVA) and Tukey test to determine the statistical significance, which was not significant in terms of chemical composition

Conclusion

The analysis of the product resulted in the complete picture of the composition and quality of the product, pomegranate juice, domestic product from household cottage industry, in terms of microbiological correctness and chemical composition. Based on the obtained results of the analyzed individual parameters, it is concluded that each of the three analyzed samples has different values. Regarding the microbiological analysis, none of the three tested samples produced in the household cottage industry meets the prescribed values of the Rule book on the conditions in terms of microbiological correctness, which must comply sustaining food in traffic, due to the increased total number of bacteria in 1 gr (ml) – (Official Gazette of BiH 2/92). Increasing the total number of bacteria in the tested samples implies that within the technological line, none of these manufacturers paid attention to the sanitary and hygienic conditions during production, dishes and rooms in which the juice itself is produced. By chemical analysis, we obtained a picture of dry matter, total sugar and total acidity content, pH values, the presence of artificial colors and vitamin C content in the tested samples. Dry matter content was recorded in quite high values, but still slightly lower in all three examined samples compared to the recommended values by literature. In samples of domestic pomegranate juice, high values of total sugars were obtained which, in relation to the obtained content of total acidity, give a satisfactory degree of sweetness over 30, what is acceptable from the aspect of eligibility of the product for consumption. Obtained values of vitamin "C" in each of the tested juice samples, once again gave the seal of approval of functional food in pomegranate in the form of a finished product, i.e. pomegranate juice and confirmed its importance in daily nutrition in terms of positive effect on human health.

Abstract

The research was conducted during 2013 - 2015 on pellic vertisol soil type. The subject-matter of this research was Bulgarian coriander cultivar Lozen 1 (*Coriandrum sativum* L.). Factor A included no treated check, 6 soil-applied herbicides – Tender EC (S-metolachlor), Silba SC (metolachlor + terbuthylazine), Sharpen 33 EC (pendimethalin), Merlin flex 480 SC (isoxaflutole), Smerch 24 EC (oxyfluorfen), Raft 400 SC (oxidiargil) and 5 foliarly-applied herbicides – Kalin flo (linuron), Eclipse 70 DWG (metribuzine), Sultan 500 SC (metazachlor), Corrida 75 DWG (tribenuron-methyl), Lontrel 300 EC (clopyralid). Factor B included no treated check and 1 antigraminaceous herbicide – Tiger platinium 5 EC (quizalofop-P-ethyl). Combinations of antigraminaceous herbicide Tiger platinum with soil-applied herbicides Tender, Silba Sharpen, Merlin flex, Smerch and Raft and foliarly-applied herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel do not reduce herbicide efficacy. Volunteer durum wheat crops in coriander crops are successfully controlled with the foliarly-applied herbicide Tiger platinum. High yields of coriander seeds are obtained with the foliar treatment with the antigraminaceous herbicide Tiger platinum after soil-applied herbicides Raft, Smerch, Sharpen, Silba and Tender. The tank mixtures of Tiger platinum with foliar herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel also lead to high seed yields. The use of the soil-applied herbicide Merlin flex does not increase the seed yield, due to its higher phytotoxicity against coriander. Sole use of soil-applied or foliarly-applied herbicides leads to lower yields due to the fact they must be combined for full control of weeds in coriander crops.

Key words: *Coriander, Herbicides, Efficacy, Selectivity, Seed yield*

Introduction

During the last years coriander significantly increased its area and became the sixth culture in Bulgaria, after only of wheat, sunflower, maize, canola and barley. In our country the best predecessors for coriander are winter cereals. Cereal volunteers along with graminaceous weeds are a serious problem in coriander fields (Delchev and Georgiev, 2015a,b).

The weeds occurring in coriander crops of are mainly from the group of the winter-spring species and from the group of early spring species (Delchev, 2015). The most frequent winter-spring weeds are: *Alopecurus myosuroides* L., *Apera spica-venti* P.B., *Bromus arvensis* L., *Avena ludoviciana* Durien., *Lolium multiflorum* L., *Anthemis arvensis* L., *Chamomilla recutita* Rauchert, *Consolida regalis* Gray, *Viola tricolor* L., *Lithospermum arvense* L., *Centaurea cyanus* L., *Papaver rhoes* L., *Agrostemma githago* L. The most frequent early spring weeds are: *Avena fatua* L., *Galium aparine* L., *Sinapis arvensis* L., *Falopia convolvulus* Leve, *Myagrum perfoliatum* L. et al. (Atanasova and Gospodinov, 2005; Atanasova et al., 2012).

Biological peculiarity of coriander is its slow growth rates in the first stages and therefore it is highly vulnerable to the competitive impact of weeds at the beginning of its vegetation and weed infestation significantly (Vaculik, 2007). Effective weed control is one the important conditions for full realization of the biological potential of culture (Mathukia et al., 2014).
The purpose of this investigation was to establish the efficacy and selectivity of some herbicides, herbicide combinations and herbicide tank mixtures on the coriander by influence of different meteorological conditions.

Materials and methods

The research was conducted during 2013 - 2015 on pellic vertisol soil type. Under investigation was Bulgarian coriander cultivar Lozen 1 (*Coriandrum sativum* L.). Two factors experiment was conducted under the block method, in 4 repetitions; the size of the crop plot was 15 m^2. Factor A included no treated check, 6 soil-applied herbicides – Tendar EC, Silba SC, Sharpen 33 EC, Merlin flex 480 SC, Smerch 24 EC, Raft 400 SC and 5 foliar-applied herbicides – Kalin flo, Eclipse 70 DWG, Sultan 500 SC, Corrida 75 DWG, Lontrel 300 EC. Factor B included no treated check and 1 antigraminaceous herbicide – Tiger platinium 5 EC. Active substances of herbicides and their doses are shown in Table 1.

Table 1. Investigated variants.

№	Variants	Active substance	Doses	Treatment period
Antibroadleaved herbicides				
1	Check	-	-	-
2	Tendar EC	S-metolachlor	1.5 l/ha	ASBE
3	Silba SC	metolachlor + terbuthylazine	3.5 l/ha	ASBE
4	Sharpen 33 EC	pendimethalin	5 l/ha	ASBE
5	Merlin flex 480 SC	isoxaflutole	420 g/ha	ASBE
6	Smerch 24 EC	oxyfluorfen	1 l/ha	ASBE
7	Raft 400 SC	oxidiargil	1 l/ha	ASBE
8	Kalin flo	linuron	2 l/ha	rosette
9	Eclipse 70 DWG	metribuzine	500 g/ha	rosette
10	Sultan 500 SC	metazachlor	2 l/ha	rosette
11	Corrida 75 DWG	tribenuron-methyl	20 g/ha	rosette
12	Lontrel 300 EC	clopyralid	500 ml/ha	rosette
Antigraminaceous herbicides				
1	Check	-	-	-
2	Tiger platinium 5 EC	quizalofop-P-ethyl	2.5 l/ha	rosette
ASBE – after sowing, before emergence				

The soil-applied herbicides were used in the period between sowing and emergence. The foliar-applied herbicides used at the rosette stage of the coriander. Introduction of herbicide combinations during rosette stage is done as herbicide tank mixtures – the mixing is done in the spray tank. All of the herbicides, herbicide combinations and herbicide tank-mixtures were applied in a working solution of 200 l/ha. Mixing of the foliar-applied herbicides was done in the tank on the sprayer. It was investigated efficacy and selectivity of herbicides and their tank mixtures. It was established their influence on seed yield. Efficacy of herbicides against weeds was appointed according to 100 % scale of EWRS (European Weed Research Society). Selectivity of herbicides to coriander plants was followed according to the 9-rate scale of EWRS (rating 1 - without damages, rating 9 - crop is completely destroyed). The mathematical processing is done with analysis of variance method.

Results and discussion

Annual broadleaved weeds in the experiment are represented by *Anthemis arvensis* L., *Chamomilla recutita* Rauchert, *Galium aparine* L., *Sinapis arvensis* L., *Raphanus raphanistrum* L., *Capsella bursa-pastoris* L., *Falopia convolvulus* Leve, *Lithospermum arvense* L., *Papaver rhoes* L., *Consolida regalis* Gray, *Viola tricolor* L., *Myagrum perfoliatum* L., *Lamium purpureum* L., *Veronica hederifolia* L., *Stellaria media* Cyr. Annual graminaceous weeds are *Avena fatua* L., *Avena ludoviciana* Durien., *Alopecurus myosuroides* L., *Apera spica-venti* P.B., *Lolium temulentum* L., *Lolium multiflorum* L., *Bromus arvensis* L. Perennial broadleaved weeds are *Cirsium arvense* Scop., *Convolvulus arvensis* L., also single plants of *Cardaria draba* L. and *Sonchus arvensis* L. Perennial graminaceous weeds are represented by *Sorghum helepense* Pers., *Cynodon dactylon* Pers. and more rarely *Agropyrum repens* L. Volunteers are represented by durum wheat (*Triticum durum* Desf.), was grown as predecessor.Soil-applied herbicides Tendar, Silba, Sharpen, Merlin flex, Smerch and Raft applied in autumn, during the period after sowing before germination of coriander, are inefficacy against *Cirsium arvense* Scop., *Convolvulus arvensis* L., *Cardaria draba* L. and *Sonchus arvensis* L., because these perennial broadleaved weeds germinate in spring (Table 2). Foliar-applied herbicides Kalin flo, Eclipse and Sultan applied in spring, during the rosette stage of coriander, are also inefficacy against perennial broadleaved weeds *Cirsium arvense* Scop., *Convolvulus arvensis* L. and *Sonchus arvensis* L. Foliar-applied herbicides Corrida and Lontrel are inefficacy only against *Convolvulus arvensis* L., because this perennial broadleaved weed germinate later, after treatment with the herbicides.

Table 2. Efficacy of some herbicides against broadleaved weeds at coriander according to the 100 % visual scale of EWRS (mean 2013 - 2015).

Herbicides		Weeds

Herbicide Tendar has the weakest efficacy against annual broadleaved weeds. It controls of 100 % only *Chamomilla recutita* Rauchert, and *Capsella bursa-pastoris* L. Tendar controls of 85 – 95 % weeds as *Galium aparine* L., *Papaver rhoes* L., *Sinapis arvensis* L., *Raphanus raphanistrum* L., *Anthemis arvensis* L. Herbicide Silba has weaker efficacy of 85 % only against *Galium aparine* L. Other four soil-applied herbicides - Sharpen, Merlin flex, Smerch and Raft have 100 % efficacy against all annual broadleaved weeds, which are represented in the experiment. Foliar-applied herbicides Kalin flo, Eclipse and Corrida are weaker efficacy against *Galium aparine* L. They control this weed from 15 % at Eclipse to 45 % at Corrida. Herbicide Sultan is inefficacy against *Sinapis arvensis* L. and *Raphanus raphanistrum* L. and has weaker efficacy against *Galium aparine* L. and *Anthemis arvensis* L. Herbicide Lontrel is inefficacy only against *Sinapis arvensis* L. and *Raphanus raphanistrum* L.

Soil-applied herbicides Tendar and Silba are inefficacy against annual graminaceous weeds *Bromus arvensis* L., *Avena fatua* L., *Avena ludoviciana* Durien. and against perennial graminaceous weeds *Sorghum helepense* Pers. and *Cynodon dactylon* Pers. (Table 3). They have weak efficacy of 40 % against volunteers of durum wheat (*Triticum durum* Desf.). Herbicides Merlin flex and Raft are efficacy against all annual graminaceous weeds except *Bromus arvensis* L. Herbicides Sarpen are efficacy against all annual graminaceous weeds except *Bromus arvensis* L. and volunteers of *Triticum durum* Desf. Herbicides Smerch, Kalin flo, Corrida and Lontrel are inefficacy against all annual and perennial graminaceous weeds and volunteers of durum wheat. Herbicides Tendar, Silba, Sharpen, Merlin flex and Raft are efficacy against *Sorghum helepense* Pers. by seeds, but are inefficacy against *Sorghum helepense* Pers. by rhizomes. Herbicide Sultan has sufficient efficacy against annual graminaceous weeds and volunteers of durum wheat but it is not efficacy against perennial graminaceous weeds. Herbicide Eclipse has antigraminaceous effect only against *Alopecurus myosuroides* L.

Table 3. Efficacy of some herbicides against graminaceous weeds and volunteers at coriander according to the 100 % visual scale of EWRS and selectivity according to the 9-rate scale of EWRS (mean 2013 - 2015).

*- volunteers of durum wheat (*Triticum durum* Desf.) (50) – against *Sorgum helepense* Pers. from seeds only, without *Sorgum helepense* Pers. from rhizomes										

Annual graminaceous weeds are *Avena fatua* L., *Avena ludoviciana* Durien., *Alopecurus myosuroides* L., *Apera spica-venti* P.B., *Lolium temulentum* L., *Lolium multiflorum* L., *Bromus arvensis* L., Perennial graminaceous weeds *Sorghum helepense* Pers., *Cynodon dactylon* Pers. and *Agropyrum repens* L., as well as volunteers of *Triticum durum* Desf. are controlled successfully by foliar-applied antigraminaceous herbicide Tiger platinium.

Combinations of Tiger platinium with soil-applied herbicides Tendar, Silba, Sharpen, Merlin flex, Smerch and Raft and with foliar-applied herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel do not reduce herbicide efficacy. From those herbicides included in the experiment only the use of soil-applied herbicide Merlin flex and herbicide combination Merlin flex + Tiger platinium leads to phytotoxicity on coriander - rating 2 by scale of EWRS (Table 3). Signs of phytotoxicity overcome difficult from coriander plants and lead to decrease of seed yield. Soil-applied herbicides Tendar, Silba, Sharpen, Smerch and Raft and foliar-applied herbicides Kalin flo, Eclipse, Sultan, Corrida, Lontrel and Tiger platinium have high selectivity - rating 1 by scale of EWRS. It was found that the lowest seed yields are obtained by alone application of herbicide Merlin flex, followed by the untreated control (Table 4). The use of soil-applied herbicide Merlin flex do not increases seed yield despite its very good herbicidal effect against both graminaceous and broadleaved weeds. The reason for this is its higher phytotoxicity against coriander.

Table 4. Influence of some herbicide combinations on seed yield of coriander (2013 - 2015).

Lontrel	-	2258	105.0	2473	106.0	2167	105.2	2299	105.4
	Tiger platinium	2451	114.0	2676	114.7	2365	114.8	2497	114.5
LSD 5 %		80	3.7	85	3.6	79	3.8		
LSD 1 %		104	4.8	110	4.7	100	4.7		
LSD 0.1 %		133	6.2	147	6.3	128	6.2		

Foliar-applied herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel and alone application of soil-applied herbicides Tendar, Silba, Sharpen, Smerch and Raft increases seed yields because the big numbers of weeds are destroyed by these herbicides. The increases of the yield by alone application of antigraminaceous herbicide Tiger platinium is less than the increase by other herbicides, because prevailing weeds in the trail are broadleaved. Foliar treatment with Tiger platinum after soil-applied herbicides Tendar, Silba, Sharpen, Smerch and Raft increases the seed yields during the three years of the investigation. Tank mixtures of Tiger platinium with herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel also lead to bigger increase in seed yields compared to yield at alone application of respective herbicides. Herbicide combination Merlin flex + Tiger platinum increases seed yield compared to alone application of Merlin flex, but not proven increase yield compared to no treated control.

Conclusions

Combinations of antigraminaceous herbicide Tiger platinum with soil-applied herbicides Tender, Silba Sharpen, Merlin flex, Smerch and Raft and foliarly-applied herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel do not reduce herbicide efficacy. Volunteer durum wheat crops in coriander crops are successfully controlled with the foliar-applied herbicide Tiger platinum. High yields of coriander seeds are obtained with the foliar treatment with the antigraminaceous herbicide Tiger platinum after soil-applied herbicides Raft, Smerch, Sharpen, Silba and Tender. The tank mixtures of Tiger platinum with foliar herbicides Kalin flo, Eclipse, Sultan, Corrida and Lontrel also lead to high seed yields. The use of the soil-applied herbicide Merlin flex does not increase the seed yield, due to its higher phytotoxicity against coriander. Sole use of soil-applied or foliar-applied herbicides leads to lower yields due to the fact they must be combined for full control of weeds in coriander crops.

Abstract

During 2014-2015, a field experiment has been carried out in the Field crops institute - Chirpan (Bulgaria) in conditions of naturally infected cotton with tobacco thrips (*Thrips tabaci* Lind.) including 4 replications of 10 m^2 for each variant. We investigated insecticides Danadim progress 400 EC (Dimethoate), Sumi alfa 5 EC (Esfenvalerat), Pirinecs 48 EC (Chlorpirifosetil), Deccis 2.5 EC (Deltamethrin), Mospilan 20 SP (Acetamiprid), Lannat 25 WG (Methomyl) and Cohinor 200 SL (Imidacloprid). For successful leading the fight against tobacco thrips, the insecticides that can be used are: Mospilan 20 SP at a dose of 15 g/da, Cohinor 200 SL at a dose of 60 ml/da, Danadim progress 400 EC at a dose of 200 ml/da, Sumi alfa 5 EC at a dose of 50 ml/da, Pirinecs 48 EC at a dose of 100 ml/da, Deccis 2.5 EC at a dose of 50 ml/da and Lannat 25 VG at a dose of 100 g/da. The best duration was observed (within the fourteenth day after the treatment) in the neonicotinoid insecticides Mospilan 20 SP and Cohinor 200 SL. The insecticides Danadim progress 400 EC, Sumi alfa 5 EC, Pirinecs 48 EC, Deccis 2.5 EC and Lannat 25 VG retain their efficacy until the 7th day after the treatment.

Key words: *Cotton, insecticides, Tobacco thrips, efficacy*.

Introduction

Tobacco thrips (*Thrips tabaci* Lind.) are polyphagous and attacks over 300 plant species (Straub *et al*., 1992).
In many countries such as Spain, India, Turkey, Israel and Pakistan, tobacco thrips are also reported to be an important pest in cotton (Aston and Winfeld, 1972; Klein *et al*., 1986; Williams, 2006; Khan, 2011; Anonymous, 2013; Din *et al*., 2015). It feeds on the various weeds (*Sinapis arvensis* L., *Capsella bursa-pastoris* Medic, *Cirsium arvense* Scop, *Chenopodium album* L.) and cultured plants (tobacco - *Nicotiana tabacum* L., sunflower - *Heliantus annuus* L., onion - *Allium cepa* L., *Cucurbita* spp.). Tobacco thrips ccurs on cotton plants throughout the growing season, but a critical period in the development of cotton is from emergence to buttoning (Radev, 1967; Radev, Stefanov, 1976; Rashev, 2012), causing the juveniles and the larvae to suck juice from the leaves and the vegetation peak, very often causing deformation of the young leaves and appearance of silver stains. Damaged leaves are curled or deformed, become stiffer and tear apart as if they were beaten by hail (Radev, Stefanov, 1976; Atakan *et al*., 1996). As an enemy whose numbers are difficult to control by useful species, it is necessary to carry out 2-3 chemical treatments every year (Stefanov, Dimitrov, 1986). For control, insecticides of various chemical groups are approved: phosphorus compounds (dimethoate and chlorpyrifosetil) which inhibit the activity of cholinesterase that degrades the acetylcholine of choline and acetic acid; synthetic pyrethroids (esfenvalerate and deltamethrin) that disrupt sodium-potassium conduction in axon membranes and gamma-aminobutyric acid suppression; carbamate insecticides (methomyl)

that block the ester and anionic sites of the enzyme acetylcholinesterase and neonicotinoids (acetamiprid and imidacloprid) that bind to the postsynaptic nicotinic acetylcholine receptors of the central nervous system and attack the Cl^{+} channels. The long-term use of these compounds for the control of tobacco thrips not only in cotton, but also in other crop plants, has resulted in its mass multiplication and spread in the country due to the low efficacy of chemical control. Many authors Zielbermints *et al*. (1979), Zilbermints and Zhuravleva (1990), Grafton-Cardwell (1991), Grossman (1994), Hollingsworth *et al*. (1997), Kerns *et al*. (1998), Denholm *et al*. (1999), Godfrey and Fuson (2001), Shelton *et al*. (2006) on the basis of efficacy and their change in the fight against tobacco thrips establish resistance and the possibility of overcoming it by using chemical compounds with different mechanisms of action. In regard to this, the aim of this study is to review the use of chemical preparations for the control of tobacco thrips in order to establish the emergence of resistance and the possibility of overcoming.

Material and Methods

During 2014-2015 in the Field crops institute - Chirpan (Bulgaria), a polish experiment was conducted in conditions of naturally infected cotton areas with tobacco thrips in 4 repetitions of 10 m2 for each variant. In the experiment, the following insecticides were included: Danadim progress 400 EC (dimethoate 400 g/l), Sumi alpha 5 EC (esfenvalerate 50 g/l), Pirinex 48 EC (chlorpyrifosetil 480 g/l), Mospilan 20 SP (acetamiprid 200 g/kg), Lannat 25 WG (methomyl 250 g/kg) and Cohinor 200 SL (imidacloprid 200 g/l). The control was treatmant with water. The initial density of the tobacco thrips is determined before treatments. The efficacy of the formulations for each variant was calculated using the Henderson-Tilton formula. After the 1st, 3rd, 7th and 14th day, the remaining living individuals in the variants and control are also counted. From each variant, 100 plants are taken and by the strapping method the available insect's adults and larvae are counted.

Results and Discussion

All tested insecticides on the first day after treatment showed a high efficacy against tobacco thrips reaching 99-100%, which dramatically reduced its population (Table 1). In the preparations with a clear contact action: Danadim progress 400 EC (Dimethoate), Pirinex 48 EC (Chlorpyrifosetil), Sumi alpha 5 EC (Esfenvalerate), Decis 2.5 EC (Deltamethrin) and Lannat 25 WG (methomyl), efficacy decreases after the seventh day, ranges from 65-79%.
While the systemic action of insecticides Mospilan 20 SP (acetamiprid) and Cohinor 200 SL (imidacloprid) remains high (90%) until the fourteenth day after treatment, which provides protection for cotton for a period of time which in contact insecticides to be achieved through two treatments.

Table 1. Efficacy of insecticides against tobacco thrips (*T. tabaci*) in 2014

Variants/ Dose	Number of the live thrips	Days after spraying, efficacy							
		1st day		3rd day		7th day		14th day	
		Number of live	E %	Number of live	E %	Number of live	E %	Number of live	E %
Dimethoate Danadim progress 400 EC - 200 ml/da	165	2	99	17	90	26	84	72	60
Esfenvalerat Sumi alfa 5 EC - 50 ml/da	136	0	100	5	96	15	89	65	56
Chlorpirifosetil Pirinecs 48 EC - 100 ml/da	135	0	100	4	97	11	92	42	71
Deltamethrin Deccis 2.5 EC - 50 ml/da	160	0	100	6	96	17	89	73	58
Acetamiprid Mospilan 20 SP – 15 g/da	158	0	100	2	99	3	98	17	90
Methomyl Lannat 25 WG - 100 g/da	172	2	99	4	98	16	91	44	74
Imidacloprid Cohinor 200 SL - 60 ml/da	185	0	100	2	99	4	98	19	90
Control	195	234		201		193		211	

Similar results are available in 2015, confirming the possibility of maintaining a low population of tobacco thrips by contacting insecticides at a range of 7 days and 14 days in systemic insecticides.
The obtained results show high efficacy of all applied insecticides. The lack of resistance and their limited use during vegetation has led to the maintenance of registered efficacy.

Table 2. Efficacy of insecticides against tobacco thrips (*T. tabaci*) in 2015

Variants/ Dose	Number of the live thrips	Days after spraying, efficacy							
		1st day		3rd day		7th day		14th day	
		Number of live	E %	Number of live	E %	Number of live	E %	Number of live	E %
Dimethoate Danadim progress 400 EC - 200 ml/da	204	2	99	10	96	38	89	95	74
Esfenvalerat Sumi alfa 5 EC - 50 ml/da	221	3	99	12	96	35	90	135	65
Chlorpirifosetil Pirinecs 48 EC - 100 ml/da	235	5	98	11	97	28	93	86	79
Deltamethrin Deccis 2.5 EC - 50 ml/da	191	5	99	7	97	26	92	118	65

Acetamiprid Mospilan 20 SP – 15 g/da	254	0	100	4	99	8	98	18	96
Methomyl Lannat 25 WG - 100 g/da	232	3	99	6	98	31	92	98	76
Imidacloprid Cohinor 200 SL - 60 ml/da	231	0	100	3	99	10	97	19	95
Control	233	253		328		385		412	

Conclusions

As a result of the studies conducted, the following conclusions can be drawn:

As a result of the treatments carried out with the approved insecticide control tobacco thrips (*T. tabaci*), the occurrence of resistance to the different chemical groups has not been established.

The duration of the contact insecticides is 7-8 days, and the system provides efficacy for 14 days.

Abstract

The experiment was performed on an agricultural field contaminated by the Non-Ferrous-Metal Works near Plovdiv, Bulgaria. The field experimental was a randomized complete block design containing five treatments and four replications (20 plots). The treatments consisted of a control (no organic amendments), compost amendments (added at 2 t/ha and 4 t/ha), and vermicompost amendments (added at 2 t/ha and 4 t/ha). Upon reaching commercial ripeness, the maize plants were gathered. Heavy metal contents in roots, stems, leaves and grains of maize were analyzed by the method of the microwave mineralization. To determine the heavy metals in the samples, inductively coupled emission spectrometry (Jobin Yvon Emission - JY 38 S, France) was used. Tested organic amendments significantly influenced the uptake of Pb, Zn and Cd by the roots, stems, leaves and grains of maize. The compost and vermicompost treatments significantly reduced heavy metals concentration in grains but the effect differed among them. The 2 t/ha compost treatment led to decreased heavy metal contents in grains bellow the regulated limits.

Introduction

Phytoremediation can be defined as the combined use of plants, soil amendments and agronomic practices to remove pollutants from the environment or to decrease their toxicity (Salt et al., 1998). This technique has many advantages compared with other remediation procedures – low economic costs and the possibility of being applied to soils, causing a minimum environmental impact. As a technology based on the use of plants, the success of phytoremediation will mainly depend on the proper selection of plants. Many researchers examine the rapidly growing, high biomass plants, including agronomic crops for their ability to tolerate and accumulate metals in their shoots. Many metal tolerant plant species, especially wheat plants of the family Gramineae, avoid toxicity through the mechanisms of exclusion and therefore are more suitable for phytostabilization than phytoextraction (Baker et al., (1994). Ebbs and Kochian (1998) established that barley (*Hordeum vulgare* L.) and oats (*Avena sativa* L.) were tolerant to metals such as Cu, Cd, and Zn and accumulated medium to high quantities of them in their tissues. According to Wierzbiska (1999), barley and maize were species with high constitutional tolerance towards Pb, whereas wheat and oats belonged to the group of cultures capable of weak heavy metals accumulation. Opposite results, however, were obtained by Vincenc et al. (1996), which indicated that heavy metals accumulation was most apparent in cereals (maize, oats, rye, wheat, and barley). The addition of organic matter amendments, such as compost, fertilizers, and wastes, is a common practice for immobilization of heavy metals and soil amelioration of contaminated soils (Clemente et al., 2005). The effect of organic matter amendments on heavy metal bioavailability depends on the nature of the organic matter, their microbial degradability, salt content and effects on soil pH and redox potential, as well as on the particular soil type and metals concerned (Walker et al., 2003). The main objective of this paper is to conduct a systematic study, which will help to determine the impact of organic soil amendments on the uptake of the heavy metals by maize (*Zea mays L.*), as well as the possibilities to use the plant for phytoremediation of heavy metal contaminated soils.

Material and Methods

The experiment was performed on an agricultural field contaminated by the Non-Ferrous-Metal Works near Plovdiv, Bulgaria. The field experimental was a randomised complete block design containing five treatments and four replications (20 plots): 1 – addition of 2 t/ha of vermicompost to the soil, 2 - addition of 4 t/ha of vermicompost to the soil, 3 - addition of 2 t/ha of compost to the soil, 4 - addition of 4 t/ha of compost to the soil, 5 - control variant. Characteristics of soils and organic amendments are shown in Table 1. The soils used in this experiment were slightly acidic, with moderate content of organic matter and essential nutrients (N, P, and K) (Table 1). The total content of Zn, Pb and Cd is high (1430.7 mg kg^{-1} Zn, 876.5 mg kg^{-1} Pb and 31.4 mg kg^{-1} Cd, respectively) and exceeds the maximum permissible concentrations (320 mg kg^{-1} Zn, 100 mg kg^{-1} Pb, 2.0 mg kg^{-1} Cd).

Table 1. Characterisation of the soil and the organic amendments used in the experiment

Parameter	Soil	Compost	Vermicompost
pH	6.5	6.9	7.5
Organic matter (%)	3.99	72.10	38.58
N Kjeldal (%)	0.24	2.22	1.57
Total P (mg kg^{-1})	642	12654	10211
Total K (mg kg^{-1})	5518	6082	10495
Total Pb (mg kg^{-1})	876.5	12.0	32.3
Total Zn (mg kg^{-1})	1430.7	170.8	270.3
Total Cd (mg kg^{-1})	31.4	0.19	0.69

The test plant was maize (*Zea mays L.*). The maize seeds were sown in each plot at a spacing of 70 cm and a seed density of 4 plants per m^2 and were grown according to conventional technology. Upon reaching commercial ripeness, the maize plants were gathered and the content of heavy metals in their different parts (roots, stems, leaves, and grains) was quantitatively determined. The concentrations of Pb, Zn, and Cd in their different parts of the maize were determined by the method of microwave mineralization. To determine the heavy metal content in the samples, inductively coupled emission spectrometer (Jobin Yvon Emission - JY 38 S, Paris, France) was used.

Results and Discussion

Accumulation of heavy metals in vegetative and reproductive organs of maize without amendment (control)

Table 2 presents the results obtained for the content of heavy metals in the vegetative and reproductive organs of the study cereal crop. In all three elements, the main part was accumulated in the roots, and which was in conformity with the results of other authors (Fassler et al., 2010). The content of Pb in the roots of maize without amendments reached to 248.4 mg kg^{-1}, Zn - 599.2 mg kg^{-1} and Cd -18.3 mg kg^{-1}. The greater part of the heavy metals, that had entered the soil, are fixed and accumulated in the roots of maize, as maize formed a powerful root system with a strong ability to uptake the nutrients. In penetration in the plazma inactivation and precipitation of considerable quantities of heavy metals takes place, probably as a result of the formation of little mobile compounds with the organic substance.

Table 2. Content of Pb, Zn and Cd (mg/kg) in maize plants (without amendments)

Element	Roots x±sd	Stems x±sd	Leaves x±sd	Grains x±sd
Pb	248.4±1.5	54.2±0.3	116.9±0.7	0.87±0.05
Zn	599.2±6.5	539.9±6.5	363.5±5.3	41.9±0.1
Cd	18.3±0.5	10.2±0.4	12.7±0.5	0.33±0.05

x- average value(mg kg^{-1}) from 5 repetitions; sd - mean standard deviation

The Pb contents in the aboveground parts of the maize were considerably lower compared to those in the root system, which showed that their movement through the conductive system was strongly restricted. However, the Zn and Cd contents in the aboveground parts are higher compared to those in the root system. Our results do not confirm finding the results of Perriguey et al. (2008) and Puertas-Mejı´a et al. (2010) who found that after absorption by the root, Cd is mainly retained in the roots and a small quantity is translocate to shoot. The content of Pb in the stems of maize without amendments reached to 54.2 mg kg^{-1}, Zn – 539.9 mg kg^{-1} and Cd – 10.2 mg kg^{-1}. The results obtained showed that the heavy metal concentrations in the stems of the maize were within the normal range (below the maximum permissible concentrations) for fodder. Heavy metal content in the leaves was lower compared to that in the root system. The content of Pb in the leaves of maize without amendments reached to 116.9 mg kg^{-1}, Zn – 363.5 mg kg^{-1}, and Cd – 12.7 mg kg^{-1}. Cd and Pb content in the leaves of the maize were below the phytotoxic levels for dry foliage but were at a higher level than the maximum permissible concentrations for fodder (30 mg kg^{-1} for Pb and 1 mg kg^{-1} for Cd). Zn content in the leaves of the crops was within the range of normal plant foliage (15 - 150 mg kg^{-1} Zn) (Hapke, 1991).

The heavy metal content in the grains of the maize was lower in comparison to that in the roots and leaves, which confirmed the results obtained by Fassler et al. (2010). The heavy metal accumulation in maize grains was likely caused by the conductive system. The content of Pb in the grains of maize without amendments reached to 0.87 mg kg^{-1}, Zn – 41.9 mg kg^{-1}, and Cd – 0.33 mg kg^{-1}. The Zn content in the grains of maize was slightly higher than the maximum permissible concentrations (40 mg kg^{-1} Zn), whereas the Pb and Cd accumulated in quantities considerably above the proposed guideline value for grains (0.2 mg kg^{-1} Pb and 0.2 mg kg^{-1} Cd). These results confirm those obtained by Madejon et al. (2002), according to whom cadmium, lead, arsenic, and copper content in grains may reach levels considered toxic for the food-web. Our results do not confirm the results of Wenger et al. (2002) who found that maize seed produced on contaminated land may be suitable for animal feed.

The distribution of the heavy metals in the organs of the studied crops has a selective character that in maize decreases in the following order: roots> leaves > stems > > grains (Fig.1).

Organic additives impact

According to the literature, the content of the organic substance in soil has a significant impact on uptake and translocation of heavy metals in soil and their uptake by plants. Zn, Pb, and Cd are adsorbed on organic matter, which generates stable forms and leads to their accumulation in organic horizons of soil and peat (Kabata Pendias, 2001).

Fig.1. Distribution of heavy metals in vegetative and reproductive organs of maize plants

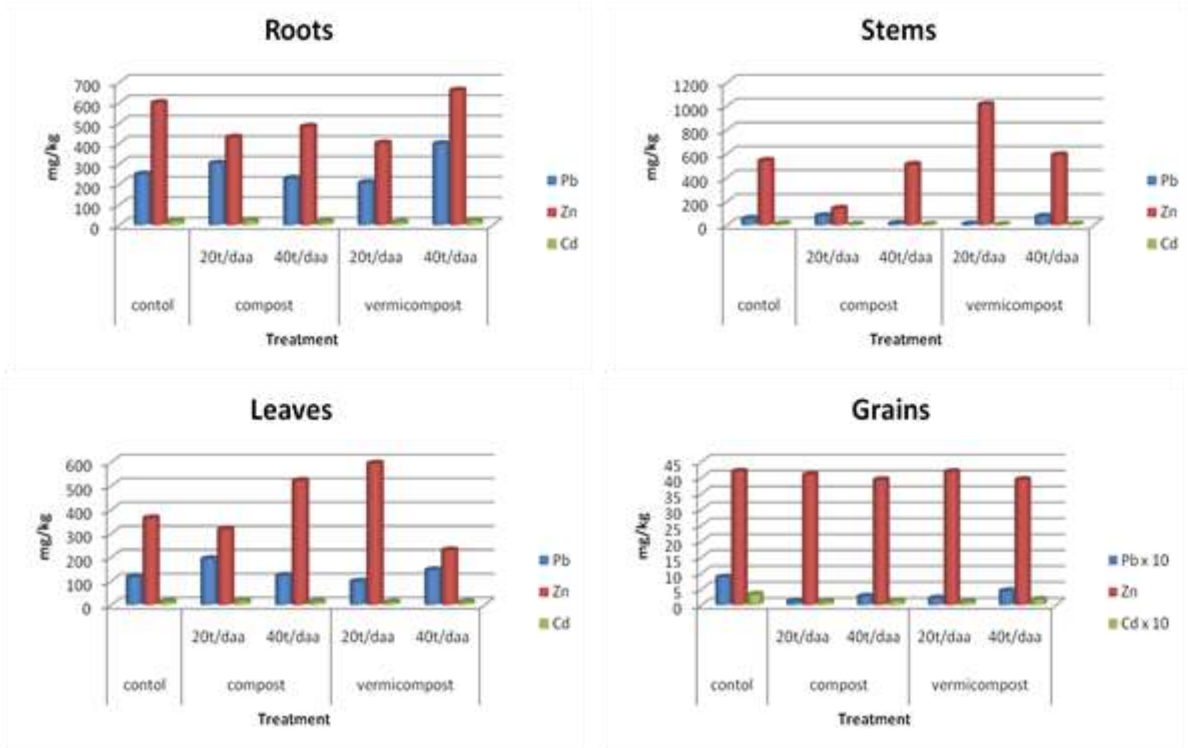

Fig. 2. Effect of the compost and vermicompost treatments on the quantity of Pb, Zn and Cd (mg kg^{-1}) in maize plants

The results for the influence of the organic additives on the accumulation and distribution of Pb, Zn, and Cd in the maize plants are presented in Figure 2. The results obtained by us showed that Pb, Zn, and Cd uptake by maize plants depended on the soil amendments and treatment (type and rate). The application of organic amendments significantly influenced the uptake of Pb, Zn, and Cd by the tested plant. Changes in heavy metals content in maize organs were rather complex. The impact of organic amendments on heavy metals accumulation in organs of maize depended significantly on their quantity. The application of 2 t/ha compost and 4 t/ha vermicompost led to increased Pb content in the roots, stems, and leaves of maize. When the soil was treated with 4 t/ha compost and 2 t/ha vermicompost Pb contents in the roots, stems and leaves of maize decreased (Fig.2). The application of 2 t/ha compost led to increased Cd content in the roots and leaves of maize. When the soil was treated with 4 t/ha compost and 2 t/ha vermicompost Cd contents in the leaves of maize decreased (Fig.2). The addition of 2 t/ha compost and 4 t/ha vermicompost leads to increase of the content of Cd in the roots. The content of Zn in the roots decreases after the addition of compost, as this decrease is more pronounced after the addition of 2 t/ha of compost. The addition of 2 t/ha vermicompost leads to increase of the content of Zn in the stems and leaves. Similar results were obtained by Putwattana et al. (2015) who found that application of cow manure and rice straw in Cd/Zn-contaminated soil increased maize growth and grain yield, and decreased Cd and Zn uptake by maize. However, heavy metal contents in grains of maize decreased in the plants treated with all amendments used in the experiments. The impact of organic amendments on Pb accumulation in grains of maize depended significantly on their quantity. The application of 2 t/ha compost led to a decrease of the Pb content in grains to 0.11 mg kg^{-1} and these concentrations were below the maximum permissible concentrations. When the soil was treated with 4 t/ha compost and 2 t/ha vermicompost Pb content remained practically unchanged (0.21-0.29 mg kg^{-1}). When the soil was treated with 4 t/ha vermicompost, Pb concentration slightly increased to 0.44 mg kg^{-1}. Cd showed a similar tendency. When the soil was treated with compost Cd content remained practically unchanged (0.11 -0.13 mg kg^{-1}). The application of 2 t/ha vermicompost led to a decrease of the Cd content in grains to 0.10 mg/kg. When the soil was treated with 4 t/ha vermicompost, Pb concentration slightly increased to 0.17 mg kg^{-1}. Organic amendment addition was especially effective for the reduction of Cd content in grains below maximum permissible concentrations (0.2 mg kg^{-1}). When the soil was treated with 2 t/ha compost and 2 t/ha vermicompost, Zn content remained practically unchanged (40.8-41.8 mg kg^{-1}). The increase in the quantity of compost and vermicompost (4 t/ha) led to a decrease of Zn content in maize grains to 39.3 mg kg^{-1} and these concentrations were slightly lower than maximum permissible concentrations (40 mg kg^{-1} Zn). Organic amendments significantly reduced heavy metals concentration in maize grains, but the effect differed among them. Also, there was a dose effect for amendments. 2 t/ha compost addition was especially effective for the reduction of Pb and Cd content in maize grains, (87% and 66%, respectively), the Pb and Cd content were bellowed regulated limits and grains can be used as livestock feed. The possibility to use maize grains for animal feed as well as the stems and leaves for nonfood purposes such as bioenergy production will make maize economically interesting crops for farms, through use of phytoremediation technology.

Conclusions

Based on the results obtained regarding the impact of organic soil amendments on the uptake of the heavy metals by maize, as well as the possibilities to use the plant for phytoremediation, the following conclusions can be made:

The compost and vermicompost treatments significantly reduced heavy metals concentration in maize grains, but the effect differed among them. Also, there was a dose effect for amendments. 2 t/ha compost treatment led to decreased heavy metal content in maize grains bellow the regulated limits and grains can be used as livestock feed. The possible use of grains for animal food will make maize economically interesting crops for farms, through use of phytoremediation technology.

The maize is a crop tolerant to heavy metals and can be grown on the heavy metal polluted soils. Maize plants are characterized by a low capacity to absorb and accumulate Pb, Cd, and Zn, and show no signs of toxicity (chlorosis and necrosis) in the content of 31.4 mg kg^{-1} Cd, 876.5 mg kg^{-1} Pb and 1430.7 mg kg^{-1} Zn in the soil. It can be referred to the group of low accumulators of Pb, Zn, and Cd and can be successfully used for phytoremediation of heavy metal polluted soils.

Abstract

The aim of this study is keeping the quality and expanding shelf-life of strawberries fruits by using Arabic gum as edible coating. We used Arabic gum in aqueous solutions of 5, 10, 15 and 20% was applied as a novel edible coating to gardener-mature strawberries which were stored at 20◦C and 80–90% relative humidity (RH) for 10 days. Fruits coatings significantly reduced decay compared to control fruits. A significantly higher weight loss in 5 and 20% Arabic gum coatings was observed compared to 10 and 15% Arabic gum coatings. The maximum firmness was maintained by the 20% Arabic gum treated strawberry fruits until 6 day. The highest decrease in lightness (L*) was observed in uncoated strawberries followed by 5% coated fruits. The lowest soluble solids (SS) at the end of the storage period was recorded in fruit coated with 20% Arabic gum. The titratable acidity (TA) values of uncoated and coated fruits during storage decreased with storage time. The highest levels of ascorbic acid were observed in control fruits, closely followed by fruits coated with 5% Arabic gum.

Introduction

According to Food and Agriculture Organization (FAO) of the United Nations, world production of strawberries has exceeded 4 million tons since 2007. In 2010, approximately 28 percent of the total production came from the United States, the largest producer among countries where statistical data are available. Other major strawberry producing countries are Turkey, Spain, Egypt, Korea, Mexico, and Poland. Although Spain, Korea, and Poland still have a high production, the growth has been slow or even negative. For example, Spain's production in 2010 was 275,000 tons, down 12 percent from ten years ago. Korea showed an upward trend, but only grew 14 percent during the same period. In contrast, Turkey, Egypt, and Mexico experienced a high growth in the same period. Production in Egypt increased more than 3 times from 70,000 tons to 240,000 tons, and Turkey's production rose from 130,000 tons to 300,000, becoming the second largest strawberry producer in the world (Bouffard, 2012).

Strawberries are one of the most popular summer fruits worldwide that are characterized with unique and highly desirable taste and flavor. They are rich in polyphenols and anthocyanins, vitamins and amino acids. The main characteristics related to the quality of the ripe strawberries are their texture, flavor (organic acids and soluble sugars content) and color (Campaniello *et al.*, 2008; Koyuncu and Dilmaçünal, 2010). Due to their very active metabolism strawberries are highly perishable and have high physiological postharvest activities which lead to short ripening and senescence periods that make their marketing a challenge (Garcia *et al.*, 1998). Loss of quality in this fruit is connected with its sensitivity to fungal infection and susceptibility to water loss, bruising, mechanical injuries and texture softening due to the lack of protective rind (Atress *et al*., 2010).

Several techniques such as modified atmosphere, controlled atmosphere, edible coatings, low temperature, ionizing radiation, plant growth regulators and chemicals have been used to reduce deterioration, extend the shelf-life and maintain quality of strawberries fruits (Singh and Singh, 2012). Modified or controlled atmosphere are common techniques for retaining quality and extending fruit shelf-life (Pesis *et al*., 2000). However, in modified or controlled atmosphere CO2accumulation can causes off flavor and anaerobic respiration (Bender *et al*., 1994). Fungicides has been used to reduce postharvest decay and extend the storage life of fruit, although fungicide resistance by pathogens, along with consumer concerns about possible risks associated with the residue of fungicides on the fruit surface (Charles *et al*., 1994).

Gum Arabic is a polysaccharide natural secretion from Acacia species and used in industries for film forming, emulsification and encapsulation purposes (Motlagh *et al*., 2006). Gum Arabic coatings effectively maintained total antioxidant and phenolic contents in tomato fruit (Ali *et al*., 2013) and in papaya (Addai *et al*., 2013). Gum Arabic treatment reduced browning, loss of ascorbic acid and total phenolic contents of tomato slices (Eltoum and Babiker, 2014). Calcium chloride has been extensively used in the fruits and vegetables sector for whole and fresh-cut commodities as preservative and firming agent. It has been observed that calcium is associated with fruit firmness, stress tolerance, ripening and senescence (Martin-Diana *et al*., 2007). Low temperature caused physiological disorders that are related to calcium content. Calcium chloride dip treatment reduced flesh browning of peach fruit (Manganaris *et al.,* 2007). Calcium chloride combined with chitosan maintained a high level of vitamin C and reduced sensitivity to chilling injury of peach fruit during refrigerated storage (Ruoyi *et al*., 2005).

Although, to the best of our knowledge, there is no report about the combined effect of gum Arabic coating on post-harvest qualities of strawberries fruits.

Therefore, the objective of this study was to elucidate the effect of gum Arabic pretreatments on physiological, biochemical and quality aspects of strawberries fruits stored at 80-90% RH for 20ºC for 10 days.

Materials and methods:

Materials:

Strawberry (*Fragaria ananassa* Duch.) was chosen for this study. Strawberries were purchased from a local market at Kafr El-Sheikh Governorate, Egypt during the 2016 winter and selected for uniformity of size and ripeness, and fruit with apparent injuries were removed. Fruit were stored at 4±1 ◦C prior to processing. All materials used for the coating in this study were of food grade, including Arabic gum powder (KB-120, Food Grade) was supplied by Elattar Trading Co., Kafr El-Sheikh, Egypt. The chemicals were obtained from El-Gomhoria Co., Tanta, Egypt, are of analytical grade. All of these experiments were conducted in the laboratory of Food Technology Research Institute at Sakha, ARC.

Methods:

Preparation of edible film:

Arabic gum coating solutions at 5, 10, 15, 20% (w/v) from 5, 10, 15 and 20 g of powder was dissolved in 100 mL purified water. The solutions were stirred with low heat (40 ˚C) for 60 min on a magnetic stirrer/hot plate (Model: HTS-1003), then filtered to remove any undissolved impurities using a vacuum flask. After cooling to 20˚C, glycerol monostearate (1.0%) was added as a plasticiser to improve the strength and flexibility of the coating solutions. The pH of the solutions was maintained at 5.6 using 1N NaOH. Arabic gum films were prepared according to the method described by (Ghulam *et al*., 2015). The coating treatments were selected according to preliminary experiments in strawberry to assure adherence and steadiness of the coatings. Fruits were washed with 0.01% sodium hypochlorite water solutions for 2 min and then air dried at ambient temperature for one hour. The strawberries were randomly divided into five lots each one containing kilogram of fruits. The strawberry fruits were immersed in each concentration of Arabic gum coating solution (5, 10, 15 and 20%) for 2–3 min and the coating solution was applied uniformly on the whole surface, while control fruit were dipped in purified water. After treatment, fruit were air-dried for 1 h. All fruits were packed in plastic boxes (40 × 30 × 12 cm) covered with polyethylene film (0.02 mm thickness) to maintain relative humidity (RH) were stored at 20±1 °C and 80–90% RH for 10 days. The samples were taken at zero time and after every two days from storage intervals for 10 days of shelf-life.

Decay percentage:

The decay percentage of uncoated and coated fruits wer calculated as the number of decayed fruit divided by initial number of all fruit multiplied by 100 (El-Anany *et al*., 2009).

Weight loss percentage:

Strawberry samples (10 fruit per replication) were weighed at initial and at the end of each storage interval. The difference between initial and final fruit weight was considered as total weight loss during that storage interval and calculated as percentages on a fresh weight basis by the standard (AOAC, 2005) method.

Fruit firmness:

Fruits firmness were assessed by using an Instron Universal Testing Machine (Model 5543 P5995 USA) connected with a computer. The force required to penetrate 10 mm inside the fruit using a probe diameter of 6 mm was measured. The machine was set with compression mode and speed of 20 mm min^{-1}. Readings were recorded on 3 points in the equatorial region of the whole fruit with skin removed and the results were expressed in terms of force recorded in Newtons (N). (Zapata *et al.,* 2008).

Color:

Color was determined according to McGuire, (1992) using the Hunter Lab System, Miniscan XE Plus colorimeter model (Model: 45/0-5, Reston Virginia, USA). Values were recorded as L* [white (100) to black (0)] and hue angle (h◦) [h◦ represents red-purple at an angle of 0◦, yellow at 90◦, bluish green at 180◦, and blue at 270◦]. The mean values of L* and h◦ were obtained from two different points along the strawberry circumference. Before readings were taken during each sampling day, the Miniscan XE Plus colorimeter was calibrated using calibration black and white tiles with values of X = 79.0, Y = 83.9 and Z = 87.9.

Soluble solids, titratable acidity and ascorbic acid:

The strawberries from each treatment were ground in a blender and juice from the fruits were used to determine the soluble solids concentration (SSC) using a Palettle Digital Refractometer (Model: PR-32_, Atago Co., Ltd. Japan). The machine was standardised using purified water before readings were taken. Titratable acidity (TA) was determined using the method of (Ranggana, 1977) by measuring the amount of 0.1N NaOH. Ascorbic acid contents were estimated using the dye 2,6-dichlorophenol–indophenol titration (DCPIP) method after (Ranggana, 1977).

Sensory evaluation:

Sensory evaluation of the fruits for pulp color, texture, flavor and overall acceptability for all the samples were done at the end of the storage period using the method of Bai *et al*. (2003) with some modifications. Based on their consistency and reliability of judgment, a panel of seven judges with age ranging from 25 to 40 years was set up. Panelists were asked to score the difference between samples where 0–2 represented extreme dislike; 3–5 fair; 6–8 good; and 9 excellent for pulp color, texture, flavour and overall acceptability.

Statistical analysis:

The experiment was conducted using a completely randomized design (CRD) with four replications. The data were subjected to analysis of variance (ANOVA) using the computer software MSTAT-C (Freed and Scott, 1986), while least significant difference (LSD) tests were used to compare differences between treatments at the 95% confidence level of each variable (Chase and Brown**,** 1997).

Results and discussion

Decay incidence (DI):

There was no visible sign of decay in coated or control fruit until two day of the storage period (Table 1). Thereafter, the coatings significantly ($P \leq 0.05$) reduced decay compared to control fruit and fruit treated with 10% Arabic gum coating remained disease free even after 8 days of storage. Many of the control fruit (68.37%) were spoiled after 6 days of storage.

Table 1: Effect of different concentrations of gum Arabic coatings on strawberry fruit decay (%) during storage.

Treatments are deferment concentrates of Arabic gum .
Values in table not followed by the same letter are significantly different ($P \leq 0.05$).

The decrease in decay percentage was probably due to the effect of the coating on delaying senescence, which makes the commodity more vulnerable to pathogenic infection as a result of loss of cellular or tissue integrity (Tanada-Palmu and Grosso, 2005). Bai *et al*. (2003) found that ‘Gala’ apples coated with 10% zein maintained their quality, similar to that achieved with the use of commercial shellac formulation, and extended apple shelf-life compared with non-coated controls. Also, Tanada-Palmu and Grosso (2005) noted that wheat gluten coatings and films extended the shelf-life of strawberries and delayed senescence for up to 16 d when stored at 7–10 ◦C.

Weight loss percentage:

Fruit coated with 10 and 15% Arabic gum had less weight loss during storage than the control (Table 2; $P \leq 0.05$) and weight loss increased gradually during the storage period. A significantly higher weight loss in 5 and 20% Arabic gum coatings was observed compared to 10 and 15% Arabic gum coatings, which could be explained by the thickness of coatings. The 5% Arabic gum coating was not so thick that it provided a sufficient barrier against moisture loss while the 20% Arabic gum coating was so thick that it completely covered the surface of the fruit. Similar results were reported by Asgar *et al*. (2010) who found that tomato fruit coated too thickly with a corn-zein film resulted in O_2 concentrations which were too low and excessive CO_2 concentrations, resulting in ethanol production. The primary reason for increased weight loss of thickly coated tomatoes might be the generation of heat and production of end-products from anaerobic fermentation (Weichmann, 1987). The basic mechanism of weight loss from fresh fruit and vegetables is by vapor pressure at different locations (Yaman and Bayoindirli, 2002), although respiration also causes a weight reduction (Pan and Bhowmilk, 1992). This reduction in weight loss was probably due to the effects of the coating as a semi-permeable barrier against O_2, CO_2, moisture and solute movement, thereby reducing respiration, water loss and oxidation reaction rates (Baldwin *et al*,**.** 1999**;** Park, 1999). The results are in agreement with the findings of Ben-Yehoshua (1969) for oranges coated with wax and those of Banks (1984), who reported that sucrose ester-based coatings on banana fruit extended their storage life through reduction in water loss and a modification of the internal atmosphere.

Table 2: Effect of Arabic gum coatings on weight loss (%) of strawberry fruit during storage

Values in table not followed by the same letter are significantly different (P≤0.05).

Fruit firmness:

Firmness of fruit significantly (P≤0.05) decreased with storage period for both treated and control fruit (Table 3). At the end of storage, control fruit clearly showed the lowest firmness. The maximum firmness was maintained by the 20% Arabic gum treated strawberry fruits until 6 day and after that time no significant differences were found among coated strawberries. Softening of fruits is due to deterioration in the cell structure, cell wall composition and intracellular materials (Seymour *et al*., 1993) and is a biochemical process involving the hydrolysis of pectin and starch by enzymes e.g. wall hydrolases. As the process of fruit ripening progresses, depolymerisation or shortening of chain length of pectin substances occurs with an increase in pectinesterase and polygalacturonase activities (Yaman and Bayoindirli, 2002). Low levels of O_2 and high levels of CO_2 limit the activities of these enzymes and allow retention of the firmness during storage (Salunkhe *et al*., 1991). In agreement with these findings, Park *et al*., (1994) reported that respiration and O_2 consumption of corn-zein coated tomatoes were lower than for non-coated tomatoes. Reduction in respiration rates of coated tomatoes could be responsible for delaying ripening which resulted in retention of firmness during storage. Similarly, Tanada-Palmu and Grosso (2005) reported that refrigerated strawberries coated with wheat gluten-based films retained their firmness better than control fruit.

Color:

The lightness (L^*) gradually decreased during storage in both uncoated and coated fruits (data not shown). The highest decrease in lightness was observed in uncoated strawberries followed by 5% coated fruits, while the fruits coated with 10, 15 and 20% Arabic gum retained their lightness values at the end of the experiment. There was a significant ($P \leq 0.05$) decrease in lightness during the storage period. As the concentrations of Arabic gum increased the lightness value also increased. Significant ($P \leq 0.05$) changes were found in hue angle and the value of (h°) decreased sharply in control as well as 5% Arabic gum coated strawberry until day 4 of storage, thereafter the reduction was slower (Table 4).

Table 4: Effect of Arabic gum coatings on color [hue angle (h°)] of strawberries fruit during storage.

Treatments (%)	Storage time (day)					
	0	2	4	6	8	10

h = hue angle (h°) [h° represents red-purple at an angle of 0°, yellow at 90°, bluish green at 180°, and blue at 270°].
Values in table not followed by the same letter are significantly different ($P \leq 0.05$).

The hue angle was maintained in fruit coated with 10, 15 and 20% Arabic gum until day 8 of storage, with a subsequent slight decrease, however no significant differences were found between 15 and 20% Arabic gum treated strawberries. The color change in uncoated strawberries were enhanced and they attained pink to red color within 2–4 days of storage compared to the fruit coated with 5 and 10% Arabic gum (6–8 days) while the fruit coated with 15 and 20% remained green even after 10 days of storage. The mechanism behind this is not fully understood and needs further investigation. It is possible that Arabic gum provided a thick barrier against ethylene production and gas exchange between inner and outer environments, and therefore delayed the ripening of the fruit during storage. Similar results were observed by Park *et al*. (1994) when they stored tomatoes coated with a corn-zein film at 21 °C. Color is an important criterion of quality and consumer acceptability, especially with respect to tomatoes (Aked, 2000). During ripening, the green chlorophyll pigment is degraded and there is accumulation of carotenoids, particularly lycopene giving the red color to the ripe tomato (Khudairi, 1972). During ripening of tomatoes, high CO_2 levels decrease ethylene synthesis, which can delay color changes (Buescher, 1979). In this study, coating of tomatoes with Arabic gum delayed color change, which was probably due to an increase in CO_2 and decrease in O_2 levels.

Soluble solids:

In general, there was a gradual increase in soluble solids (SSC) during the complete storage period (Table 5). The SSC was significantly higher ($P \leq 0.05$) in control compared to coated fruits and the reduction in SSC in coated fruit was directly proportional to the concentration of the coating. The lowest SSC at the end of the storage period was recorded in fruit coated with 20% Arabic gum, and showed that the coatings provided an excellent semi-permeable film around the fruit, modifying the internal atmosphere by reducing O_2 and/or elevating CO_2 and suppressing ethylene production. Decreased respiration rates also slow down the synthesis and use of metabolites resulting in lower SSC **(**Yaman and Bayoindirli**,** 2002).

Table 5: Effect of Arabic gum coatings on soluble solids (%) of strawberries fruits during storage

Treatments (%)	Storage time (day)					
	0	2	4	6	8	10

Treatments are a deferment concentrates of the Arabic gum.
Values in table not followed by the same letter are significantly different ($P \leq 0.05$).

Titratable acidity:

The titratable acidity (TA) values of uncoated and coated fruits during storage decreased with storage time (Table 6) and the value was significantly higher ($P \leq 0.05$) in 20% Arabic gum treated fruit compared to the control. The increase in TA was directly proportional to the Arabic gum concentration. The low level of (TA) in control fruit compared to coated fruit suggests that the Arabic gum coating delayed ripening by providing a semi-permeable film around the fruit. Since organic acids, such as malic or citric acid, are primary substrates for respiration, a reduction in acidity is expected in highly respiring fruit (El-Anany *et al.*, 2009). It is also considered that coatings reduce the rate of respiration and may therefore delay the utilization of organic acids (Yaman and Bayoindirli, 2002). Retention of titratable acidity has been reported previously for
various fruit treated with edible coatings and films (Yaman and Bayoindirli, 2002; Tanada-Palmu and Grosso, 2005).

Table 6: Effect of Arabic gum coatings on titratable acidity (%) of strawberries fruits during storage

Treatments (%)	Storage time (day)					
	0	2	4	6	8	10

Values in table not followed by the same letter are significantly different ($P \leq 0.05$).

Ascorbic acid:

The ascorbic acid (vitamin C) content of coated and uncoated strawberry fruit increased to maximum after 8 days of storage and subsequently declined after 10 days (Table 7). The highest levels of ascorbic acid were observed in control fruits, closely followed by fruits coated with 5% Arabic gum. This increase in ascorbic acid content was in parallel with the increase in other parameters associated with ripening. In strawberries fruits, ascorbic acid content increases with maturity and stage of ripening (Mathooko, 2003), however once fruits reach the full ripe stage, ascorbic acid content starts to decline (AOAC, 1984). The slower increase in ascorbic acid in coated fruits suggests that the coating slowed down but did not prevent the synthesis of ascorbic acid during ripening. Similar slowing down of the increase in ascorbic acid during ripening has been reported with high CO_2 storage atmospheres for tomatoes (Mathooko, 2003).

Table 7: Effect of Arabic gum coatings on ascorbic acid (mg/100g) of strawberries fruits during storage

Treatments (%)	Storage time (day)					
	0	2	4	6	8	10
Control	09.3^{k}	15.3^{ef}	18.2^{c}	20.4^{ab}	21.1^{a}	20.5^{ab}

15	09.3^{k}	09.8^{k}	10.8^{jk}	11.7^{ij}	12.5^{hi}	11.7^{ij}
20	09.3^{k}	09.9^{k}	10.7^{jk}	11.8^{ij}	12.6^{hi}	11.9^{hij}

Treatments are a deferment concentrates of the Arabic gum.
Values in table not followed by the same letter are significantly different (P≤0.05).

Sensory evaluation:

Sensory evaluation of uncoated and coated fruits at the end of the storage period revealed significant (P≤0.05) differences in pulp color, texture, flavor and overall acceptability (Table 8). The 10% Arabic gum coated fruit had the highest scores in all parameters after 10 days of storage, while those coated with 15 and 20% Arabic gum developed poor pulp color and inferior texture and had flavors. The latter fruit were not acceptable to the panel of experts. Compared with 10% Arabic gum, control fruit and fruit treated with 5% Arabic gum had lower scores for flavor and overall acceptability. These results suggest that Arabic gum upto10% can be used successfully as an edible coating for prolonging the shelf-life and improving strawberry fruit quality during storage at 10 ˚C. Similar results were observed by El-Anany *et al*. (2009) when they treated 'Anna' apples with Arabic gum coating.

Table 8: Sensory evaluation of strawberry fruit after treatment with different concentrations of Arabic gum and 20 day of storage.

Treatments (%)	Pulp color	Flavor	Texture	Overall acceptability
Control	2.3^{d}	1.6^{e}	1.2^{e}	1.5^{e}
5	4.3^{bc}	4.2^{bc}	3.6^{c}	3.5^{c}
10	8.2^{a}	8.0^{a}	8.5^{a}	8.3^{a}
15	4.4^{b}	4.3^{b}	4.2^{b}	4.3^{b}
20	3.9^{c}	4.1^{bc}	3.6^{c}	3.8^{c}

Treatments are a deferment concentrates of the Arabic gum.
Values in table not followed by the same letter are significantly different (P≤0.05).

Conclusion

The results of this study indicate that strawberry fruit coated with 10% Arabic gum showed a significant delay in the change of weight, firmness, titratable acidity, soluble solids concentration and color during storage at 20 ˚C as compared to uncoated control fruit. In addition, sensory evaluation showed that 10% Arabic gum coating maintained the overall quality of the strawberry fruit during storage. Further studies should be conducted on the gaseous exchange of Arabic gum coatings in relation to the development of new formulations and their application to different climacteric fruit and vegetables.

Abstract

The present study aimed to evaluate the prevalence and contamination level of *E. coli* in retail beef available on the Egyptian market, to investigate the antimicrobial activity of thyme essential oil (EO) against *E. coli* in minced beef, and to detect its effect on sensory quality attributes of minced beef. A total of 120 fresh beef samples from Egyptian butcher's shops were microbiologically screened for *E. coli* screening. The results show that 27 samples (22.5%) were found to be contaminated with *E. coli* strains, represented as follows: $O_{26}:H_{11}$(3.33%), $O_{111}:H_2$ (5.83%), $O_{44}:H_{18}$ (0.83%), $O_{55}:H_7$ (1.67%), O_{86} (0.83%), $O_{114}:H_{21}$ (0.83%), O_{124} (1.67%), $O_{125}:H_{21}$ (3.33%), $O_{127}:H_6$ (2.5%) and $O_{128}:H_2$ (0.83%). The antimicrobial activity of thyme (thymus vulgaris) EO against *E. coli* count (cfu/g) in the fresh minced beef were detected by using different concentrations of thyme EO. In our study, non-O157 *E. coli* serogroups may be also a cause of shiga-toxin producing *E. coli* (STEC) illness. Thyme EO has antibacterial activity against *E. coli* at 0.5% concentration. The thyme EO slightly positively affects the sensory quality attributes, such as color, odor, texture and overall acceptability of minced beef. So, thyme EO may help in improving the safety and sensory quality of minced beef. Advanced research may be needed to allow its practical application, and to determine the optimal concentration to overcome its intense aroma.

Keywords: *E. coli, thyme essential oils, beef, minced beef, prevalence.*

Introduction

Beef is the most common source for pathogenic *E. coli* (Andrews, 2014), which can be classified into enterotoxigenic (ETEC), enteropathogenic (EPEC), shiga-toxin producing *E. coli* (STEC) and entero-invasive (EIEC) pathotypes. ETEC causes gastroenteritis and diarrhea in humans specially infants in developed countries. EPEC specially in poor sanitation causes mild to severe diarrheal symptoms. STEC specially enterohemorrhagic *E. coli* (EHEC) can cause bloody diarrhea, blood-clotting problems, kidney failure, and death. EHEC strains have been traced also to ground meats, which usually begins as watery diarrhea, then progresses to mild dysentery -diarrhea that often contains blood and mucus (FDA, 2012).
Plant essential oils are gaining a wide interest in food industry, as their active components have a wide spectrum of antimicrobial activity, against food-borne pathogens and spoilage bacteria (Gutierrez et al., 2008, 2009). The antimicrobial activity of these oils is due to their chemical structure, as they contain hydrophilic functional groups, such as hydroxyl groups of phenolic components and/or lipophilicity of some essential oil components (Dorman and Deans, 2000). On the other hand, their use in food preservation remains limited mainly due to their intense aroma and toxicity problems. Several authors have reported changes in the organoleptic properties of the food when these oils are used. The use of combinations of

different food preservation methods could solve this problem. The ingestion of high doses of essential oils can induce serious toxicity problems. Thus, the balance between the effective compound dose and the risk of toxicity is necessary. Moreover, the use of essential oils remains expensive, so their use as preservatives needs further studies (Lucera et al., 2012). Thyme EO has high inhibitory activity, particularly against Gram-positive bacteria, rather than Gram-negative bacteria (Marino et al., 2001 and Skandamis et al., 2002). Thyme EO obtained by steam distillation of the fresh flowering aerial parts of Thymus vulgaris L., T. zygis Loefl. ex L. or a mixture of both species (Baser and Buchbauer, 2010). Thyme EO is stated to possess bactericidal properties. It is active against *E. coli* and spoilage flora in meat products. The antibacterial activities of thyme EO are mostly attributable to the phenolic compounds and to the hydrocarbons which can be bactericidal or bacteriostatic depending on their effective concentration (Rassooli et al., 2006; Kotan et al., 2010; Helmy, 2012 and Küçükbay et al., 2014). Therefore, the objectives of this study were to investigate prevalence of *E. coli* in raw retailed beef, and to evaluate the efficiency of thyme EO as antimicrobial agent against *E. coli* in raw minced beef. Also, enhancement of sensory characteristics of raw minced beef using thyme as essential oil.

Materials and Methods

Isolation and identification of E. coli: A total of 120 fresh blade steak samples of beef (250 gm of each) were collected, in the winter of 2015, from different butcher's shops in Cairo and Menoufia of Egypt. The samples were transferred quickly to the animal health research institute lab (Shebin El-Kom, Egypt) in an ice box under complete aseptic conditions without undue delay. Ten grams of the examined sample were homogenized in a Stomacher-Blender (Seward Medical, London, England) with 90 ml of sterile buffered peptone water (0.1%) for 2.5 minutes to provide a homogenate of 1/10 dilution, decimal serial dilutions were prepared. One ml of each previously prepared serial dilutions was inoculated into 3 sterile tubes of MacConkey broth with inverted Durham's tubes then incubated at 37°C for 48hours (ICMSF, 1982). A loopful of each positive tube (color changes and gas production) was streaked onto plates of EMB agar (Oxoid CM 69) and incubated at 37° C for 24 hours. Typical colonies (Greenish metallic with dark purple center) were picked up and transferred into nutrient agar slants and incubated at 37 °C for 24 hours, for further identification (FAO, 1992). Biochemical identification tests were performed as described by Koneman et al. (1994). Serological identification of *E. coli* isolates was carried out according to Varnam and Evans (1991).

Detection of antimicrobial activity of thyme essential oil against E. coli: The ready-made thyme oil (Thymus vulgaris) used in this study were purchased from El Captain company for extracting natural oils, plants and cosmetics, El Obour city - Cairo - Egypt. This oil was analytical reagent grade and stored in amber-colored bottles at 4°C until use. A total of 2.5 kg of the fresh minced beef meat were irradiated to eliminate natural microbial populations in Gamma irradiation unit, Egyptian atomic energy authority, Cairo, Egypt by Gamma irradiation using Indian Gamma Cell (Ge 4000 A, dose 5 kgy and dose rate 1.915 kgy/hr) (Huq et al., 2015).

E. coli reference strains were obtained from media unit, food hygiene department, animal health research institute, Dokki, Giza, Egypt. EMB Agar was supplied by Merck, Darmstadt, Germany for enumeration and identification of *E. coli*. Four to five isolated colonies of the tested strains were picked by sterile inoculating loop and inoculated in tubes of sterile peptone water 0.1% (5 ml in each) and were then incubated at 37°C/24 hrs. From this culture, dilutions up to 10^{-10} were plated on EMB agar to determine the cell concentration. *E. coli* cell

count was adjusted to 10^4 cfu/ml with tube dilution methods. The number of cfu/ml was considered as initial inoculum load to inoculate into fresh minced meat (Barbosa et al., 2009).
The irradiated minced beef was immediately prepared and was inoculated with *E. coli* (10^4 cfu/g), then mixed thoroughly by gently squeezing the bags by hand. It was subdivided into equal subgroups (100 g each). Essential oil of thyme (% v/g) was homogenized with the minced beef subgroups to achieve final concentrations of 0.5, 1 and 1.5% for oil. Phosphate buffer saline (PBS) was used for treatment of control (untreated) samples. The essential oil is mixed with the minced beef samples for a further 30 seconds to ensure even mixing. Each sample was packed in polyethylene bag, labeled and stored at 4°C (Jay, 1992 and Kantachote and Charernjiratrakul, 2008). Samples prepared according to ISO (1999). Sensory evaluation (color, odor and texture) according to Pearson and Tauber (1984) and *E. coli* were counted after 3 hours and 24 hrs intervals during storage at 4°C, using the serial dilutions and spread plate technique for each sample in a triplicate manner (ICMSF, 1996).
The results were analyzed Statistically according to the guidelines of Feldman et al. (2003).

Results and Discussion

Contaminated raw meat specially at the retail level is one of the main sources of food-borne illness (Bhandare et al., 2007). The presence of *E. coli* isolates on the meat surface will render the meat spoiled and unsafe to the consumer as they are encountered in causing food poisoning and they reflect the hygienic standard of the butchers' shops. Also *E. coli* serotypes isolated from meat constitute public hazard specially in cases of gastroenteritis, cystitis, pyelonephritis, peritonitis (Nossair et al, 2015). Our results show that 27 samples (22.5%) were found to be contaminated with *E. coli* strains, which classified into four serogroups as follows; EHEC as $O_{26}:H_{11}$(3.33%) and $O_{111}:H_2$ (5.83%), EPEC as $O_{44}:H_{18}$ (0.83%), $O_{55}:H_7$ (1.67%), O_{86} (0.83%) and $O_{114}:H_{21}$ (0.83%), EIEC as O_{124} (1.67%) and ETEC as $O_{125}:H_{21}$ (3.33%), $O_{127}:H_6$ (2.5%) and $O_{128}:H_2$ (0.83%). *E. coli* contamination may be attributed to bad eating habits, long food supply chain with increased movement and poor hygiene practices, poor hygiene and improper preparation practices in consumer homes as kitchen utensils (Erickson et al., 2015). The results differ from a study to a study based on the exposure of each study to sources of bacterial contamination. Moustafa (1993) isolated nearly the same isolates of *E. coli* but in a high ratio (34 %) of meat samples; the serotypes were O_{26} (4%), O_{55} (8%), O_{111} (6%), O_{119} (4%), O_{124} (2%) and untyped strains (10 %). Also, a higher percentage of *E. coli* were serologically identified from the examined beef samples by Edris et al. (2013) from Menoufia abattoirs, the serotypes were $O_{26}: K_{60}$ (15%), $O_{86}: K_{61}$ (15%), $O_{111}: K_{58}$ (25 %). Also, Iyer et al. (2013) stated higher incidence rates 65 % of *E. coli* in the small butcher shops in Jeddah market where serotypes were $O_{124}: K_{72}$ (5%), $O_{128}: K_{67}$ (10%), $O_{119}: K_{96}$ (5%), $O_{124}: K_{72}$ (5%) and untypable (5%). While lower results were obtained by Chapman et al. (2001) as 1.4% of beef samples were *E. coli* contaminated from butcher shops. Also *E. coli* was isolated in a lower ratio by Philips et al. (2001) who recovered 10.3% *E. coli* strains of 1275 examined beef carcasses and Iroha et al. (2010) who isolated 8% *E. coli* from raw beef samples collected from Abakaliki abattoir, Ebonyi state, Nigeria. All *E. coli* serotypes obtained in our study were non-O157 *E. coli* serotypes; Which in turn can be transferred to human and constituting a public health problem, as urinary tract infection, colecystitis or septicemia (Rahman and Kang, 2009). Recent studies indicate that non-O_{157} *E. coli* serogroups may be also a cause of STEC illness. Reports from countries that export beef to USA, indicated that non-O_{157} STEC are of primary importance elsewhere. Consequently, USA authorities are taking an increasing interest in non-O_{157} STEC, to begin testing foods for the presence of 5 serogroups (O_{26}, O_{45}, O_{103}, O_{111}, and O_{145}) (Alexander and Colin, 2010). Non-O_{157} STEC serotypes including O_{26}, O_{103}, O_{111}, O_{113} and O_{121} were also, commonly associated pathogenic (Acheson, 2000). E. *coli* O_{26} was the most frequent *non-*O_{157} STEC infections in USA between 1983 and 2002 (Brooks et al, 2005). *E. coli* O_{26} and O_{111} were an important cause of human infections in Europe and Korea (Su and Brandt, 1995). *E. coli* O_{111} serotypes were considered as STEC and EHEC types. *E. coli* O_{127} caused attachment and destruction lesions in the intestine without toxin production (Mossel et al, 1995). Regarding the sensory analysis, the thyme essential oil slightly positive affect the color, odor, texture and overall acceptability than control one. The general organoleptic characteristics (color, odor and texture) and overall acceptability of the meat in untreated minced beef samples(control) and thyme oil treated samples at 0.5%, 1% and 1.5% were good, very good, very good and very very good, respectively, after 3 hours; after 1day the results were fair, medium, good and very good, respectively; after 2days the results were poor, fair, medium and good, respectively; after 3days the results were very poor, poor, fair and medium, respectively; after 4 days, the results were very poor, very poor, poor and fair, respectively. The use of natural antibacterial compounds, such as extracts of plant essential oils is reported in the literature to improve the shelf life of meat (Jamilah et al., 2008; Jałosnska and Wilczak, 2009). Thyme EO has high inhibitory activity, particularly against gram-positive bacteria, rather than gram-negative bacteria (Marino et al., 2001). In respect of our current study, different concentrations of thyme EO on *E. coli* counts (CFU/g) artificially inoculated in minced beef samples (initial *E. coli* load at zero hr. = $7.9\times10^7 \pm 5.1 \times10^5$ CFU/g) was reported as following: the control samples counts were $1.6\times10^7 \pm 1.1\times10^6$ after 3 hrs, $3.1\times10^7 \pm 2.6\times10^5$ at 1st day, $3.4\times10^7\pm1.7\times10^7$ at 2nd day, $1\times10^8 \pm 7.2\times10^5$ at 3rd day, $1.3\times10^9 \pm 9.5\times10^6$ at 4th day, while the thyme oil treated 0.5% samples counts were $1.1\times10^4 \pm 8.5\times10^2$ after 3 hrs, $1.4\times10^3 \pm 8.7\times10^2$ at 1st day, $6.7\times10^2 \pm 1.2\times10^2$ at 2nd day, $5.1\times10^2 \pm 9.5\times10$ at 3rd day, $3.2\times10^2 \pm 1.9\times10$ at 4th day, the thyme oil treated 1% samples counts were $1\times10^5 \pm 1.3\times10^4$ after 3 hrs, $3.4\times10^4 \pm 2.6\times10^2$ at 1st day, $1.5\times10^4 \pm 7.9\times10^2$ at 2nd day, $1.7\times10^3 \pm 1.8\times10^3$ at 3rd day, $1.2\times10^3 \pm 8.9\times10^2$ at 4th day, finally the thyme oil treated 1.5% samples counts were $1.2\times10^6 \pm 1.1\times10^5$ after 3 hrs, $3.1\times10^5 \pm 1\times10^4$ at first day, $1.3\times10^5 \pm 4.5\times10^3$ at 2nd day, $3.3\times10^4 \pm 2.6\times10^3$ at 3rd day and not detected at 4th day. In conclusion, we found thyme EO had significantly inhibitory effect on *E. coli* growth of at 0.5% concentration. Thyme oil was from the most active essential oils against E. coli (with bacterial activity 50 values ranging from 0.057 to 0.28) (Friedman et al. 2002). Thyme is one of the most active essential oils against bacteria. Furthermore, addition of thyme oil at concentrations of 0.5 and 1% caused a significant reduction in microbial growth (Lucera et al. 2012).

Conclusion

In conclusion, our study showed that serogroups other than O157:H7 may be a significant source of human illnesses in Egypt. Certain serogroups have a higher association than others with illness in humans as O_{26}, O_{111}, O_{44}, O_{55}, O_{86}, O_{114}, O_{124} O_{125}, O_{127}, and O_{128}. But food contamination may be better controlled using natural preservatives. This study showed that thyme EO possess an antibacterial activity against E. coli at 0.5% concentration. It can be concluded that the thyme EO slightly positive affect the sensory acceptability of minced beef. Accordingly, thyme EO may be added to meat to prevent food borne pathogens and to extend shelf-life.

A DATE PALM DISEASE CAUSED BY *ACREMONIUM STRICTUM (CEPHALOSPORIUM)* IN SAUDI ARABIA

Mohammad Fawzy RASHED

Agric. Res. Cen. Plant pathology research institute- Fruits and Woody Trees Dept. Giza Egypt
*Corresponding author: dmfawzy@windowslive.com

Abstract

Acrimonium strictum is reported as a new causal agent of a disease in date palm (*Phoenix dactylefera*) in Saudi Arabia. A study was carried out in Awqaf Al Rajhi Date Palm Research Center- Plant Disease Department – Al Kharj- Al Riyadh Saudi Arabia to assess the pathogenicity caused by *A. strictum* in our date palm. Symptoms and necrosis caused by *A. strictum* in susceptible cultivars showed small brown necrosis streak at midrib of fruit stalk in an early stage. There was increase in number and size as the disease progresses; then extended to the bases of fruit strands due to death of bases and strands wilt, the infection of fruit strand caused drying the fruits and their fall. *A. strictum* attacks the bunches and move quickly inside and out the tissues causing brown necrosis and death of the tissues. The isolation and pathogenicity tests were made two times between 2015 - 2016 in both and identification of the pathogen was done by classic method in Plant pathology research institute, Fungi department. The confirmation of results by Biolog technique and DNA sequence were done. Proper temperature for infection was between 20 -30 ° C and the optimum 25° C. When testing the susceptibility of varieties of infection, more varieties like Medjool, Saqae and Kholas were susceptible to infection and the most resistant to infection were Barhy and Khidri. The best results in the control of the fungus *in vitro* were due to use of Karpendazem followed Topsen $M_{70,}$ at the same time, the worst results were seen with the use of Abredion follwed Karant (Cupper hydroxide).

Keywords: *Acrimonium, date palm, Fruit stalk, Fruit strand, Bunch, Biolog, DNA*

Introduction

Date palm (*Phoenix Dactylefera* L.) is a very important tree in the Arab world and Saudi Arabia is not an exception but it is more important with the great variation of varieties . It is known that the recorded diseases of date palms such as Bayoud caused by *Fusarium oxysporum f.sp. albedinis* , black scorch caused by *Thielaviopsis paradoxa* , diplodia disease caused by *deplodia phoenicum* and *Botryodiplodia theopromae* (Barakat, F.M. *et al*1992). Inflorescence decay caused by *Mauginiella scaettae* , *Thielaviopsis paradoxa* and *Fusarium moniloforme then Graphiola* leaf spot caused by *Graphiola phoenicis* (Djerby M 1981 , Alzyat 2002.) Date palm is affected by all diseases that affect the growth and the productivity. A new disease (bunch blight) which affect the crop directly because it causes the welt of the fruit strands. The symptoms scored for the first time by Al Meleigi 2004 in Saudi Arabia, but the record that causes *Fusarium moniliforme* , reported Rashid and Abdul Hafeez 2001 infection of bunches, fruit stalks and fruit strands with *Fusarium moniliforme*. Yuvol Cohen 2010 recorded that the cause of fall of fruits and bunch blight with *Fusarium Proliferatum.* Benkee Thiyam and Sharma (2013) reported that *Fusarium moniliforme* causes falling of fruit in the date palm. *Acremonium strictum* is pathogenic to many monocotyledonous and dicotyledonous crops, causing leaf desiccation on one side of the midrib of these plants, plant wilt and abnormal, discoloured vasculature of the stalk near the soil line. Vasculature of the plant forms orange, red and brown bundles, usually resulting in death. Infection of *A. strictum* is systemic, and the fungus can be isolated from all tissues of the plant. Isolates have been found in plant seeds, which is probably the route of dissemination of the fungus and the crops affected by *A.strictum* include *Acacia*, *Ficus*, Glycine *Gossypium*, *Triticum* and *Zea*. Because of its ubiquitous presence in soils, *A. strictum* negatively impacts many agricultural plants.

Materials and Methods

Area of study: This study was conducted during the period from February 2015 to June 2016 in Al Kharj province. It consisted of 20 date palm field in Al Kharj and Al Qaseem. The total number of date palm trees was estimated to be around 230000 trees with the total area about 1500 ha and production of about 5000 tons.

Isolation and identification: Samples of affected tissues of symptomatic trees represents fruit stalks and strands of infected trees collected from Al Kharj and Al Qaseem province and kept in plastic bags and transferred to laboratory(in Al Kharj) for investigation. Individually samples were cut into small pieces 0.5 cm, surface sterilized for 2 min in a Sodium Hypochlorite solution (1.5%), washed twice with sterile distilled water and placed on Potato Dextrose Agar (PDA) and incubated for 3-7 days at 26°C. Emerged colonies from the tissue pieces were transferred to PDA and incubated at 26°C for 7 days. The single spore was transferred to a PDA slants and stored at 4°C for further studies. Colonies were described according to morphological characteristics. Specific keys and references are used to identify the fungi to the genus level (according to the taxonomic systems of Ellis (1971), Barnett and Hunter (1972), Nelson *et al*. (1983) and Paulin-Mahady *et al*. (2002). Isolates well be deposited in the ARC PPRI Fungi Lab. 25/8/2015 and GSFMO, KSA for further identification using Biolog technique (Singh, 2009) and DNA sequence (Pryce et *al.,* 2003).

Biolog and Molecular Identification: Filamentous fungi are known to have unique biochemical pathways. The Biolog FF Microplate was recently introduced for rapid identification of common filamentous fungi based on their abilities to utilize 95 discrete substrates. The substrate utilization fingerprints were useful in selecting media components for media optimization of secondary metabolite production for the various cultures. In general, a strong correlation was found among substrate utilization, growth, antimicrobial activity and presence of the responsible secondary metabolites. The method was used for replication of isolated fungi and in the differentiation of closely related variants within one species. The isolates were grown on 2% malt agar for 5 days and then processed according to Singh (2009).The identification was confirmed by molecular tool. DNA sequence-based approach for the accurate and timely identification of fungi by sequencing polymerase chain reaction (PCR) products with a rapid automated capillary electrophoresis system. A simple DNA extraction method and PCR amplification using universal fungal primers was used to amplify ribosome DNA from a range of isolates and reference strains. The internal transcribed spacer (ITS) DNA region was sequenced using automated dye termination sequencing. This identification was conducted according to Pryce *et al,* 2003.

Evaluate the pathogenic capability: Pathogenicity tests were conducted in vitro on healthy detached samples representing different parts of date palm (fruit stalks). Healthy cuttings 25 cm long of the middle part of fruit stalks of Kholas cultivar were surface sterilized with 70% ethyl alcohol. The desired fungus well grows on PDA medium in Petri dishes for seven days at 28°C. For inoculation, pieces of the desired fungal growth were inserted into artificially made wounds (5 mm long x 3 mm deep) made at the center of fruit stalks cuttings. Proper controls were also prepared using PDA agar plug without pathogen. Three replicate were used for each treatment. All inoculated cutting of fruit stalks were kept in plastic boxes supplemented with wet cotton at room temperature according to the methods described by Molan *et al*., (2004) and Barakat *et al* .,(1992). The size of damaged affected tissues around the point of inoculation was measured (mm) 10 days after inoculations as follow: width *long= area of lesion mm.(means of three replicates for each treatment)

Effect of temperature: The pathogenicity tests were done in the effect of temperature, but the inoculated parts were incubated at different temperatures such as 17, 20, 25, 30 and 35 C^o, (3 replicates for each temperature degree), the results were obtained after 15 days of incubation.

Varieties susceptibility: Pathogenicity tests were carried out on several cultivars such as Barhi, Kholas, Saqaey, Medjool and Khadri. They were incubated at 25C^o. The results were taken after 15 days of incubation. The results were calculated by measuring the area of the spot caused by the fungus. .(means of three replicates for each treatment)

In-vitro* evaluation of different fungicides against *Acremonium Strictum

The efficacy of non-systemic fungicides and systemic fungicides against *Acrimonium strictum* were assessed by poisoned food technique (Sharvelle, 1961). Required quantities of individual fungicides based on active ingredients (a.i.) were added separately into potato dextrose agar (PDA) to get the desired concentration of the fungicides. Later 25 mL of the poisoned medium was poured into sterile Petri plates. Mycelial discs of five mm size from actively growing culture of the fungus were cut out by a sterile cork borer and one such disc was placed at the center of each PDA plate. Control was maintained without adding any fungicides to the medium. Each treatment was replicated thrice. Then plates were incubated at 26±1C^o for nine days and radial colony growth was measured. The efficacy of a fungicide was expressed as percent inhibition of mycelia growth over control that was calculated by using the formula given by Vincent (1947). The percent values were converted to arc sin transformations, the data were analyzed statistically.

$I = \frac{(C-T)}{C} \times 100$ I= Percent inhibition

C= Radial growth in control (mm)
T= Radial growth in treatment

Four fungicides used in this trial as follow:

Trade name of fungicides	Commen name of fungicides
Topsin M70	**Thiophanatmethyl 70%**
Carbandazim	**Carbandazim 50%**
Corval	**Abredion 50%**
Carant	**Cupper hydroxide77%**

Concentrations/ppm (10,30,50,100) for each fungicide.

Results and Discussion

Orchard Symptoms

As shown in Figure 1- 1, 2 and 5 the parasite attacks fruit stalks causing elongated brown color   and then extends longitudinally and internally causing necrosis of tissues and the parasite attacks   the bases of fruit strands (Figure 1- 3 and 6) causing brown necrosis then deterioration leads to the death of the tissues and drying of fruit strands and fruits (Figs.1- 4 and 6)

Figure 2

.

Pathogenicity test:

.10 (control)

11 (treated)

.12 (treated)

13 (treated)

Figure 3.

Fig.3-10 non inoculated ,there is no symptoms, while in Fig.3-11, 12 inoculated with fungus, the symptoms were clear after 15 days of inoculum. In the same time in Fig.3-13 The result obtained after 25 days, there was a development of infection and the symptoms included fruit stalk and fruit strand completely. Re-isolated from a distance of 25 centimeters from the place of the first inoculum was conducted

Effect of temperature:

Table (1) area of lesion after 15 days of inoculated of fungus and incubated under different temperatures

Temperatures	17C^o	20 C^o	25C^o	30 C^o	35 C^o
Area of lesion mm.	50	90	140	130	60

From Table 1 it is clear that the infection spread in a wide moderate temperature range, which is the time of the differentiation of fruit stalk and the emergence of flowers and the holding of fruits of date palm during February, March and April in Saudi Arabia, which means that the activity of the pathogen coincides with the activity of flowering, pollination and fruit.

Varietal susceptibility:

Table (2) area of lesion after 15 days of inoculated of pathogen in different of date palm cultivars and incubated under 26 C^o .

Cultivars	Barhi	Kholas	Saqaey	Medjool	Khidry
Area of lesion mm.	25	125	150	180	25

Figure 4.

It is clear from the results that the most sensitive cultivars of infection was Medjool Fig.4-17 and followed by Saqaey Fig.16 and Kholas Fig.4-15 while the least sensitive was Barhi Fig.4-14 and Khidry Fig.4-18 cultivars . *A. strictum* has been shown to be involved in some myoparasitic relationships, as well as a wide range of plant endophytic and parasitic relationships(Rivera-Varas, *et al.,* 2007) and further studies are required to determine A. strictum's use as a biological control agent and role as a parasite that reduces crop yields. A. strictum exhibits metabolism of many products that imply future agricultural and pharmaceutical significance (Chen, *et a.,l* 2008 and Chang, Jianing *et al.,* 2013)

Disease Control (*In vitro* studies)

Table (3)Evaluation of different fungicides against *Acremonium Strictum*:

Means of linear growth of *A. strictum* (mm.)

	Fungicides(A)			
Concentrates(B)	Carbendazim	TopsinM$_{70}$	Corval	Carant
10ppm	7.0	12.0	29.5	80.0
30 ppm	7.0	10.5	35.3	80.0
50 ppm	7.0	7.7	32.3	80.0
100 ppm	7.0	7.0	31.8	75.0

LCD 5% (A) = 1.120 (B) = 1.120 (A) × (B) = 2.240

It is clear from Table 3 that the highest inhibitory of fungus was with Karpendzim followed by Tobsen(thiphanatmethyl) and that the least inhibitory was with the Carant (copper hydroxide) pesticide and this is consistent with Rashid *et al.*, (2007) and Rashed (2014) in the treatment of palm diseases systemic pesticides, especially Tobsen and Carbendezim.

Conclusion

The purpose of this research is to identify the new causative agent ((Acremonium strictum (is recorded for the first time on date palms). Experiments on the conditions of the infection and their economic effects on the date palm crop have been defined and tested. The susceptibility of the infected varieties was studied. Medjool variety was the most susceptibility to the infection, while the Khidry variety was the least susceptible to infection. The recommended of the control of this disease are doing with the control of the inflorescence decay with the same pesticides(Carbendazim good affective) and the same time because it is associated with the appearance of spathes of inflorescence date.

MASS PRODUCTION OF THE FACULTATIVE PARASITIC MITE, *AEGYPTUS RHYNCHOPHORUS*, AS A NATURAL ENEMY AGAINST THE RED PALM WEEVIL IN EGYPT

Sally Farouk ALLAM[1], Ahmed Rabie EL-BADAWY[2]

[1]Department of Zoology and Agricultural Nematology, Faculty of Agriculture, Cairo University, Egypt
[2]Plant Protection program, Faculty of Agriculture, Cairo University, Egypt
*Corresponding author: sallyfmallam@gmail.com

Abstract

The present investigation studies mass production of the facultative parasitic mite, *Aegyptus rhynchophorus,* on sugar cane inoculated with fungi *Memnoniella* spp. And artifice culture from *Memnoniella* spp. Only as bio control agents against the red palm weevil in Egypt. *Aegyptus rhynchophorus* ectoparasite on pupae results in deformed adults of the red palm weevil, thus reducing damage to palms caused by the red palm weevil .A new method of mass production of facultative parasitic mites is easy for Egyptian farmers to apply. *Agyptus rynchophorus* (Family: Trachyuropodidae) was propagated on sugar cane inoculated with fungi and with cultures from fungi only. The aim was to determine the level of success of mass production of *Agyptus rynchophorus.* The duration of tray was 30 days, and the unit was one tray. Every unit has five pieces from sugar cane and unit from fungi was one petri-dish from PDA. The number of parasites increased two fold with sugar cane inoculated with fungi and the culture from fungi only. The researchers determined biological aspects such as life cycle, type of progeny, number of deposited eggs, oviposition period, pre-oviposition period, fecundity, incubation period and behavior. The results was promise in propagative of mite .the life cycle ranged from 13-15days in female, 9-16 in male, type of progeny five females per one male in one fold on culture of fungi and number of deposited eggs ranged from 30 to64 in one fold on sugar cane and culture of fungi only respectively.

Key words*: Red palm weevil (R.P.W), Aegyptus rhynchophorus, Rhynchophorus ferrugineus, mass production, biological aspects.*

Introduction

The red palm weevil (RPW), *Rhynchophorus ferrugineus* Olivier (Coleoptera: Curculionidae) is an economically importance invasive tissue borer that has host range restricted to palm trees, mostly young trees less than 20 years old, where the stem of the young palm is soft and juicy and easily penetrated (Eppo, 2008; Salama *et al.*, 2009; El-Mergawy and Al-Ajlan,(2011).There are varying degree of bio relationships between mites and other invertebrates. The most interesting and best known being the association of mites with insects, these relationships could be either predacious, parasitism or phoresy .The relationships of predacious and parasitism play an important role in the biological control of insect pests by suppressing their population where certain predatory and parasitic mites are well known to be capable of regulation. Members of several mite families attack Coleoptera insects. Biodiversity of mites associated with the red palm weevil *R. ferrugineus*is varying degrees of bio-relationship between each of the associated, ecto, endoparasitic, predaceous, phoretic and fungivorus mites.Studies on some mites associated with the red palm weevil have been reported by Gomaa, 2006 who isolated three mites pecies associated with (RPW). El-Bishlawy and Allam(2007) recorded new genus and new species, *A. rhynchophorus*

(Trachyuropodidae) associated with pupae and adults of RPW. Abde-El-Hamed (2009) recorded another species *Aegyptus zaheri* with differ stages of RPW in Egypt. Al-Dhafar and Al-Qahtani (2012) recorded three mite species associated with RPW, one of these *Aegyptus alhessa* n. sp. (Gamasida, Trachyuropodidae) as a parasite on eggs, pupae, cocoons and adults of RPW. Mazza. *et al*. (2014) reviewed the natural enemies of Rhynchophorus species in both their native and introduced regions of the world, to assess the possibility of biological control of this taxon. Its natural enemies in the Mediterranean region, because the impact of this pest in this recently colonized area is particularly remarkable and also the recent trend in species management is looking for indigenous natural enemies. The present study aims to mass production of *Aegyptus rhynchophorus* on sugar cane pieces inoculated with *Memnoniella* spp. And culture from *Memnoniella* spp. on PDA media for utilization of the facultative mite as bio control agent against red palm weevil. Biological aspects were studied under temperature at 25℃ ±2 and70% RH and dark light.

Materials and Methods

Collect red palm weevil

Last instar larvae,pupae adults and materials from their habitats of *Rhynchophorus ferrugineus* were collected, using a hatchet, from the trunk of the infested palm trees in Ismailia governorate, Egypt during spring, summer and fall through the years of 2016 and 2017. Adults and immature stages of *R. ferruginus*, in addition to materials from their habitats, were transferred to the laboratory of Acarology of the Faculty of Agriculture, Cairo University.

Extraction of mite

From red palm weevil: insects were carefully examined individually by using the dissecting microscope, then the detected mites were removed gently with a fine brush or needle from different parts of the insect cadavers via spiracular plats, under elytra, wing axillaries, antennal bases, coxacal cavity, the thorax region, abdomen and inner elytra. The pupae cocoons were ruptured searching for the mites on the pupae surface.

From insect habitat: Each sample was mixed carefully and put in petri-dishes were examined by using the dissecting microscope.

Identification and Description.

Identification and description of mites were based mainly on those given by El-Bishlawi and Allam (2007-2010).

Source of food

The types of food used in the present study. A piece of sugar cane inoculated with *Memnoniella s*pp. cultures from fungi only (petri dish with media PDA for growth fungi).

Mass production unit: mass production culture pieces of sugarcane inoculated with fungi were put in plastic unit (43 cm in length, 25 cm in width and 9 cm height); fungi were cultured in a petri dish (9 cm diameter and 1.5 cm height), each unit was put in incubator at 25 ℃ ±2.

Experimental procedure: After preliminary tests we noticed that mites can live for 30 days on a piece of sugarcane, after cutting of a linear break, maintained in incubator at 25℃ and 70% humidity. Therefore, we put five pieces of sugarcane, on every piece put five male and five female from one species of mite and recorded the data every day. Typically it will take place in a closed environment such as incubator in laboratory and growth room when mass production by farmers *A. rhynchophorus* must be situated to a warm, dark and humid climate. Each piece of sugarcane examined and determined the stage of mites, behaviour, and numbers of mites in fold on one cm in all units. Biological phenomena were observed on one female and male such as Incubation period - Larval stage - protonymphal stage - Dutonymphal stage - Total immature stage - Life cycle - preoviposition - Oviposition - Fecundity – sex ration.

These phenomena were very important to know how try the mass rearing to mass production in these mites that can be used by Egyptian farmers.

Procedure of SEM study: the live specimens from mite and fungi were cleaned in several baths of distilled water to remove the debris from observation under the scanning electron microscope.They were then briefly submerged in distilled water near boiling point in order to force extension of appendages. Specimens were then fixed in 3.5% concentration of glutaraldhyde for 6 hours, dehydrated in ethyl alcohol, dried using the critical point procedure, individually affixed to stubs using double-sided sticky tape, and sputter coated with gold-palladium. Microscopy was performed with a JEOL GM 4200) microscope. Scanning electron micrographs of the mites and fungi are presented. Shams El-Dean *et al*. (1989).

Statistical analysis: T-test was applied in all data at possibility (0.05 and 0.01) SD was obtained for all data.

Results and Discussion

Large number of *A. rhynchophorus* from female and male produce from one fold in (1 cm^2) was mean 3.60 (female or male with sex ration) on sugar cane (Table 2) on the other hand was mean 4.2 on culture fungi only. The daily rate number of eggs was 2.375–2.86 on sugar cane inoculated with fungi and fungi only respectively (Table 1). Life cycle in one fold was respectively 14.87–13.72 days on sugar cane inoculated with fungi and fungi only. Sex ratio was respectively 4:3–15:4 female to male on sugarcane inoculated with fungi and fungi only. Our life cycle in one fold was shorter than results by Allam *et al*. (2014) they found that the duration of life cycle of *A. rhynchophorus* were 22 and 21.1 days for female and 21.7 and 19.8 days for male when reared on pupae and sugar cane respectively

They also reported that the duration of life cycle in affected by type of applied diet our results agree with their opinion also Allam *et al*. (2014) determined daily rate was 0.9 eggs when the female was fed on pupae of R.P.W and also on sugar cane at 25 °C and 70% R.H

Some biological studies

When the mite propagated on sugarcane inoculated with fungi and culture of fungi only respectively at 25℃ (Table 1), the incubation period recorded was 4 and 2 days, the larval stage 3.8 and 3.5 days, the protonymphal stage 3.5 and 3.75 days, the deutonymphal stage average 4 and 6 days. The total immature stages were long 11.33 and 12.55 days, the preoviposition period lasted for 4.5 and 2 days) ,the oviposition periods were (18 and 16 days). The shorter periods in comparison to sugar cane inoculated with fungi may be due to carbohydrates in sugar cane more than in (PDA) media.

Behaviour

Mites aggression beside and inside colonies of fungi (Fig. 1B). Sugar cane pieces must be always humid for long period to growth inoculated fungi. Drying in sugar cane pieces effect on growth fungi and mite. When we started folds in trays by young female the production of mites were better than started by mother female. Although number of eggs in sugar cane were larger than on culture of fungi only but the number of progeny that complete life cycle on culture of fungi only were (95%) larger than on sugar cane. These results supported the finding of Sobhi (2006) and Abdelhamed (2009), who found that uropodid mites *Agyptus* spp. affected significantly on some biological activities of red palm weevil .when the uropodid (parasitoid) mite released on the pupae stage of the red palm weevil induced malformation in the pupae as well as increasing adults malformation up to 50% compared to 3.3% in control. Also El-Beshlawi and Allam (2007) found that when *A. rhynchophorus* was put with red palm weevil pupae it caused deformation in wings, and death when found in great numbers (500-1000 mite per insect stage).

Table (1): Duration of development stage (in days) and fecundity of *Aegyptus rynchophorus* (Trachyuropodidae) propagated on sugarcane inoculated with *memnoniella* spp. *and* culture from fungi only *memnoniella* spp.At 25℃ ±2

Conclusion

Very large quantities of parasitic mites can be produced with a relatively low laboratory investment. Open rearing systems production was continuous, low stress levels during collection, better environmental control. *A. rhynchophorus* is a facultative parasite that may be propagated on other media except pupae of R.P.W. This feeding behavior lead to easy mass production and application on date palm. The feeding behavior, biotic and abiotic factors on the mass production of *A. rhynchophorus* leads to promising bio control agent against R.P.W on date palm especially in Arab countries. On the other hand mass production mostly needs practical persons-and pure cultures from mites and fungi, the contamination with other fungi and other mite especially Acarid mites may happen. Mass production lead to existing closed developed methods that can be scaled up for quantities from parasitic mites. We confirmed the successes of mass production of facultative parasite mite with 25 °C, 70% relative humidity and dark light to provide biological control of Red Palm Weevil stages. These data support promising alternative in integrated pest management programs. Previous results lead to this facultative parasite can survive and produce other parasites that can be used in controlling pupae of R.P.W. Density on sugar cane pieces it is important if we apply by using sugar cane pieces as carrier with mites

Future studies

Comparison between two or three ways of application with *A. rhynchophorus.* This facultative parasite would be needed in Bio control programs

Abstract

Quinoa is a very promising crop in Egypt, especially in new reclaimed or poor salty soil areas where many other crops cannot be cultivated. The present work was designed to illustrate different biological and chemical changes may be occurred during storage periods in quinoa seeds. Three different quinoa lines seed were stored for zero, 1, 2, 3 and 4 years. Stored seeds, for different periods, were used to determine viability, water content and fungal population on seeds. Chemical analysis for nutrient components i.e. carbohydrates, fats and proteins were determined. Special attention was paid to aflatoxin content in stored quinoa seeds. Aflatoxin was determined in stored seeds under low and high relative humidity (RH) conditions. Aflatoxin was also determined in whole seeds, peeled seeds (without saponin) and in bran obtained after peeling seeds (with high content of saponin) to illustrate different factors lead to aflatoxin accumulation in stored seeds. Obtained data showed that percentage of water in seeds and germination were reduced by increasing storage period. Fats and proteins were also reduced by increasing storage period whereas slight increase was noticed in carbohydrates. Saponin was drastically reduced by increasing storage period. Fungal population was increased by increasing storage period. No or very low traces of aflatoxin B1 were detected in whole quinoa seeds, peeled seeds or bran of quinoa seeds, when these materials were stored at low RH (30- 37%). When whole quinoa seeds were stored at high RH (65 – 72%) all aflatoxin types were detected in considerable high values.

Keywords: *Quinoa, Storage, Saponin, Aflatoxin, Chemical changes*.

Introduction

In country like Egypt where the population is very high and the cultivated area is very limited, crop like quinoa (*Chenopodium quinoa* Willd.) can play an important role in food supply. This because quinoa can be cultivated, and give considerable yield, in new reclaimed poor sandy soil with saline water (Rasmussen *et al*. 2003, El-Assiuty *et al.,* 2014, Abd El-Moity *et al.,* 2015 and Yazar *et al.*, 2015). Quinoa is considered as a good source for essential amino acids especially lysin (Bhargava *et al.* 2006 and Stikic *et al.*, 2012).Storage of quinoa seeds (pseudo cereal) for different period may affect seed quality.

Many investigators studied effect of storage, for relatively short period, on seed viability (Parsons, 2012 and Souza *et al.* 2016). Investigators also studied the changes occurred in protein and fats contents (Castellion *et al.,* 2010 and Shaban, 2013). According to available literature, no studies were done on relation between storage period, percentage of RH, fungal population and aflatoxin content.

The present work studied changes may be occurred in quinoa seeds, during storage periods up to four years. Viability of seeds expressed as percentage of germination, was assessed. Changes in nutrient components i.e. carbohydrates, fats, and proteins were also studied. Special attention was paid to aflatoxin content in quinoa seeds either as whole seed, seeds

without saponin (peeled seeds) or bran resulted after mechanical remove of outer layer. Quinoa seed also tested for aflatoxin under low RH or high RH conditions. Aflatoxin content also correlated with changes in saponin content in seeds and fungal population on seeds.
The aim of this work is to figure out proper storage period of quinoa seeds (propagation material) also to study changes occurred in seeds regarding nutrition value. Aflatoxin contents and factors lead to increase or inhibit toxin production were also considered.

Material and Methods

Three quinoa lines (Code: Q19, Q26 and Q31) were kindly obtained from FAO in 2013 among many other lines. During 2013, lines were propagated and selected according to suitability to Egyptian conditions. Samples of the selected three lines, 10 kg of each, were packed in paper bags and stored under room conditions (25- 30°C and 30- 37 RH) for 0, 1, 2, 3 and 4 years. At the end of storage periods samples of each batch were taken and used to determine the following parameters.

1 - Viability of seeds (percentage of germination)

Twenty quinoa seeds were placed in clean Petri dish, each contain 2 filter papers supplemented with 25 ml of water. Five plates (100 seeds) were used for each treatment. All plates were kept under room temperature (25- 30°C). Percentage of germinated seeds was recorded after 24, 48 and 72 hours. The final percentage of germination was calculated using the following formula:

$$\text{\% of seed germination} = \frac{\text{No. of germinated seeds X100}}{100}$$

2 - Water content of seed

Samples of different quinoa seeds (100 gm), stored for different periods, were placed in aluminum foil. Aluminum foil with seeds were kept in oven at 70 °C for 24 hour and then transferred to oven 105°C till complete dryness and then percentage of water content was calculated.

3 - Nutrient content, carbohydrate, fats and protein

Samples of different quinoa lines, stored for different periods, were used to determine percentages of fats, using methods developed by AOCS Official Procedure (2005).
Protein was determined as described by AOAC International (1980) whereas carbohydrates were calculated according to Mayer *et al.*, (2007).

4 - Fungal population

One gram of different quinoa varieties seeds, stored for different periods, were added to a flask contained 9 ml or 99ml sterilized distilled water to prepare 1:10 and1:100 dilutions, respectively. Flasks with water and quinoa seeds were shaken on electric shaker for 1 hour. One ml of each dilution was poured in sterilized Petri plate; contain 10ml of milted warm (45°C) Rose Bengal medium (Johnson *et al*., 1960) to isolate fungi. Three plates were used for each treatment. All plates were incubated at 25°C. After 5 days plates contain Rose Bengal were examined. Developed fungal colonies were purified and examined according to colony characteristics and morphology of the mycelia and spores using light microscope, to identify types of developed fungi. *Aspergillus* spp. were identified using key developed by Raper and Fennell (1965). Whereas *Penicillium* spp. were identified according to Raper and Thom (1949). *Alternaria solani* was identified as described by Krishnapa and Shetty (1990).

5 - Aflatoxins studies:

5- a-Effect of storage period, saponin layer, fungal population under low RH on aflatoxin content in stored quinoa seeds

Samples of quinoa seeds stored for different periods; *i.e* zero, 1, 2, 3, and 4 years under room conditions (25 - 30°C) and (30- 37% RH); were used to determine aflatoxin B1, B2, G1 and

G2 content in different samples using HPLC (High pressure liquid chromatography), AOAC official methods, (2000) ch., 49 (Modified). Saponin, in different quinoa lines, stored for different periods was also determined to correlate storage period with saponin content and aflatoxin production under low RH conditions. Saponin was determined using method mentioned by Obdoni and Ochuko (2001).To illustrate role of saponin in aflatoxin production whole seed, peeled seeds (without saponin) quinoa bran (contain high amount of saponin) were stored at room conditions (25 - 30°C and 30- 37% RH) for 3 months. Stored ingredients (whole seeds, peeled seeds and quinoa bran) were used to determine aflatoxin contents using the previously mentioned method.

5-b-Role of high RH on aflatoxin production on quinoa seed in relation to fungal population and saponin content.

Samples of all quinoa lines, stored for different storage period, were taken and kept under (25 - 30 °C and 65- 72% RH) for one month. Aflatoxin in ppb was determined, to illustrate role of RH in toxin production. Percentages of saponin and fungal population were also determined to correlate production of different types of aflatoxins (B1, B2, G1 and G2) with these two factors under high RH condition.

Results and Discussion

Length of storage period in addition to storage conditions play important role in viability and chemical content of storage quinoa seeds. Data in Table (1) indicate that when pseudo cereal of quinoa were stored under low RH and 25-30°C for one year all tested quinoa lines showed high germination percentage ranged from 99% in case of line Q31 to 92% in case of Q26. After two years storage, different quinoa lines seed varied in percentage of germination. Percentage of germination was drastically reduced in line Q19 and only 35% was recorded whereas the other two lines showed 83% for line Q31 and 90% for line Q19. When quinoa seeds were stored for three or four years absolutely no germination was noticed in all tested quinoa lines. When percentage of water content in seeds reached 9.7% or less no germination was noticed in any of tested quinoa seeds, these results support finding of Gurses *et al.*, (2001). The cause of seed deterioration and loss of viability is a complex process (Begum *et al.* 2014). Water content, catalase, peroxidase and lipase were recorded as active factors in seed ageing. In present work water content was significantly reduced also percentage of fates was drastically reduced in non-viable seeds which means increase lipase. These results confirm work of Begum *et al.* (2014) who correlate ageing of seeds by increasing lipase percent.

Table (1): Correlation between water content in quinoa seeds, storage period and percentage of germination

Quinoa lines	Storage period in years	%Water content	Percentage of germination
Q31	0	11.2	99.0
	1	10.3	99.0
	2	9.7	83.0
	3	9.3	00.0
	4	9.2	00.0
Q26	0	11.0	99.0
	1	10.9	92.0
	2	9.9	90.0
	3	9.3	00.0
	4	9.1	00.0
Q19	0	11.1	99.0
	1	10.3	93.0

	2	9.8	35.0
	3	9.2	00.0
	4	9.0	00.0

Effects of storage period on nutrient contents in quinoa seeds were also studied. Data in Table (2) clearly indicate that positive correlations between length of storage period and percentage of losses in protein and fats, in all tested quinoa seeds, were detected. This is in harmony with work of Cakmak *et al.* (2009) who confirm this information. Reduction in protein and fats also can be due to respiration activities which consume some of these stored materials as source of energy. Different quinoa lines varied in percentage of losses in protein. Line Q26 and Q19 were the most stable ones and only 1.8 and 1.2 % reduction in protein content were noticed after one year storage compare with 9.2 reduction in Q31. After 4 years storage, slight differences in protein losses were detected among the three quinoa lines under test. Fats show very slight reduction during the first storage year whereas great significant reduction in percentage of fats were detected after 4 years storage and percentage of reduction reached 43.6% in quinoa Q31compare with 35.5 and 35.7% in Q26 and Q19, respectively. This may be due to that fats are used as a main source for energy Stefanello *et al.*, (2015). On the contrary, percentage of carbohydrates was increased in all quinoa lines. Percentage of increase was positively correlated with length of storage period. This confirms work of Olayinka *et al*. (2016).

Table (2): Effect of storage period on nutrient content in quinoa seeds

Quinoa lines	Storage period in years	Carbohydrate		Fats		Protein	
		%	% increase	%	% reduction	%	% reduction
Q31	0	57.3	0.0	9.4	0.0	17.4	0.0
	1	59.6	4.0	9.2	2.1	15.8	9.2

	1	59.3	3.0	8.2	2.4	16.4	1.2
	2	62.3	8.2	6.7	20.4	15.7	5.4
	3	64.2	11.5	6.3	25.0	14.8	10.8
	4	68.5	19.5	5.4	35.7	13.1	21.1

To figure out role of saponin, fungal population and RH on aflatoxin production this experiment was carried out. Data in Table (3) show that absolutely no aflatoxin was detected when whole quinoa seeds (surrounded with layer of saponin) were stored for zero to 4 years at low RH (30- 37%) in presence of *Aspergillus* spp. and *Penicillium* spp. When saponin was removed and peeled seeds were stored at low RH (30- 37%) for 3 months a few traces of aflatoxin B1 were detected on peeled seeds and also on the quinoa bran (Mixture of saponin, proteins and carbohydrates). This means that RH and presence of saponin as a solid barrier layer surrounding quinoa seeds play the most important factors in aflatoxin production. At removal of this solid saponin few traces (0.8 ppb on peeled seeds and 0.7ppb on quinoa bran) were detected even in presence of low RH. These results are in harmony with work of Soetan *et al*. (2006), who state that saponin acts as antimicrobial factor.

Table (3): Relation between saponin cover, fungal population and aflatoxin content

Treatment	% Protein	Aflatoxin (ppb)				fungi* (c.f.u./gm)
		B1	B2	G1	G2	
Quinoa seeds (all lines) stored for 0-4 years	15.9-13.1	0.0	0.0	0.0	0.0	100-1400
Peeled seeds	4.5	0.8	0.0	0.0	0.0	100
Quinoa bran	5.1	0.7	0.0	0.0	0.0	1800

* *Aspergillus* spp., *Penicillium* spp. and *Alternaria solani*

To determine role of high RH on aflatoxin production, samples of different quinoa seeds, stored for different periods up to 4 years were stored under RH (65- 72) for one month. Different types of aflatoxins, percentage of saponin, in addition to fungal population (c.f.u./ gm) were determined to figure out responsible factors lead to aflatoxin production. Data in Fig. (1) and Table (4) show that clear positive correlations were detected between length of storage period of all quinoa line seeds, and amounts of all aflatoxin types, when these seeds were stored at high RH (65-72). The highest amount of aflatoxins was detected when line Q26 was stored for four years and 2112.6 ppb /kg of seeds was calculated compare with the other two lines Q31 and Q19 where only 1986.4 and 1608.7 ppb /kg were detected respectively. The lowest aflatoxin content was appeared when Q26 was stored for one year and only 732 ppb / kg of seed was calculated, compare with 1428 and 887.2 ppb / kg of quinoa seed when lines Q31 and Q19 seed were stored for the same period. These results can be explain in the light of the fact that, production of aflatoxin by microorganisms is controlled by many factors, e.g. high humidity (Pratiwi *et al.*, 2015), protein contents (Liu *et al.*, 2016), presence of responsible microorganisms and also presence of some inhibitors such as saponin (Soetan *et al.*, 2006 and Ahmed *et al.*, 2012). The presented data show clearly, that the highest value of aflatoxin 2112.6 ppb was noticed at presence of the low percent of saponin 0.29% compare with 0.75% saponin when the lowest aflatoxin value (732) was detected. These data confirm work of Jun *et al*. (2004) who mentioned that saponin act as inhibitor for fungal growth. Fungal population also plays important role, obtained data show that lowest fungal population was correlated with high percentage of saponin and with lowest percentage of aflatoxin and vise verse. Data also show that clear variation in hosting fungi and consequently amount of aflatoxin. Quinoa Q26 was the most hospitable quinoa line and 1400 c.f.u/g were counted in seeds stored for 4 years. This because saponin inhibit growth of *Aspergillus* spp. consequently reduce amount of aflatoxin (Ezeabara *et al.*, 2014). Data in Table (4) indicate that different types of aflatoxin varied in quantities according to length of storage period and quinoa line. All aflatoxin types were positively increased by increase storage period in all quinoa lines, stored for any storage period. Aflatoxin G1 showed the highest concentration compare with the other three types B1, B2 and G2. Whereas B2 showed the lowest content in all materials under test. G2 occupied the third rank after aflatoxin G1 and B1.

Table (4): Types of aflatoxin in relation to storage period and quinoa seed lines

Quinoa lines	Storage period in years	Aflatoxin(ppb)				Total aflatoxin (ppb)	% Saponin
		B1	B2	G1	G2		
Q31	1	389	27.9	974	37.1	1428.0	0.78

Fig. (1): Correlation between, storage period, under high RH, fungal population and aflatoxin content in three different quinoa lines.

Conclusion

Quinoa seeds, as propagation material, can be stored at room conditions (25- 30°C and 30- 37 RH) for one to two years without significant reduction in viability of seeds. Relative humidity is the most important factor in aflatoxin production in quinoa pseudo grain so, quinoa seeds stored for human consumption should be stored under low humidity condition (30- 37%)RH to avoid aflatoxin accumulation. Remove saponin layer from quinoa seeds lead to stimulation of aflatoxin production. Protein content was reduced by 20% whereas fats were drastically reduced (more than 40%) after 4 years. To keep high nutrient quality of quinoa grains, storage period can be 1- 2 years only.

Abstract

In Georgia, one of the centers of origin of wheat, rust pathogens are common. Rust surveys throughout different geographical zones of Georgia indicated that wheat leaf rust caused by *Puccinia triticina f. sp. tritici* occurred with low incidence (1-20%) in 2014-2015 wheat growing seasons. Disease severity varied from 5% to 100% depending on the environment and varieties. Wheat leaf rust was first observed in the fall-planted wheat plots in Colchis Lowland around mid-May. In June-July, it spread across the other zones characterized by more temperate dry climate. The virulence of 114 single isolates was characterized on the set of 20 North American leaf rust differential near-isogenic lines. In addition, eight supplemental tester lines carrying Lr19, Lr20, Lr23, Lr25, Lr27+31, Lr29, Lr36 and Lr37 were included to confirm virulence. According to seedling virulence surveys the majority of isolates were virulent on lines with the resistance genes: Lr1, Lr2a, Lr3ka Lr2c, Lr3, Lr11, Lr14a, Lr26, Lr 23, Lr30 and LrB. Virulence in genes, Lr16, Lr17, Lr18, Lr20 and Lr24 was high in both years. No virulence was found in Lr28, Lr29, Lr27+31, Lr41 and Lr42. Low virulence (1.8-13.2%) was recorded in genes Lr9, Lr19, Lr10 and Lr21. Sixteen pathotypes were described in *Puccinia triticina* population. The most common pathotype PKTTL, PTKNL and PFTPL were occurred in 14.0-12.3% of the isolates. Dominant pathotypes consist of 13-15 virulence genes. The existence and severity of leaf rust natural infection were assessed in two growing seasons on the 85 entries of Trap Nurseries (5th ILRTN-14 and 6th ILRTN-15). Resistance of 60 % of entries was indicated. Among them 34.1% showed R type. Moderate resistance to leaf rust have been expressed on lines with genes Lr17, Lr18, Lr19, Lr21, Lr28, Lr29, Lr37, Lr 10+ 27+31.

Keywords: *wheat rust, virulence, resistance genes, pathotypes*

Introduction

Wheat in general is the major stable crop in Georgia, which is one of the centers of origin of wheat (Zhykovsky, 1973). Wheat rusts are common in Georgia. Leaf rust of wheat, caused by *Puccinia triticina* Eriks, is a potentially dangerous disease. It occurred annually throughout most of the wheat growing areas of Georgia in 30 years ago (Naskidashvili and Sikharulidze, 1998). However, incidence and severity of leaf rust have decreased in the recent years. Breeding of resistant cultivars is the most economically profitable and effective way to control of disease. Difficulty of breeding for leaf rust durable resistance is due to highly variability of pathogen. Virulence surveys aim to monitor shifts of pathotype frequencies, to know the virulence variation in the natural pathogen population and to help breeders in developing resistant varieties. Virulence surveys of the wheat rusts conducted in Georgia during 2009-2015 were financially supported by ICARDA. The present paper reports on the determination of virulence frequencies in Georgia by means of seedling tests and field evaluations.

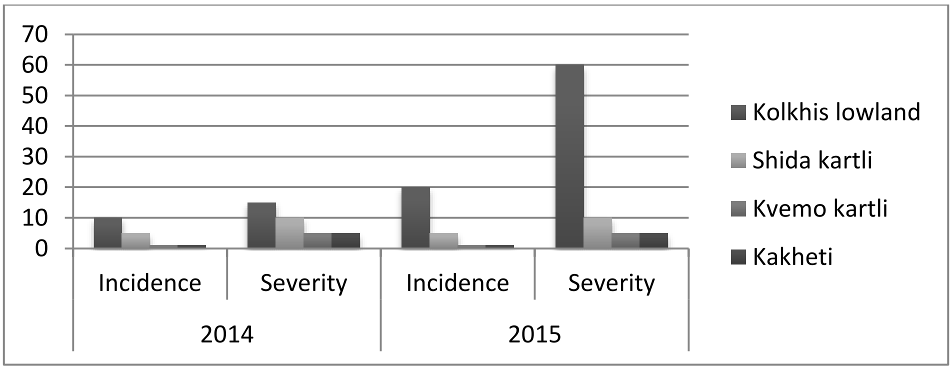
Materials and Methods

During 2014-2015 growing seasons leaf rust collections were taken from wheat commercial fields, small private plots and breeding stations through major wheat producing areas of Georgia. Observation of wheat fields and sampling were conducted using standard methodology (Yahyaoui *et. al.*, 2003). The main area of commercial sowings was occupied by varieties Bezostaya 1, Lomtagora 123, Tanya and Jagger. Each collection was used to inoculate 7 day-old wheat seedlings of universally susceptible cultivar Thatcher. After 6-10 days, the leaves were trimmed so that only one uredinium remained on each plant. Spores from single uredinia were collected separately and were used to inoculate 1-week old seedlings differential set consisting of near-isogenic lines of Thatcher, each with a different resistance genes: *Lr1, Lr2a, Lr2c, Lr3a, Lr9, Lr16, Lr24, Lr26, Lr3ka, Lr11, Lr17, Lr30, LrB, Lr10, Lr14a, Lr18, Lr21, Lr28, Lr41, Lr42* (Table 1). The differential set was provided by CIMMYT. In addition, tester lines carrying *Lr19, Lr20, Lr23, Lr25, Lr27+31, Lr29, Lr36* and *Lr37* were included to confirm virulence. Plants were inoculated with water-spore suspensions of each single pustule isolate and placed in a dew chamber overnight. The next morning, seedlings were maintained in a greenhouse from 20^0C to 28^0C. Twelve to fourteen days after inoculation, plant reaction was scored using the 0-4 scale described by Johnston and Browder (1966). Seedlings with the infection types 0, ; 1 and 2 were considered resistant response (R), while infection types 3, 4 and X were considered susceptible ones (S) (Roelfs *et al*, 1992). The races (pathotypes) were recorded according to North American *Prt* Nomenclature (Long and Kolmer, 1989). Factor of virulence, value of polymorphism and coefficient of diversity of pathogen population were accounted (Ayala, 1989; Groth and Roelfs, 1987). We also obtained the valuable information on virulence genes by observation of Trap Nurseries: 5^{th} ILRTN-14 and 6^{th} ILRTN-15 planted in two geographic zones. For disease severity evaluation the modified Cobb's scale (Peterson *et. al.*, 1948) was used.

Results and Discussion

Thirty five locations were surveyed covering the main wheat growing areas of five agro-ecological zones. Rust surveys throughout different geographical zones of Georgia indicated that wheat leaf rust caused by *Puccinia triticina f. sp. tritici* was occurred with low incidence (1-20%) in 2014-2015 wheat growing seasons. As diagram 1 shows the disease severity varied from 5% to 100% depending on the environment conditions and wheat varieties. Wheat leaf rust was first observed in the fall-planted wheat plots in Kolchis lowland around mid-May, in June-July, it spread across the other zones, which are characterized by more temperate dry climate (Diagram 1).

Diagram 1. Incidence and severity of wheat leaf rust in Georgia



During 2014-2015 twenty nine samples were collected from commercial wheat fields and nurseries across four agroecological zones of Georgia. Three to five single-pustule isolates were derived from each samples. In total one hundred fourteen isolates of *Puccinia triticina* were evaluated using isogenic lines to identify pathogen virulence. In all, sixteen pathotypes were described based on infection types to the twenty near-isogenic lines (Table 1). A total of twelve pathotypes were found in collection from Kolkheti zone, thirteen - from Shida kartli and ten - from Kakheti and Kvemo kartli zones. Frequency of pathotypes was varied between 0.9-14.9%. Pathotypes PKTTL(virulence to genes *Lr1*,*Lr 2c*, *Lr3a*, *Lr 16*, *Lr 24*, *Lr 26*, *Lr3ka*, *Lr11*, *Lr17*,*Lr*30, *Lr*B, *Lr10*, *Lr14a*, *Lr18*, *Lr21)* and PTKNL (virulence to genes *Lr1*, *Lr 2c*, *Lr3a*, *Lr9*, *Lr16*, *Lr24*, *Lr26*, *Lr11*, *Lr17*, *Lr*30, *Lr*B, *Lr14a*, *Lr 21*) were the most prevalent in *Puccinia triticina* population. They constituted 14.9% and 12.3% of all isolates, respectively. Races PFTPL, TRPPF, THRPL, TPTPF, TTTPP, TKTNP and THTPP were distributed with frequency ranged between 11.4-5.3%. The frequency of races PMTTP, PTTPP, PMTPF, PRTPB, PHTPF, FHTPP and PHTNP was low 4.4-0.9%. Races FHTPP and PHTPF were found only in Kvemo Kartli zone and race PHTNP was found only in Kakheti zone. Dominant races consisted of 13-15 virulence genes. The diversity of *P. triticina* was slightly higher in 2015 than in 2014. According to Gleason index (H_G=0.14) the level of genetic diversity of *P.triticina* population was low. However, the factor of virulence (Fv-18.9) and polymorphism (p-0.8) were high. Jaccard similarity index (SI) comparisons showed that LR collections from different zones were similar, SI varied between 50-75%. Only both Kakheti and Kvemo kartli zones had less common races (SI=31.1%). Low diversity of leaf rust population can be explained by small commercial fields and similar genotypes of producing wheat cultivars.

Table 1. Frequency of races of *Puccinia triticina* identified on 20 differential lines in Georgia in 2014-2015

All analyzed isolates were virulent to genes *Lr2c*, *Lr3a*, *Lr14a*, *Lr23*,*Lr25*, *Lr26*, *Lr30* and *LrB*. Virulence frequencies to lines with genes *Lr1*, *Lr3ka*, *Lr11*, *Lr16*, *Lr17*, *Lr18*,*Lr20 and Lr21* were 64.9-99.1% of isolates across the country. Low virulence (18.4%) was recorded to lines with gene Lr10. Virulence to lines with genes *Lr9*, *Lr19* and *Lr24* occurred in 50.8, 55.2 and 65.8% of the isolates, respectively. These genes were very effective against to wheat leaf rust during many years (Sikharulidze *et al.*, 1993; Sikharulidze and Bedoshvili, 2005). Virulence frequencies (41.2%) to genes *Lr41* and *Lr42* were identical. Frequency of virulent isolates to gene *Lr10* was low (23.7%). Virulence to genes *Lr28*, *Lr29* and *Lr27+31* was not found in any of the tested isolates (Table 2).

Table 2. Frequency of isolates of *Puccinia triticina* virulent to near-isogenic lines with resistance genes in Georgia in 2014-2015

According to results of observation of Trap Nurseries 5th ILRTN-14 and 6th ILRTN-15 the resistance of 60 % of entries was indicated. Among them 34.1% showed R type. Resistance and moderate resistance to leaf rust have been expressed on lines with genes *Lr17, Lr18, Lr19, Lr20, Lr21, Lr28, Lr29, Lr37, Lr10+ 27+31.*
Population of *P. triticina* distributed in Georgia is much differed with populations from other countries by virulence structure (Kolmer *et.al.* 2013; Kolmer and Hughes, 2013; Babayants *et. al*, 2015).

Conclusions

Thus, population of leaf rust occurred in Georgia in 2014-2015 was highly virulent. Considerable changes in the populations from year to year have been connected with virulence to genes *Lr9, Lr19* and *Lr24.* There was no significant difference in virulence genes and races between populations occurred in the different geographic areas. The level of population diversity was low (H_G= 0.14). The results of research are very useful for future breeding programs.

Abstract

The aim of this study was to examine the allelopathic potential of three important weed species in cereals: *Papaver rhoeas*, *Cirsium arvense* and *Convolvulus arvensis* on germination and early growth of winter wheat. Bioassay experiments were made in the laboratory in 2016. The water extracts from air dried and grinded shoots and roots were made in different concentrations (2.5%, 5.0% and 7.5%). Winter wheat seeds were taken into Petri-dishes, treated with 15 ml solutions, and put into thermostat at 20 °C in the dark. The germination percentage was evaluated and the whole length of primary roots and shoots was measured on the 8th day of the assay. The statistical analysis has been done by using two-factorial analysis of variance (ANOVA). The strongest inhibitory effect of shoot extracts on root length of winter wheat was detected with *Convolvulus arvensis* followed by *Papaver rhoeas*, inversely root extract of these weeds caused stimulatory effect. It was determined that root extracts of examined weeds stimulated the shoot length of wheat. Stimulation increased with concentrations. On the basis of the results, we established that shoot and root extracts of *Papaver rhoeas, Cirsium arvense* and *Convolvulus arvensis* had allelopathic effect on germination and growth of winter wheat seedlings. The allelopathic effect of shoot and root extracts of examined weeds were different. In the experiments we observed both, inhibiting and stimulating effects. The effects were changed by concentrations, and usually the higher concentrations caused the strongest effect.

Keywords: *allelopathy, Papaver rhoeas, Cirsium arvense, Convolvulus arvensis, winter wheat.*

Introduction

Allelopathy is defined as the direct influence of a chemical released from one plant on the development and growth of another, or can defined like this: it is a form of interference; plants influence each other in chemical way by releasing secondary metabolites. It is known that allelopathic substances are induced by environmental stresses. Allelopathic compounds may be released into the environment from plants by: root exudation, leaching, evaporation and decomposition of plant residues in the soil. Allelochemicals may reduce the needs for herbicide use in weed management. Using allelochemicals alone may not be a perfect weed management technology but it may be a supplementary tool for weed control in the field. It is extremely difficult to demonstrate allelopathy in nature because of the complexity of plant interference which includes positive, negative and neutral effects on each other (Christensen, 1993).

Weeds cause annual losses of about 10% in agricultural production (Anderson, 1987). A lot of weeds are now reaching importance as a factor of weed control for having special types of allelochemicals. These allelochemicals are able to suppress germination and growth of several other weeds, some of which are herbicide resistant.

According to Torra et al. (2008) field poppy (*Papaver rhoeas* L.) is one of the most important broadleaf weed in winter cereals, it is a strong competitor, which can decrease the wheat yield up to 32% (Kazinczi et al. 1997).

Creeping thistle (*Cirsium arvense* L.) is an insufferable, very competitive perennial weed which reduces productivity of crops, pasturelands and fruit trees, so can causes large economic losses (Kazinczi et al., 2001). Allelopathic effects of *Cirsium arvense* plant extracts and residues on agronomic crops and weeds have been reported in many studies (Helgeson-Konzak 1950; Bendal, 1975; Stachon-Zimdahl, 1980).

According to Kazinczi et al., (2004) which reported inhibitory effect of watery extracts from fresh roots, stems and leaves of *Cirsium arvense* on germination and growth of wheat and other crops. Allelochemicals of creeping thistle are vanillic acid, caffeic acid, ferulic acid, p-coumaric acid, chlorogenic acid, p-hydroxybenzoic acid (Hussain et al., 1987)

Field bindweed (*Convolvulus arvensis* L.) is a twining, perennial weed that reproduces by both, seeds and adventitious shoots turn up from a spreading root system. It becomes a problem when competes strongly with many crops such as wheat, corn and causes their yield decrease (Holm et al., 1977; Weaver-Rilly (1982). Field bindweed has several allelochemicals, as p-Hydroxybenzoic acid, p- coumaric acid, pyrogallic acid, protocatechuic acid, resorcinol, chlorogenic acid, caffeic acid, syringic acid, ferulic acid, salicylic acid, cinnamic acid (Hegab- Ghareib, 2010)

Materials and Methods

The study was intended to evaluate the allelopathic effect of three important weed species on germination of winter wheat *(Triticum aestivum L.)*. Common poppy (*Papaver rhoeas*) from *Papaveraceae* family, creeping thistle (*Cirsium arvense*) from *Asteraceae* family, and field bindweed (*Convolvulus arvensis*) from *Convolvulaceae* family were collected from different cultivated fields belonging to Georgikon Faculty on May 2016. Roots from stem and leaves were separated in laboratory and after were cut into small pieces and were dried in exsiccator for 24h in 50 °C. The dried roots and shoots were stocked in paper bags in dark condition at room temperature until use. Experiment was conducted in Laboratory in Georgikon Faculty. Allelopathic effects of these three weed species on winter wheat *(Triticum aestivum L.)* were studied in 2016 in two parts, first part for extract of the shoots and second part for the extract of the roots. Watery extracts have been made from *Papaver rhoeas*, *Cirsium arvense* and *Convolvulus arvensis* shoots and roots separately in three concentrations: 2.5%, 5.0% and 7.5%. Solutions were created with tap water and let 24h to soaking. The extracts were filtered after 24 hours, and were used immediately. Fifty pieces of winter wheat seeds were placed into Petri-dishes and treated with 15 ml solutions. In control Petri-dishes 15 ml tap water was used. Petri dishes were put into thermostat and held at 20 °C in dark. All treatments were made in four replications. The germination percentage was studied and the whole length of primary roots and shoots was measured on the 8th day of the bioassay. The statistical analysis has been done by using the SPSS computer program, two-factorial analysis of variance (ANOVA). Mean differences was computed using Duncan Multiple Range Test (DMRT). Correlation analysis for the root length and shoot length was done by using Excel program.

Results and Discussion

The length of the wheat's primary roots are significantly different between plant parts on 1% ($p<0.01$) significant level (table 1). PAPRH with concentration 7.5% have made significant difference between length of the wheat primary root treated with root extract (144.99 mm) which was 20.28% longer than length of the root treated with shoot extract (120.54 mm). Common poppy 2.5% and 5.0 % can be seen that there is no significant difference between root and shoot extract.

In treatments with CIRAR solutions weren't significant differences between root and shoot extract even that are used three different concentrations. CONAR caused significant differences in all three concentrations in both root and shoot extract. Extracts decreased the growth of wheat's primary root, beside the 2.5% root extract which increased it.

Table 1. The length (mm) of wheat's primary root treated with weeds solutions

Weed concentration %	Root length treated with weed extracts		
	Shoot extract	Root extract	**Mean B (Plant part)**
Control	127.28	127.28	127.28^{abc}
PAPRH 2.5	114.77	123.55	119.16^{cde}
PAPRH 5.0	127.12	131.38	129.25^{ab}
PAPRH 7.5	120.54^{b}	144.99^{a}	132.77^{a}
CIRAR 2.5	124.27	131.95	128.11^{abc}
CIRAR 5.0	131.57	134.24	132.91^{a}

Extract from the roots resulted 74.60 mm length of the wheat's shoot in average, 13.47% longer than wheat's shoot from extract of the shoot, where the average length of wheat's shoot were 65.74 mm (table 2). The all root extracts stimulated the growth of wheat's shoot. Shoot extracts from PAPHR 2.5 and 5% decreased the growth of wheat, but contrary all root extracts stimulated it. According to Ravlic et al. (2012) similarly our measuring PAPRH caused significant reduction in shoot length in all treatments compared to the control. Shoot extract of PAPRH inhibited length of shoots while root extract stimulate it. CIRAR solutions increased the shoot length of wheat, but CONAR shoot extracts hindered the shoot development of wheat. Similarly, Pilipavicius and Romaneckas (2014) established that winter wheat shoot length growth was stimulated by all over-ground part water extract of *Cirsium arvense*.

Table 2. The length of wheat seedling's shoot (mm) in different treatments

Weed concentration %	Shoot length treated with weed extracts		
	Shoot extract	Root extract	**Mean B (Plant part)**
Control	68.57	68.57	68.57^{cd}
PAPRH 2.5	64.12	69.27	66.69^{cd}
PAPRH 5.0	60.91^{b}	70.56^{a}	65.75^{cd}

Table 3. is showing the percentage (%) of wheat germination which are not significantly different between plant part. According to Ravlic et al. (2012) watery extract from fresh part of PAPRH significantly reduced germination of wheat. In our experiment root extracts not significantly influenced the germination. Application of shoot extract of PAPRH resulted in higher germination percentage of wheat except for 2.5% treatment.

Table 3. The percentage (%) of wheat germination by different weed solutions

Weed concentration %	Percentage (%) of wheat germination		
	Shoot extract	Root extract	**Mean B (Plant part)**
Control	93.5	93.5	93.50
PAPRH 2.5	91	93.5	92.25

Pilipavicius and Romaneckas (2014) established that over ground part of creeping thistle water extracts at low concentrations have tendency to stimulate winter wheat germination which is similar to our experimental results. Watery extracts prepared from *C. arvense* rootstock showed similar regularity showing stimulation and suppression effects on winter wheat grain germination as in its over-ground part. In this experiment root extract in low concentration inhibited, and in high concentration stimulated the germination.
According to Yarnia et al. (2008) all weed extracts of CONAR (leaf, shoot, root, flower extracts) with 4 different concentration (1:5, 1:10, 1:15, and 1:20) decreased germination but root extract showed highest prohibition, extracts of root and other parts of weed at 1:5 concentration totally inhibited germination. In our experiment we did not experienced germination hindering effect of field bindweed extracts, however these results are not significant.

Conclusion

On the basis of our results we established, that shoot and root extracts of *Papaver rhoeas, Cirsium arvense* and *Convolvulus arvensis* had allelopathic effect on germination and early growth of winter wheat. *Convolvulus arvensis* considerably influenced the development of wheat, followed by *Cirsium arvense*. The root extracts stimulated the growth of winter wheat, while shoot extracts inhibited it. Stimulating effect depended on concentrations of extracts.

Abstract

The aim of this study was to determine the individual and combined toxic effects of MYSTIC 250 EC fungicide (tebuconazole 250 g/l) and lead acetate on the development of chicken embryos. The chicken eggs were dipped in the solution or emulsion of the test materials for 30 minutes on the first day of incubation (day 0). The applied concentration of lead acetate was 0.01% and of fungicide MYSTIC 250 EC was 0.1%. The chicken embryos were examined on day 19 of incubation by the followings: rate of embryo mortality, body mass, type of developmental anomalies by macroscopic examination. The body mass was evaluated statistically by the one-way ANOVA, the embryo mortality and the developmental anomalies was analysed by Fisher test. The body weight of the embryos in all treated groups applied the test items individually or simultaneously was significantly decreased compared to the control group. The embryo mortality was increased statistically in the embryos treated with lead acetate alone or in combination with MYSTIC 250 EC fungicide. The frequency of developmental abnormalities was sporadic in all treated groups. Our teratogenicity study revealed that, the individual toxic effect of lead acetate and tebuconazole containing fungicide formulation (MYSTIC 250 EC) was embryotoxic but not teratogenic in chicken. Based on the results, there is an addition type toxic interaction between tebuconazole containing MYSTIC 250 EC and lead acetate resulted in increased embryotoxicity due to the concomitant exposure.

Keywords: Ecotoxicology, Tebuconazole, Toxic interaction, Lead acetate, Chicken embryo

Introduction

The chemical plant protecting process is one of the most important polluting activities in the agricultural production. The ecosystem of a given habitat can be contaminated simultaneously by sprayed pesticides and other xenobiotics, e.g. heavy metals due to the agricultural activities during the plant protecting processes. Therefore, the chemical load can be occurred as a complex problem, so the combined toxic effect, i.e. toxic interaction of at least two substances can expected and the components can modify the effect of each other. Recently, the examination of the combination of heavy metals and other chemicals gained significant ground in both avian (Fejes *et al*., 2001; Kertész, 2001) and mammalian (Institóris *et al*., 2001; Pecze *et al*., 2001) toxicology research studies. Furthermore, the interaction effects are examined not only in the field of ecotoxicology, but also in all other areas that deal with health care and chemical safety issues (Oskarsson, 1983; Danielsson *et al*., 1984; Speijers and Speijers, 2004).

The different agricultural areas offer sources of food, shelter and breeding places to wild birds, therefore the sprayed pesticide and other chemical substances can contaminate not only the adults, but the embryos developing in egg, as well. The eggs of the wild birds may be exposed to different chemicals on the cultivated lands at the same time and their toxic effects may appear in embryo mortality and developmental anomalies. Teratological tests carried out on avian embryos provide useful data for environmental protection and facilitate the development of environmental-friendly chemical plant protection techniques (Várnagy *et al.*, 1996). The aim of our study was to examine the toxic effect and interaction of lead acetate and a tebuconazole containing fungicide (Mystic 250 EC) on chicken embryos after administration of single compounds and simultaneously by immersion technique.

Materials and Methods

Farm chicken eggs with good fertile potential (Goldavis Ltd., Hungary) were used in the experiment. The eggs based on their size and weight were divided into four homogenous groups (40 eggs in each), and were incubated in Ragus type table incubator (Vienna, Austria) ensuring the required temperature (37–38ºC), the relative humidity (65–70%) and the daily rotation. The chicken eggs were dipped into the solution or emulsion of the test materials for 30 minutes on day 0 of incubation. During the single and simultaneous administration lead acetate (Reanal-Ker Ltd., Budapest) with a concentration of 0.01% and 0.1% of Mystic 250 EC tebuconazole containing fungicide (Nufarm Hungary Ltd., 360 g/l) corresponding to that used in plant protection practice were applied. The control group was treated with tap water. The details of the experimental design are presented in *Table 1*. All eggs and embryos were examined and processed on day 19 of incubation. During the processing rate of embryo mortality, body mass of embryos and type of developmental anomalies were registered.
The distribution of body weight of the live embryos was controlled by Comparison-Quantile Plot and was analysed statistically by One-Way ANOVA. Data of groups were compared by Tukey and Dunnett tests. The statistical analysis of the results of embryo mortality and developmental abnormalities were performed by Fisher's exact test (Baráth *et al.*, 1996).

Table 1. Experimental design

Group	No of egg	Treatment (concentration)	
		Lead acetate	Mystic 250 EC
I (control)	40	-	-
II	40	0.01%	-
III	40	-	0.1%
IV	40	0.01%	0.1%

Results and Discussion

The average body weight of the embryos was 19.51±1.11 g in Group II that was significantly lower as compared to the control (20.34±1.28 g, $p=0.05$). Due to tebuconazole (0.1%) treatment the body weight was 19.32±1.4 g that was significantly lower than the control. The simultaneous administration of lead acetate (0.01%) and tebuconazole resulted significant decrease ($p=0.001$) of average body weight (Group IV: 18.48±1.22 g) as compared to the control

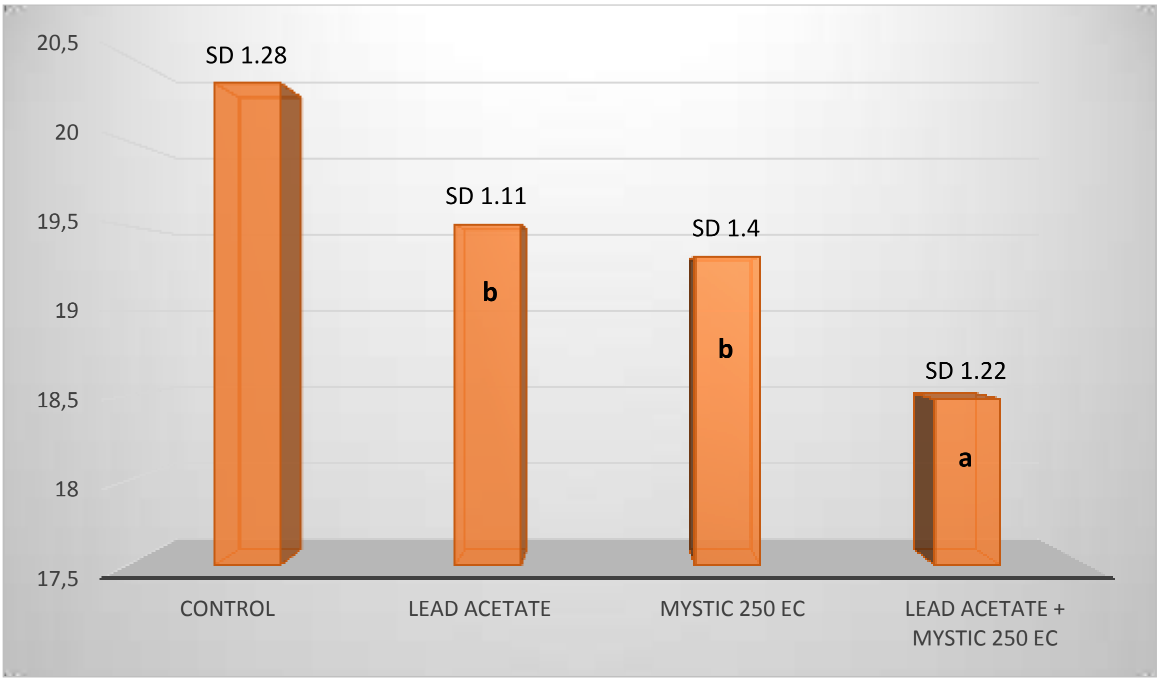

Figure 1. Body weight (g) of the chicken embryos on day 19 of incubation from teratogenicity test on Mystic 250 EC and lead acetate after single and simultaneous administration
a: Significance decrease as compared to the control($p=0.001$)
b: Significance decrease as compared to the control($p=0.05$)

The results of the embryo mortality is presented in *Table 2*.

There was one died embryo in the control group (2.7 %). The single administration of lead acetate increased the mortality up to 26.6%. The changes were statistically significant as compared Group I (control). The application of 0.1% Mystic 250 EC caused 2.6% of mortality in the treated embryos in Group III.

Table 2. Embryonic death and developmental anomalies from teratogenicity test of lead acetate and Mystic 250 EC in chicken embryos after single and combined administration

Group	Treatment	No of embryos showing abnormality/No of live embryos	Death No/ No of live embryos	Rate of developmental anomalies (%)	Mortality (%)
I	Control	0/37	1/37	0	2.6
II	Lead acetate	3/30	8/30[a]	10	26.6
III	Mystic 250 EC	1/37	1/37	2.7	2.6
IV	Lead acetate + Mystic 250 EC	3/31	7/31[a]	9.6	22.5

a: Significant difference as compared to the control ($p=0.05$)

Due to the simultaneous administration of 0.01% lead acetate and 0.1% tebuconazole induced significant increase of embryomortality 22.5%. Developmental abnormalities were not recorded in the control group (*Table 2*). The 0.01% lead acetate induced leg deformation and open abdomen (Group II: 3 embryos) without statistical difference as compared to Group I. One embryo shows teratogenic malformation after a single administration of Mystic 250 EC (leg deformation, Group III). The simultaneous administration of the fungicide (0.1%) and lead acetate induced leg deformation, growth retardation and beak malformation in the survivor embryos (Group IV). The results of the individual teratogenicity studies on lead acetate in chicken are in accordance with results of toxicity studies in other species. Depending on the dose, lead has embryotoxic potential and may cause developmental anomalies (Ferm and Carpenter, 1967; Várnagy and Budai, 1995). Similar results were found in chicken embryos treated with 0.01% lead acetate (lower body weight, higher rate of embryo mortality) but the developmental anomalies were not significant versus the control group (Juhász, 2009). Tebuconazole is a common triazole fungicide that has been extensively used for fungi control. Jinghua *et. al*.(2016) showed that tebuconazole could reduce cell viability, disturb normal cell cycle distribution and induce apoptosis of human placental trophoblast cell line HTR-8/SVneo (HTR-8). Bcl-2 protein expression decreased and the level of Bax protein increased after tebuconazole treatment in HTR-8 cells. The results demonstrated that this fungicide induced apoptosis of trophoblast cells via mitochondrial pathway. Tebuconazole suppressed human trophoblast invasion and migration through affecting the expression of protease, hormones, angiogenic factors, growth factors and cytokines. As the invasive and migratory abilities of trophoblast are essential for successful placentation and fetus development, their findings suggest a potential risk of triazole fungicides to human pregnancy. According to the published literature the toxicity of many pesticide combinations is at least additive. In some cases pesticide mixtures, if they particularly contain insecticide component, have been shown to be synergistic effects, with reported increase in toxicity up to 100-fold. However, these effects are species, time and dose dependent, therefore difficult to predict it routinely (Thompson, 1996).

Conclusions

The single treatment of lead acetate with 0.1% concentration induced embryotoxic effect in chicken embryo which manifested in significant decrease of body weight and elevated rate of embryo mortality. The tebuconazole containing MYSTIC 250 EC plan protection product with fungicidal action was also embryotoxic on chicken embryos and resulted statistically significant reduce of body weight. Due to the simultaneous application of lead acetate and Mystic 250 EC the embryo mortality was statistically higher than the individual effect. Developmental abnormalities were sporadically observed due to the single and concomitant administration (leg and beak deformation, growth retardation, open abdomen). Based on the results, there are presumably addition-type toxic interaction between lead acetate and Mystic 250 EC that highly reduce the viability of the embryos.

VIROLOGICAL EXAMINATION OF PUBLIC ORNAMENTAL PLANTS

György PÁSZTOR*, Erzsébet NÁDASY IHÁROSI, András TAKÁCS

Plant Protection Institute, University of Pannonia, Georgikon Faculty, Hungary
*Corresponding author: pasztor018@gmail.com

Abstract

Ornamental plants are gaining an increasing role because of the increasing urbanization.In Hungary, about 30-32 million annuals are cultivated annually. The annual ornamental plants dominate in the public spaces of Hungary, where 30 - 40 of the species are generally cultivated. The widespread species of the annuals are the Cockscomb species (*Celosia spp*.), Petunia species (*Petunia* spp.), Begonia (*Begonia spp*.), Sweet potato (*Ipomoea batata*) and Impatiens (*Impatiens spp*). The purpose of our research was to determine the natural viral infection of planted plant material and the epidemiological significance of these viruses.Our study was carried out from samples collected from the flower beds in the spring, summer and autumn (depending on the time of planting) of 2016, from Keszthely, Zalaegerszeg, Óhid, Türje, Tekenye, Sümeg and Zalaszentgrót settlements in Zala county. One of the most common methods for diagnosing plant viruses was used - the double antibody sandwich (DAS ELISA). In case of 56 samples, viral infections were detected from ten samples. Tomato spotted wilt virus (TSWV) was present in five samples (two *Celosia*, one *Impatiens*, one *Begonia*, one *Tagetes*) after serological testing. In five-five cases, Tomato mosaic virus (ToMV) was diagnosed in one *Tagetes*, two *Callistephus*, two *Dianthus*, as well potato virus A (PVA) in two *Begonia*, two *Celosia* and one *Impatiens*. Potato Y virus (PVY) was found in three cases (one *Celosia*, one *Begonia*, one *Tagetes*) and in one case Cucumber mosaic virus (CMV)(one *Impatiens*). The registered viruses from these species have never been detected before not just in Hungary, but worldwide, according to the „Viruses on Plant Virus Descriptors and Lists" from the VIDE Database web site.

Keywords: *annual, ornamental plants, virus infection, serological methods*

Introduction

Thanks to the ever-increasing urbanization, ornamental plants have an increasing role in our public spaces. Annual or perennial ornamental plants become the most decisive elements of our gardens, parks and public spaces. Worldwide, the goal is to crop plants whose decorative value does not decrease as a result of stress.But the examination of virus resistance from the producer side is not essential. The aim of the breeding is to emphasize the decorative value of ornamental plants. Because of that, it does not know exactly which viruses can infect those plants, and how the potential of infection affects the spread of viruses. Not to mention, as a result of viral infection, the lifespan and decorative value of these plants are significantly reduced. In Hungary, about 30-32 million annuals, 10-12 million bishops are cultivated annually (Boróczky, 2002), out of which 25% is in public space and 75% in private gardens. Cultivation of plants is essentially under greenhouse conditions, and after spring, they are planted in flower beds and in various flower pots. Apart from their decorative value, they have an impact on our mood and have a big role to play in creating a good city scene. In the public areas of Hungary, the annual ornamental plants dominate mostly, which was confirmed during the survey and collection of the samples. Nearly 100 species are used in flower beds, 30 - 40 of which are commonly cultivated. The number of perennials in areas of the survey are considerably lower. From the annuals, the widespread species are the cormorant species (*Celosia spp*.), petunia species (*Petunia spp*.), begonia (*Begonia spp*.) .The new entrants are the sweet potato (*Ipomoea batata*) and the impatiens species (*Impatiens spp*.). With the breeder's work this list is constantly expanding, the number of ornamental plants we have today is over 100 species. In Hungary, ornamental plants are grown in fragmented areas and in outdated facilities, so it cannot keep up with the continued expansion of demand in any product group. Accordingly, 95% of propagating material comes from imports. The largest importers in Europe are the Netherlands, Italy and Hungary (Jankuné, 2010). As a result of global warming and climate changes in future, in Hungary, more ornamental plants - which can easily adapt to drier climatic conditions - should be planted in public space, and provide people with the appearance of nature between concrete walls. Virology of plant material from abroad is, in many cases, either inadequate or completely absent, hence increasing the risk of supply infected propagating material, and even new viruses may enter the domestic flora. In order to avoid it, the examination of the Hungarian plant stock requires continuous attention so that the potential host plants are continuously examined and filtered. The aim of the experiment was the virological examination of the annual ornamental plants of public spaces, and the determination of the epidemiological significance of detected viruses.

Materials and methods

Our study was carried out from samples collected from the flower beds of the spring, summer and autumn (depending on the planting of the ornamentals) 2016, from Keszthely, Zalaegerszeg, Óhid, Türje, Tekenye, Sümeg, Zalaszentgrót settlements, in Zala county, near Keszthely, Hungary. In total 56 leaf samples from the annuals were tested: *Impatiens walleriana* (14), *Ipomoea batata* (7), *Celosia argentea* (7), *Begonia* species (5), *Tagetes* species (5), *Callistephus chinensis* (7), *Zinnia elegans* (4), *Dianthus barbatus* (5), *Petunia* species (3). Our aim was to collect samples that showed symptoms of viral infection, but there were also samples from asymptomatic individuals, as well. The collected samples was stored frozen until the serological test was done. In order to detect viral infection, DAS ELISA serological method was used. In the this survey Cucumber mosaic virus (CMV), Tobacco mosaic virus (TMV), tomato spotted wilt virus (TSWV), potato Y virus (PVY), Potato X virus (PVX), potato virus A (PVA) and tomato mosaic virus (ToMV) reagents were used. To identify the new viral host plant relationships, „Viruses on Plant Virus Descriptors and Lists" from the VIDE Database web site was used.

Results and discussion

The samples were grouped according to the collected plant species, so that the evaluation could encompass a particular region. Of the fifty-six samples, ten were infected with viruses (Table 1.). There were no viral infections detected in three species (*Ipomoen batata*, *Zinnia Elegans and Petunia x hybrida*). The tomato spotted wilt virus (TSWV) was present in five samples (*Impatiens*, *Begonia*, *Celosia*, *Tagetes* and *Dianthus* species) In five-five cases, Tomato mosaic virus (ToMV) (*Celosia*, *Tagetes*, *Impatiens*, *Dianthus* and *Callistephus* species) and Potato virus A (PVA) (*Impatiens*, *Begonia*, *Celosia*, *Tagetes* and *Dianthus* species) were also diagnosed. Potato Y virus (PVY) was found in three cases (*Begonia*, *Celosia* and *Tagetes* species) and in one case Cucumber mosaic virus (CMV) were found in an *Impatiens walleriana* sample (Table 2.) Tobacco mosaic virus (TMV) and potato X virus (PVX) could not be found in any of the samples. In four cases, virus complex was present. In the case of one *Begonia* sample and a *Celosia argentea*, complex virus infection was detected, the sample showed TSWV, PVY, PVA infection complex. In one *Tagetes* sample presence of TSWV, ToMV, PVY complex was diagnosed, and in one *Impatiens walleriana* the TSWV, CMV, PVA complex. Five of the seven tested viruses were identified during the test.

Table 1: The viral infection of the species according to the DAS ELISA serological test (Source: Author's elaboration based on the obtained results)

Plant species	Amount of collected samples	Amount of infected samples
Impatiens walleriana	14	1
Ipomoea batata	7	0
Celosia argentea	7	2
Begonia species	5	2
Dianthus barbatus	7	2
Callistephus chinensis	4	1
Tagetes species.	5	1
Zinnia elegans	4	0
Petunia x hibryda	3	0
All samples:	56	10

Table 2: The viruses found in the investigated samples (highlighting new host-virus relationships in red) (Source: Author's elaboration based on the obtained results)

	Impatiens walleriana	*Begonia spp.*	*Celosia argentea*	*Tagetes spp.*	*Dianthus spp.*	*Callistephus spp*
TSWV	1	1	1	1	1	0
CMV	1	0	0	0	0	0
PVY	0	1	1	1	0	0
PVA	1	1	1	1	1	0
ToMV	0	0	1	1	2	1

More than 18% of the examined plants has been found infected by polyphagous viruses. In four cases, complex infection has been founded. Although the extent of the infection is not significant, its presence or the complexity of the viruses is, as much of the viral infections in these ornamental plants are not included in the international database. The test highlights how unproven propagation is a growing problem. Several viruses have been detected earlier amongst the examined species (Table 3.), but infections discovered during the research have revealed new host-parasitic relationships. These relationships were characterized from a symptomic point of view. PVA virus infection has not been described yet for any ornamental plant either of the following: *Impatiens Walleriana*, *Begonia* species, *Celosia argentea*, *Tagetes* species, *Dianthus* species and *Callistephus* species. Similarly, it has not been described that the TSWV, ToMV and PVY can infect the *Celosia argentea*, PVY the *Begonia* and *Tagetes* species and the ToMV the *Tagetes*, *Dianthus* species and *Callistephus chinensis* too.

Table 3.: Previously identified viruses in the examined plant species

	Impatiens walleriana	*Begonia species*	*Celosia argentea*	*Tagetes species*	*Dianthus species*	*Callistephus species*

Conclusions

The viral infection of ornamental plants is a less-researched topic in Hungary. The importance of the research is underpinned by the current uncontrolled propagating material flow into domestic markets, with new diseases, including viruses that can enter the ecosystem of the Carpathian Basin. In order to prevent this, research has been set up to identify new host plants. Increasing emphasis should be placed on the destruction of infected plants, but the more constant monitoring of the propagation material. This will reduce the risk of viruses became epidemic, which in many cases leads to economic damage. Results of this survey carrying important economic and viral epidemiological informations, as these ornamental plants can spread easily and can also cause damage to other important horticultural and arable crops. The results of the current research also show the spread of TSWV, which is a dangerous polyphagous virus, infecting crops and ornamental plants too (Parella, 2003). The spread of the virus is particularly important because the infection is carried by viral vectors like thrips which, due to the warming, can spread not only in the greenhouses but also on the field crops. By continuous monitoring of propagation material and the destruction of contaminated crops, economic damage can be reduced or prevented (Horváth, 1999/a). The choice of appropriate cultivation technology plays an important role in ornamental crop production as well. In many cases, providing adequate protection against pests and pathogenic microorganisms is difficult. The biggest problem is the plant pathogenic viruses, since chemical plant protection is not solved (Horváth, 1999/b). One option is prevention against viral diseases. As with other plants, with herbaceous ornamental plants, because of the unlimited quantities of propagating material and goods, the viruses that have not yet been counted in our country have significantly increased. It is a concern as the economic significance of these plants is less so that their susceptibility to viruses is less explored. Based on previous research results, it can be concluded that the ornamental plant growing industry has no production group that does not affected infected by the viral infections.

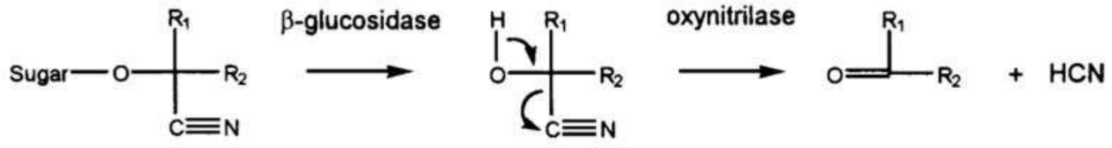
Abstract

Injudicious use of chemical inputs in agriculture poses challenge to sustainable agriculture. Cassava (*Manihot esculenta* Crantz) is a climate resilient crop cultivated in tropical and subtropical countries for its tuber as food, feed, and industrial products. Nevertheless, owing to the presence of Cyano-glucosides, leaves and tuber rinds are often thrown as waste or rather underutilized. The insecticidal principles from such bio-waste have been isolated and made formulations to manage certain important pests of horticultural crops. Current management strategy relies upon application of very toxic synthetic insecticides, although complete control of the pests could not be achieved. An extensive laboratory and field study was conducted on insects of contact applications were possible. Excellent package of control was developed both by prophylactic and curative means against the banana weevil (*Odoiporous longicollis* Oliver and *Cosmopolitus sordidus* Germer) management and over many of the noxious pests of vegetable and fruit crops. Lethality studies suggest the scope of cassava bio-pesticides as an alternative over synthetic pesticides specifically to the borer and sucking pests. The thick waxy coating of mealy bug and white fly were a major hurdle to the synthetics to act while cassava bio-pesticide formulation removes it by a spray to expose it and kill. Dose, concentration and application strategies of the bio-formulation have been standardised individually for some of the major pests, and large scale validation was done at the farmers' fields in three geographically and agro-climatically distinct zones of Kerala state, India and established its potency to manage the dreaded pests.

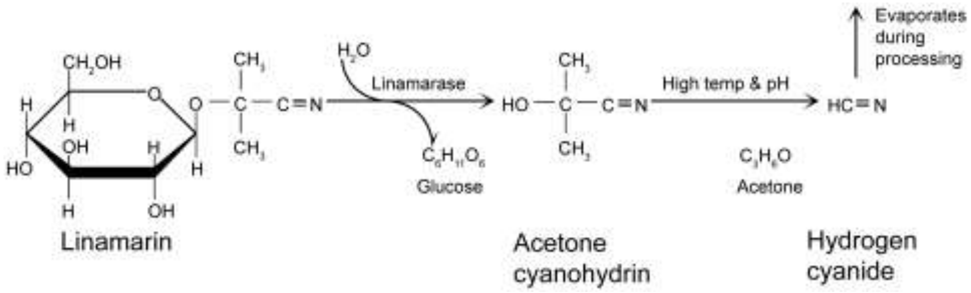
Keywords: *Cassava bio-pesticide, Odoiporous longicollis, Cosmopolitus sordidus, Pest management.*

Introduction

Cassava (*Manihot esculenta* Crantz) is the most important calorie-producing crops grown as a staple or subsidiary food for 450-500 million people in 26 tropical and subtropical countries. After harvest large portion of the biomass such as cassava leaf (2 t $^{-ha}$) fruits (3t $^{-ha}$) and tuber rinds (15-23% of the tuber) are generally discarded as waste. Cassava leaf is a storehouse of protein and minerals, despite the anti-nutritional factors like Cyano-glycosides present in the plant is a challenge in its diversified use. Most of the Cyano-glycosides in nature are Cyanogenic and since they have a nitrile group α to the glycosidic linkage, hydrolysis of this by specific enzymes will lead to the formation of Hydrogen Cyanide (Yang and Tanaka, 1999).



Linamarin is a potential cyanogenic glycoside present in cassava and it generates HCN when cell-lysis happen usually during herbivore consumption.



However, some growers use the leaves as cattle feed after removing the toxic principle by sun drying. Literature shows that cyanogen has been used as a potential biopesticide (Price, 1985; Yong-lin Ren and Desmarchelier, 1998; Yong-lin Ren and Allen, 2001; Cortes *et al.*, 2003; Lisbeth *et al.*, 2003).

Current study deals with the effectiveness of cassava biopesticide over various pests of horticultural crops. Effectiveness conferring lethality was the general scale of measurement throughout the study. Lethality measurement of Hydrogen cyanide present and isolated in the extract of Cassava namely '*Menma*' on BPW was worked out. Since the bio-efficacy of Hydrogen cyanide in *Menma* against the BPW was done in every lethality perspectives such as Lethal Concentration $(LC)_{50}$, Lethal Doss $(LD)_{50}$ and Knock Down Time $(KDT)_{50}$, the study promises the minimum respective amount of application for the management. Synthetic insecticides cannot be 'replaced' in a point of time but it should be judiciously reduced through other means of pest management measures that is effective and organic, which includes botanical preparation. *Menma* promises a quality as equal to synthetics while being completely organic. Pests such as aphid, mealy bug, thrips and weevil were generally scrutinised in a management perspective throughout the study and promising results were observed.

Materials and methods

Maintenance of test insects

Aphid: The common pea aphid (*Acyrthosiphon pisum*) were reared in green house garden and adult female aphids were transferred into long-pea cut-parts of 3 cm length using a brush and were kept in 100 ml bottles with amber coloured glass plates as lid. Mealy bug: Paracoccus marginatus were reared in potted chilly plants in cages that restrict parasitoid entry and climatic hazards. Insects were collected as per requirement from the inoculum in 100 ml containers with air-permitting cloth as lid.

Thrips: Gynaikothrips uzeli were reared in garden weeping fig Ficus benjamina and samples required were collected by opening the curled infected leaves and transferring it into 100 ml containers with fresh uninfected leaves. Weevil: Samples of adult Odoiporus longicollis collected from the banana fields of Thiruvananthapuram district were maintained in the laboratory at 26±3° C, RH 60 ± 10% and L:D 12:12 in an incubator. The pupae collected were maintained separately in 100 ml plastic container and its mouth was covered by muslin cloth. On emergence, the adults were transferred into one litre plastic container and they were provided pseudostem (50gm) for feeding. Adults with approximately two weeks old, irrespective of sex, were selected for the study.

Production of biopesticide

The insecticidal principle (Hydrogen Cyanide) was isolated from cassava leaves (variety H-97), those were collected from the farm of ICAR-Central Tuber Crops Research Institute, Thiruvananthapuram, by using the cassava biopesticide extraction unit commissioned at the biopesticide laboratory. The active principles isolated from the leaf were named as "*Menma* and its cyanogen content was estimated using spectrophotometer and gas chromatography. *Menma* was used for trial within 30 after production.

Estimation of cyanogen in the extract

Cyanogen in the biopesticide Menma was estimated with a modified method of Breuer and Rumball, (2007). Menma- 20 ml, was taken in a 100 ml conical flask and into which one drop of 0.5 M NaOH was added (Breuer and Rumball, 2007). By adding 0.1 ml of the newly prepared Rhodanine indicator (Breuer and Rumball, 2007), it was titrated against 0.0103 M AgNO3 solution until reaching the endpoint reached (colour change), and the cyanogen in the sample was estimated.

Toxicity Study

Common pea aphid (Acyrthosiphon pisum): Cyanogen present in the biopesticide Menma was diluted to 0 to 20 ppm (1, 2, 4, 8, 10, 20 ppm), and was stored in an airtight container. The test solution was poured into a plastic container of 100 ml capacity, and the test insects, >500 nos x 3 long-pea cut-parts. each were transferred in to the container.

Papaya mealy bug (Paracoccus marginatus): Cyanogen present in the biopesticide Menma was diluted to 0 to 40 ppm (1, 2, 4, 8, 10, 20, 30, 40 ppm), and was stored in an airtight container. The test solution was poured into a plastic container of 100 ml capacity, and the test insects, >50 nos x 3 leaves. each were transferred in to the container.

Weeping fig thrips (Gynaikothrips uzeli): Cyanogen present in the biopesticide Menma was diluted to 0 to 80 ppm (1, 2, 4, 8, 10, 20, 40, 80 ppm), and was stored in an airtight container. The test solution was poured into a plastic container of 100 ml capacity, and the test insects, >20 nos x 3 leaves, each were transferred in to the container.

Banana Pseudostem Weevil (Odoiporus longicollis): Cyanogen present in the biopesticide Menma was diluted to 0 to 100 ppm (1, 2, 4, 8, 10, 20, 40, 80 and 100 ppm), and was stored in an airtight containers. The test solution was poured into a plastic container of 100 ml capacity, and the test insects, 5 nos. each were transferred in to the container.

To avoid direct contact between the test solution and insects, an aluminium mesh (160 mesh/ square inch) was fixed in the container just above this solution, and onto it the infected samples/ insects were placed. LC50 and LD50 studies were worked out.

Data analysis

The LD_{50} was calculated along with their respective intercepts and slopes using SAS 9.3 statistical software. All the data pertained to mortality were corrected using Abbott's formula (Abbott, 1925). ANOVA was used for comparison of treatments and time of exposure.

Results and discussion

A positive correlation between the concentration of cyanogen in the biopesticide *Menma* and mortality of aphids, mealy bugs, thrips and weevils were observed ($P<0.001$) (Fig. 1a, 1b).In all the treatments, the treated aphids and mealy bugs were alive at one minute after treatment, except with 3 ppm and concentration above; however with 5 ppm, mortality was significantly higher than with all other treatments ($P<0.001$). Mortality of the treated insects was also noticed due to the treatment with *Menma* at low concentration of cyanogen, but it was delayed. This result is in corroboration with Hensen *et al.* (1991) who reported that mortality of thrips in cut flower due to the treatment of cyanogen was less in batches treated with lower concentration than the treatment with higher concentrations. Thrips show only 10% mortality in 10ppm at 1 minute after treatment while exhibit a cent percentage mortality at 15ppm. Weevils are the most resistant and they demand a minimum concentration of 20 ppm for a minute to exhibit 10% mortality and it demand 35ppm to assure 100% mortality (**Fig. 1**).

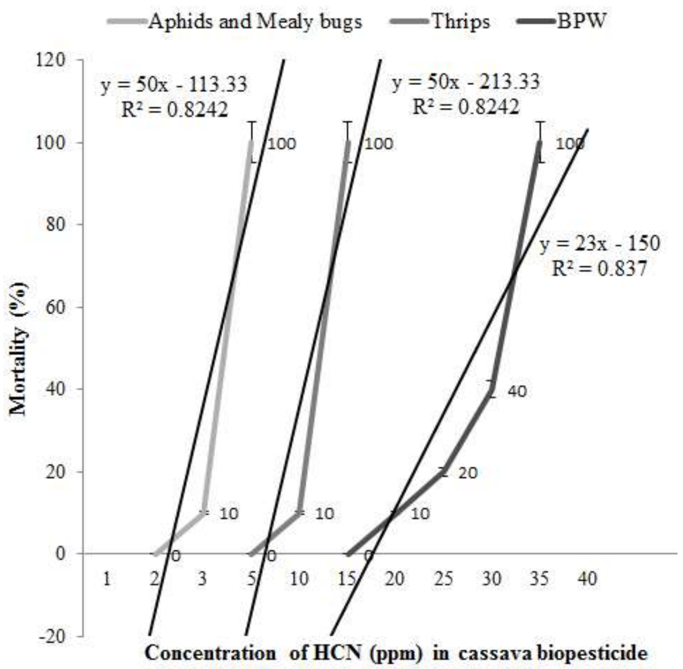


Fig. 1: Effect of concentration of HCN on the cassava biopesticide on different pests of horticultural crops.

The formulation with 300 ppm of cyanogen when exposed at different doses *viz*. 0.25, 0.5, 1, 3, 4 and 5 ml, a positive correlation was noticed between the dose and mortality of the test insects (Table 2). Mortality of aphids and mealy bugs were even observed in 1ml dose. Thrips demand 3 ml dose to achieve significant mortality. BPW delayed at lower dose (2 to 3 ml), but at higher dose (over 4 ml) its death started as early as 10 minutes after treatment (MAT) and reached complete mortality at 4 HAT. However, no death was observed in the untreated as well as in 0.25 and 0.5ml batches for all the insects even for long hours of exposure. Cent per cent mortality was achieved at 10 ml dose within 1 HAT (**Fig. 2**). Hansen *et al.* (1991) observed a variation in the mortality of certain quarantine pest of Hawaii at different concentration of hydrogen cyanide fumigation.

Two-way ANOVA significance sketch showcase the studies conducted were significant to above 95% limit to all the variable parameters such as, concentration, dose and exposure over time (**Fig. 3**).

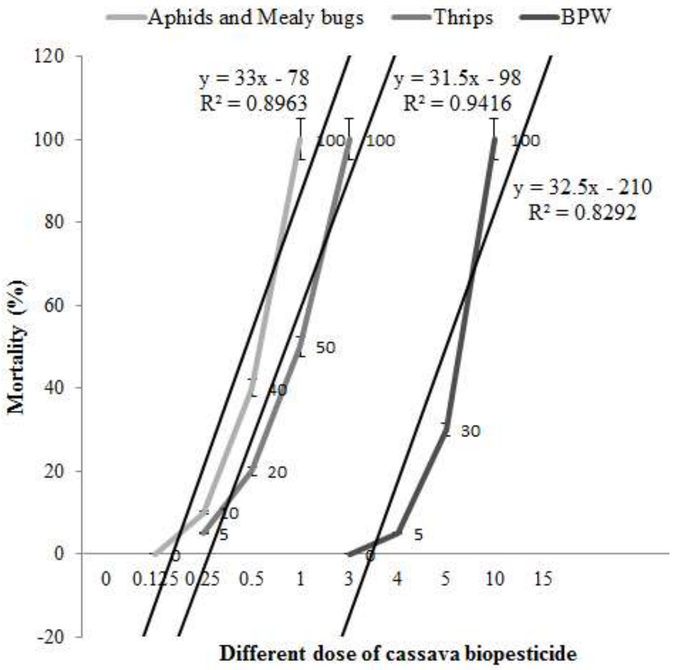

Fig. 2: Effect of different dose of cassava biopesticide over various pests of horticultural significance.

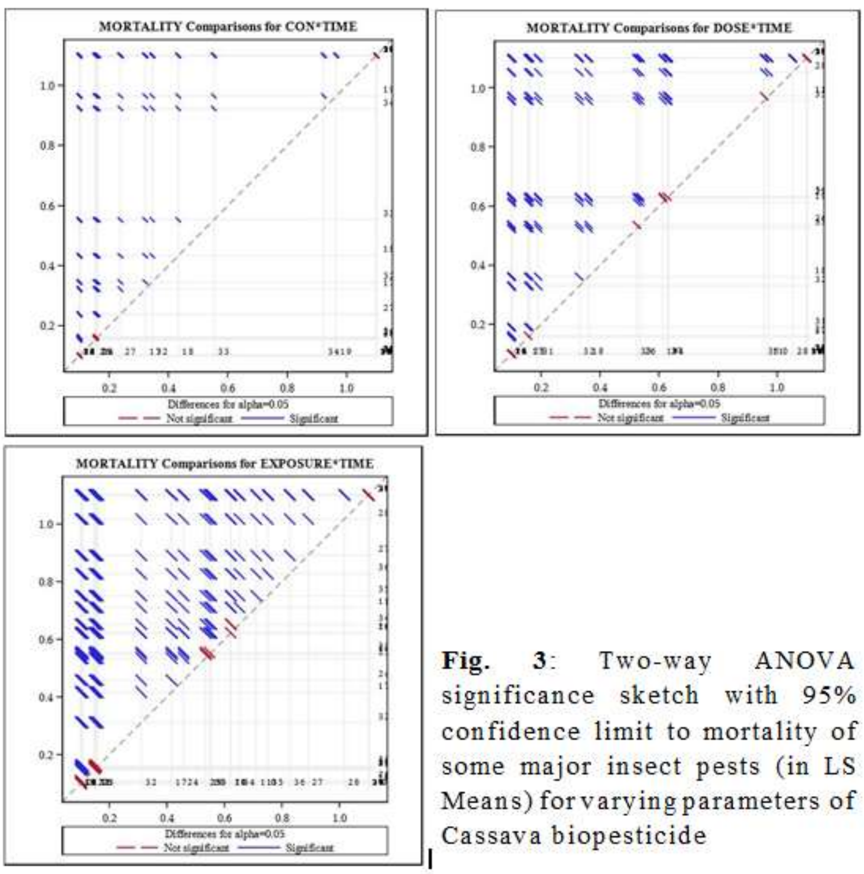

Fig. 3: Two-way ANOVA significance sketch with 95% confidence limit to mortality of some major insect pests (in LS Means) for varying parameters of Cassava biopesticide

Cassava biopesticide is thus a promising alternative to synthetic pesticides since it exhibits a very significant pesticidal property and is organic. Aphids, mealy bugs, thrips and weevils are major villains to horticultural crops and confer a cumulative pre-harvest damage of more than 80-90%. Since agriculture confers the most significant footprint in the biosphere than any other human activity this promising bio-utility can definitely assure sustainability and will also make cassava farmers to earn from a general bio-waste.

Conclusion

Use of plant products to protect pests associated with horticultural crops is an age-old practice. The present study focuses on the use of an underutilised plant parts such as leaf and tuber rind of cassava for the production of biopesticides against borer pests of fruits and tree crops; the efficacy of the biopesticide, Menma against many of the pests in horticultural crops has been established. The study also details the lethality status of cyano-glycosides present in the extract Menma over such pests. Mortality of the treated insects such as aphids and mealy bugs were noticed in 1HAT due to the treatment with Menma at concentration of Hydrogen cyanide at 5ppm or 1ml doss of 300ppm. In thrips the minimum required concentration for cent per cent mortality in 1HAT is 15ppm or 3ml doss of 300ppm of HCN. 35ppm or 10ml doss of the same is demanded by weevil to exhibit 100% mortality for the same foresaid duration. Though Hydrogen Cyanide is a publicised toxin its potential as an organic, degradable, volatile, accessible, cheap and effectiveness marks this as a perfect solution addressing many issues in pest management. As per WHO, Carbon monoxide is more toxic than HCN to humans but both will be lethal only in confined conditions of fumigation.

Abstract

Nowadays some of the traditional food technologies and formulations are being replaced with new ones. In addition to providing healthy and nutritious food, the new methods have potential to reduce risk factors. Using infrared irradiation heat for milk pasteurization as a technology with the high thermal efficiency can be a good alternative to traditional methods of milk processing.
Also by replacing potassium chloride instead of sodium chloride in the formula of the salt water of white cheese, the adverse health effects resulting from the consumption of sodium chloride can be prevented. In this study, by using the infrared radiation heat, raw cow milk prepared of Zanjan University animal husbandry was pasteurized and then white cheese produced from it in 2016. The white cheese was placed in four different formulations of brine containing 1) NaCl: KCl, 10:0 percent 2) NaCl: KCl, 7.5: 2.5 percent, 3) NaCl: KCl, 5:5 percent and 4) NaCl: KCl, 0:10 percent for 21 days at a temperature of 8° C. Then the microbial and characteristics of the cheeses were evaluated. Cheeses produced using two pasteurization methods of classical and infrared irradiation had no significant differences in the coliform, yeast and mold counts. Also a comparison of data means resulting from the analysis of the cheese characteristics show that the changing the formula of the brine had no significant effect on the microbial load.

Key Words: *NaCl, KCl, White Cheese, Brine, Infrared pasteurizing, microbial*

Introduction

Cheese is the ripened or unripened soft, semi-hard, hard, or extra-hard product, which may be coated, and in which the whey protein/casein ratio does not exceed that of milk (CODEX GENERAL STANDARD FOR CHEESE. 283-1978)[6]. Cheese contains less water than milk, and so has different organoleptic properties and shelf life than milk (Walstra et al., 2006). Cheese can be more useful than milk in high protein diets, also its proteins are highly digestible (Renner, 1993). Traditional production of white cheese in brine has been popular for centuries in small-scale caw keeping farms and that way it was difficult to set the standard for the properties and composition of the cheese. Along with the recent developments in dairy product processing industry and with the integration of mechanization and automation, large-scale production of cheese became possible (Ozer, 2014).
Salting is an important stage in the process of cheese. Salt is considered as an additive commonly used in the food industry and plays a vital role in the food processing, including food protection, helping to improve the flavor, the impact on proteolysis, water activity and

[6] . www.fao.org/input/download/standards/175/CXS_283e.pdf

strength in the tissue (Reddy and Marth, 1991; Guinee, 2004a; Guinee and Fox, 2004). Salt provides about 90 percent of the sodium in the human diet (He et al., 2012). In the structure of the salt, the sodium intake is very important to control the membrane potential of the cell and absorption of nutrients in the small intestine. In order to maintain the blood volume, osmotic pressure on the cell and also transportation of nervous signals, sodium is essential (Strazzullo et al., 2009; He and MacGregor, 2010). Although salt plays an important role during food processing, but has been known to be a major risk for diseases such as osteoporosis due to urinary excretion of calcium chloride, kidney stones and high blood pressure (Beumi et al., 2002; Kotchen, 2005; Massey, 2005; Heaney, 2006). The World Health Organization has recommended food manufacturers to reduce the use of salt (WHO, 2007). Meat, dairy, bakery and other food products, each include a different percentage of sodium uptake by the body in different classes in the world for example, the daily intake of sodium through cheese in England, France, America and Australia, have been reported 7.8, 9.2, 8.2 and 5% namely (Meneton et al., 2009; Anderson et al. , 2010). So many efforts have been made for producing low-salt cheese using different techniques such as reducing the amount of salt or partial replacement of salt in cheese with other materials (Guinee and O'Kennedy, 2007). Reducing the salt content of the Cheddar cheese and the effects of these changes on the microbial growth were done by Schroeder and colleagues (1988b). Replacing salt with other materials such as potassium chloride, calcium chloride and magnesium chloride may be considered as a successful strategy to reduce the amount of salt (Kilcast and den Ridder, 2007). Also partial replacement of sodium chloride with potassium chloride revealed that the quality of the cheese has not significantly changed (Guinee, 2004b). Potassium chloride salt is acknowledged as a potential alternative to sodium chloride in cheese making. Increasing potassium intake has been reported as a protective factor for people with hypertension (Fregly, 1981; Reddy and Marth, 1991). A mixture of potassium chloride and sodium chloride has been successfully used in cheese production and no adverse effects have been reported on the quality of the cheese (Fitzgerald and Buckley, 1985). Several studies have also been made on the effect of replacing sodium chloride with potassium chloride on the properties of Cheddar (Reddy and Marth, 1993a), feta cheese (Katsiari, et al., 1997; 2000a), Kefalograviera cheese (Katsiari et al., 2001a), and Fynbo cheese (Zorrilla and Rubiolo, 1994; Zorrilla et al., 1996), but there is not any investigation on white cheese made of IR pasteurized milk and aged in KCl substituted brine. Infrared heating is an alternative preservation method with a higher thermal efficiency, which transfers thermal energy in the form of electromagnetic waves. Recent applications of infrared heating indicate this technology is a viable alternate for the pasteurization of liquid foods, in addition it can decontaminate foodstuffs in both liquid and solid foods with retaining higher levels of health promoting compounds (Hagh Nazari. 2014). The aim of this research is to study the effects of replacement of NaCl with KCl salt on the microbial properties of ripened white brined cheese made from pasteurized milk using infrared irradiation.

Materials and Methods

Cheese making method: for the preparation of cheese, raw milk from the dairy farm of Zanjan University was prepared. Raw milk was pasteurized using flavor wave Turbo device that emits infrared waves at 72 °C for 15 seconds has shown in figure 1. The temperature of the process was checked by a digital thermometer model TES made in China. For comparing and evaluating the effects of the pasteurization methods, the milk was also pasteurized using classic (conventional) methods. After pasteurization of milk, 200 ml of milk was poured in lidded plastic containers of the same shapes in 3 replicates equaled 24 samples.

Figure 1: flavor wave Turbo device

After the milk temperature reached to 35 °C; the kefir starter solution to the volume of 2 ml along with calcium chloride to the amount of 0.02 % of the milk were added to the pasteurized milk. The samples were transferred to an incubator made by Memmert Company in Germany at 35 °C. And 20 minutes after adding the starter, the fungal rennet Valiren made in America was added to the amount of 0.0025 g to each container at 35 °C. After clot formation, clots were left without cutting for 12 hours in 18 °C to continue fermentation, coagulating and dewatering. The resulting clots were transferred to salt solutions containing: 1) NaCl: KCl, 10:0 percent 2) NaCl: KCl, 7.5: 2.5 percent, 3) NaCl: KCl, 5:5 percent and 4) NaCl: KCl, 0:10 percent for 21 days at a temperature of 8° C. After ripening, microbiological tests were conducted on the cheese. Microbiological tests: to evaluate the effect of potassium chloride on the microbial load of the produced cheeses, after the period of ripening, the cheeses were sampled and the total microbial load (ISIRI 2406, 2008), Coliform count (ISIRI 5486-1.2, 2002), fungi count (ISIRI 10154, 2007), coagulase positive *Staphylococcus aureus* count(ISIRI 6086-3, 2006), detection of the presence of *Salmonella* (ISIRI 4413, 2010) and detect the presence of E. coli (ISIRI 5234, 2000) was measured.

Statistical analysis: The data obtained via examination of cheeses prepared of two types of pasteurized milk with two methods of infrared and classical irradiation and four types of salt formulas were analyzed by means of factorial method using Mstatc statistical software. The obtained meanings were compared with Duncan's method.

Results and discussion

Microbiological analyses:
The results of the pasteurization of milk are shown in table 1. The total microbial count by the infrared radiation method has declined more than the classic method (Table 1).

Table 1: The total microbial count of milk processed by the infrared radiation method and the classic method

CFU	Raw Milk	Classic Pasteurized Milk	IR Pasteurized Milk
Total Microbial Count	3244000 ± 24000	68880 ± 2200	48110 ± 2600

The comparison of the Coliform count of cheese prepared with pasteurized milk using infrared radiation and Classic method at 72° C for 15 seconds is shown in Figure 2.

	10 % NaCl	7.5:2.5 % - NaCl:KCL	5:5 % - NaCl:KCL	10 % kCl
IR	35,67	38,67	38,67	39
Classic	38,67	38,33	39,33	40

Figure 2: The comparison of the Coliform count of cheese prepared with pasteurized milk using Infrared radiation and Classic method at 72° C for 15 seconds.

The above results show that the changes in the brine formulation also had no significant effect on the coliform count of the cheese. The mold and yeast count data by comparing the four formulations of aging cheeses in brine are shown in figure 3.

	10 % NaCl	7.5:2.5 % - NaCl:KCL	5:5 % - NaCl:KCL	10 % kCl
IR	26,67	29,33	33,67	30,33
Classic	31	33	31,33	29,67

Figure 3: Comparing the four formulations of aged cheeses in brine respected to their yeast and molds.

The results primarily in high common salt ripened cheese show that the yeast and mold count in IR processed cheese is lower than classic method ones and by decreasing the amount of common salt in samples, the 2 manners of the production don't show any significant difference in yeast and mold count in ripened cheese especially in 10% KCl brine formulation.

Other microbiological results on related culture media and following tests of ripened cheese samples show that there is no *Staphylococcus aureus* coagulase-positive, no *E. coli* per gram of cheese, but containing an average 38 and 35 colonies of coliforms, 31 and 26 colonies of mold and yeast per gram in classic and IR method of pasteurization respectively, and salmonella is negative at 25 per gram of two types of cheeses. Overall, a comparison of data means resulting from the analysis of the cheese characteristics show that the changing the formula of the brine had no significant effect on the microbial load.

The use of potassium chloride in the formula of the cheese brine:

The reason for the replacement of sodium chloride with potassium chloride, is achieving a product that reduces harmful effects to health caused by the consumption of sodium chloride. In addition to the fact that the product is supposed to be acceptable in terms of evaluated properties. Reduced sodium salt, cheese is very soft, bitter, less salty, and has a strong off-flavor and shorter shelf life (Ying Lu, 2012). Potassium chloride (KCl) has a similar structure and salty flavor as sodium chloride (salt) and partial replacement of salt with potassium chloride can be used to lower salt content in foods. Moreover, potassium can lower the blood pressure and the risk of heart disease or stroke. Thus, potassium chloride is a potential substitute for salt in the cheese.

Effects of brine formula on microbial properties of cheese

The researchers also reported that the initial pH of the cheese is specified according to the pasteurization method, the type of milk used to make cheese, the microbial load of the raw milk and the starter culture type. While the pH of the ripened cheese is specified according to the ripening temperature, period length and the type of rennet used (Lindsay, 1982; Aly, 1985; Katsiari et al., 1998, 2000, 2001). Partial replacement of sodium chloride with potassium chloride with different levels of substitution (10:00 percent sodium chloride - potassium chloride, 7.5:2.5% sodium chloride - potassium chloride, 5:5 % sodium chloride - potassium chloride and 10:00 percent potassium chloride - NaCl) had no significant effect on pH values. These results are similar to findings of Katsiari in 1998, 2000 and 2001. This researcher replaced (3% sodium chloride, 1.5:1.5 percent sodium chloride - potassium chloride and 3% potassium chloride) on Kefalograviera cheese and observed no significant change in the pH of the cheese. (Katsiari et al., 1998, 2000, 2001).

The microbiological properties of the produced cheeses in different brine formulations showed no significant difference between the cheeses produced from various ratios of NaCl and KCl. These findings can be confirmed by Kamleh et al investigations (2014). They investigated on the effect of partial replacement of NaCl with KCl on the microbiological characteristics of fresh and mature Akkawi cheese and they recorded that all tested microorganisms increased with storage but in general did not differ between salt treatments, specifically between control (100% NaCl) and (70% NaCl, 30% KCl) samples which this article's results also suggest similar collected data as the studies made.

The effect of infrared radiation in cheese production

Examining the microbiological properties of the produced cheeses showed no significant difference between the cheeses produced from pasteurized milk using the infrared and classic methods, but due to the high heat performance in the infrared radiation, the pasteurization process of milk is approximately 75% faster than the classic method. It is considered a more suitable method for pasteurization of milk compared to the classic method, especially due to the heat shock effect on microbial cellular structure. For confirmation of this subject, yeast cells (*Candida albicans* NBRC 1950, *Saccharomyces cerevisiae* NBRC 1067) and fungal spores (*Aspergillus niger* NBRC 4781) were subjected to IR heating as a pasteurization method by Nakata et al in 2015. The obtained results showed that IR heating was fairly effective than thermal conductive heating for killing microorganisms. Also the activation energy for the death of fungi by IR irradiation was slightly less than thermal conductive heating (Nakata et al 2015). The efficacy of infrared (IR) heating for inactivation of *Staphylococcus aureus* in milk was studied to investigate the potential of IR irradiating technology in milk processing by Krishnamurthy (2008). The results demonstrated that IR heating has a potential for effective inactivation of *S. aureus* in milk (Krishnamurthy, 2008). The reason of microbial death is recorded due to the cell wall damage, cytoplasmic membrane shrinkage, cellular content leakage and mesosome disintegration of IR-treated microorganisms (Krishnamurthy, 2008). The efficacy of near-infrared (NIR) heating to reduce *Salmonella enterica* serovar *typhimurium*, *Escherichia coli* O157:H7, and *Listeria monocytogenes* in ready-to-eat (RTE) sliced ham compared to conventional convective heating by Won Ha (2012). Also they determined the effect of NIR heating on hams' quality by measuring their microbial count. NIR heating for 50 s achieved 4.1-, 4.19-, and 3.38-log reductions in surface-inoculated *S. Typhimurium*, *E. coli* O157:H7, and *L. monocytogenes* respectively, whereas convective heating needed 180 s to attain comparable reductions for each pathogen. All above studies confirms this project's results due to the higher efficiency and saving energy consumption via IR assisted systems in comparison of classic method of pasteurization.

Conclusion

In general, from this study it can be concluded that changing the formulation of the used brine has no effects on microbial properties.

The microbiological properties of the produced cheeses in different brine formulations showed no significant difference between the cheeses produced from various ratios of NaCl and KCl.

The effect of infrared radiation in cheese production showed no significant difference between the cheeses produced from pasteurized milk using the infrared and classical methods, but the pasteurization process of milk is approximately 75% faster than the classic method due to the high heat performance in the infrared radiation.

Abstract

Forest berries are an essential biological resource that provides the population with a complex of mineral, organic substances, and medicinal properties. Wild berries are widely distributed in the mountain forests of Eastern Kazakhstan. Research requires the ecological safety of these resources in the system "plants-food products", since there are significant industrial enterprises in the region that determine the biogenic migration of toxic elements. The aim of the research was to study the gross concentrations of heavy metals in the berries of the mountain forests of Eastern Kazakhstan, harvested for use as food. The research subjects were *Ríbes rúbrum L.*, *Rósa aciculáris Lindl.*, *Vaccínium myrtíllus L.*, selected during the expeditions in 2016 on the territories of the forest ecosystems of Rudniy Altai. Heavy metals were determined by the method of atomic absorption spectrometry. The results of the studies showed that the chemical elements studied were installed in all samples. The range of heavy metals in Cu content was within the range of 3.44-4.84 mg/kg, for Zn – 8.02-9.3 mg/kg, for Mn – 32.7-37.3 mg/kg, for Pb – 0.25-0.31 mg/kg, for Co– 0.4-0.43 mg/kg, for Cd–0.02-0.026 mg/kg. Analysis of the concentration of heavy metals in the selected samples showed no excess of the maximum permissible levels. However, in some samples, the concentrations of detected heavy metals reached the boundary of the permissible limits. The obtained results of research characterize the wild berries of the forest areas of Eastern Kazakhstan as safe for use in food and medicinal purposes.

Keywords: *environmental monitoring*, *heavy metals, plant resources, Kazakhstan.*

Introduction

Currently, the study of plant resources for the purpose of their rational use, restoration and protection is becoming increasingly important. A careful study of the plant resources of forest ecosystems is a part of a broader area that relates to their use in various branches of the economy, medicine and food. The using of wild species for maximum satisfaction of needs is possible only with a thorough study of plant resources, which are an integral part of natural resources (Petrik et al., 2003; Chistilin, 2008; Hisamov and Kulagin, 2003).

Complex usage of forest resources provides for harvesting not only wood products, but also non-timber resources, with which forests are rich. This group includes mushrooms, berries, food, medicinal, technical, honey and fodder plants, bark, and forage, etc. The collection and harvesting of non-timber forest by-products, their use, represents a certain source of income in industrial, technological and entrepreneurial activities. Non-timber forest resources have a considerable price, often significantly higher than the cost of timber. The annual income from cranberries from 1 hectare of a bog is 5-7 times higher than the income from wood, which grows over 80 to 100 years. According to expert estimates, the market value of the commercial wild-berry stock in the country's forests is more than $ 10 billion, and the value of the commercial mushroom stock is $ 5 billion. in year. The revenues of the forestry of Belarus from the harvesting of products of spurious forest use and secondary forest resources in 2013 amounted to about 5 billion Belarusian rubles. Only 40% of non-timber resources are used, and the remaining 60% remain untouched throughout the world (Griboedova and Mashkanova, 2011; Tipcina, 2013). FAO research found that by-products are the main source of food in most developing countries, animal feed, additional food components, medicinal herbs and other food products that provide seasonal income in many regions of the world (FAO, 2001; FAO, 2013). Such studies are pioneering in Kazakhstan. It is required to determine the species diversity, the ecological quality of raw materials, the biological productivity of objects suitable for harvesting and processing in food technologies for forest areas in the long term. The abundance of wild berries in the mountain forests of Eastern Kazakhstan, growing near industrial plants, makes them a priority for biocomplex research in modern conditions. The purpose of the study was to study the gross concentrations of heavy metals in the berries of the mountain forests of Eastern Kazakhstan, polluted as a result of wind-dust transfer and harvested for food purposes.

Material and Methods

The research subjects were forest berries of mountain forests of Eastern Kazakhstan, harvested by the local population for use as food. Samples of red currant berries (*Ríbes rúbrum L.*), rose hips (*Rósa aciculáris Lindl.*), blueberry (*Vaccínium myrtíllus L.*) were selected during the expeditions of 2016 on the territories of forest ecosystems of Rudnyi Altai (50°45'N 86°36 'E). All samples were collected on the floodplains of the river Lugovatka, in the vicinity of Ridder. The figure 1 shows the scheme of the territory of the Kazakhstan part of the Altai with an indication of the location of the industrial center Ridder. The area has a temperate climate conditions. The average annual rainfall is around 600 mm. August is the driest month. Fully matured berries are harvested in green appearance period in July. The berries were stored at normal atmosphere and modified atmosphere packaging conditions.

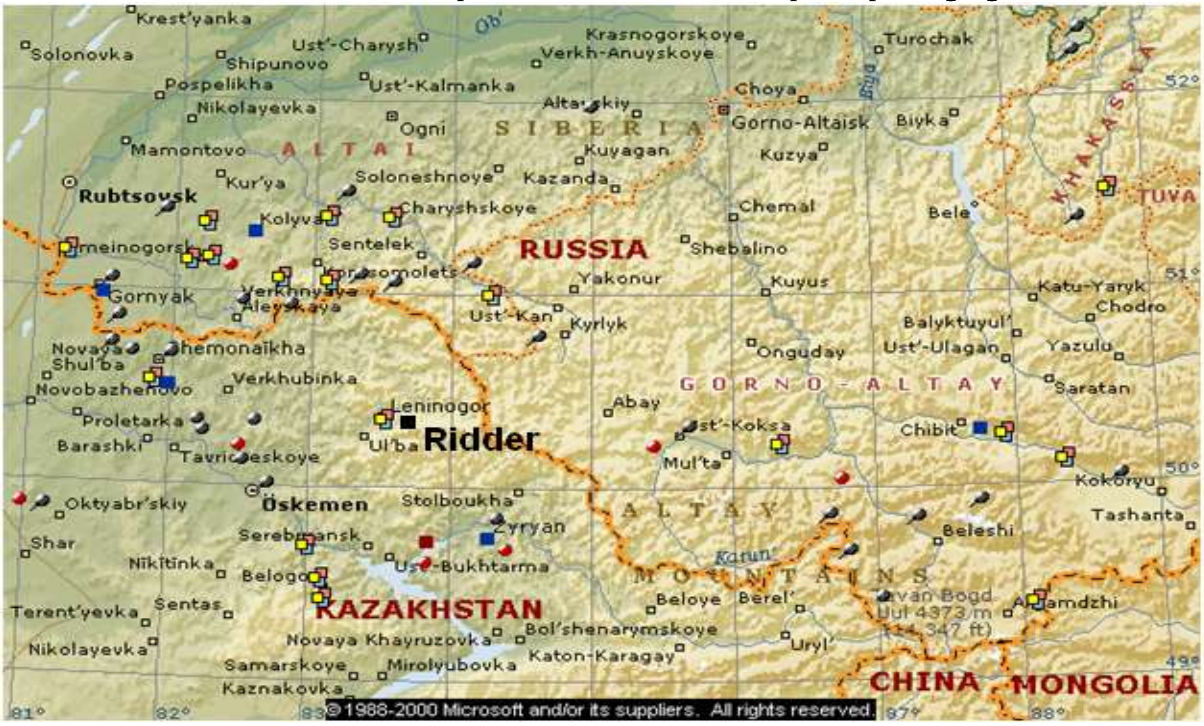

Figure 1. Scheme of the territory of Ore Altai (Evseev, 2004)

Determination of species of berry crops was carried out in accordance with the "Determinant of vascular plants of the Republic of Kazakhstan" (Abdullina, 1998). Preparation of samples and determination of heavy metals were performed in accordance with GOST 26929-94 «Raw material and food-stuffs. Preparation of samples. Decomposition of organic matters for analysis of toxic elements» (GOST 26929-94), GOST 30178-96 «Raw material and food-stuffs. Atomic absorption method for determination of toxic elements» (GOST 30178-96) and also by methodical instructions on atomic absorption methods for the determination of toxic elements in food products and food raw materials (Methodical instructions, 1992). Statistical processing of data, the level of error determined by the method contained in the above-mentioned GOSTs.

Results and Discussion

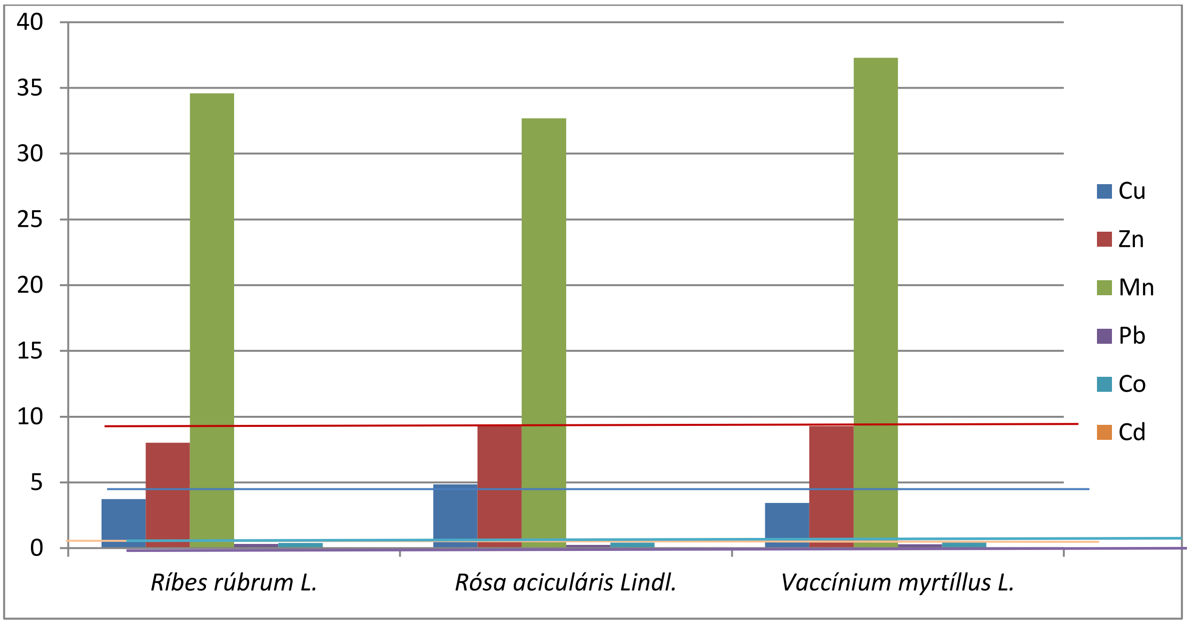
The territory of the Republic of Kazakhstan is covered by forests for 4-4.5%, the majority of forest ecosystems are located in the regions of Eastern Kazakhstan. The main types of forests are mountainous areas of the Kazakhstan part of Altai, which is called Rudnyi Altai. Due to its unique landscape and biological diversity, fir, cedar, pine, deciduous (birch-aspen) and mixed forests are widespread in this region. Rational use of the forest lands of the Rudnyi Altai provides for increasing the productivity of forests, which is one of the main tasks facing the forestry in the region at the present stage. The potential of plant forest resources, as shown in separate works (Kalachev, 2014, Sorajic and Zerdelic, 2015, Filipovic *et al.*, 2015, Erturk *et al.*, 2015), makes it possible to use them in various aspects. The study of biological indicators of plant resources of individual regions in order to search for new plant species containing biologically active substances is extremely important in the food industry, pharmacology. One of the important directions is the definition of ecological safety of raw materials of wild species used in food technologies. The study of the features of the accumulation of heavy metals in plant resources, including forest berries, is of current interest to many scientists (Angelova *et al.*, 1999; Rademacher, 2003; Moilanen *et al.*, 2006; Golami *et al.*, 2012; Johnny, 2014). at present 4 elements (cadmium, lead, zinc, cobalt) are subject to compulsory rationing in plant resources and derived vegetable oils in Kazakhstan according to regulatory documents,. Manganese and copper are determined in vegetable oils according to various technical requirements, (GOST 26929-94, GOST 30178-96).
The results of the studies showed that the chemical elements studied were installed in all samples. The range of heavy metals in Cu content was within the range of 3.44-4.84 mg/kg, for Zn – 8.02-9.3 mg/kg, for Mn – 32.7-37.3 mg/kg, for Pb – 0.25-0.31 mg/kg, for Co– 0.4-0.43 mg/kg, for Cd–0.02-0.026 mg/kg. The results of determining the content of heavy metals in the investigated berry crops are shown in Table 1.

Table 1. Concentrations of heavy metals in samples of forest berries, mg/kg (x : average value from 5 repetitions ; sd : mean standard deviation)

№	Objects	Cu (x ± sd)	Zn (x ± sd)	Mn (x ± sd)	Pb (x ± sd)	Co (x ± sd)	Cd (x ± sd)
	Extremely permissible concentrations	5.0	10.0	-	0.4	0.5	0.03
1	*Ríbes rúbrum L.*	3.72±0.14	8.02±0.13	34.6±0.6	0.31±0.02	0.4±0.1	0.02±0.01
2	*Rósa aciculáris Lindl.*	4.84±0.26	9.3±0.42	32.7±0.4	0.25±0.11	0.41±0.1	0.02±0.01
3	*Vaccínium myrtíllus L.*	3.44±0.41	9.28±0.47	37.30±0.7	0.3±0.6	0.43±0.2	0.026±0.02

*Source: Author’s elaboration based on the laboratory research.

To determine the conformity of forest berries in terms of levels of heavy metals, the norms "Sanitary Rules and Norms 2.3.2.1078-01" (SanRules, 2009) for a biological active additive on a plant basis were used. Analysis of the data in Table 1 shows that all selected samples of forest berries meet regulatory requirements. Figure 2 shows a comparative-comparative picture of the accumulation of various heavy metals in the types of berries studied.



Graph 1. Accumulation of various heavy metals in the studied berries

Experimental studies of the contamination of forest berries were below the Extremely permissible concentrations (EPC). Presumably, the sources of pollution of forest berries are the industrial enterprises of the region, providing wind-dust-transfer of elements in the air stream. On the Rudnyi Altai are various mining enterprises, which have a significant technogenic impact on natural ecosystems: in the Rudnyi Altai - Zolotushinskoye, Zmeingorskoye, Korbalikhinsky and other gold-pyrite barite-polymetallic; In the Gornyi Altai - Sinyukhinskoye gold-copper-skarn, Kalgutin molybdenum-tungsten quartz-greisen, Aktash, Chagan-Uzun mercury ore and others (Gusev, 2010). Ridder is on the 9th place out of the list of 10 contaminated cities in Kazakhstan according to KazGidroMet specialists (Smailov, 2014). Table 2 lists the index of atmospheric pollution (IAP) for large cities of the republic.

Table 2. Quality of atmospheric air in urban areas

Urban area	The index of atmospheric pollution (IAP)
Almaty	11.5
Kyzylorda	11.4
Shymkent	8.6
Ust-Kamenogorsk	7.6
Taraz	7.4
Karaganda	7.0
Temirtau	6.9
Zhezkazgan	6.5
Ridder	5.2
Atyrau	4.8

* Data on RSE "Kazhydromet"

It is shown that the city of Ridder is included in the first ten cities of Kazakhstan with increased IAP.

Conclusions

It has been established that all samples of contaminated forest berries are contaminated with all certain elements. *Vaccinium myrtillus L*. is contaminated with the greatest number of heavy metals (Mn, Co, Cd) to the greatest extent. *Rósa aciculáris Lindl.* occupies an intermediate position and accumulates two elements - Cu, Zn. *Ríbes rúbrum L*. is the least polluted, since the highest concentration of Pb is determined in it. The level of contamination of berries Cd objects are arranged in the order *Vaccínium myrtíllus L., Ríbes rúbrum L.* and *Rósa aciculáris Lindl.;* Pb - *Ríbes rúbrum L., Vaccínium myrtíllus L.* and *Rósa aciculáris Lindl*. The contamination of forest berries Co and Zn shows the same picture and determined the following order: *Vaccínium myrtíllus L., Rósa aciculáris Lindl.* and *Ríbes rúbrum L.* Experimental studies of the contamination of forest berries were below the EPC. Perhaps the transfer of dust particles in the dynamics is reduced during the ripening period of berries. Also, important is the atmospheric precipitation, which can wash away pollution from vegetative parts of plants. Thus, research on the territory of forest ecosystems of mountain forests in Eastern Kazakhstan showed a satisfactory state of contamination of forest berries with heavy metals. In this paper, the determination of heavy metals in forest berries (only on the example of *Ríbes rúbrum L., Rósa aciculáris Lindl., Vaccínium myrtíllus L.,).* Species diversity of forest berries in the region is much broader, which requires continuing research to ensure food security of the population. The most important conclusion established in the course of the studies is that all samples selected meet the requirements of regulatory documents on the criterion of environmental safety.

Abstract

Soil is the first link of the ecological chain soil-food-animals-human, and for this reason it has an important role in the distribution and transfer of radionuclides in fodder. The natural radionuclides come from the soil to the crops by means of migration and contribute for the total radiation burden in the population. The goal of this study was focused on investigation of the radioactivity in corn, and presence of natural radionuclides, and on the basis of the specific activity of the crops, we will calculate the dose which the human receives if the person consumes the examined crops. The corn samples were collected in 2016 from different locations in the surrounding of the city of Skopje. The sampling was performed so that 3 samples were taken from every location, which is in accordance with the recommendations from IAEA. The samples are measured on an instrument – gamma spectrometer (Canberra Packard) by using the program GENIE 2000. The values of specific activity and the calculated doses obtained in this study, regardless of the location, did not exceed the safety limits, pointing out the insignificant danger for radiation which arises from soil radionuclides which are naturally present. From the indicated above it follows that at a current level of radioactive contamination of corn, it would not be necessary to take measures in regard to reduction of the radioactive contamination, considering that the values of the radioactive contamination, compared to the level of radiological contamination of natural origin, are lower.

Key words: *radioactivity in corn; radionuclides; gamma spectrometry.*

Introduction

The radioactive contamination of animal feed, which is the most important factor for the radiation safety of people through the food chain, imposes the need of continuous radiation control of various types of crops for animal use. Usually radionuclides penetrate in crops from the soil through the root system. The very radioactive contamination of soil can be caused by radioactive substances of natural origin, however also radioactive isotopes that are a result of the experimental nuclear explosions, nuclear reactors, as well as a many other atomic techniques and plants. The behavior of radionuclides in soil, their retaining and transfer to plants, are very complex processes that depend on many factors (Jasinka, 1980). In the soil are present about 40 different radionuclides whose contribution is different (Bockok, 1981; Tzortzis et al., 2004).
The entry of radionuclides from the soil to plant crops depends on certain factors such as: the soil type, physical and chemical properties of the soil, the fertility of the soil, its texture, pH, conductivity, carbonate and sulfate content, etc. (Clarck and Smith, 1988). In addition, the use

of phosphate fertilizers in agricultural land, such as phosphorus fertilizers, which are extremely rich in radioactive substances and belong to products of uranium decomposition, increases the contamination of plants (Abdel-Rassoul, 2007). The level of radioactive contamination of soil will mainly determine the extent to which the radioactive substance will reach the organs of the corn, and further into the other links of the trophic chain. It is necessary to pay attention to the contamination of radioactivity in soil and its absorption in corn. Thus, keeping in mind that the main purpose of the radioactive contamination investigation is its impact on people, there are numerous undertaken studies for the crops radioactivity (Vasconcellos, 1987; Arogunjo et al, 2005; Tahir, 2005; Al-Kharouf et al, 2008; Changizi et al, 2013). The purpose of this study was to examine the level and redistribution of certain radionuclides in maize production, as well as to provide preliminary (preparatory) assessment of the doses of earth exposure of the population in the surrounding of the city of Skopje, and to assess the potential danger for radiation of the population that lives in the areas under research.

Materials and methods

Sampling. The corn samples were collected during the summer of 2016 from different locations in the surrounding of the city of Skopje. The corn samples with the root are collected so that three samples with a quantity of 1 kg are taken from each location. During the sampling, it was ensured that the micro-location is a flat terrain, which excludes the consequences of a possible horizontal translocation of radionuclides. The collected samples were carefully cleaned and root, stem, leaf, and fruit were separated.

Afterwards, the samples were air-dried at room temperature for a period of approximately three weeks in order to remove the moisture. After the drying, the samples were crushed, placed on a stand and grinded to a predetermined particle size according to the analytical requirements, and in the end the samples were passed through a sieve. The homogenized samples were packed in plastic containers that had the same geometry as the one for the reference materials wherewith the measurement equipment was calibrated.

Instrument. Gamma ray spectrometry technique was used for determination of radioactivity of the tested samples. The spectrometer consisted of an HPGe detector, model 3020 (Canberra Packard, Meriden, CT, USA), with an active volume of 180 cm^2, relative efficiency of 30 %, an operating voltage of 3000 V, and a resolution of 2 keV at 1332.5 keV. The detector was enclosed in massive 12 cm thick lead shielding and internal lining of 2 mm high purity cooper. Data acquisition and analysis were performed with 8192 channel digital analyzer; the duration of the acquisition interval for each sample was 65 ks. The activity of ^{226}Ra was determined from the gamma lines associated with low half-live time daughters of ^{214}Bi (609.31, 1120.29, and 1794.49 keV) and ^{214}Pb (351.93 keV). The ^{232}Th activity was determined by 338.4, 911.2 and 969.1 keV gamma lines form ^{228}Ac and its decay products. The gamma line at 1460.8 keV was used to determine the activity of ^{40}K.

Efficiency calibration was performed with mixed calibration standard sources MBSS2, supplied from the Czech Metrological Institute, Inspectorate for Ionizing Radiation. In order to determine the background distribution in the detector environment, empty sealed Marinelli beaker with the same geometry was measured at equal counts as the soil samples. The analysis procedure included the subtraction of the background spectrum.

Absorbed dose rate in air (D). The natural decay of radionuclides in the soil is one of the main sources of the human exposure to radiation. This level of radiation is different depending on the content of minerals and radioactive elements of each region. The dose of gamma radiation which is due to natural radioactive contents of the soil is important for the population in the area where they live. The rate of absorbed does in the air for the radionuclides with a height of 1 meter above the ground surface was calculated on the basis of the instructions provided below (UNSCEAR 2000).

$$D(nGy/h)=0.462A_{Ra}+ 0.604\ A_{Th}+0.042\ A_k \quad (1)$$

where A_{Ra}, A_K and A_{Th} accordingly are the average activity concentrations of ^{226}Ra, ^{40}K and ^{232}Th, expressed in Bq/kg.

Calculation of the external hazard index (H_{ex}). The external hazard index is calculated with an equation proposed by Beretka and Mathew (1985).

$$H_{ex} = C_{Ra}/370+ C_{Th}/259+ C_K/4810 \quad (2)$$

where H_{ex} is the external hazard value, C_{Ra}, C_{Th} and C_K are the mean activity concentrations (Bq kg^{-1}) of ^{226}Ra, ^{232}Th and ^{40}K, respectively. The value of this index must be less than unity, thus keeping the radiation hazard insignificant. The maximum value of H_{ex} = 1, corresponds to the upper limit of Ra_{eq} (370 Bq kg^{-1}).

Calculation of radium equivalent activity. As the distribution for ^{226}Ra, ^{232}Th and ^{40}K in soil samples in not uniform, exposure to radiation can be defined in terms of radium equivalent (Ra_{eq}), to compare the specific activity of the radionuclides of (Beretka and Mathew, 1985). The radium equivalent activity could be defined as:

$$Ra_{eq} = A_{Ra} + 1.43A_{Th} + 0.077A_K \quad (3)$$

where A_{Ra}, A_{Th} and A_K are the specific activities (Bq kg^{-1}) of ^{226}Ra, ^{232}Th and ^{40}K, respectively. By defining the Ra_{eq} according to previous equation, it is assumed that 370 Bq kg^{-1} ^{226}Ra or 259 Bq kg^{-1} ^{232}Th or 4810 Bq kg^{-1} ^{40}K produce equal gamma dose rate (Singh et al, 2005).

Results and discussion

Determination of a specific activity. In Table 1 the average radionuclide concentrations for ^{226}Ra, ^{232}Th and ^{40}K obtained from three measurements of individual corn samples are presented, associated with the respective standard deviations (SD).

Table 1. Mean values of specific activities of values of 226 Ra, 232Th and 40K in corn samples

	Specific activity*±SD		
	^{26}Ra	^{232}Th	^{40}K
C1	0.40±0.1.0	0.06±0.02	108.15±2.00
C2	1.30±0.40	<MDA	99.00±2.00
C3	0.16±0.04	0.02±0.12	69.70±1.00
C4	0.73±0.42	0.08±0.03	85.35±1.50
C5	0.17±0.11	<MDA	99.86±1.54
C6	0.40±0.05	0.17±0.20	115.54±2.40
C7	0.08±0.33	<MDA	115.26±2.00
C8	0.29±0.20	0.15±0.03	92.00±1.70
C9	0.38±0.20	0.10±0.40	89.57±1.50
C10	0.61±0.21	1.02 ±0.45	117.21±2.50
C11	0.48±0.20	0.30±0.25	78.02±2.00
C12	0.61±0.25	0.11±0.20	195.97±2.00
C13	0.33±0.15	0.17±0.05	107.50±2.35
C14	0.62±0.08	0.94±0.04	112.48±2.50

The presented results in the table are mean values from measurements performed on corn samples taken from 14 different locations, 3 samples from each location. It can be concluded that corn absorbs ^{232}Th significantly less than ^{226}Ra, which is in accordance with the physical-chemical properties of this radionuclide. By analyzing potassium which is necessary for the normal course of the life functions of crops, another behavior can be observed i.e. the transport from the soil to the corn is more intensive.

The concentration of activity of ^{40}K in corn is greater than the one of ^{232}Th and ^{226}Ra, which is consistent with the literature data (Saracević, 1990).The average activity concentrations for ^{226}Ra, ^{232}Th and ^{40}K and their ranges were 0.44 Bq kg^{-1} (0.08-1.30 Bq kg^{-1}), 0.22 Bq kg^{-1} (0.08-1.02 Bq kg^{-1}) and 105.68 Bq kg^{-1} (69.70-195.97 Bq kg^{-1}), respectively. The global average concentrations of the respective radionuclides are 40 Bq kg^{-1} (^{226}Ra), 40 Bq kg^{-1} (^{232}Th) and 580 Bq kg^{-1} (^{40}K) (UNSCEAR, 2008). According to the results presented (Table 1) the levels of ^{226} Ra, ^{232}Th and ^{40}K for the corn samples cultivated in the Skopje city surounding are lower than the levels determined for USA and Brasil (in Akhtar, 2005; in Changizi et al, 2013).

Absorbed dose rates. On basis of the data for activity concentrations applying the equations 1-3, absorbed dose rate in air (D), radiation risk index (H_{eks}) and radium equivalent (Ra_{eq}) were calculated, and the respective results are presented in Table 2.

Table 2. Obtained results for absorbed dose rate in air (D), radiation risk index (H_{eks}), radium equivalent (Ra_{eq})

	Specific activity*		
	D(nGy/h)	H_{eks}	Ra_{eq}
C1	4.76	0.023	8.81
C2	4.87	0.024	8.92
C3	4.24	0.014	5.55
C4	3.95	0.019	6.20
C5	4.27	0.021	7.85
C6	5.13	0.025	9.30
C7	4.87	0.024	8.97
C8	4.08	0.020	7.29
C9	3.74	0.020	7.04
C10	5.81	0.029	11.09
C11	3.67	0.018	6.91
C12	8.57	0.042	15.85
C13	4.76	0.023	8.85
C14	5.31	0.027	9.52

The mean value of the absorbed dose for corn samples is 4.85 nGy/h and it is lower than the global average value of 55 nGy/h (Al-Hamarneh and Awadallah, 2009). The average value of the H_{eks} radiation risk index is 0.02, which shows that there is no significant radiation risk for the population in the surrounding of Skopje. From the table itself, it may be seen that the specific average for the radium equivalent Ra_{eq} for corn samples is within the range from 5.55 to 15.85 Bq/kg and it is below the maximum recommended limit, i.e. 370 Bq kg^{-1} (El-Aydarous, 2007).

Conclusions

The results of this study are completely compared to the international values and the results of other studies in other countries in the world. It was found that the natural levels of radioactivity in the vicinity of Skopje are not with the range of high risk and they are in accordance with the international standards. The amount of radioactive elements in corn was so low that the health of consumers was not threatened. From the indicated above it arises that at the current level of radioactive contamination of corn, it would not be necessary to undertake measures related to reduction of radioactive contamination, considering that the values of radioactive contamination, compared to the level of radiological contamination of natural origin, are lower. These results can be used as reference values for current assessment of doses due to natural radioactivity in the surrounding of the city of Skopje.

Abstract

In fruit growing production in the Republic of Macedonia, plum growing is of great importance. Knowledge of the chemical composition of plums has significant importance for human nutrition as well as for technological processing. The aim of this research was to determine the difference in the chemical composition of fresh and dried plum fruits from the cultivars *stenlej* and *cacanska rodna*. The examinations were done in 2014. The chemical properties of fresh and dried plum fruits were determined. Drying of plums was done in a ventricular dryer with heated air. All of the tested parameters had higher values in the dried plums of both cultivars than in the fresh ones. The content of the total dry matter was higher in the dried plums of the *stenlej* cultivar (79.90%) and the *cacanska rodna* cultivar (84.00%) than in the fresh plums of the *stenlej* cultivar (17.10%) and *cacanska rodna* (19.80%). Total acid content was higher in the dried plums of the *stenlej* cultivar (0.40%) and *cacanska rodna* (0.30%). In the fresh plums this value was 0.85% for the *stenlej* cultivar and 0.97% for the *cacanska rodna* cultivar. The content of vitamin C in the dried plum fruits of the *stenlej* cultivar was 7.00 mg% and 6.80 mg% in the *cacanska rodna* cultivar. In the fresh plums this value was 5.60 mg% for *stenlej* and 4.80 mg% for *cacanska rodna*. The content of mineral matter in the dried plums of the *stenlej* cultivar was 2.50% and the dried plums of the *cacanska rodna* cultivar was 30.30%. In the fresh fruits, the content of mineral matter is 0.52% for the *stenlej* cultivar and 0.40% for *cacanska rodna*.

Key words: *Plums, Ventricular drying, Chemical composition.*

Introduction

Plum (*Prunus domestica L.*), genus *Prunus* is cultivated on all continents and it is ranked fourth in fruit growing. The first written documents for the plum are from Greece, 6th century BC. It is thought that the plum is native to Western Asia and that it was made with spontaneous hybridization between *Prunus spinosa* and *Prunus cerasifera*. It grows like a medium-high tree. Different cultivars vary considerably according to color, size and characteristic of growth (Bulatović, 1989; Pantelić M. 1993). Usually every plum yields many fruits, almost equal in size. It has a round or oval fruit. It has a blue, red, creamy yellow or light green color depending on the variety (Robertson et al., 1996). The flesh of the fruit is tasty and juicy with a yellowish color with a smooth seed in the middle (Cvejanov et al., 2004).

In the fruit production in the Republic of Macedonia, the cultivation of plums is of great importance. According to the number of stems and production, it occupies the second place immediately after the apple. The large production of plums in our country is due to the fact that it has a multipurpose usable value. On the other hand, there are modest requirements for climatic and soil conditions. It operates in hilly mountainous areas where other fruiting species are less represented.

The plum fruits contain 75-87% water and 13-25% dry matter. The taste of the fruit depends on the ratio of sugars and organic acids. In the fruit of the plum, glucose prevails in relation to fructose. The flesh part of the fruit contains up to 0.69% pectic substances that have a significance in the technology of production of marmalades, jellies and similar products. Of the minerals most contains potassium and phosphorus, and in a smaller amount of calcium, magnesium and iron. Pro vitamin A, vitamin B and C, folic acid, niacin and vitamin B6 are the most commonly present vitamins (Santos and Silva, 2008). It contains chlorophyll, carotenoids and anthocyanins, which are the most important dyes in the fruit plum. A good source is of flavonoids and polyphenolic antioxidants (Hui, 2010; Ertekin et al., 2006). The plum is low calorie fruit. It has a high energy value that is twice as big as apple fruits. It can be consumed in fresh condition, it can be dried and processed (Vereš, 2004).

Knowing the chemical composition of fruit plums is important for human nutrition, but also for the technological processing (Marković, 1986; Paliyath, 2008). The chemical composition of fresh fruit is of great importance for the choice of technological processes and quality properties of end products (Niketić-Aleksić, 1988).

Fruit plums contain a large amount of water, which reduces their durability in fresh condition (Barbosa-Canovas et al., 2007). The presence of water in the plums in large quantities allows for the development of various biochemical processes as well as the development of microorganisms (Jašić, 2007; Taiz and Zeiger, 2006). With their drying, i.e. dehydration, the water from fresh fruits is removed, causing unfavorable conditions for the development of microorganisms as causers for the internal decay (Barrett, 2004; Welti-Chanes et al., 2005).

The aim of drying is to remove a part of the water from the fruit plums, while retaining all other properties and nutrients in a same shape.

Dried fruits of plums should have all the qualitative characteristic: adequate size, meatiness, healthy fruit with sweet taste and good appearance that has the natural taste and smell (Chen, 2008). In addition, it should have a certain amount of humidity as well as an appropriate chemical composition in terms of the dry matter content, sugar content, total acids.

The aim of this research was to determine the difference in the chemical composition of fresh and dried fruit plums from the cultivars of *stenlei* and the *cacanska rodna*.

Materials and Methods

In this research, as a material for work, fresh and commercially dried plums from the cultivar *stenlej* and *cacanska rodna* were used. The cultivar *stenlej* mature in the second half of August and it is medium lush. The fruit is medium-sized, oval-shaped, dark blue. The meat is green yellow, firm, juicy, easily separated from the bone. The cultivar *cacanska rodna* is maturing in late August and it also is medium lush. The fruit is medium large, egg-shaped and dark blue. The meat is yellow, firm, juicy, sweet and quality.

After harvesting, a visual assessment of the examined cultivars of plums has been performed.

The qualitative properties of the examined cultivars of plums has been determined by determining the mechanical and chemical properties. The examination was conducted in 2014 in Valandovo region.

From mechanical properties were determined: height, width and thickness of the fruit, weight of the fruit and participation of the bone in the mass of the meat.

The chemical properties of fresh and dried fruit plums has been determined. The drying of the plums was performed in a ventricular drier with heated air. The principle of drying is precisely made to produce a distinctive odor and appearance of the plum.

From the chemical properties of fresh and dried plums from the cultivars *stenlej* and *cacanska rodna*, the following parameters were determined:
Content of total water was determined by drying the material in dryer on temperature of 105°C (Sarić et al., 1989);
Content of total dry matter was determined by calculation when from 100%, the percentage of hygroscopic water (Sarić et al., 1989);
Content of vitamin C - determined by the Thilmans method based on the redox reaction between L-ascorbic acid and organic color 2.6 dichlorophenolindophenol;
Total acid content - determined by the method of neutralization with 0.1 M NaOH solution in the presence of the indicator 1 % solution of phenolphthalein indicator;
Content of total carbohydrates - determined by HPLC method;
Content of mineral matter (ash) - determined with material burning at a temperature of 500 °C;
Content of nitrogen (N) - determined using Kjeldhl method (Sarić et al., 1989);
Content of phosphorus (P_2O_5) - determined by using atomic emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
Content of potassium (K_2O) - determined by incineration of the material with concentrated H_2SO_4 and plamenfotometar (Sarić et al., 1989);
Content of calcium (SAT) - determined by using atomic emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
Content of magnesium (Mg) - determined by applying atomic; emission spectrometry with inductively coupled plasma (ICP - AEC) (Sarić et al., 1989);
Proteins – determined with calculation when the % N is multiplying with coefficient 6.25
In dried plums, two pretreatments were made, and three variants were getting: variant M1 - control variant; Variant M2 - where the pretreatment was performed with a 2% solution of ascorbic acid for 5 minutes; Variant M3 - where the pretreatment was carried out with 3% potassium metabisulphite for a period of 5 minutes. The content of the mineral matters nitrogen, phosphorus, potassium, calcium and magnesium, as well as the protein content, was analyzed only in the three cultivars of dried plums.

Results and Discussion

The mechanical and the chemical content are specific for each kind of plums. The mechanical properties are basic requirement for cost-effective production of plums. Size is an important characteristic for each plum kind. By analyzing the mechanical properties, is determined the weight ratio of separate parts of the plums in percentage. Chemical composition of the plums means the content of all ingredients in the plums including the water. The mechanical properties were determined by measuring 50 fruit plums separately for each cultivar. From the performed measurements (Table 1), it was determined that the plums from the cultivar *stenlej* have higher average height (48.4 mm), larger width (35.2 mm), greater thickness (33.8 mm), larger mass of the fruit (33.4 g) and greater participation of the bone in the mass of meat (5.46 g) compared to the fruit plums from the cultivar *cacanska rodna.*

Table 1. Mechanical properties of fresh *stenlej* and *cacanska rodna* plum cultivar

Cultivar	Average high (mm)	Average width (mm)	Average thickness (mm)	Average fruit mass (g)	Bone part in the plum mass (g)
Stenlej	48.40	35.20	33.80	33.40	5.46
Cacanska rodna	41.0	31.80	28.40	26.40	4.50

Table 2. Chemical composition of fresh plums from *stenlej* and *cacanska rodna* cultivar

Components	*Stenlej* fresh plum	*Cacanska rodna* fresh plum
Total water (%)	82.90	80.20
Total dry matters (%)	17.10	19.80
Total acids (%)	0.85	0.97
Vitamin C mg/100g	5.60	4.80
Mineral matters (ash) (%)	0.52	0.40
Total carbohydrates (%)	8.10	8.90

From the data presented in Tables 2, 3 and 4, can be concluded that the total water content is higher in the fresh plums of both cultivars, where it is 82.90%, in *stenlej* cultivar and 80.20% in *cacanska rodna* cultivar, and in dried fruits, the highest content of total water is in the variant M3 (21.20%) in *stenlej* cultivar and 18.00% in the cultivar *cacanska rodna.*
The content of total dry matters is in correlation with the content of total water and its value is 19.80% in the fresh plums from *cacanska rodna* cultivar, i.e. 84.00% in the variant M2 from dried plums from *cacanska rodna* cultivar.
The fresh plums from *cacanska rodna* cultivar have higher content of total acids (0.97%). The highest content of total acids in the dried plums have the variant M1 in *stenlej* cultivar (0.40%), i.e. in *cacanska rodna* cultivar (0.30%).

Table 3. Chemical composition of dried plums from *stenlej* cultivar per variants

Components	M1	M2	M3
Total water (%)	20.30	20.10	21.20
Total dry matters (%)	79.70	79.90	78.80
Total acids (%)	0.40	0.35	0.20
Vitamin C mg/100g	6.50	7.00	6.80
Mineral matters (ash) (%)	2.50	2.20	2.00
Total carbohydrates (%)	10.40	9.90	10.30
N (%)	0.80	0.73	0.65
P (%)	1.25	1.10	0.95
K (%)	1.23	1.17	1.25
Ca (%)	1.90	1.20	1.60
Mg (%)	0.95	0.60	0.80
Proteins (%)	5.00	4.56	4.06

Table 4. Chemical composition of dried plums from *cacanska rodna* cultivar per variants

Components	M1	M2	M3
Total water (%)	16.50	16.00	18.00
Total dry matters (%)	83.50	84.00	82.00
Total acids (%)	0.30	0.22	0.20
Vitamin C mg/100g	6.30	6.80	5.40
Mineral matters (ash) (%)	3.10	3.30	2.90
Total carbohydrates (%)	12.70	11.90	11.80
N (%)	0.50	0.47	0.35
P (%)	1.10	0.80	0.82
K (%)	1.05	1.25	1.30
Ca (%)	1.40	1.10	1.30
Mg (%)	1.20	1.10	1.15
Proteins (%)	3.12	2.93	2.19

In the fresh plums from *stenlej* cultivar is getting higher content of vitamin C (5.60%) as well as higher content of mineral matters (0.52%). The highest content of vitamin C in both dried plum cultivars was determined in variant M2 (7.00% in *stenlej* cultivar and 6.80% in *cacanska rodna* cultivar), where the pretreatment was made with 2% solution of ascorbic acid. The highest content of mineral matters in dried plums, was determined in the variant M1 in *stenlej* cultivar (2.50%) and in variant M2 in *cacanska rodna* cultivar (3.30%). In the fresh plums, the content of carbohydrates is lower than in the dried plums. The highest content of carbohydrates in dried plums was determined in variant M1 (10.40%) for *stenlej* cultivar and 12.70% for *cacanska rodna* cultivar. The content of mineral matters: nitrogen (0.80% in *stenlej* cultivar and 0.50% in *cacanska rodna* cultivar), phosphorus (1.25% in *stenlej* cultivar and 1.10% in *cacanska rodna* cultivar), calcium (1.90% in *stenlej* cultivar and 1.40% in *cacanska rodna* cultivar), magnesium (0.95% in *stenlej* cultivar and 1.20% in *cacanska rodna* cultivar) and proteins (5.00% in *stenlej* cultivar and 3.12% in *cacanska rodna* cultivar) is the highest in dried plums from the variant M1.

The content of potassium has the highest value in both cultivars of dried plums in variant M3, where the pretreatment was made with 3% solution of potassium etabisulphite. From the presented data can be concluded that the two cultivars of plums are suitable for ventricular drying because their chemical composition after drying does not change in negative direction. From the three cultivars of dried plums, the variant M1 which has no pre-treatment, is characterized with the best chemical composition. Therefore, this variant is recommended for consumption, as a food with a rich chemical composition and excellent nutritional properties.

Conclusion

Based on the analyses and the obtained results for determining the influence of drying technology on the chemical composition of the plum fruits from the cultivars *stenlej* and *cacanska rodna*, the following conclusions can be made:

The chemical composition of the plums is of special importance for human nutrition, but also for the choice of the technological processing;

In the three cultivars of ventricular dried plums, higher content of all tested parameters in both cultivars has been determined, compared with fresh plums;

The two cultivars of dried plums from the control variant, M1, have the highest content of nitrogen, phosphorus, calcium, magnesium and proteins;

Dried plums from variant M1, which had no pre-treatment, are characterized with the best chemical properties;
The potassium content in the two cultivars of dried plums is the highest in M3 variant, where the pretreatment was made with 3% solution of potassiummethabisulphite;
Ventricular drying is in the initial stage in our country. With the introduction of ventricular in general practice, will increase the income of farmers, production, employment and foreign exchange inflows into the country.

Abstract

The impact of biofertilizers on the dynamics of the total number of bacteria, fungi, actinomycetes and nitrobacteria and aerobic celulitic microorganisms in the soil has been examined. Tests were performed on different types of soils under crop of strawberry, Swiss chard and lettuce. The experiment was placed in random block system in two variants and three repetitions. Variants in the experiment were: Variant 1 - Control and Variant 2 - using microbiofertilizers. The biofertilizers were foliarly applied, with dorsal nozzle every fifteen days during the crop vegetation. The application of microbiofertilizers with strawberry started from the time of flowering of the culture, until the completion of harvesting the strawberry every seventin days, and the chard and lettuce from planting the crop by the end of vegetation also every fifteen days. Microbiofertilizer has been used, the Microbiological fertilizer Slavon. Before the application the fertilizer gets dissolved in water 1:100 (100ml/10l). Before the application the microbiofertilizer agrochemical analysis of the soil was carried out. We found that the application of microbiofertilizers affects the dynamics of microorganisms in the soil and increases their number during the vegetation in three cultures. The highest numbers of examined groups of microorganisms in the soil is found at the end of the vegetation in all three cultures, and the lowest number at the beginning of the vegetation. The use of microbiofertilizers affects the improvement of biogenosis and biological activity of the test soil, in order to produce environmentally safe and healthy product.

Keywords: *Soil, Microorganisms, Swiss chard, Strawberry.*

Introduction

Biofertilizers have an organic origen and promote the primary agricultural production. They are used to improve the physico-chemical properties of the soil, increasing the fertility of the soil and productivity of the observed crops by increasing the microbial activity. (Malik et al., 2005; Galloway et al, 1995). The use of biofertilizers reduces the use of agrochemicals by making them exceptionally favorable in the production of health-safe food. (Červenski et al., 2013; Vasić, 2014). Biofertilizers are used as fertilizers in which bacterial and fungal cultures produce phosphatases and supply plants with wood-affordable phosphorus or they are used in combination with nitrogen-fixing bacteria that supply plants with nitrogen. (Najdenovska et al., 2012; Govedarica, 2000). The most active relationships between plants and microorganisms are established in the rhizosphere of soil (Kennedy, 2005). Microorganisms participate in the exchange of materials and energy in nature. They play a major role in one of the most important processes in the ground. Microorganisms are carriers of the process of biological nitrogen fixation (Govedarica et al., 1996, 1997). With the use of microbiological fertilizers, trough foliar application on the agricultural crops, the use of skimmers of nitrogen fertilizers is reduced, the adoption of plant phosphorus is facilitated by the plants, they affect the dynamics of microorganisms and the microbiological processes that indirectly influence the maintenance and increase of fertility At the beginning (Najdenovska et al., 2013; Djordjević et al., 2004). According to Miskoska-Milevska et al., (2012), the effect of microbial fertilizers depends on the strain of bacteria, the concentration of the bacterial cells in the inoculant, the type of plants, the application of agromeliorative measures and the physico-chemical properties of the soil. Through the application of microbial fertilizers, ie the introduction of living microorganisms in the soil, the plants are provided with nutrients and a healthy environment is maintained and production of environmentally sound products is allowed (Najdenovska and Djordjevic, 2009).

The purpose of the research in this effort is to examine the influence of the application of microbial fertilizers on the dynamics of different groups of microorganisms in the soil, in conditions of organic farming and production of health-safe strawberry, marl and shrimp.

Material and Methods

The examination of the dynamics of microorganisms in the soil with the application of microbiofertilizers was carried out on alluvial soil type under sowing of strawberry (*Fragaria spp.*), Swiss chard (*Beta vulgaris, var.vulgaris, L.*) and lettuce (*Lactuca sativa, L.*). The experience with strawberry from the homogeneous variety Alba is set on the experimental area of 200 m2, in the village of Stracinci, Skopje. The strawberry is grown on black foil. The taste with swiss chard and lettuce was placed in greenhouses in the village of Piperevo, Strumica. The lettuce was grown on a total area of 67.5 m^2, with the basic size of the experimental plot of 7.5 m^2 or (3 x 7.5 m^2 = 22.5 m^2 x 3 = 67.5 m^2). The swiss chard is cultivated on a total area of 70.2 m^2, with the basic size of an experimental plot of 7.8 m^2 or (3 x 7.8 m^2 = 23.4 m^2 x 3 = 70.2 m^2), in the period from March to Month of May. The trial with the three examined cultures was set in two variants in three repetitions per random block system. The variants of the experiment were: Variant 1 - without the use of microbiophyllators and Variant 2 - by application of microbiophyllizers. Biofilterers are applied folially, with a dorsal spray every seven days during the vegetation of the crops. The application of microbiophalizers on strawberries began at the period of flowering of the crop to the end of the harvesting of strawberry, and in the shrubs and lettuce from the planting of the crops until the end of the vegetation. During the test, the microbiophalizer Slavol was used. Prior to application, the microbiological fertilizer was dissolved in water at a ratio of 1: 100 (100 ml / 10 l). During the cultivation of the culture, appropriate agrotechnology (irrigation and spraying of crops) was applied. Agrochemical analysis of the soil was performed prior to the application of microbiophalizers. The following parameters were determined: pH value; Content of available nitrogen, phosphorus and potassium; Content of carbonates; Content of humus. All parameters were determined according to standard methods by Bogdanović et al., 1966. The soil samples were taken at depths from 0 to 30 cm. The strawberries were taken three times during the vegetation: the first trial at the very beginning of strawberry flourish (first decade of April), the second rehearsal before the start of the first harvest (first decade of May) and the third rehearsal after the last (fourth) strawberry harvest (End of May). In the experiment with swiss chard and lettuce, three soil samples were also taken: First test at the stage of 4 petals (April); Second trial in the growth phase (May) and the third trial in the phase of technological maturity.

Trough microbiological analysis of the soil, the dynamics of: azotobacteria, ammonifiers, aerobic cellulolithic microorganisms, fungi and total number of bacteria were determined.

The number of microorganisms is determined by an indirect method of seeding the appropriate dilution of the soil suspension of selective nutrient substrates (Govedarica and Jarak, 1997).

Results and discussion

Soil is an open, biological system in which there is a constant exchange of energy and circulation of the materia under the influence of several factors, among which the most important are the biological. The biological factors include all living organisms, and from all living organisms, carriers of the circular motion of the material in the soil are microorganisms (Kennedy, 2005). Although they represent less than 1% of the basic starting component with their role in the transformation and circulation of the material, microorganisms represent a basic chain in the formation of quality and fertile soil. The soils in a region with a climate such as ours are rich in microorganisms. Their number and variety is conditioned by several factors, including: the physico-chemical characteristics of the soil, the pH value and the water-air regime at the ground (Kiss et al., 1978); Biological factors such as the appearance of the plant and the influence of man through his activity; And applications of agro-technical measures (Jarak et al., 1990; Jarak et al., 1999).

Table 1. Agrochemical analysis of soil

Crop	Soil properties (0-30 cm of depth)						
	pH		Available nutrients (mg 100 g^{-1})			Percent	
	H_2O	KCl	N	P_2O_5	K_2O	Humus	$CaCO_3$
Strawberry	7.60	7.00	5.50	18.20	28.30	2.70	0.20
Letuce	7.35	6.73	6.50	14.10	31.10	1.20	/
Swiss chard	8.02	7.43	6.50	23.90	20.00	3.60	2.30

According to pH the value is based on strawberry and marl, which is neutral, but poorly ground under the shade. What all three layers do is medium-low, nitrogen is available. According to pH the value is based on strawberry and marl, which is neutral, but poorly ground under the shade. What all three layers do is medium-low, nitrogen is available. Lower-order nitrogen is available under strawberry and letuce, and it is well-fertilized under the sowing of swiss chard. Good fertility is available to all three. Highly fruitful according to the content of the humus under the strawberry and lettuce sowing, and well-fertilized under the sowing of swiss chard. The soil is poorly carbonated under strawberry and swiss chard, and there is no presence of carbonates under the seeds of lettuce. Table 2 shows the dynamics of the microorganisms in the root of the strawberry. The number of nitrogen bacteria in the course of strawberry vegetation has been steadily rising. The vegetation period is an important factor that influences the microbiological activity in the soil (Jarak et al., 1990). The highest number of azotobacter (904) was recorded in the last vintage phase. The number of ammonifiers is increasing during the growth of strawberries. Most ammonifiers (74534) are determined by variant V2 at the last vintage. Most of the cellulite microorganisms were recorded in the soil (12307) in the period of strawberry cutting prior to the application of microbiological fertilizers. The following two phases have a decrease in the number of cellulite microorganisms. The content is higher in the control variant in comparison to the treated variant.

The highest number of fungi was recorded in the soil (596), during the period of cutting before the use of microbiological fertilizers. Microbiological fertilization decreases the number of gaps in the soil, which is positively because it improves the pH of the soil.

Microbiological fertilizer has a positive effect on the total number of microorganisms. The lowest content of the total number of microorganisms (133974) is determined during the cutting period, and the highest in the third phase (683167) in the control variant.

The lowest content of total number of microorganisms (133974) was determined in the blooming period, and the highest in the third phase (683167) in the control variant.

Table 2. Dynamics of microorganisms in soil under sowing of straberry

Type of microorganism	1. Start of flowering	2. First harvest		3. Last harvest	
		B1	B2	B1	B2
Azotobacter	596	751	683	782	904
Ammonifier	22435	42176	34210	47904	74534
Cellulite microorganisms	12307	9487	4868	10680	4730
Fungi	596	95	78	186	161
Total number of bacteria	133974	306122	171052	683167	649101

Table 3. Dynamics of microorganisms in soil under sowing of swiss chard

Type of microorganism	1. 4 leaves phase		2. growth phase		3. technological maturity phase	
	B1	B2	B1	B2	B1	B2
Azotobacter	5	20	12	24	25	40
Ammonifier	434000	13642000	527000	719000	472000	1236000
Cellulite microorganisms	66000	13100	69200	34000	68100	54900
Fungi	31530	40880	2690	2300	9670	7030
Total number of bacteria	55000	120000	357000	428000	687000	12593000

Table 4. Dynamics of microorganisms in soil under sowing of lettuce

Type of microorganism	1. 4 leaves phase		2. growth phase		3. technological maturity phase	
	B1	B2	B1	B2	B1	B2
Azotobacter	33	36	47	34	28	12
Ammonifier	1743000	16000	273000	1295000	470000	694000
Cellulite microorganisms	8200	45900	23500	40400	57300	72100
Fungi	27540	6990	4260	2350	6830	6720
Total number of bacteria	3200	3800	224000	1235000	1388000	1437000

Table 3 shows the dynamics of microorganisms in swiss chard soil. The largest number of azotobacter (47) is determined in the control variant in the second phase. The number of azotoocters in the third phase is the lowest compared to the other phases. The number of ammonifiers has increased in the second (1295000) and in the third phase (694,000) in variant 2. The number of cellulite microorganisms has a tendency to rise in the three stages of the test. The highest number is determined in variant 2 (40400) in the second and 72100 in the third stage. The total number of fungi tends to decline in the second and third stages of the test. The largest number of fungi (27540) are in the control variant of the first phase of the trial, and the smallest number (2350) in the second phase of the trial in variant 2. The lowest total number of bacteria in the first phase of the test, and the largest in the third phase of the trial. In all three phases of the trial, the highest content of total bacteria is determined in variant 2 where the microbiological fertilizer is used. The number of azotobacter increases from the first to the third stage of the test. In variant 2, in all three phases, a higher number of azotobacter was determined in relation to the control variant. The smallest number of azotobacker (5) was determined in the control variant of the first phase, and the largest number of azotobacter (40) was determined in variant 2 of the third stage of the test. In all three phases of the trial, most of the ammonifiers were achieved in variant 2 compared to the control variant. Most of the ammonifiers (13642000) are determined in variant 2 of the first phase of the test, while in the second and third phasess there is a decrease in the number of ammonifiers. The number of cellulite microorganisms in the three stages of the trial is greatest in the control variant. The highest number of cellulite microorganisms (69200) was obtained in the control variant of the second phase. The number of fungi in both variants is greatest in the first phase, and in the second and third phasess their number is declining. The total number of bacteria increases from the first to the second and third stages. A higher number of total microorganisms in the three stages of the trial was determined in variant 2 with respect to the control variant. The total number of bacteria is the largest (12593000) in variant 2 in the third stage.

Conclusion

Based on the results obtained from the study of this paper, it can be concluded that the application of microbiophalizers affects the increase in the number of all investigated groups of microorganisms in the soil under sowing of strawberry, swiss chard and lettuce during vegetation, with the exception of fungi whose number is reduced during vegetation. The highest prevalence of azotobacter, ammonifiers and cellulite microorganisms was observed in the third phase of the soil test in the three crops. The number of fungi is the highest in the first phase of the soil test in all three cultures. The use of microbiophyllators has an impact on the improvement of the biogenicity and biological activity of the investigated soil, without the use of mineral fertilizers, and in order to produce an environmentally safe and healthy product. All this suggests that the application of microbiofertilizers should take their place in modern agricultural production.

Abstract

GM foods or GMOs (genetically-modified organisms) is most commonly used to refer to crop plants created for human or animal consumption using the latest molecular biology techniques. These plants have been modified in the laboratory to enhance desired traits such as increased resistance to herbicides or improved nutritional content. Malnutrition is the most threatening aspect in present scenario. We have not quantity and quality of food for alarmingly increasing population. GM crops can play vital role in malnutrition especially overcoming the nutritional deficiencies disorders. Only six Asian countries involve in adoption having very low proportion. The GM crops adoption by the Asian countries is question mark. The enhancement of desired traits had traditionally been undertaken through breeding, but conventional plant breeding methods were very time consuming and were often not very accurate. GM crops are now also being developed for the production of recombinant medicines and industrial products, such as monoclonal antibodies, vaccines, plastics and biofuels. Genetic engineering, on the other hand, can create plants with the exact desired trait very rapidly and with great accuracy. In 1990 china was the first who commercialize the first transgenic plant. Food and Drug Administration Authority approved commercially the flavor Savor Tomato in 1994.This genetic manipulation delayed ripening after harvesting.GM products which are currently in the pipeline include medicines and vaccines, foods and food ingredients, feeds and fibers. Locating genes for important traits, such as those conferring insect resistance or desired nutrients-is one of the most limiting steps in the process.

Keywords: *Food safety, genetically modified food. Environment, Biodiversity, Toxicity.*

Introduction

Genetically modified organisms are produced by the use of novel molecular techniques to transfer the gene of interest from distinct specie to another. Organism having a foreign gene inserted in its genome is called as transgenic. According to Schneider and Schneider (2002) modification in the genetic constitution through DNA recombinant technology results in the development of genetically-modified foods (GM foods). Use of genetic engineering made it possible to transfer gene of interest from wild relatives and distinct species that is impracticable through conventional breeding. Genes could not only be transferred from the plant species but from non-plant species (Whiteman, 2000).About 90 million hac area was grown by GM crops in 2005 out of which 33.9 million hec area is under developing countries (Kimenju and Groote, 2007; James, 2006). Technology is rapidly adopted in some parts of Asia, north and South America (Kimenju and Groote, 2007).Malnutrition is a global issue but developing countries are at a greater risk to it. Malnutrition in its both aspects as protein deficit food intake or intake of food deficit in iodine, iron, zinc and vitamin A has negative impact on health and mental growth of human (Muller and Krawinkle. 2005). Insufficient food intake, insufficient energy intake and mineral deficiency are major causes of malnutrition. Kramer and Allen (2015) reported 26% stunted growth, 3 % mortality in children worldwide while 45 % of children were found underweight during year 2012. World population is increasing day by day and is predicted to rise by 30 % up to 2050. According to Whitman (2000) world population is 6 billion currently which is expected to double in next 50 years. To ensure the food demand for rising population masses sustainable economic yield must be ensured. Thus food security issues are putting a lot of pressure to increase agricultural productivity and biotechnology can be used as efficient tool to achieve the goal. Biotechnological tools are highly adopted by developing countries to increase crop productivity because they are at a greater risk of food insecurity. Improved health and nutrition of the consumer by the use of genetically modified food has been reported (Bouis, 2007). Introgression of dwarfing gene through conventional breeding overcome the lodging and also increases the economic produce of wheat and rice crop. Sudden boost in the yield resulted in Green revolution in 1960's. Use of genetic engineering is making a pace in the current research world as "Gene Revolution" is the revolution predicted in 21st century. Bouis (2007) has postulated 3 possible ways GM crops could benefit the human nutrition i.e. through increased yield by the transfer of novel gene, through reduced chemical contamination in B.t crops and through transfer of genes for improved micro nutrition. Genetically modified crops are not only grown as crops but can also be used for other purposes. Research on genetic modification for the incorporation of edible vaccines in tomatoes and potatoes is in progress while GM poplar tree have been found effective in remediation of metal toxic soils (Whitman 2000).Genetic Engineering is a novel technique which is used to enhance quantity and quality of agricultural production. Several important crops have been modified for increased yield and quality attributes. However use of technology is controversial and further research is also required for a better understanding of the technology and its role in food security. A lot of expertise and high cost input is also required for growing GM crops which lacks in the developing countries.

Extent of food security and malnutrition:
Food unavailability is concomitant to human malnutrition. Food security does not always meant for the availability of sufficient food but a complete diet comprising of all essential nutrients (minerals & vitamins). Diet plan is a major cause of malnutrition. Unavailability of food, poor asses to food and improper utilization of food were reported as determinant of hunger in the world (Stein, 2007).More as one billion people from 6 billion people were found undernourished (FAO, 2009). Schmidhuber and Tubiello (2007) predicted 5-170 million more people at the risk of hunger up to 2080. Booth and smith (2001) discussed food insecurity, its causes and its negative impact on health of Australian nation. Developing nations has greater intake of staple food and whole grains but low intake of fruits and vegetables that are enriched source of minerals. People consuming rice as staple food experience color blindness because rice lack carotene in it. Wheat is staple food in Pakistan and wheat flour is consumed after milling. Wheat embryo contains sulphur and selenium while bran contains iron, zinc and copper (Gregori et al., 2000; Lyons et al., 2005).Protein energy malnutrition is major problem in developing countries (Waterlow, 1997). More than one in seven people suffer with malnutrition due to unavailability of sufficient and quality food (FAO, 2009). Currently more than 3 billion people suffered with micronutrient deficiency (Mason and Garcia, 1993; Welch et al., 1997; Welch and graham, 2004; WHO, 1999; World Bank, 1994). Lack of sufficient mineral and vitamin in the food termed as

hidden hunger because its consequences are not visible (Stein, 2010).There are 49 essential nutrient required by human for metabolic pathway and deficiency of a single nutrient can led to stunted growth and development (Welch and graham, 2004). Some minerals are required in greater quantity while some are required in trace amount. Nutrients exist in soluble or non-soluble form but their availability depends upon the presence of promoter or anti-nutrients (white and broadly, 2005). A major part of population is deficit in micro nutrients. 60-80 % people were found to be deficit in iron, mare than 30 % deficit in zinc, 30 % deficit in iodine and 15 % deficit in selenium (Kennedy et al., 2003; Combs, 2001). Iodine deficiency disorders were reported highest in Mediterranean region (32%) while 20 % in Africa, 15 % in Europe, and 12 % in Asia (Ramakrishnan, 2002). Bouis (2007) reported deficiency of vitamin A, iron and iodine as major contributor towards human malnutrition. More than 60 countries and large proportion of children in Asia, Africa and America suffered with vitamin A deficiency (Ramakrishnan, 2002). Iodine deficiency leading to endemic goiter is common disease with high prevalence in developing countries. Iron deficiency lead to reduced hemoglobin and anemia due to depletion of iron stores. Losses vary with the age and food intake however children and pregnant women are at greater risk (Ramakrishnan, 2002). Iron deficiency may not led to anemia all the time but 50-60 % of anemia is due to iron deficiency (Stein, 2005; Stein 2010).Several health hazards are associated with human malnutrition ranging from diarrhea to mental retardness and even death can occur. Mental retardness, abnormal physical activities and fetus mortality are consequences of iron deficiency anemia. Zinc deficiency has mild impact on health of infants and children (Stein, 2005; Stein 2010). Iron deficiency led to mental retardness and goiter in women (De benoist et al., 2004). Calcium deficiency caused rickets, arthritis and other bone diseases (Thacher et al, 2006; DeLucia et al, 2003)Mineral deficiency led to several diseases and had significant negative impact on social and economic growth (Stein, 2007). 0.2- 4.7 % decrease in annual economic growth due to malnutrition was reported by Acrand (2001). 50 % of world population suffered with vitamin deficiency (Naqvi et al, 2009). Vitamin deficiency includes the deficiency of B6, B12, folate and riboflavin. Serious health hazards were reported due to vitamin deficiency. B12 deficiency was also reported in developed countries like United States (Allen et al, 2001). Folate and riboflavin deficiencies are common in developing countries like Asia and Africa (Ramakrishnan, 2002).

Genetically modified crops to overcome malnutrition:
First genetic modification was practiced by Calgene in tomato to induce vine ripened taste. It was named as Flavr-Savr tomato and approved in 1993 (Schneider and Schneider, 2002).In later 1980's genetic modification in plants was initiated for medicinal purpose but use of technology was controversial in debates (Azadi and ho, 2010).Genetic modification in maize was done to induce pest resistance and improved grain quality. Bt-corn was engineered to enhance resistance against corn borer, armyworm and earworm. Bt gene was transformed from Bacillus thuringiensis which produce a toxin to kill insects. Bt-corn was approved for general cultivation by USDA in 1995 (Schneider and Schneider, 2002). Maize crop is deficit in lysine and tryptophan. Two mutant genes opaque2 and floury2 were used to increase lysine content in maize but high lysine genes made the endosperm soft. High lysine kernels were prone to breakage and rot. Thus A modifier gene was transferred to elucidate the negative attributes (Poehlman, 2013). Elite transgenic corn was created in South Africa by the modification in 3 different pathways for the enhancement of B-carotene, ascorbate level and folate level (3 different vitamins) (Naqvi et al, 2009).Phytic acid reduced the bioavailability of several essential micronutrients. High content of phytic acid was reported in cereals and oilseed crops which is harmful for human and animal consumption (shi et al 2007). Lpa1 mutant gene engineered in corn reduced phytic acid content improving its nutritional value

(Shi et al 2007).Rice has marginal quantity of folate, iron, provitamin A and vitamin E while significant quantity is present in leaves (Beyer, 2010). Provitamin A is precursor of vitamin A which is good for vision, eye sight, immunity and bone growth. Deficiency of vitamin A can cause night blindness. In making of golden rice, first time a complete metabolic pathway was engineered. Phytoene synthase was limiting factor in production of carotenoids (Paine et al, 2005) exchanged with lycopene to increase vitamin A production (Poehlman, 2013). 23 folds increase in total carotenoids was observed when psy1 gene was used in combination with crt1 obtained from Erwinia uredovora (Paine et al, 2005) this led to the development of Golden rice2.Improvement in provitamin A through conventional breeding is difficult because there is low genetic variability for the trait. Folate deficiency in rice endosperm was treated with the transfer of two pathway genes from model plant Arabidopsis thaliana (Beyer, 2010).Iron deficiency in rice endosperm is also a major problem as rice is a staple food for more than 3 billion people in the world. Varietal variation for iron content in rice endosperm varies from 1 to 8 ppm while high variability was reported for zinc content (Beyer, 2010). There is a great potential to increase micro nutrient content (Fe and Zn) in wheat because high genetic variability in mineral content prevails in the seed and other plant parts (White and Broadley, 2005).Banana is highly deficit in minerals and vitamins. Enhancement through conventional breeding is difficult because commercial banana is triploid thus genetic transformation can improve the micronutrient content.

BT banana and BT cassava were produced to lower the cost of insecticide control chemicals. Minipathway" was transformed in potato successfully for the enhancement of vitamin A precursor (Diretto et al, 2007).Bt cotton reduced the input expenses and fewer health issues were observed due to less use of pesticides (Huang et al, 2002). Qaim and zilberman (2003) reported higher yield gains in Bt cotton due to increased yield, less chemical usage and low labor input charges. GM corn has increased yield while genetically modified soybean required low input and chemicals (Azadi and Ho, 2010). Viswanathan and lalitha (2010) reported a significant role of B.t cotton in combating food security issues, malnutrition and to overcome poverty in cotton growing states. B-carotene level was improved in carrot and potato, corn with high lysine content, lettuce with enhanced Iron and tomato with improved lycopene have been developed through genetic engineering (Naqvi et al, 2009).Bio fortification of the crops can help to overcome issue of malnutrition. Plant with slower growth has more accumulation of minerals in edible parts but they have reduced yield and small seed size (Whitman and broadly, 2005).

Conclusion

Food security has become a major issue globally due to increasing population. High and substantial grain yield can overcome the issue. Use of novel molecular technique in agricultural crops can ensure better quantity and quality of food produced. GM crops are widely adopted across the world. GM crops are framed as technological solution to ensure high food productivity under adverse natural condition while on other hand genetically modified crops are thought to have some ethical issues. A comparative study for GM acceptance in UK and Australia reveals that former has some resistance in acceptance by government and consumers while later has accepted it open heartedly (Dibden et al, 2013). There is greater concern about whether use of genetically modified crops has more benefits or risks. Possible risks include poor digestibility, presence of toxins and Aller-genicity if GM crops could pass the test for these attributes they can be allowed for general cultivation (Paarlberg, 2010). Keeping in view the risks of using G.M crops scientists suggested the farmer community to adopt organic farming which is not feasible for the farmer community of developing countries due to less output (Azadi and Ho, 2010). Replacement of conventional breeding with genetically modified technology will lead to unavailability of non GM seed in coming years (Dibden et al, 2013).Modification in genetic makeup of organisms and their use in the food chain may have some risks. GM food should be environment friendly and safe for intake and should allow for cultivation after proper risk assessment (Godfray et al, 2010). In developing countries, national agriculture program, food safety regulation policy and intellectual property rights help in the adoption of GM crops (Raney, 2006). Genetic transformation is way more efficient and less time consuming than conventional breeding.

Abstract

This paper outlines the method of reducing energy demand for drying grain through the use of heat recovery from humid air extracted from a crossflow dyer. The use of heat exchanger to recover heat from the extract air and to transfer the recovered heat to the cold, dry, external air results in a significant reduction of the primary energy demand for heating of the cold external air. At low external air temperatures, it is possible to recover, from the extract air, both the sensible heat and the latent heat from condensation of water vapour. The design solution with direct heat recovery from the extract air to the supply air has been presented. For selected design setpoints of a drying room and design solutions with heat recovery in summer and autumn, both the achievable reduction of the primary energy demand for thermal air treatment and the resultant increase in the energy demand for air transport, due to the use of heat recovery exchanger, have been estimated. The energy balance of a crossflow dryer has indicated that the use of systems with heat recovery results in the significant reduction of the energy demand for drying grain in range 25-35%.

Keywords: *Drying grain, Heat recovery, Energy demand.*

Introduction

Grains, collected during harvest season, are stored in silos when their moisture content is at a required level that ensures safe storage. Also, in the silos, the air temperature is maintained to ensure proper storage conditions. Moisture content of cereal crops, especially maize, when harvested, is rarely adequate for storage and has to be decreased to the optimum level through drying processes (Bakker-Arkema et al. 1996). A standard approach involves drying cereal grains by heated airflow passing through and assimilating the moisture. For decades high-capacity continuous-flow crossflow dryers (see Ferrum 2017 for examples of cross-flow dryers used currently) have been most widely used in industrial-scale applications worldwide (Bakker-Arkema 1984, Kreyger 1972). A substantial body of research has been conducted since to improve the end quality of grain (Gustafson et al. 1981), to understand thermodynamic processes within the dryer (Brooker et al. 1992), to develop models enabling simulation of processes within the dryer (Khatchatourian et al. 2013) and, finally, to reduce primary energy consumption through air recirculation or basic heat recovery (Bakker-Arkema et al. 1996, Pierce et al. 1981, Lai et al. 1977). Treatment of the drying air has been identified as a particularly energy-intensive operation. Different technologies to prepare the drying air have been thus investigated with particular emphasis on the method of heating. For instance, energy efficient options include heating the drying air by using natural energy resources, i.e. solar energy (Johansson et al. 2012) or systems with a closed circulation of the drying air and heat pumps, used for energy flow and preparation of the drying air, gain popularity (Chua et al. 2002). During harvesting the open-cycle dryers, that use external air heated before passing through cereal grains, are most commonly used. In these dryers, the humid airflow, after assimilating the moisture from cereal grains, is removed to the outside. The external airflow for drying may be heated either externally (central system used by different end-users) or individually (heat supply dedicated to the dryer). Depending on the technology and availability, solid, liquid and gaseous fuels may be used (Acasio et al., 1992). Currently, heating the air supplied to the drying room usually involves the gas burning directly within the drying air (Maier & Bakker-Arkema, 2002). This technology ensures high efficiency of heat recovery from the combustion gas, due to negligible energy losses for heat transfer from the flared gas to the heated air. The temperature of the heated drying air directly affects the drying efficiency. The maximum temperature allowed depends on the type of cereal grain and its end-use. The drying air temperature in crossflow dryers typically range from 80 - 110°C (Maier & Bakker-Arkema, 2002). The drying airflow passes through the cereal grain, the air temperature decreases to 45 - 60°C and the air humidity increases to 30 - 35 g/kg_{ps}, to be subsequently removed and all the energy once used for treatment wasted. In Poland, a harvest season for basic grains is in July and August, whereas for maize in the second half of October, November and often even in the first half of December. Corn grains harvested in the autumn usually have the highest moisture content. Simultaneously, the external air temperatures are the lowest. Drying corn grains under these conditions requires the largest energy demand to dry the unit weight of grain. In addition, drying corn grains under such conditions, with a moisture content exceeding 40%, often requires two-stage treatment. The humid air removed from the dryer has a high thermal potential, a high specific enthalpy, relative to the external air parameters. As a result, an attempt to recover energy from the extracted air and using the recovered heat to reduce energy demand for heating the drying airflow seems to be rational and economically justified. The above applies especially to the autumn period when the external air temperature is the lowest and the moisture content of grain is the highest. Under these conditions, the energy of moisture condensation of the extract air may be used to heat the external air. This is particularly energy effective because the heat of condensation is several times higher than the specific heat capacity of air. In other words, the decrease in the extract air temperature, from which moisture is released, is minimal compared to the increase in the heated external air temperature. There are two reasonable technical solutions for the heat recovery from the extract air and its subsequent use for heating the drying air. Two main distinctions between the solutions correspond to the method of heat transfer from the extract airflow to the external airflow and the relative distribution of both airflows. The first solution is based on the use of plate heat exchanger, in which the extract air while flowing on one side of the heat exchanger transfers heat through the baffles to the external air flowing on the other side. The extract airflow and the external airflow pass through the same heat exchanger, thus these are required to be distributed into the same area. The second solution is based on the use of two air-liquid heat exchangers connected by pipework with circulating water (aqueous glycol). In the heat exchanger installed in the extract air, the heat is accumulated and transferred to the circulating water from which heat is subsequently released to the external air through the heat exchanger installed therein. In this way, the external and extract airflows may be separated. In both solutions the heat exchanger surfaces on the extract air side are exposed to the deposition of impurities. In order to reduce the negative effects of pollutants sedimentation on the efficiency of the drying processes, including reducing the flow of drying air and reducing the efficiency of heat recovery from the extract air, the extract air should be cleaned before passing through the heat exchanger or alternatively the heat exchanger surfaces need to be periodically cleaned. Treating the extract air can be cumbersome in operation especially in the case of airflow polluted with moist corn residue. Removing impurities from the surface of heat exchangers is relatively easy for plate exchangers, but particularly challenging for air-liquid exchangers with a developed heat exchange surface on the air side. This paper focuses on the design solution with the plate heat exchanger and demonstrates the possibilities of reducing the energy demand for grain drying by recovering heat from the extract air.

Material and Methods

Fig. 2.1 a) shows a schematic of a proposed heat recovery system utilising waste heat from the humid air, extracted from a crossflow dryer, to preheat the drying air (external airflow) in the diaphragm plate exchanger. In order to ensure a rational efficiency of heat recovery, heat exchanger consisting of two sections is used, through which the counter-flow cross airflows exchanging heat are designed to pass. Under the assumption that mass flows of the extract air and the external air are equivalent, the efficiency of heat recovery can be estimated from the expression:

$$\eta_t = \frac{t_{z\prime} - t_z}{t_u - t_z}, \qquad (2.1)$$

where t_z denotes the external air temperature at the inlet of the exchanger, °C; t'_z is the external air temperature after passing through the heat exchanger, °C; t_u denotes the extract air temperature from the dryer at the inlet of the exchanger, °C.

Fig. 2.1. b) shows Mollier i-x chart with exemplary simulations of air treatment processes during the cereal grain drying with heat recovery from the extract air in summer (oc) and autumn (oj), respectively. This chart shows, for the assumed efficiency of heat recovery η_t = 0.6, average parameters of: external air in summer and autumn (Zoc, Zoj), external air preheated in heat recovery exchanger (Z'oc , Z'oj), drying air supplied to the dryer (Z''oc , Z''oj), extract air from the dryer at the inlet of heat recovery exchanger (Woc, Woj) and the exhaust air (Woc ', Woj').

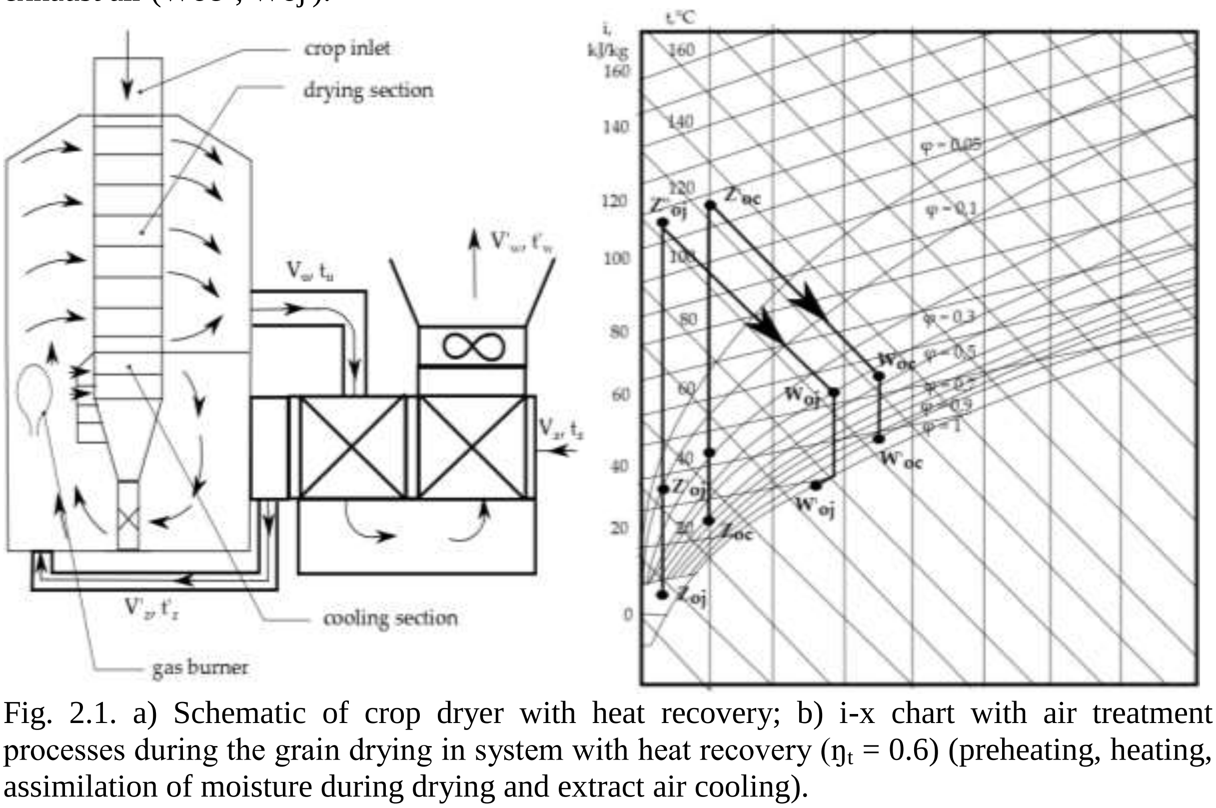

Fig. 2.1. a) Schematic of crop dryer with heat recovery; b) i-x chart with air treatment processes during the grain drying in system with heat recovery (η_t = 0.6) (preheating, heating, assimilation of moisture during drying and extract air cooling).

The energy effects of including preheat of the drying air have to be considered in the context of air treatment and transport. The ratio of renewable energy (recovered in the heat exchanger) and the total energy demand for heating the drying airflow can be determined from the expression:

$$U_O^c = \frac{(t'_z - t_z)}{(t''_z - t_z)} \cdot 100\%, \qquad (2.2)$$

where U_o^c denotes the portion of renewable energy recovered in the plate heat exchanger in the total energy supplied to heat the drying air,%; t_z, t'_z , t''_z denote air temperatures in points Z, Z' and Z" in i-x chart, °C.

The use of heat recovery exchanger, however, increases the energy demand for transport of drying air. The increase in the fan power, associated with additional airflow resistances through the heat exchanger, can be calculated from:

$$\Delta N = \frac{10^{-3}\, V\, \Delta Pw}{\eta_w \eta_s \eta_p} \qquad (2.3)$$

where ΔN denotes the increment of fan power, kW; V is the external and extract airflow, m^3/s; ΔPw denotes the sum of the airflow resistance of the external and extract air passing through the heat recovery exchange, Pa; η_w, η_s, η_p are performance of fans, motors and gears, respectively.

Results and discussion

Preheating the drying air in the heat recovery exchanger results in the significant reduction in the primary energy demand supplied externally. The data extracted from air treatment simulations in Fig. 2.1. b) indicate that in the summer, the use of system with heat recovery reduces the primary energy consumption for heating the drying air by approx. 21% while in the autumn by approx. 28.5%. Discrepancies in the efficiency of heat recovery between the two seasons are caused by differences in the external air temperatures. The efficiency of heat recovery increases with decreasing external air temperatures. At lower temperatures (autumn design conditions in the figure) the surface temperature of heat recovery exchanger is lower than the dew point temperature of extract air. As a result, heat for condensation of water vapour from the extract air is utilised, thus improving the energy effects of heat recovery. In general, increasing thermal efficiency of heat recovery reduces the primary energy demand for heating the drying air as shown for summer (dashed line) and autumn (continuous line) periods in Fig. 2.2 a). The curves have been developed based on the airflow parameters used to prepare simulations in i-x chart in Fig. 2.1. b). Depending on the efficiency of heat recovery η_t, the use of recovered heat to preheat the drying air reduces the primary energy demand for heating the drying air by 15%-25% in summer and 25%-35% in autumn, respectively. However, adding the heat recovery exchanger to the system leads to the increase in the airflow resistance of the dryer, thus also the increase in the fan power requirement. The increase in the efficiency of heat recovery, which grants better energy effects, simultaneously triggers the increase in the energy demand for air transport. Fig. 2.2 b) shows the approximate relationship (increasing trend) between the airflow resistance and the thermal efficiency of heat recovery. In order for the new design solution to work and to guarantee energy savings, the reduction in primary energy demand for air treatment, induced by heat recovery, has to outweigh the energy gains due to higher energy costs of air transport. Fig. 2.3 presents comparisons of the energy balance in the dryer as a function of thermal efficiency of heat recovery. Bar charts in Fig. 2.3. show: the total energy demand (E, kW) for heating $1m^3/s$ (1.2 kg/s) of drying air, and the corresponding breakdown into the primary energy demand, supplied by gas burner, heat recovered in heat exchanger and additional fan power, for summer and autumn conditions. The breakdown of total energy demand for air treatment and transport reveals that under actual design conditions it is always energy-beneficial to recover heat from the extract air expelled from the dryer. The use of recovered heat increases (up to 35%) with the increase in the thermal efficiency of heat recovery. The additional energy demand due to the increase in the fan power requirement for air transport is significantly lower (up to 20 times lower) than the recovered heat output. For example, for a crossflow dryer with a drying capacity of 10 Mg/h, it is possible to reduce the energy demand supplied to the dryer by 600-900 kW with corresponding increase in the fan power by 26-66 kW, respectively. As an aside, note that, the increase in the efficiency of heat recovery η_t ought not to impede exploitation and everyday use of the dryer. To ensure longevity of the system and the delivery of anticipated energy effects, a proper maintenance of the heat recovery exchanger is required, by either purifying the extract air prior to passing through or cleaning the exchanger surface on the extract side regularly.

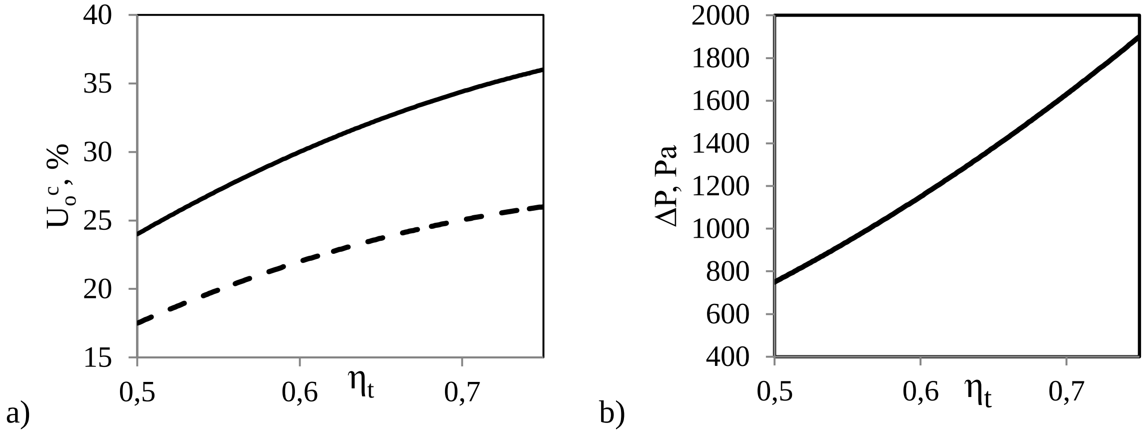

Fig. 2.2. a) Energy savings U_o^c , in %, caused by heat recovery in the plate exchanger as a function of thermal efficiency of heat exchanger for summer (dashed line) and autumn (continuous line); b) Airflow resistance as a function of thermal efficiency of heat exchanger.

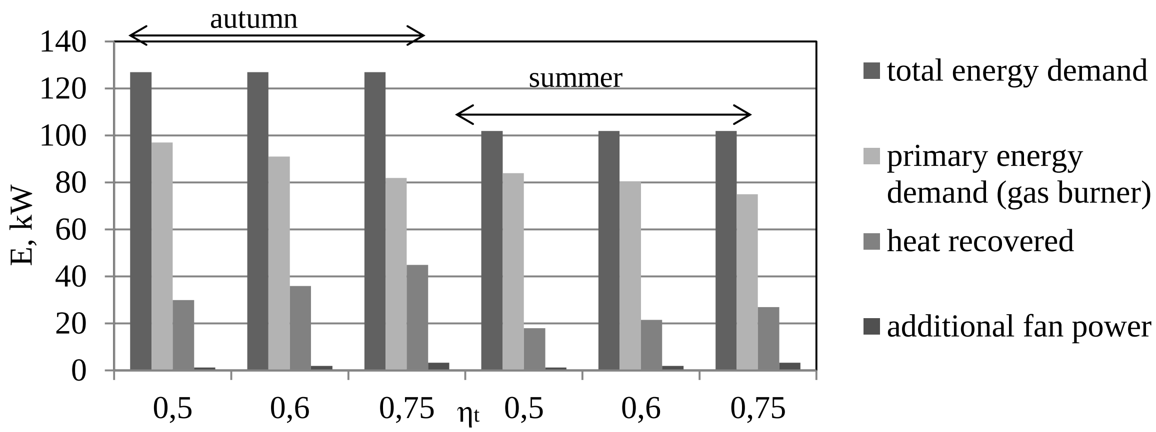

Fig. 2.3. Energy demand for air treatment and transport of $1m^3/s$ of drying air in a crossflow dryer using a plate heat exchanger to recover heat from the extract air.

Conclusions

Nowadays there is a worldwide trend towards reducing primary energy consumption. Somewhat surprisingly technologies used in agriculture still remain one step behind and modernisation of design solutions is required to ensure sustainable agriculture. This paper is aimed at revising grain drying in crossflow dryers and proposing a new energy-efficient design solution. Our new design solution involves using heat recovered from the air extracted from the crossflow dryer to preheat the drying air. By adding a heat recovery exchanger to the system, the primary energy consumption is reduced through the utilisation of energy recovered. The use of heat recovery to preheat the drying air leads to:

The decrease in the size of heating devices by 15 to 35%, corresponding to the limitation of the energy demand supplied to the dryer.

The increase in the resistance of the drying airflow through the dryer, thus also the increase in the fan power.
The need to either purify (filter) the extract air before passing through the heat recovery exchanger or alternatively clean the exchanger surface on the extract air side regularly.

The analysis of system performance revealed that:
Under actual conditions of operation, heat recovery from the air expelled from the dryer is always energetically beneficial.
The increase in efficiency of heat recovery leads to a greater use of recovered heat to preheat the drying air.
The increase in electrical power demand of fan drives, as a response to the increase in the efficiency of heat recovery exchanger, is significantly lower than the heat output.
The effect of contributions of this conceptual research into reducing energy demand for crop drying begins to flourish in Poland, where first systems with heat recovery from the extract air from the dryers have been created as a result of cooperation between Feerum and Wroclaw University of Science and Technology.

Abstract

The North American grapevine leafhopper *Scaphoideus titanus* Ball 1932 (Hemiptera: Cicadellidae) is a major pest of grapevine in Europe, being the main vector of the phytoplasma pathogens associated with the *Flavescence dorée* disease. In 2016, a field survey was conducted to evaluate the presence of *S. titanus* in vineyards in the viticulture region Dealurile Moldovei (North-Eastern Romania). The research comprised sixteen vineyard plantations, newly created within the national program of reconversion and restructuring of vineyards developed in the country since 2011. All plantations were subjected to pesticide treatments. No insecticide treatment was applied against *S. titanus*. Yellow sticky traps were used for sampling of leafhoppers. The captures on the yellow sticky traps indicated that *S. titanus* was present in all investigated vineyard plantations. Its population was different in size from one plantation to another. On average, 8 to 88 specimens of *S. titanus* (mixed population of adults and larvae) per trap were collected over the period from June to October.

Key words: *vector control, population dynamic.*

Introduction

The North American grapevine leafhopper, *Scaphoideus titanus* Ball 1932 (Hemiptera: Cicadellidae) is a major pest of grapevine in Europe, because it produces damages directly by sucking for feeding and indirectly by transmitting the phytoplasmas associated with *Flavescence dorée* (FD) disease (Mori *et al.,* 2002; Galetto *et al.*, 2016). FD disease is the most dangerous among the yellowing diseases of European grapevines (Bertaccini and Duduk, 2009). The insect is a monophagous species on plants of *Vitis* genus and develops one generation per year from May to September (Chuche and Thiéry, 2014). Phytoplasmas are bacteria-like organisms that infect the phloem tissues of plants and are transmitted from one plant to another by sap-sucking insect vectors such as leafhoppers and planthoppers (Ploaie, 1981; Weintraub and Beanland, 2006). The distribution of *S. titanus* in Europe, presented in the EPPO Global Database in 2017, showed that this insect is present in Austria, Bosnia-Herzegovina, Bulgaria, Croatia, Czech Republic, France, Hungary, Italy, Moldova, Montenegro, Portugal, Romania, Serbia, Slovakia, Slovenia, Spain and Switzerland. The presence of *S. titanus* in Romania was first recorded in the south part of the country in 2009 (Chireceanu *et al.,* 2011). Spreading of *S. titanus* from one area to another can be done through multiple ways, either by its movement or by various transport vectors. The human activities are considered one of the main long-distance dispersal way of the insect (Bertin *et al.,* 2007; Chuche and Thiéry, 2014; Riolo *et al.,* 2014). Commercial activity with grapevine planting material which contains overwintering eggs of the pest plays a significant role in its spreading between distant geographical zones (Boudon-Padeau *et al.,* 2005; Maixner, 2005). The aim of the paper was to evaluate the presence of the grapevine leafhopper *Scaphoideus* *titanus* in young vineyard plantations from the viticulture region Dealurile Moldovei (North-Eastern Romania), recently created within the framework of the program of reconversion and restructuring in Romanian viticulture.

Materials and methods

In 2016, the presence of *S. titanus* was evaluated in sixteen vineyard plantations, set up within the national program of reconversion and restructuring of vineyards, distributed in five vineyards in the viticulture region Dealurile Moldovei, situated in the North-Eastern part of Romania. The plantations were of 2-8 years old and belonged to some owners in the region. The surveyed plantations included national and international grape cultivars. The planting material was from local sources (Tămâioasa românească cl 36 Pt. variety) and EU (the other varieties). All plantations were subjected to different chemical sprays: fungicides to prevent or reduce the infections by specific pathogens, and acaricides against mites (*Tetranichus sp.*) and insecticides against grape moth (*Lobesia botrana* Den et Schiff). No control measures were applied against *S. titanus*. Yellow sticky traps, produced in Romania, were used for sampling of leafhoppers and also for monitoring of *S. titanus* population (adults and larvae). For each vineyard plantation, five traps were set up and replaced every two weeks from June to October. The information for vineyard plantation is given in table 1.

Results and discussion

The presence of the grapevine leafhopper, *S. titanus* known to be vector of FD phytoplasma (Mori *et al.*, 2002; Galetto *et al.*, 2016), was recorded in all the sixteen vineyard plantations generated through the national conversion program in viticulture, which were surveyed in the viticulture region Dealurile Moldovei (the North-Eastern part of Romania) in 2016. The distribution of vineyard plantations and *S. titanus* presence are illustrated in Figure 1.

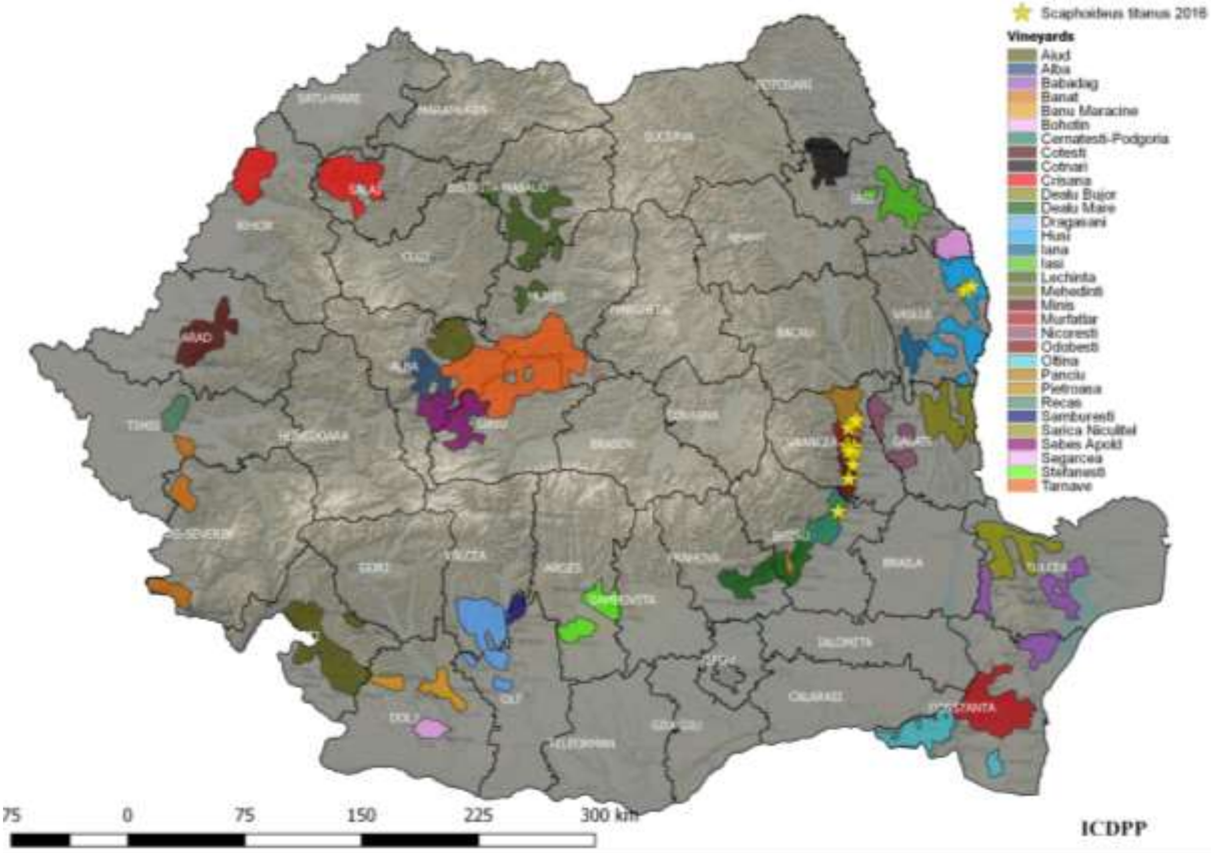

Figure 1. Map of distribution points for *S. titanus* in young vineyard plantations surveyed in 2016 in the viticulture region Dealurile Moldovei (Map performed by V. Fătu).

The whole abundance of *S. titanus* (larvae and adults) in surveyed grapevine plantations is shown in figure 2.

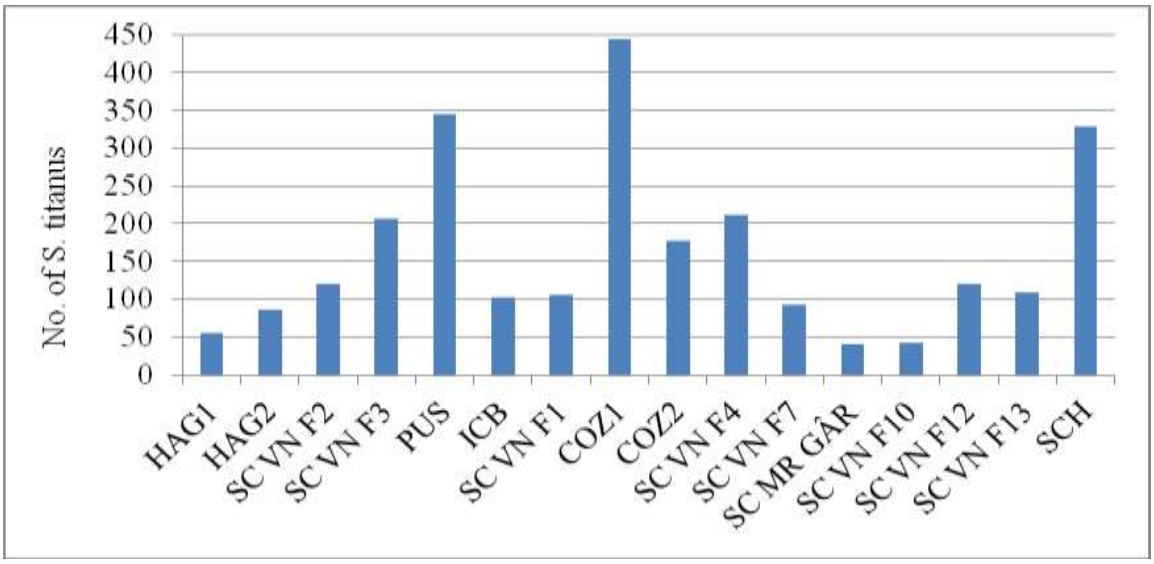

Figure 2. The total number of *S. titanus* collected on yellow sticky traps in the young vineyard plantations in the viticulture region Dealurile Moldovei monitored in 2016.

The population of the pest was variable from one plantation to another. Differences were noted both among grapevine plantations belonging to different vineyards and between plantations in the same vineyard. On the entire survey period, the abundance of the pest fluctuated between 41 and 444 captures per grapevine plantation, with an average density ranged from 8.2 to 88.8 captures per one yellow sticky trap. The lowest levels of abundance were estimated in three grapevine plantations, two situated in Dumbrăveni and Grebănu (Cotești vineyard) and one in Odobeşti (Odobeşti vineyard), with 41 and 43 specimens, and 55 specimens per plantation, respectively. The highest presence of *S. titanus* was noted in the grapevine plantation in Vârteşcoiu, (Odobeşti vineyard) with 444 specimens, followed by two plantations in Ţifești Sârbi (Panciu vineyard) and in Huşi (Huşi vineyard) with 347 and 338 specimens, respectively.

The differences in abundance of the *S. titanus* population could be the result of the characteristics of the vine plantations, such as their age, varieties and origin of planting material, but also of the influence of insecticides against the grapevine moth applied differentially from one plantation to another. *L. botrana* is the most important insect pest in vineyards in Romania, and its control is achieved by an insecticide treatment scheme with one application for each of its three generations. Because currently no insecticide treatments are applied against *S. titanus* in vineyards in Romania, the treatments for *L. botrana* could be interpreted as having influence on *S. titanus*.

Chuche and Thiéry (2014) established a threshold of three adults of *S. titanus* per yellow sticky trap per week for the pest control in vineyards in Bordeaux region. Our capturing data in vineyards from Moldavian hills showed a density of *S. titanus* ranged from 0.51 to 5.55 specimens per trap per week. Only in three out of the sixteen surveyed vineyard plantations, the pest registered a level that exceeded the threshold indicated in France, namely 5.55, 4.34 and 4.23 individuals per trap per day. Thus, the need for insecticide treatments against *S. titanus* in these plantations can be taken into consideration in the following year.

Dynamics of captures of *S. titanus* in the vineyard plantations monitored in 2016 is shown in figure 3.

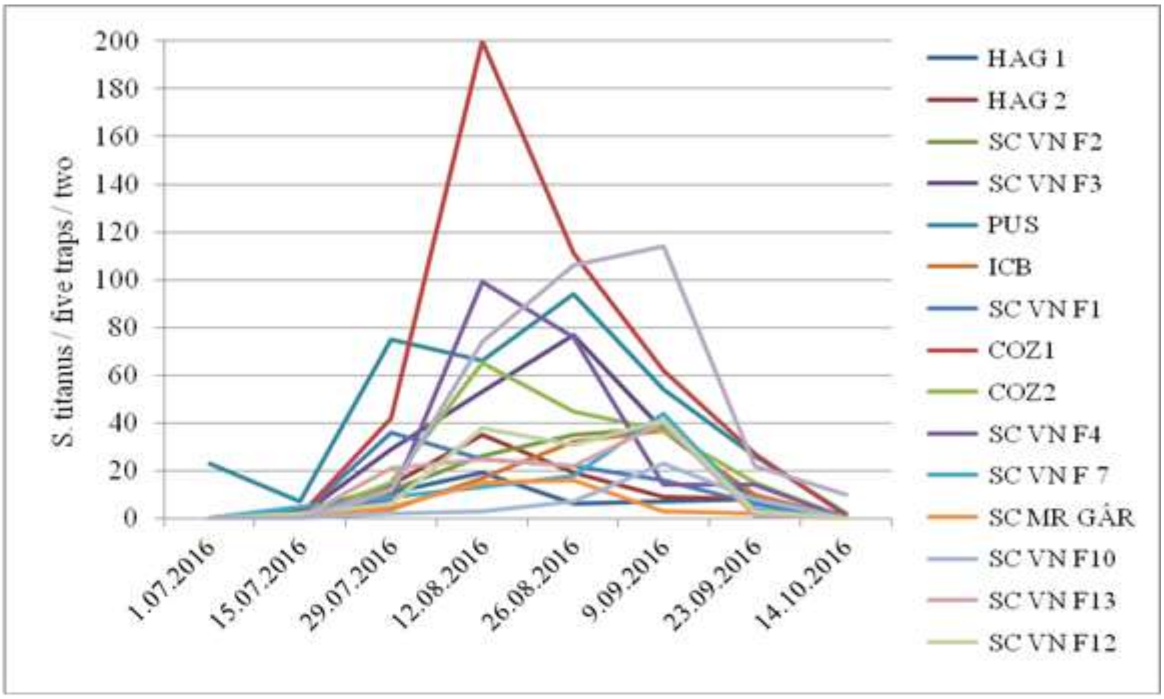

Figure 3. Dynamics of S. *titanus* captures in young vineyard plantations in the viticulture region Dealurile Moldovei in 2016.

According to our results, *S. titanus* was present on yellow sticky traps in vineyard plantations from the middle of June until the middle of October. The date of starting captures varied among the sixteen plantations. The captures of *S. titanus* on yellow sticky traps started to appear during the second part of June in one plantation, the beginning of July in nine plantations and the end of July in the other six. The captures of adults were finished at the end of September for most plantations, except three plantations where the last adults were trapped till the middle of October. The bi-weekly trapping data showed that *S. titanus* reached a maximum in the number of catches during the period from the middle of August to the beginning of September, confirming the results in the literature that showed the insect developing one generation per year (Chuche and Thiéry, 2014; Tóthová *et al.*, 2015).

Conclusion

The monitoring results showed that the North American grapevine leafhopper *Scaphoideus titanus* was present in all vineyards in the region Dealurile Moldovei surveyed in 2016, newly created within the national program of reconversion and restructuring in Romanian viticulture. There were variations in the abundance of the insect population depending on the age and cultivars of the grapevine plantations. The pest density ranged from 0.51 to 5.55 specimens per trap per week. Grapevine growers are encouraged to monitor the presence of *S. titanus*,o evaluate its population and to decide upon the control measures.

Abstract

Yellowing or reddening of the grapevine leaves, represent a group of diseases which are widely spread in the regions of intensive vine -growing all over the world and are usually associated with phytoplasma etiology. A study was performed to investigate the changes in the content of pigments (chlorophylls, carotenoids), total phenols, and total and reducing sugars in the leaves of the four grapevine cultivars (Pinot Noir, Cabernet Sauvignon, Riesling, Traminer) collected at the Miniş-Maderat vineyard in Western Romania in 2016, naturally affected by symptoms typical to infections with phytoplasma. Quantification of the above mentioned compounds was made using specific spectrophotometric methods. The results showed that the amount of total chlorophyll and carotenoids were markedly reduced in the leaves collected from the symptomatic vine plants of all the varieties studied. In the red varieties affected by the symptoms, a decrease in chlorophyll was observed by approximately 45% compared to healthy plants. Among the varieties analyzed can be observed depending on the chlorophyll content that Riesling is probably more sensitive, compared to red varieties (Pinot Noir, Cabernet Sauvignon) being severely affected by phytoplasma. Similar results were obtained for the content of total phenols compounds. However significant increase in total sugars content was observed in the leaves of the affected vines compared to the healthy ones.

Keywords: *chlorophyll, polyphenols, leaves, total sugars, disease*

Introduction

Different symptoms such as reddening of leaves and stems, the greening of non-green flower organs, overall yellowing, sterility of flowers, formation of bunch fibrous secondary roots, decline and dwarfism of plants are associated with phytoplasma that cause numerous diseases in a diverse ranges of economically important species including crops grapevine, ornamental plants, fruit trees, and vegetables (Martelli and Boudon-Padieu, 2006; Firrao *et al*., 2007; Bertaccini and Duduk, 2010; Gharechahi *et al*., 2016; Dermastia *et al*., 2017).

In grapevine, phytoplasma induce disorder such as leaf yellowing or reddening, leaf rolling, lack or incomplete lignifications and necrosis of shoots, shriveled grapes decrease of yield and/or decline of vineyard. These symptoms suggests that phothoynthesis and thus carbohydrate metabolism may be perturbed (Lepka *et al.* 1999; Bertamini and Nedunchezhian, 2001a; Bertamini and Nedunchezhian, 2001b; Bertamini *et al*., 2002b; Martelli and Boudon-Padieu, 2006; Musetti, 2009; Rusjan *et al*., 2012; Ploaie and Chireceanu, 2012; Prezelj *et al*., 2016; Dermastia *et al*., 2017). Carbohydrate metabolism is shown to be changed in infected grapevine plants, accumulation of carbohydrate assimilates

in photosynthetic source tissues induces feedback inhibition of photosynthesis causing chlorosis (Bertacini and Duduk, 2010).
Some reports have investigated the biochemical and physiological compounds involved in interactions between many plants and phytoplasma (Leon *et al*., 1996; Lepka *et al*., 1999; Bertamini *et al*., 2002a; Bertamini *et al*., 2003; Maust *et al*. 2003; Musetti *et al*., 2004; Junqueira *et al*., 2004; Musetti, 2009; Rusjan *et al*., 2012; Hameed et al., 2017).
However, only few studies were found related to biochemical and physiological changes in grapevine plants induced by phytoplasma infections (Bertamini and Nedunchezhian, 2001a; Bertamini and Nedunchezhian, 2001b; Bertamini *et al*., 2002a; Rusjan *et al*., 2012; Prezelj *et al.*, 2016; Punelli et al., 2016. Also, this type of study was not carried out on the cultivars studied by us Pinot Noir, Cabernet Sauvignon, Riesling and Traminer.
The aim of this study was to investigate the physiological and biochemical response induced by yellowing and reddening symptoms associated with phytoplasma infections rate in grapevine leaves of different cultivars (two red cultivars and two white cultivars).

Materials and Methods

The leaves of four grapevine cultivars (Pinot Noir, Cabernet Sauvignon, Riesling, Traminer) analyzed in our study were collected in the 2016 year, from grapevine plants naturally affected by symptoms specific to phytoplasma infections located in vineyards of Experimental Station from area Minis -Maderat (Romania). Leaf pigments, chlorophyll a (Chl a), chlorophyll b (Chl b) and carotenoids (Car) were extracted from infected and uninfected plants, overnight at 4°C with 100% (v/v) acetone, in extraction ratio 1:15 and after crude extracts were centrifuged at 6000 rpm for 20 minutes. Supernatant was used to estimate pigment concentrations spectrophotometrically according to methodology described by Lichtenthaler and Wellburn, 1985. The results were expressed as mg/g fresh weight and calculated based on formulas of Lichtenthaler and Wellburn (1985). Total phenolic compound content was estimated in the healthy and symptomatic grapevine leaves of each cultivars studied by using the method described by Singleton and Rossi,1965 used Folin- Ciocalteu reagent. Total phenolics express as mg phenols (in terms of catechol) per 100g fresh tissue. Collected leaves with and without yellowing or reddening symptoms were analyzed for reducing sugars and total sugars content. Soluble or reducing sugars were extracted from 0.1 g fresh leaves by boiling in 80% ethanol for 15 min on water bath. Extracts were centrifuged at 2500 rpm for 5 minute for clarification and supernatant decanted and the sediment rextracted twice**.** Total sugars were assayed using the phenol sulfuric acid method (Dubois, 1956). Reducing sugar contents were assayed using the dinitrosalicylic acid method (Miller,1959).

Results and Discussion

Pigments, chlorophylls a and b play an important role in light absorption during photosynthesis (Prezelj *et al*., 2009). Carotenoids are accessory pigments involved in lipid membrane stabilization in chloroplasts and in photosystem protection.
Data obtained showed that, there are significant differences in the chlorophyll content of the leaves between healthy plants and those with symptoms specific to phytoplasma infections (table 1).
In plants without symptoms, total leaf chlorophyll concentration was 2.30 mg/g FW for red cultivars and 2.46 mg/g FW for white cultivars. The total chlorophyll content was reduced around 45% in the symptomatic leaves of red varieties and 50% for white cultivars and this being correlated with leaf discolouration. Leon *et al*., (1996) reported drastically chlorophyll reduction around 60% in coconut palms tissues affected by lethal yellowing. Among cultivars

analyzed in this study it can be observed depending on the total chlorophyll content that Riesling is probably more sensitive being severely affected by specific symptoms to phytoplasma infections. Zafari *et al*., (2012) reported that content of total chlorophyll and carotenoids was significantly decreased in phytoplasma infected leaves of lime and the leaves presents chlorosis. Also several investigators have shown that reduction of chlorophylls can interfere in phothosynthesis capacity of apple, mungbean leaves, corn, grapevine leaves infected with phytoplasma (Bertamini and Nedunchezhian, 2001b; Bertamini *et al*., 2002b; Bertamini *et al*., 2003; Junqueira *et al*., 2004; Hameed *et al*., 2017). Some authors have argued that decrease in both Chl a and Chl b content could be the result of an enhanced chlorophyllase activity in phytoplasma infected leaves (Bertamini and Nedunchezhian, 2001a; Bertamini *et al*., 2002b). The Chl a/ Chl b ratio, which is used as stress indicator decreased from 2.02 value in leaves without symptoms to 1.5 in symptomatic leaves for all cultivars studied (table1). Similar results have been reported by Bertamini *et al*., (2001a), Bertamini and Nedunchezhian (2001b), Beratmini *et al*. (2002a), Bertamini *et al*., (2003) and Zafari *et al*. (2012). However, in contradiction with our results, Rusjan *et al*., (2012) supported that the Bois noir infections did not affected Chl a/Chl b ratio in Chardonnay leaves.

Table 1. Variation of chlorophyll and carotenoids content in symptomatic and healthy grapevine leaves of cultivars studied

Cultivars	Chl a (mg/g FW)	Chl b (mg/g FW)	Chl (a +b) (mg/g FW)	Chl a/ Chl b	Carotenoids (mg/g FW)	Car / Chl(a+b)
Pinot Noir healthy	1.47±0.6	0.73± 0.2	2.20±0.8	2.01	0.47±0.05	0.23
Pinot Noir affected	0.60±0.7	0.38±0.3	0.98±0.7	1.58	0.16±0.08	0.16
Cabernet Sauvignon healthy	1.65±0.6	0.71±0.4	2.36±0.9	2.32	0.35±0.06	0.15
Cabernet Sauvignon affected	0.65±0.3	0.44±0.4	1.09±0.8	1.48	0.15±0.04	0.14
Riesling healthy	1.76±0.7	0.70±0.2	2.46±0.6	2.51	0.47±0.05	0.19
Riesling affected	0.82±0.7	0.48±0.3	1.30±0.7	1.71	0.18±0.07	0.14
Traminer healthy	1.42±0.6	0.53±0.3	1.95±0.9	2.68	0.31±0.05	0.16
Traminer affected	0.49±0.5	0.41±0.4	0.90±0.5	1.20	0.12±0.04	0.13

The data are means ±SE of three replicates of each experiment

According to our results, Car/Chl ratio decreased in leaves affected by symptoms of all cultivars studied. These results are different from those obtained by Bertamini and Nedunchezhian, (2001a) and Zafari *et al*., (2012) which showed as this ratio increased in infected leaves with phytoplasma.

Carotenoids content was decrease from 0.47 mg/g FW in unaffected leaves of Pinot Noir cultivar to 0.16mg/g FW in symptomatic leaves. The carotenoid content of the white cultivars varies in the same way. Thus in symptomatic leaves, carotenoid amount decreased by 40%. Our results are in agreement with the findings of Rusjan *et al*., (2012) and Zafari *et al*., (2012).

In our study there was no significant difference in total phenols of symptomatic and non-symptomatic plants (table 2). However, total phenols content decreased slightly in affected leaves compared to healthy leaves for all cultivars studied. This results were similar with those of Musetti *et al*., 2000 that observed a lower content of phenols in *Catharanthus roseus* phytoplasma infected. However, another studies showed that phenolics content increase in corn, apple, grapevine, coconut palms phytoplasma infected (Leon *et al*., 1996; Lepka *et al*., 1999; Maust *et al*., 2003; Junqueira *et al*., 2004). Our results demonstrated that symptomatic leaf tissue of all cultivars studied exhibited higher total sugars and reducing sugars content compared with healthy leaves (table 2). This results are in agreement with results of Lepka *et al*., (1999) and Bertamini and Nedunchezhian, (2001a). Accumulation of total sugars in infected leaves is indeed a common effect of phytoplasma infections (Leon *et al*., 1996; Lepka *et al*., 1999; Maust *et al*.,2003; Junqueira *et al*., 2004). Also, Prezelj *et al*., (2016) shown that the concentration of reducing sugars in symptomatic leaves of cv. Blaufränkisch infected with FD, are slightly higher, while those of total sugars significantly increase upon infection. On the contrary, Zafari *et al*., (2012) demonstrated that total soluble sugars and reducing sugars contents decreased in phytoplasma infected lime leaves reached to ca 70% and 60 % of the control value, respectively.

Table 2. Variation of reducing, total sugars and total phenols content in symptomatic and healthy grapevine leaves of cultivars studied

Cultivar	Reducing sugars g/kg FW	Total sugars g/kg FW	Total phenols g/100gFW
Pinot Noir healthy	35.4±1.50	51.2±1.10	0.55±0.02
Pinot Noir affected	49.1±0.90	76.3±1.00	0.40±0.03
Cabernet Sauvignon healthy	38.1±1.08	64.8±1.51	0.40±0.05
Cabernet Sauvignon affected	53.1±0.50	78.1±0.61	0.35±0.05
Riesling healthy	24.8±2.11	40.2±1.70	0.25 ±0.08
Riesling affected	36.3±2.03	60.5±1.09	0.17±0.09
Traminer healthy	27.1±0.25	47.4±1.41	0.35±0.09
Traminer affected	39.7±0.64	64.6±1.30	0.25±1.02

The data are means ±SE of three replicates of each experiment

Conclusions

Our results indicate that the physiological and biochemical compounds were widely affected in grapevine that develop reddening or yellowing symptoms. These foliar symptoms observed could lead to decrease of yield and vigour of grapevine plants. Symptomatic grapevine plants present an increase concentration of total and reducing sugars and a slightly low phenol content. Also, decrease of phenols in symptomatic leaves was accompanied by decrease of chlorophyll and carotenoids content.

Abstract

The antinutritive effect of soluble non-starch polysaccharides (NSPs) in monogastric animals is mainly associated with their physiological effects on the digestive medium due to their viscous nature. Soluble NSPs increase the viscosity in the small intestine, hampering the digestion process. Insoluble NSPs impede the access of endogenous enzymes to their substrates by physical entrapping. Extract viscosity values of grains could be used as predictors of anti-nutritional properties of NSP in cereals. The study had in view the effect of the extraction conditions and the soluble NSP concentration of the feed water extracts on the dynamic viscosity (DV). The experiments were carried out on samples of forage mixtures with different structures, and different proportions of wheat (WF1 and WF2) and barley (BF1 and BF2). The water-soluble fraction was obtained using a single extraction at a ratio 1:2 (w/v), with (procedure 1) and without (procedure 2) endogenous enzyme inactivation. DV in wheat containing feeds is lower than those in barley containing feeds. The viscosity values of the water extracts obtained after endogenous enzymes inactivation are higher than those obtained without enzymes inactivation, when the soluble NSPs were hydrolyzed and consequently their molecular mass reduced. Higher correlation between dynamic viscosity and cereal content in the feed was observed in procedure 1: r = 0.9877 for BF1, r = 0,9885 for BF2, r = 0.9827 for WF1 and r = 0.9887 for WF2 as compared to procedure 2: r = 0.9849 for BF1, r = 0.9348 for BF2, r = 0.8474 for WF1 and 0.9454 for WF2.

Keywords: *non-starch polysaccharides, dynamic viscosity, wheat, barley.*

Introduction

In animal nutrition as "non-starch-polysaccharides (NSP)" are summarized polysaccharides, which cannot be degraded by endogenous enzymes and therefore reach the colon almost indigested (Saki, 2005). Non-starch polysaccharides from various cereal grains are considered to have anti-nutritive effect in poultry nutrition if they are present in diets at high concentrations (Bach Knudsen, 2001). The increase in the digesta viscosity in monogastric animals decreases the nutrient diffusion (Fengler and Marquardt, 1988), reduces the rate of the feed transit (Salih *et al*., 1991 and increases the microbial growth in the small intestine (Feighner and Dashkevicz, 1988).

The cell wall polysaccharides of cereals are comprised mainly of arabinoxylans and β-glucan, with smaller quantities of cellulose (Lineback and Rasper, 1988). The NSP content and type can also differ among grains. The NSP content relative to dry matter is lower in wheat kernel (11.4%) than in rye (13.2%) and barley (16.7%). Arabinoxylan is the predominant NSP in wheat (6-8%) and rye (8.9%), while β-glucan is the predominant NSP in barley (7.6%) (Schweizer and Würsch, 1981).

These polysaccharides are typically long polymeric carbohydrate chains containing up to several hundred thousand monomeric units (Choct, 1997). Monosaccharides commonly present in cereal cell walls are: (a) *hexoses*: D-glucose, D-galactose, D-mannose, (b) *pentoses*: L-arabinose, D-xylose, and (c) *acidic sugars*: D-galacturonic acid, D-glucuronic acid and its 4-O-methyl ether.

The NSP may be relatively simple, such as the cereal ß-D-glucans which are linear polymers of glucose with ß-(1-3),(1-4) glycosidic links. The other major cereal polysaccharides, the arabinoxylans, are more complex being composed of two sugars, arabinose and xylose, in a branched structure (Caprita *et al*., 2010).

The main physicochemical properties of NSP that are of nutritional significance include: (a) hydration properties; (b) viscosity; (c) cation exchange capacity; and (d) organic compound absorptive properties (Smits and Annison, 1996).

The detrimental effect of soluble NSP is mainly associated with the viscous nature of these polysaccharides and their physiological effects on the digestive medium (Caprita and Caprita, 2011). Soluble NSP increases the viscosity of the small intestinal chime, generally hampering the digestion process, whereas insoluble NSP impedes the access of endogenous enzymes to their substrates by physical entrapping (Bedford, 1995; Steenfeldt *et al*., 1995). Almost all water-soluble polysaccharides produce viscous solution (Caprita and Caprita, 2012). The viscosity of a polymer solution is directly related to the fundamental molecular properties (molecular conformation, molecular weight, and molecular weight distribution) and concentration of the polymer (Caprita *et al*., 2011). Extract viscosity values of grains could be used as predictors of anti-nutritional properties of NSP in cereals.

The study had in view the effect of the extraction conditions and the soluble NSP concentration of the feed water extracts on the dynamic viscosity (DV).

Materials and Methods

Samples of forage mixtures with different structures and different proportions, of wheat (WF1 and WF2), and barley (BF1 and BF2), were milled by a laboratory grinder at a 600 μm sieve. The water-soluble fraction was obtained using a single extraction at a ratio 1:2 (w/v), with endogenous enzyme inactivation (procedure 1) and without endogenous enzyme inactivation (procedure 2). In procedure 1 we incubated the sample with 80% (v/v) ethanol at 80°C, than added water to the pellet and incubated it at 40°C for 2 h with constant stirring. In procedure 2 we skipped the incubation step with ethanol. The extracts were centrifuged for 10 minutes at 5,000 rpm and 25°C, using a Hettich 320R centrifuge. Following the centrifugation, an aliquot of 0.5 mL supernatant was taken and the dynamic viscosity determined using a Wells Brookfield Cone/Plate Digital Viscometer, Model DVIII Cone CP-40. Viscosity measurements were carried out at 100 rpm and at a constant temperature of 25°C.

Results and Discussion

DV in wheat containing feeds is lower than those in barley containing feeds. The viscosity values of the water extracts obtained after endogenous enzymes inactivation are higher than those obtained without enzymes inactivation when the soluble NSPs were hydrolyzed and consequently their molecular mass reduced. DV increased with wheat concentration: from 1.8 cP (WF1 with 0% wheat) to 2.40 cP (WF1 with 40% wheat) and from 1.91 cP (WF2 with 0% wheat) to 2.55 cP (WF2 with 40% wheat) for procedure 1, and from 1.35 cP (WF1 with 0% wheat) to 1.56 (WF1 with 40% wheat) and from 1.16 cP (WF2 with 0% wheat) to 1.38 (WF2 with 40% wheat) for procedure 2 (Figures 1 and 2).

DV increased with barley concentration: from 2.02 cP (BF1 with 0% barley) to 2.54 (BF1 with 30% barley) and from 2.29 cP (BF2 with 0% barley) to 3.06 (BF2 with 40% barley) for procedure 1, and from 1.68 (BF1 with 0% barley) to 2.10 (BF1 with 30% barley) and from 1.57 cP (BF2 with 0% barley) to 2.08 (BF2 with 40% barley) for procedure 2 (Figures 3 and 4).

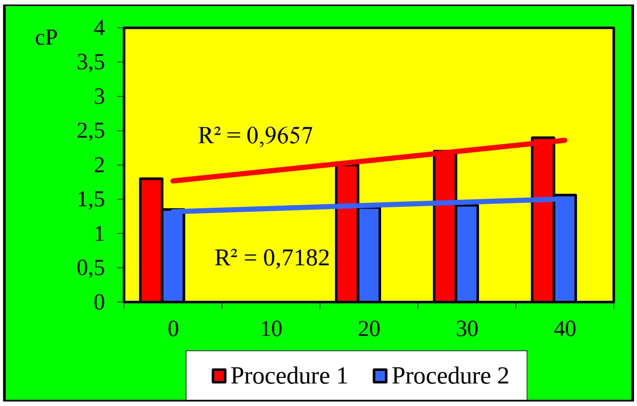

Figure 1. The positive correlation between viscosity and wheat concentration in WF1

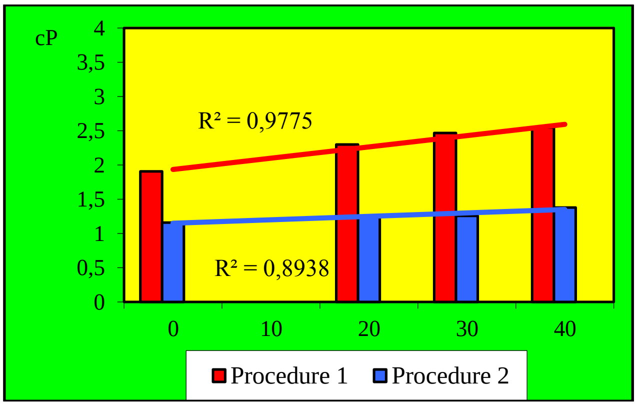

Figure 2. The positive correlation between viscosity and wheat concentration in WF2

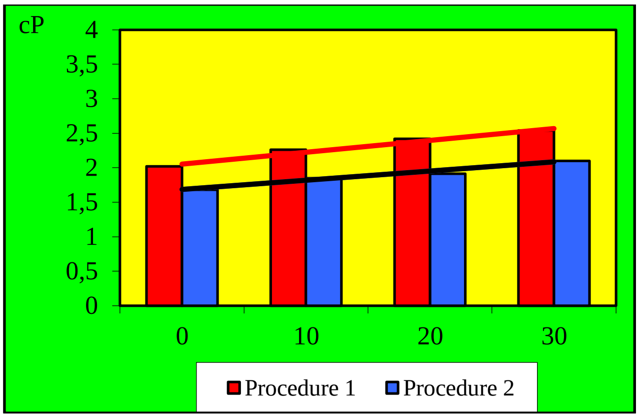

Figure 3. The positive correlation between viscosity and barley concentration in BF1

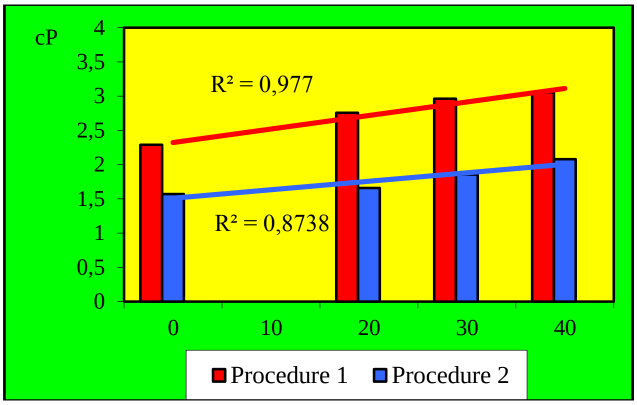

Figure 4. The positive correlation between viscosity and barley concentration in BF2

Higher correlation between dynamic viscosity and cereal content in the feed was observed in procedure 1: r = 0.9877 for BF1, r = 0,9885 for BF2, r = 0.9827 for WF1 and r = 0.9887 for WF2, as compared to procedure 2: r = 0.9849 for BF1, r = 0.9348 for BF2, r = 0.8474 for WF1 and r = 0.9454 for WF2.

Conclusions

Water extract viscosities correlated well with the wheat and barley concentrations of the feed samples. Higher dynamic viscosities and a better correlation between wheat and barley proportion was obtained when extraction was preceded by inactivation of enzymes.
Procedure without endogenous enzyme inactivation has the advantage that it is faster and does not require ethanol consumption.

Abstract

Cereal grains are major sources of dietary fiber (DF), an important component of food and an important contributor to human health. Based on their water solubility DF is classified as soluble dietary fiber (SDF) and insoluble dietary fiber (IDF). Barley contains substantial amounts of both SDF and IDF. The predominant water SDF in barley is β-glucan (7.6%). Soluble dietary fibers, such as β-glucans, lower blood cholesterol and glucose concentrations partly because of their capacity to increase the viscosity of intestinal chime. Soluble polysaccharides give viscous aqueous solutions. The physical and physiological properties of β-glucans are of commercial and nutritional importance. Food processing is mostly based on heating. Heat treatment alters the properties of plant cell wall and modifies the composition and solubility of fibers, which modifies the water extract viscosity (WEV). The experiments had in view the effect of dry heat treatment (in forced air oven, and microwave oven) on the SDF fraction in barley, revealed by determination of WEV. The experimental data revealed that thermal processing has a marked effect on the viscosity of SDF. Heat treatment increased WEV and also demonstrated that the proportion of SDF in the total DF content of the cooked flour increased with cooking time. A redistribution of the total DF content from insoluble to soluble components occurs. An increase in WEV of 73% occurred when heating at 150ºC for 10 minutes, and of 56% when heating at 180ºC for 5 minutes. When heating 90 seconds in microwave, WEV increased with 41%. Further heating (120 seconds) decreased WEV.

Keywords: *dietary fiber, barley, β-glucan, water extract viscosity, heat treatment*

Introduction

The quality of food is strongly related to the nutritional and therapeutic properties, and the effect on consumers' health. Dietary fiber (DF) is an important component of food. DF includes all non-starch polysaccharides resistant to digestion in the small intestine and fermentable in the large intestine. Based on their water solubility, DF is classified as soluble dietary fiber (SDF) and insoluble dietary fiber (IDF) (Chawla and Patil, 2010; Tungland and Meyer, 2002). Soluble fiber includes gums, mucilages, pectin and some hemicelluloses. Insoluble fibers are cellulose, lignin, and the rest of the hemicelluloses; these fibers provide structure to plants (Henley and Misner, 1999; Anderson *et al*., 2011). Although poor in caloric or nutritional value, food fiber has significant health benefits and may assist weight control. Fiber deficiency is linked to a higher risk of digestive conditions, raised cholesterol levels and some intestinal cancers. Barley contains substantial amounts of both soluble and insoluble dietary fiber. During digestion, soluble fibers turn into gel like substances, slow down digestion process in the stomach and intestines, stabilizing blood glucose levels, and increasing the uptake of minerals and other nutrients. Insoluble fibers consist of the parts of plants which cannot be digested at all, moving whole through the digestive system; insoluble fibers increase stool volume and stimulate normal bowel contractions thus reducing passage-time through the colon, improving health in the intestinal tract, and reducing digestive complaints (American Heart Association, 2011; Anderson and Bridges, 1988; Esposito *et al*., 2005). The predominant water SDF in barley is β-glucan (7.6%). Woodward *et al*., 1983 determined the chemical structure and physicochemical properties of water-soluble barley β-glucans. These glucans consist of a population of molecules with molecular weights ranging from 10^4 to 10^7 and are responsible for the high viscosity of β-glucan solutions (Caprita and Caprita, 2012). Soluble dietary fibers, such as β-glucans, lower blood cholesterol and glucose concentrations partly because of their capacity to increase the viscosity of intestinal chime. Soluble polysaccharides give viscous aqueous solutions (Caprita *et al*., 2011a). The viscosity properties depend on molecular weight or molecule size (linear or branched), ionically charged groups, surrounding structures, and concentration of DF (Caprita and Caprita, 2011b). In aqueous solutions, water molecules penetrate the amorphous regions of soluble DF. The increase in viscosity is explained by formation of Ca^{2+} bridges and hydrogen bonds, resulting in a loose network that can hold considerable amounts of water (Caprita *et al*., 2010a; Caprita *et al*., 2010b; Mongeau, 2003). The physical and physiological properties of β-glucans are of commercial and nutritional importance. Food processing is mostly based on heating. Thermal processing of plant tissues alters the physical and chemical properties of plant cell wall and modifies the composition and solubility of fibers, which modifies the water extract viscosity (WEV) (Izydorczyk *et al*., 2000, (Caprita and Caprita, 2011a). The experiments had in view the effect of dry heat treatment of barley on the soluble fraction of DF, revealed by determination of WEV.

Materials and Methods

Barley samples were milled by a laboratory grinder to 500 μm granulation, and thermal processed by heating in a forced air oven, or by exposing to microwave radiations. Samples were heated for 5, 10 and 15 minutes at 150 ºC and 180ºC in a Froilabo AC60 forced air oven. The microwave treatment was made in a Vortex WD800D-823 oven (800 W and 2450 Hz), for 30, 60, 90 and 120 seconds. The water-soluble fractions were obtained using a single extraction at a ratio of flour to water of 1:2, by shaking the tubes at 150 rpm for 60 minutes at 40ºC, using a LabTech LSB-015S water bath. The obtained extracts were centrifuged for 10 minutes at 5,000 rpm and 25°C, using a Hettich 320R centrifuge. The dynamic viscosity was determined using a cone/plate viscometer Brookfield Model DVIII Cone CP-40, at 100 rpm and 25°C, and the relative viscosity was calculated.

Results and Discussion

Thermal processing of plant tissues alters the physical and chemical properties of plant cell wall. The experimental data reveal that thermal processing increased the soluble dietary fraction in barley. In general, the changes in the DF composition during cooking may be attributed partly to the redistribution of the insoluble and soluble components of DF, and partly to the formation of resistant starch (Caprita *et al*., 2011b).

The obtained experimental data, presented in Table 1, show the effect of thermal treatment on the soluble fraction of DF in barley, effect revealed by the determined values of the water extract viscosities. The relative viscosity value of water extract from untreated barley flour was 2.95 cP.

Thermal treatment at 150ºC produced an increase of water extracts viscosities. The proportion of SDF from total DF increased with the heating time. The experimental data suggest a conversion of the IDF into SDF. An increased temperature breaks week bonds between polysaccharide chains and split glycosidic linkages in the DF polysaccharides (Selvendran and Robertson, 1994). As consequence, the architecture of the fiber matrix may be modified and insoluble fiber solubilized (Margareta and Nyman, 2003).

Table 1. Viscosities of water extracts from thermally treated barley flour

Viscosity (cP)	Treatments of barley flour: temp. and time (minutes and seconds)									
	Forced air oven						Microwave radiations			
	150 ºC			180 ºC						
	5’	10’	15’	5’	10’	15’	30’’	60’’	90’’	120’’
Dynamic viscosity	3.62	3.99	3.59	3.64	3.33	3.01	2.01	2.68	3.34	3.18
Relative viscosity	4.64	5.11	4.60	4.60	4.21	3.81	2.51	3.39	4.17	4.02

The relative viscosity of water extract increased up to 5.11 cP (73% increasing) when barley was heated 10 min. at 150ºC, and up to 4.60 cP (56% increasing) when heated at 180ºC for 5 minutes. A decrease in WEV was observed when barley was heated 15 minutes at 150ºC, and 10 and 15 minutes at 180ºC, suggesting formation of water insoluble resistant starch (Figure 1).
The microwave radiations treatment increased WEV up to 4.17 cP (41% increasing) after 90 seconds (Figure 2). Further microwave treatment decreased WEV to 4.02 cP (after 120 seconds).

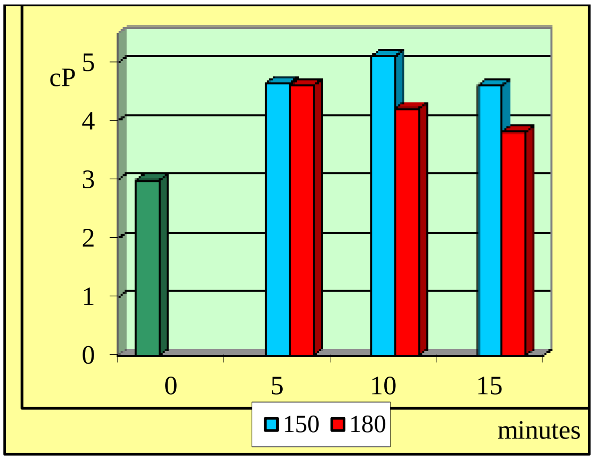

Figure 1. Relative viscosities of water extracts from barley heated in forced air oven at 150ºC and 180ºC, for 5, 10 and 15 minutes

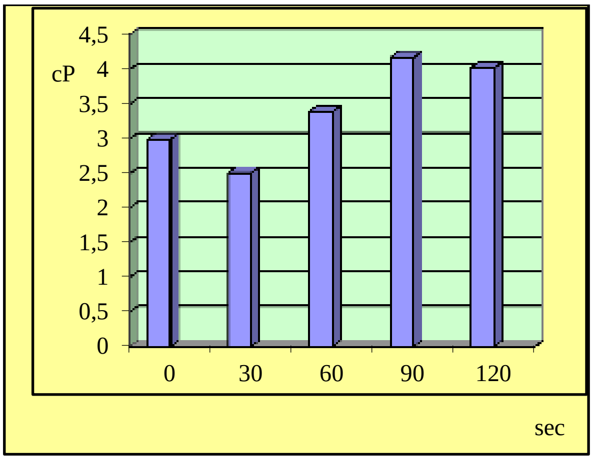

Figure 2. Relative viscosities of water extracts from barley heated in microwave oven for 30, 60, 90 and 120 seconds

Conclusions

The increase of the soluble dietary fiber proportion in the total dietary fiber content in barley, produced by the thermal treatment for 10 minutes at 150ºC, suggests a redistribution of the total dietary fiber content from insoluble to soluble components.
A decrease in water extracts viscosities when barley was heated 15 minutes at 150ºC, and 10 and 15 minutes at 180ºC, and at microwave treatment for 120 seconds, suggest the formation of water insoluble resistant starch.

Abstract

The chestnut moth leaf miner, *Cameraria ohridella* Deschka & Dimic represents in the Huşi area a dangerous pest, which outbreaks causing damages every year. In this paper flight dynamics the butterflies followed traps type Atra-CAM. The butterflies flight situation is as follows: In 2015 the flight of hibernate generation butterflies started on 8.05, and it is finished on 21.05. The maximum flight curve was recorded on 21.05 when they were captured a total of 389 samples; The flight of the first-generation butterflies has started on the 21.06, and he concluded on 31.07. The maximum flight curve was recorded on 30.06 when they were captured a total of 410 samples; The flight of the second-generation butterflies started on 1.08, and it's concluded on 3.09. The maximum flight curve was recorded on 15.08 when they were captured a total of 400 samples. In 2016 the flight of hibernate generation butterflies began in May, on 09.05, and he finished on on 21.06. The maximum flight curve was recorded on 31.05 when they were captured a total of 380 samples; The flight of first generation butterflies has started on the 26.06, and he finished on on 31.07. The maximum flight curve was recorded on 13.07 when they were captured a total of 290 samples; The flight of second generation butterflies started on 3.08, and he finished on on 15.09. The maximum flight curve was recorded on 15.08 when they were captured a total of 400 samples.

Keywords: *flight of butterflies, dynamic, traps, AtraCam.*

Introduction

Cameraria ohridella Deschka & Dimic has as its main host the ornamental chestnut, *Aesculus hippocastanum* L., a common ornamental species in Europe, being preferred in line for the rich shade it gives. The species was reported in Macedonia in 1985 around Lake Ohrid, very close to the border with Albania, and was described as a new species for science a year later. The true origin of the species is not yet known.The genus *Cameraria* is not represented by other species in Europe, but some species belonging to the genus are found in Asia and North America. This supports the hypothesis of the introduction of the species into Albania by Chinese travellers, and after the introduction of the species, the spread of adult birds began, with the expansion of the species area first in the states of the former Yugoslavia in the late 1980s (Skuhravy, 1999).Between 1993 and 1998 it expanded to the Czech Republic, Slovakia, Slovenia, Germany, Hungary, Switzerland and Poland, and between 2002 and 2004 it was reported in Great Britain, Spain, Russia and Denmark and Lithuania. In Romania, the presence of the insect was first reported in the western area of the country, in Timisoara, in 1996, in 1998 being also observed in the centre of the country, in Cluj-Napoca. In 2005, the insect was observed in Vaslui County, and since 2006 the insect fighting warning alerts have begun to be issued.

Material and methods

To track the dynamics of the butterfly flight, were used the traps with specific pheromones of the Atra-CAM type. They were located in the research area, a trap for each location, park, and alignment. From May to September, readings were made at intervals of 2-4 days, depending on climatic conditions. At 6-week intervals, the pheromone inside the trap also changed (Augustin, 2004). The catches of each reading have been removed. This method was performed the curve of occurrence of butterflies adult and maximum flight course was carried out and the warning chart trebuies of the treatments applied against this pest.

Results and Discussion

Moth mining of chestnut leaves, *Cameraria ohridella* Deschka & Dimic also represents a dangerous pest in the Husi-Vaslui area, which has spread and caused more and more damage every year.

1. THE NATURAL ENVIRONMENT AND THE PEDOCLIMATIC CONDITIONS IN WHICH RESEARCH HAS BEEN

Presentation in brief of Husi area, Vaslui county

The geographic and mathematical position of Huşi is at the intersection of the parallel 46º41 ' north latitude and the meridian of 28º03' east longitude. Geographically, the city is located in the southwestern part of the Huşi Depression, a part of the Central Moldavian Plateau, which falls on the Barlad Plateau, as a subdivision of the Moldavian Plateau in northeastern Romania.

In the south-north direction it is between the towns of Galaţi and Iaşi (about 130 km and 83 km respectively), and in the east-west direction is approximately equally between the towns of Barlad and Chisinau, at the boundary between the Russian plateau and the Dobrogea.

Climate considerations of agricultural years 2014, 2015 and 2016.

Analyzing the average temperatures, precipitation and relative humidity in the air during the three years, 2014, 2015 and 2016, during the vegetation period, the following are observed:

- in 2014-2015 (Table 1) the spring was warmer than the normal multiannual period with values between 1.9-3.9°C (March - May), the rainfall exceeded normal, with values between 11.2 mm (March) and 10.3 mm (May) and were below normal in April with a deficit of 11.3 mm, and the monthly average humidity was 74% (March) and 69% (April - May).

The summer is characterized by higher than normal multi-annual temperatures, with values ranging from 0.7 to 2.1°C, and the rainfall recorded a deficit in July and August between 14.22 and 22.3 mm, and in June Exceeded normal by 52.6 mm. September has recorded temperatures that exceeded the multi-annual by 1.1°C and rainfall by 46.3 mm. The absolute minimum temperature was -12.7°C, recorded on January 12; The absolute maximum was + 35.5°C recorded on July 29, and the last spring frost was on March 29, -2.0°C.

The first frost in the fall: - 1,6 º C = 20 octomber 2015

The last frost in the spring: - 1,6 º C = 30 marts 2016

- in 2015-2016 (Table 2) the spring was warmer than the normal multiannual period with values between 0.1 - 5.6°C (March - May), precipitation exceeded normal, with values of 4.0 mm in March, 51.0 mm in April and 118.9 mm in May, and the monthly average relative humidity had values below the multiannual average in March and April (-5, respectively, -3 units) and were over multiannual in May with more 7 units.
- The summer is characterized by temperatures that did not exceed the much normal multiannual values, with values ranging from 0.4 - 2.2°C, and the precipitations recorded a deficit in June and August between -60.0 mm and -38, 5 mm, and in July they exceeded normal by 81.6 mm. The month of September recorded temperatures that exceeded the multi-annual by 1.7°C and the rainfall had a deficit of - 35.5 mm.

2. CONSIDERATIONS ON THE BIOLOGICAL CYCLE AND DYNAMICS OF ADULT FLIGHT *CAMERARIA OHRIDELLA* DESCHKA DIMIČ

The research carried out during the two years was aimed at studying the biological cycle, the dynamics of adult flight, and influencing climatic factors on the species *Cameraria ohridella* Deschka Dimič in order to issue warning bulletins by proposing chemical treatments as measures to limit the population, Climate in the Huşi area, Vaslui County.

For the pursuit of *Cameraria ohridella* adult flight, pheromone traps, Atra-CAM, were used. Thus, a trap / location was used, and baits were changed monthly from May to September 2015 and 2016. Adult flight performance ratings were made 3 times a week.

In order to correlate the data obtained with the meteorological data, the sums of the actual temperature ranges (over 12°C.) were calculated for each stage of evolution.

Dynamics of *Cameraria ohridella* Deschka Dimič adult flight in Husi village in 2015

In 2015 (Table 3), the first generations of the third (hymnal) generation appeared on 05.05, at a Σ (tn - to) = 118.06°C. The adult adult flight lasted 15 days, between May 12 and June 3, and peaked between May 23 and 26. After June 6, adult flight began to decline, so that for 3 days, June 15-18, there was no flight. Third-generation (G3) adult flight lasted 38 days (04.05-12.06).

Table 3

Dynamics of adult flight of *Cameraria ohridella* Deschka Dimič in Huşi, 2016

Butterflies of generation I-a (G1) started the flight on 19.06, at a Σ (tn - to) = 446,80°C. The adult flight lasted 18 days, between 28 June and 15 July, and the maximum flight was

recorded between 01.06 and 09.07. After 15.06, the flight began to drop, so it overlapped the second generation. The flight time of the first generation cannot be said with precision.
Adults of the second generation appeared on 04.08, at a Σ (tn - to) = 939.23°C, the flight was recorded between 04-21.08, for 22 days and the maximum was recorded 06-15 August, for 9 days. Adult flight of the 2nd generation (G2) lasted 38 days (04.08 - 12.09) and overlapped with adults of the 1st generation.
In 2016, the first captured adults of the 3rd generation (hymnal) appeared on 10.05, at a Σ (tn - to) = 85.25°C (Table 4). The adult flight was between May 21 and June 6, for 20 days.

52,95^{0}C	41	362,36^{0}C	-	783,42^{0}C	27

Flight flight in May was influenced by heavy rainfall for 16 days when 179 mm precipitation occurred. After June 10, adult flight began to decline, so that for 3 days 22 -25 June, no flight was scheduled. The Third Generation Flight (G3) Flight lasted 39 days (10.05 - 18.06).After 25.07, the flight began to decline, but it did not stop, so it overlapped the second generation.
Adults of the second generation began to appear on 11.08, at a point (tn - to) = 833.96°C, the flight took place between 13 and 28.08 for 15 days and the maximum flight curve was recorded during the 13 - August 18. Adults flew until 9 September.

Conclusions

To monitor the flight dynamics of *Cameraria ohridella* adults, sex-specific Atra-CAM traps were used. So:
in 2015, third-generation adult flight (G3) lasted 38 days; The large flight lasted 15 days between 12 May and 03 June and peaked during the period 23-26 May when 320 and 290 butterflies were collected. For the first generation (G1), the adult flight lasted 18 days between June 28 and July 15, and the maximum flight was recorded on 01 and 03 July. After 15.06, the flight began to drop, but it did not stop, so it overlapped the second generation; The flight of the second generation was recorded during the period 04-21.08 for 22 days and the maximum was recorded during the period 06-15 August for 9 days.
In 2016, the adult flight of the third-generation (third) generation was between May 21 and June 6, for 20 days, the maximum was recorded on May 23. Third-generation (G3) adult

flight lasted 39 days. For generations I (G1), the flight took place between 03 and 25 July, for 22 days and a maximum flight between 06 and 12 July. The flight of adults of the first generation (G1) overlaps the raid of adults of the 2nd generation. Generation II (G2) had a large flight between 13 and 28.08, for 15 days, and the maximum flight curve was recorded during the 13th - August 18 and flew until September 9.

In 2015, temperatures were higher than the normal multiannual temperature, so the absolute minimum temperature was -12.7 After 25.07, the flight began to decline, but it did not stop, so it overlapped the second generation and the absolute maximum was + 35.5°C and the rainfall had a deficit in the months July and August between 14.22 and 22.3 mm.

The year 2016 is characterized by temperatures that did not exceed the much normal multiannual, so the absolute minimum temperature was -21,8 ○ C and the absolute maximum was + 35,7 °C and the rainfall had a deficit of - 35 , 5 mm.

Abstract

The paper aimed to present the main pathogens of two-rowed barley and wheat crops and the yields obtained in 2016 at S.C. SPORT AGRA SRL Amzacea, Constanța district (Romania) on demonstrative plots. Climatic conditions of autumn 2015 and spring 2016 provided a favorable development of the crops. Protection against foliar diseases of the two grain crops was done using three fungicides treatments with Bumper 250 EC, Artea 330 EC and Prosaro 250 EC, no attack of powdery mildew (*Blumeria graminis*) was registered. The attack of *Rhyncosporium secalis* and *Pyrenophora tritici-repentis* in two-rowed barley presented a low level. On wheat, the pathogens *Septoria tritici* and *Pyrenophora tritici-repentis* had low attack levels, except the cultivars Hybiza, Hylux and Avenue with higher attack. The pathogen *Puccinia striiformis* had the lowest values of attack, except the variety Avenue and Pescador. Concerning the correlation between the yields and the pathogens incidence and severity, the lowest yields in wheat crop were obtained with Hybiza (4740 kg/ha) and Avenue varieties (4860 kg/ha). The highest yields were obtained with Genius (8401 kg/ha) and Katarina varieties (8400 kg/ha). For two-rowed barley crop, the lowest yield was 8450 kg/ha for Wendy variety and the best yields were 8800 kg/ha for Henriette variety. Quality indices of wheat grains were between 74.6 for Hylux variety and 81.0% hectoliter mass for WinterGold variety.

Key words: *yield, pathogen status, barley varieties, wheat varieties, Dobrogea region, Romania*

Introduction

In the last 7 years, various grain varieties created by foreign companies have been placed in cultivation without being deeply known their behavior in the climatic conditions of the Romanian district, Dobrogea. Romanian varieties of winter grains occupies a percentage of more than 70% of the cultivated area (Roman Gh. V. et al., 2011). The paper aimed to present the main pathogens of two-rowed barley and wheat crops and the yields obtained in 2016 at S.C. SPORT AGRA SRL Amzacea, Constanța district, on demonstrative plots. 15 varieties of wheat, 3 varieties of two-rowed barley were analyzed regarding their behavior in the climatic conditions from Amzacea area, in agricultural year 2015-2016. The efficiency of integrated control is directly dependent on the biology of the pest, parasite-host plant relationship, being influenced by climatic conditions that characterize a particular crop area or a certain stage of the plant vegetative cycle (Jinga V. et al. 2010, 2014).

Materials and methods

Experience has been placed on S.C. SPORT AGRA S.R.L. Amzacea, Constanta. The studied crops are winter crops: two-rowed barley and wheat. The experience was situated on a land belonging to the South Dobrogea plateau, represented by cambic chernoziom with a profile deeper than other chernoziоms, a blackish-brown soil of 40-50 cm thickness, medium texture (Demeter T., 2009). The content of nutrients was: mobile P index - 72; N index - 4; Humus - 3.11; K index - 200; Neutral pH - 7.2. The climate is deeply temperate continental, with an average annual temperature of 10.7 - 11.7 °C, with a high temperature in the period 20th June to 15th August. Quantity of precipitations during the vegetation period was presented in Table 1.

This area is the most arid in the country, with 69-year multi-annual average rainfall of 401 liters. Sowing was carried out on 16th October 2015. Treatment of seeds was carried out with Yunta Quattro 373,4 FS (clotianidin 166.7 g/l + imidacloprid 166.7 g/l + protioconazol 33.3 g/l + tebuconazol 6.7g/l) in dose of 1.6 l / ton. Due to the climatic conditions of the year 2016, for the prevention and control of foliar and ear diseases, 3 treatments were performed: Treatment I (14 April) – Bamper 250 EC (propiconazol 250 g/l), 1 l/ha; Treatment II (2 may) – Artea 330 EC (cyproconazole 80 g/l + propiconazol 250 g/l) 0.4 l / ha; Treatment III (21 may) – Prosaro 250 EC (tebuconazole 125 g/l + protioconazole 125 g/l) 0.75 l / ha. Karate Zeon 50 CS (lambda-cyhalothrin 50 g/l), at a dose of 0.75 l/ha were used for specific pest control.

The attack rate was calculated with the formulas RA=FxI/100 (F% –frequency of the attacked organs, I % -intensity of organs' attack.

Results and discussions

Observations on phytosanitary status of winter crops and collections of biological samples were made on April 2016 (table 2). Technological elements such as: prior crop, basic fertilization, sowing date, amount of seed, emergence date, and plant density were presented in table 3. Due to the high rainfall throughout during April and May, the attack of pathogens that cause diseases in cereal crops was very aggressive, requiring the 3 pesticides treatments. It can be seen that all three treatments reduced the intensity of the attack. Pathogen attack of

Rhyncosporium and *Pyrenophora* on two-rowed barley presented a RA (degree atack) low (0.6-2.1%). In the wheat crop, the pathogens *Septoria* and *Pyrenophora* showed attacks low (2-3%), except varieties Hylux (6.4%, 7.0%, respectively) and WinterGold (8.1%, 5.6 %respectively), with greater attack. *Puccinia striiforme* pathogen presented low levels of attack (1.5%), except the variety Avenue (2.5%).

After the 3 fungicide treatments, foliar diseases were stopped at basal leaves (Figure 2 with details). The last 3 leaves and the ear were protected due to phytosanitary treatments. It contributed to the achievement of high productions of about 8 tons in the two-rowed barley and 4 wheat varieties. Data on yields obtained in experimental plots are shown in Table 3. For two-rowed barley crop, the lowest yield was 8450 kg/ha for Wendy variety and the best yields were 8800 kg/ha for Henriette variety . Quality index 64,0-65,0 The highest yields in wheat were obtained with Genius (8401 kg/ha) and Katarina varieties (8400 kg/ha). Quality indices of wheat grains were between 74.6 for Hylux variety and 81.0% hectoliter mass for WinterGold variety.

Conclusions

To prevent and control the pathogens that cause diseases in autumn cereal crops were necessary, in climatic conditions of the 2016 year, 3 treatments with fungicides. *Rhyncosporium* and *Pyrenophora* pathogens showed a low degree attack to two-rowed barley. In wheat crop, pathogens *Septoria* and *Pyrenophora* showed reduced attack degrees, as the pathogen *Puccinia striiforme*. The yields obtained in conditions of 2016 ranged from between 8450-8800 kg / ha and quality index 64,0-65,0 for two-rowed barley , and yield between 4740 to 8401 kg / ha for wheat. For all varieties analyzed, hectoliter weight was influenced by rainfall, showing values between 74.6 to 81MHl.

EFFECT OF EPIN EXTRA REGULATOR ON DEVELOPMENT OF BARLEY GROWING ON Cd-CONTAMINATED SOIL

Nadezhda LOI*, Natalya SANZHAROVA

Russian Institute of Radiology and Agroecology, Obninsk, Russian Federation
*Corresponding author: loy.nad@yandex.ru

Abstract

Chemical plant protection products, in particular herbicides, whose action can be considered as a kind of stress for the plants, can have a depressive effect on culture. The use of plant growth regulators in the cultivation of grain crops is aimed to obtain agricultural products with a minimum content of toxic and hazardous substances and improving the environmental situation. A presowing treatment of barley seeds, Elf variety, by the growth regulator Epin extra, when herbicide Agritox used for the crop cultivation, significantly increases the root index of plants both growing on soils with the background and increased Cd concentrations. At the same time the using of the growth regulator does not reduce a depressive effect of the herbicide on the photosynthetic activity of 30-day plants. The presence of Cd in soil in high concentration does not significantly affect the accumulation of K and Ca by 30-day plants, and at the same time increases the Mg content in plants. Using of herbicide Agritox leads to a decrease in the productivity of barley varietie Elf on 9-13% when plants grow on soil with the background concentrations of Cd. The shortage of the crop is due to a decrease in the number of grains and their mass in the lateral shoots. High content of Cd ions in soils reduces negative effect of herbicide Agritox. Using plant growth regulator Epin extra does not lead to significant changes in the yields of barley of Elf variety.

Introduction

The result of human economic activity is an increase in the technogenic burden on agroecosystems and an increase in the concentrations of pollutants in agricultural soils. Toxicity of heavy metals (HMs) for living organisms are defined as properties and level of concentration of the elements themselves, and their migration ability in various ecosystem components, as well as the degree of accumulation in the tissues and organs of animals and plants (Ulyanenko et al., 2004). It is known that Cd is one of the most phytotoxic pollutants, possessing with a high potential to accumulate in biological objects and having a resemblance to the physiologically important organic compounds in a vegetative organism. The underlying mechanism of toxicity to plants connected with the change of enzyme activity and a violation of metabolic reactions, resulting in the inhibition of photosynthetic processes in the early stages of ontogenesis (Melnychuk, 1990; Chernykh et al., 1999). Wide application in agriculture of various protection Drugsand plants growth regulators (PGR), most of which are biologically active substances (BAS), can lead to changes in absorption plants ions HM (Kabata-Pendias et al., 1989). However, it is known that the use of biologically active substances in processes is designed to ensure the mobilization of nutrients from the soil, change the availability of nutrients, have an impact on migration of easily movable substances, reduce the negative impact on surroundings agrochemicals. Modern technologies of cultivation of grain crops are focused on reception of agricultural production with the minimum maintenance of toxic and dangerous substances and improvement of ecological conditions. Chemical plant protection products, in particular herbicides, whose action can be considered as a kind of stress for the plant organism, can have a depressive effect on culture. Marked selectivity of action the drugs (Nemchenko, 1994). For example, exceeding the recommended rate of herbicide consumption with the active substance diethylethanolammonium salt, exerted a depressing effect on wheat and maize, but practically did not affect barley plants. The addition of sodium Humate (at a concentration of 0.001%) to the tank mixtures contributed to a decrease of the herbicide inhibitory effect on plants. The purpose of our research was to study the possibility of using the plant growth regulator (Epin extra, S) in order to reduce the negative effect of increased Cd in the soil on the development of barley, when treated with herbicide Agritox, WC.

Material and Methods

The studies were carried out in a vegetation experiment on spring barley (*Hordeum vulgare* L.) of the Elf variety. The plants were grown in vessels with a capacity of 5 kg sod-podzolic medium loamy soil, containing: RN_{KCl} - 6.4 mg-eq / 100 g soil; Humus - 2.1%; P_2O_5 - 23.0, K_2O - 17.0 mg / 100 g of soil.

To ensure the normal development of plants before planting, mineral fertilizers were introduced into the soil in the form of aqueous solutions of NH_4NO_3, KCl and KH_2PO_4 salts at the rate of N - 1.0 g, K_2O - 0.7 g and P_2O_5 - 0.7 g per 5 kg of soil (Zhurbickiy, 1968).

Simultaneously with the introduction of batteries into the soil, Cd was added as a solution of the Cd $(NO_3)_2$ * $4H_2O$ salt at a dose of 20 mg / kg soil (designation Cd_{20}).

The seeds were pre-treated on a laboratory rotor RVO-64 in all variants of the trial with fungicide Baitan universal, WP (flow rate 2 kg / t) and in some variants (according to the experiment scheme) by the plant growth regulator Epin extra, S (a.s. Epibrassinolide). Epin extra increases the energy of germination of seeds, stimulates the immune system of plants, increases resistance to pathogens and rots, neutralizes the effect of nitrates, HM, radionuclides and other stressful situations. The application rate of the preparation for seed treatment is 200 ml / ton of seeds (Directory of...2015). In the tillering phase, barley plants were treated with herbicide Agritox, WC (a.s. - dimethylamine + potassium + sodium salt, mixture) at a rate of 1.5 l / ha (Directory of...2015).

The scheme of the experiment included five options: 1 - control without seed treatment by the plant growth regulator and without herbicide application (C); 2 - treatment of plants in the tillering phase with a herbicide (H); 3 - presowing seed treatment with the Epin extra preparation, S (hereinafter "Epin") + treatment of plants in the tillering phase with herbicide (E + H); 4 - treatment of plants with a herbicide against the background of Cd (Cd_{20} + H); 5 - presowing seed treatment by Epin + treatment of plants with herbicide against the background of Cd (Cd_{20} + E + H). Repeatability is threefold.

During the vegetation period, phenological observations were carried out and the morphometric parameters of plant development (developmental phase, height, leaf surface area (ALS)), raw and air-dry plant masses and water retention capacity were determined. The height of the plants was measured from the soil surface to the end of the last leaf, and, beginning with the stage of earing, to the end of the ear. The plants were selected for analysis (5 per each vessel) at the beginning of the tube exit (30 day old plants) and in the earing phase (60 day old plants).

The morphological indices (Piankov et al., 2000) were calculated: leaf (ratio of the leaves mass to mass of the whole plant), root (ratio of the mass of the underground organs to the mass of whole plant), stem (ratio of the stems mass to the mass of the whole plant) and generative (Generative organ to the mass of the whole plant).

The content of macroelements (Mg, K, Ca) and Cd in 30-day-old barley plants after "wet" ashing was determined by atomic absorption spectrophotometry in an air-acetylene flame using a Perkin-Elmer device.
For the statistical processing of the results by the dispersion method, the Microsoft Excel 97 software package was used..

Results and Discussion

In the process of monitoring the growth and development of barley during the growing season (from shoots to harvesting), there were no significant differences in the dynamics of changes in plant height when the herbicide Agritox was used and without it (variants C and H).
When growing barley in soil contaminated with Cd at a concentration of 20 mg / kg - about 10 MPC (variant Cd_{20} + H), a slowing down of the stages of organogenesis of plants (in comparison with option C) was noted. This was reflected in the height of the plants at the beginning of the earing phase (a decrease of 8-15%). However, at the time of harvesting, the height of the plants when grown on contaminated soil exceeded by an average of 10% the height of the plants in variants with a background content of Cd in the soil. Presowing seed treatment with Epin did not have a positive effect on the height when plants were grown both on the background (E + H) and on the increased Cd content in the soil (Cd_{20} + H + E). Analysis of datas from 30 daily plants (Table 1) revealed a statistically significant decrease, compared to the control, of the leaf surface index (ILS) in the variant where barley in the tillering phase was treated with Agritox. In this case presowing seed treatment with the Epin regulator did not reduce the negative effect of the herbicide on the intensity of photosynthetic processes: the incidence of ILS was noted to be 13% with respect to control (the differences were significant at P = 0.05).

Table 1. Indicators of development of 30-days barley plants (development phase - the beginning of the exit into the tube)

Option	ILS (%)	Weight of one plant (g)		Relative content water (%)
		Wet	Dry	
C	66.7	3.9	0.6	84.7
H	59.4*	4.2	0.7	84.4
E + H	57.9*	3.5	0.6	83.2
Cd_{20} + H	62.7	3.7	0.6	84.0
Cd_{20} + H + E	63.3	3.6	0.6	83.8
SSD_{05}	4.6	0.9	0.1	1.7

Here and below: * - differences with control data are significant at P = 0.05

At the same time, when growing barley in soil contaminated with Cd, no significant effect of Agritox on the photosynthetic activity of 30-day plants was detected, according to the ILS. The growth regulator (Epin) did not introduce additional changes in the value of the indicator. Thus, the negative effect of herbicide application was more significant than the increased content of Cd (about 10 MPC) in the soil.
The treatment of barley with a herbicide, regardless of the presence of Cd in the soil, did not affect the wet and dry biomass, as well as the water retention capacity of plants.
An analysis of the results from development of 60 daily barley plants (spike) showed that presowing seed treatment of PGR ambiguously influenced the morphological development indices. The use of Epinum promoted the root growth index by 6-38% in herbicide variants, regardless of the chemical toxicant content in the soil. In the same variants of the experiment, a decrease in the stem index (by 5%) was noted with no effect on leaf and generative indices

(Table 2). Consequently, the use of the herbicide contributed to an increase in the mass of the roots and a decrease in the weight of the stems.

Table 2. Characteristics of the growth of 60 daily barley plants (development phase - earing)

Option	Plant indices (%)			
	Root	Cauline	Sheet	Generative
C	3.4	61.3	28.6	6.7
H	5.0	60.0	26.3	8.7
E + H	6.3*	58.1*	28.2	8,4
Cd_{20} + H	5.3	59.6	28.5	6.5
Cd_{20} + H + E	6.9*	58.4*	28.7	6.0
SSD_{05}	2.3	2.8	2.7	3.1

The increase of the root index as a result of preseeding seed treatment by Epin is of great importance for the resistance of barley plants to disease control. Plants that have a powerful root system are more enduring to the development of root rot (Geshele, 1971). This indicator breeders Are used when selecting plants to create resistant to root rot varieties.

Decrease in the stem index in variants with the use of Epin, in comparison with the control (without negative influence on the development of the generative index), indicates the possibility of using the growth regulator Epin on tall barley varieties in order to reduce their height, i.e. Preseeding seed treatment by Epin, can be a preventive method of combating barley lodging.

It is known that at the same concentration of Cd in the soil, its absorption by different plants can vary greatly. Plants relatively easily absorb from 0.4 to 7% soluble Cd, which is not immobilized in the root system, but moves in the plant, concentrating in different organs in different organs (Lukin et al., 2004). The accumulation of Cd in plants in excess concentrations leads to an imbalance of nutrients, causes a disruption in the synthesis and functions of many physiologically active compounds, as a result of which the intensity of the accumulation of macroelements by plants is changed (Kabata-Pendias et al., 1989).

In our experience, statistically significant differences in the accumulation of Cd in 30 daily barley plants were not detected (Table 3). The presence of Cd in elevated concentrations in the soil did not significantly affect the accumulation of 30 daily plants by K and Ca, while increasing the magnesium content in plants. Mg is an integral part of chlorophyll, and its lack can reduce the photosynthetic activity of plants (Lukin et al., 2004). This correlates with the value of barley ILS when grown on contaminated soil (control level) and with a background metal content below control (Table 1).

Epin did not significantly affected the supply of macroelements from the soil to the plants in the early phases of their development (Table 3).

As is known, the general orientation and magnitude of the effects revealed at the early stages of plant development (at the age of 30 days) and observed at the stage of crop formation are well correlated (Annenkov et al., 1991). This justifies the use of the results obtained on 30 day plants to predict the content of macroelements and Cd in the barley crop.

Table 3. Concentration of macronutrients and Cd in 30-days-old barley plants

Option	Concentration of macroelements (mg / kg x 10^{-3}):			Concentration of Cd, mg / kg
	К	Ca	Mg,	
C	9.6	13.5	2.0	1.6
H	9.6	12.4	2.1	1.7
E + H	8.2	12.7	2.1	1.6
Cd_{20} + H	8.3	12.3	2.2*	56.0*

Cd_{20} + H + E	6.8	14.3	2.4*	59.5*
SSD_{05}	3.3	3.1	0.2	8.6

By analyzing the structure of barley yield of Elf grade, has been concluded that its productivity was reduced (by 9-13%) in variants using the Agritos herbicide when growing Cd content in soil at the background level (Table 4).

Table 4. Structure of barley yield of Elf (average per plant)

Option	Main Escape			Side shoots	
	The length of the ear (cm)	Number of grains (PC)	Grain weight (g)	Number of grains (PC)	Grain weight (g)
C	7.61	22.67	1.11	22.90	0.92
H	7.65	22.50	1.16	15.62*	0.69*
E + H	7.71	22.19	1.06	16.27*	0.69*
Cd_{20} + H	7.96	22.69	1.14	19.21	0.79
Cd_{20} + H + E	7.63	22.22	1.11	19.69	0.80
SSD_{05}	0.49	1.84	0.11	4.94	0.18

The increased amount of Cd ions in the soil neutralized the negative effect of the herbicide, and the use of Epin did not lead to any changes in the yield of barley of the Elf variety.

Conclusions

Application of the plant growth regulator Epin for the presowing treatment of barley seeds of the Elf variety contributes to a reliable growth of the root and decrease of the plant stem index when processing the crops with Agritox herbicide, regardless of the Cd content in the soil (background and many times exceeding the MPC), and to increase the Mg accumulation in plants at elevated levels Ions of heavy metal.

The treatment of barley plants in the tillering phase with the herbicide Agritox, WC (in variants without the introduction of Cd into the soil) has an inhibitory effect on the photosynthetic activity (ILS) of 30 daily plants, which affects the yield of the crop (yield reduction by 9-13%). The use of the growth regulator Epin for the treatment of barley seeds at a dose of 200 ml / t does not reduce the negative effect of Agritox herbicide on ILS.

METHOD VALIDATION FOR THE SIMULTANEOUS DETERMINATION OF ACTIVE INGREDIENTS OF ACARICIDE ABAMECTIN AND ETOXAZOLE IN PESTICIDE FORMULATIONS

Sanja LAZIC, Dragana SUNJKA*, Slavica VUKOVIC

Faculty of Agriculture, University of Novi Sad, Serbia
*Corresponding author: draganas@polj.uns.ac.rs

Abstract

Formulation of the products based on active ingredients abamectin and etoxazole and lack of the official CIPAC (*Collaborative International Pesticides Analitycal Council*) and/or AOAC (*Association of Official Agricultural Chemists*) methods for their determination as individual components in pesticide products, let to need for the development of new methods. Abamectin is a contact and digestive insecticide/acaricide which belongs to the chemical group of avermectins, while etoxazole is an acaricide belonging to the group of oxazolines. In this study, simple, rapid and precise method for simultaneous determination of abamectin and etoxazole in pesticide products was developed and single-laboratory validated. For the analysis, LC system an Agilent Technologies 1100 Series with Zorbax SB-C18 column (5 μm, 250 mm × 3 mm i.d.) was used. Analytical standards of abamectin and etoxazole and samples were diluted in acetonitrile and ultrasonically dissolved. The best separation was achieved using a mobile phase consisting of 0.5% CH_3COOH/acetonitrile (30/70), at a flow rate of 0.75 ml/min and UV detection at 254 nm. Column temperature was 25 °C, injected volume was 1 μl. Retention times for abamectin and etoxazole were 5.348 min and 4.244 min, respectively. Under the selected conditions, the repeatability of the method expressed as relative standard deviation (%RSD) was less than 0.41%. The accuracy of the method, determined from recovery experiments through standard addition procedure, was found to be acceptable.

Keywords: *abamectin, etoxazolee, HPLC-DAD, determination.*

Introduction

The quality of pesticide products is crucial for their safe use in agriculture since the inadequate quality of pesticides leads to a number of consequences, such as reduction of its biological efficacy, the occurrence of phytotoxicity to cultured plant, negative impact on the environment. The procedure for quality control of pesticide products is conducted by laboratories that fulfill standards of the system ISO/IEC 17025, which implies the application of validated methods, well-equipped laboratories, and engagement of qualified personnel. Identity and content of the active ingredient, impurities of toxicological significance, physicochemical properties of the product have been tested by use of standard CIPAC (*Collaborative International Pesticides Analytical Council*) or AOAC (*Association of Official Agricultural Chemists*) methods.

However, development of corresponding methods is conditioned by deficiency of standard methods for certain active ingredients, or their combinations in products of different formulations. In order to use the method in a laboratory, with the aim of compliance verification with the prescribed criteria, it must be validated, which includes a set of tests and documentation of the characteristics of the method with the goal to demonstrate that the given

method corresponds to a specific analytical purpose. Use of validated methods is one of the basic requirements of Standard ISO/IEC 17025 and OECD principles of good laboratory practice (GLP).
According to CIPAC, corresponding methods are not available for the analysis of abamectin, a contact and digestive insecticide/acaricide which belongs to the chemical group of avermectins, and etoxazole, an acaricide belonging to the group of oxazolines, as well as for simultaneous determination of these two active ingredients in pesticide formulations.

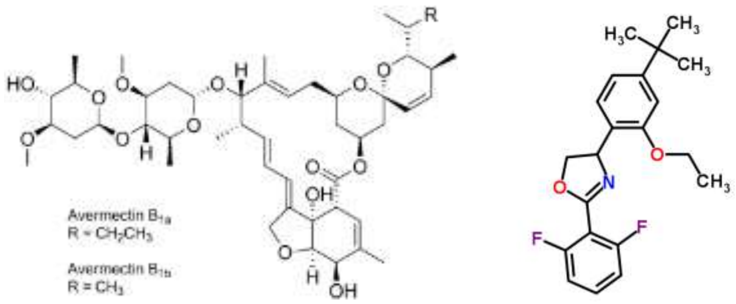

Figure 1. Structural formulas of abamectin and etoxazole

In this study, a simple and precise method for simultaneous determination has been developed for the determination of insecticides abamectin and etoxazole in pesticide products, respecting guidelines FAO/IAEA (2009).

Material and methods

Chemicals and standard solutions

Standard solutions of abamectin (98.9%, Dr Ehrenstorfer) and etoxazole (98%, Riedel-DeHaen) were prepared by diluting of a corresponding quantity of analytical standards in acetonitrile. During the analysis, the solutions were kept in dark at 4 °C. A series of solutions in concentrations of 0.1 up to 1.0 mg/ml was prepared by dilution of the standard mixtures. The freshly prepared working solutions were used to establish the precision of the chromatographic system through repeatability testing and to define the linearity of response for each individual component. As certified referent material was not available, samples with the previously determined content of the studied active ingredients were enriched by the known quantity of abamectin and etoxazolee analytical standards. The appropriate quantity of a sample (154.2 mg, 141.5 mg, 132.3 mg) was weighted into a volumetric flask and dissolved in acetonitrile. Active ingredients were dissolved by sonication with acetonitrile and directly measured. All solutions were filtered through membrane filter of 0.45 μm and analyzed by HPLC-DAD.

HPLC analysis

For the analysis, LC system an Agilent Technologies 1100 Series was used. The best separation was achieved using a Zorbax SB-C18 column (5 μm, 250mm × 3 mm internal diameter) and a mobile phase consisting of 0.5% CH_3COOH/acetonitrile (30/70), at a flow rate of 0.75 ml/min and UV detection at 254 nm wavelength. The column temperature was 25 °C, injected volume was 1 μl.

Validation of the method

According to IAEA guidelines, validation was performed by check of the following analytical performance parameters - linearity, repeatability of the injection, limits of detection and quantification and accuracy.

Results and Discussion

The best determination of abamectin and etoxazole was achieved under previously described conditions. Qualitative HPLC analysis of the presence of a certain ingredient was carried out on the basis of retention times, while the quantitative ones were based on the size of the analytical signal. Chromatogram of abamectin and etoxazolee standard is presented in Figure 2. Maximum peaks of abamectin and etoxazolee were established at 4.244 min and 5.348 min, respectively.

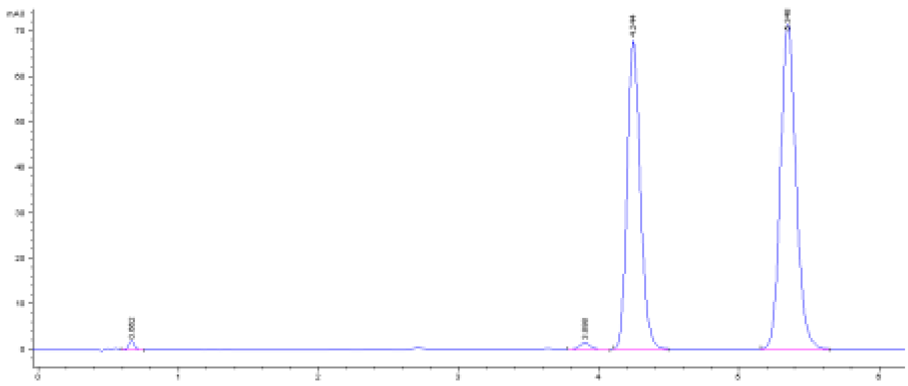

Figure 2. HPLC-DAD chromatogram of abamectin and etoxazole standards mixture in acetonitrile

Except on the basis of retention times, component identification was achieved also by comparison of UV-VIS spectrum of the unknown peak with the spectrum of the referent standard (Dudar, 2009). Figures 3 and 4 present spectra of abamectin and etoxazole analytical standards in acetonitrile solution. On y-axis are given values of the current signal detector (mAU), while on x-axis are wavelength values (nm).

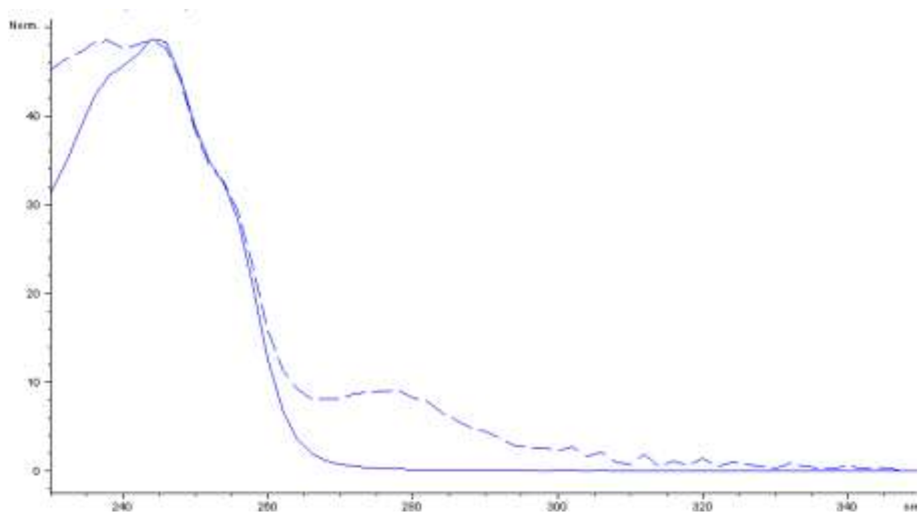

Figure 3. Overlapped UV spectra of *avermectin* B_{1a} *and* B_{1b} *in abamectin, in acetonitrile*

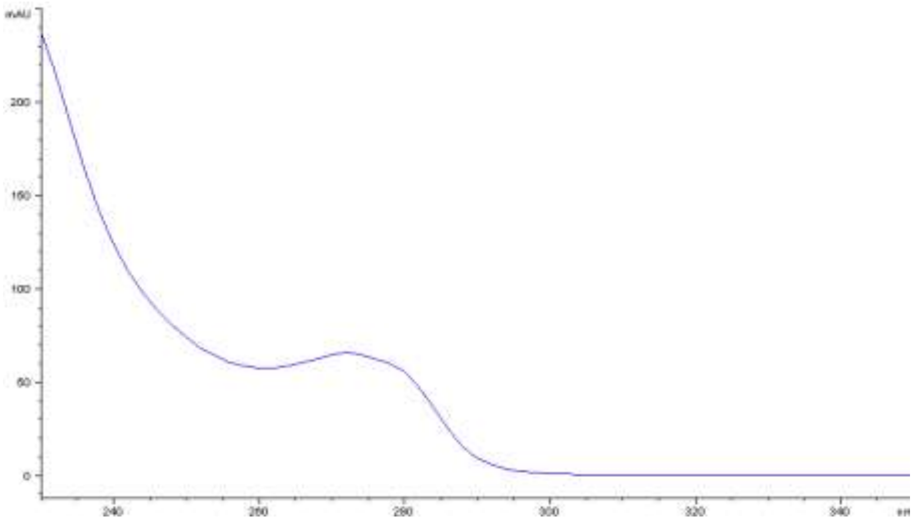

Figure 4. UV spectra of etoxazole in acetonitrile

Validation parameters

Verification of chromatograph conditions was carried out by check of detector response linearity, repeatability of the injection and accuracy of the method, as well as by determination of detection limit and quantification.

Linearity

Linearity is determined by a range of the analytical procedures and it is presented by a regression equation. It is defined as a possibility to detect a signal directly proportional to the concentration or amount of the analyte within the given scope. The linearity range depends on the nature of analytes and detector type. The linearity of detector response was determined on five concentration levels by injecting of the standard abamectrine solution within the range of mass concentrations of 0.1 – 1.0 mg/ml and the standard solution of etoxazole within the range of mass concentrations of 0.1 – 1.4 mg/ml. A calibration curve was defined as dependence of the peak area from concentration and expressed by regression equation with correlation coefficient (R^2) (Table 1).

Table 1. Linearity parameters

Abamectin	Etoxazole
y=1446.0x+30.27	y=864.2x+24.14
R^2 = 0.996	R^2 = 0.997

The obtained values of regression coefficients suggest that increase of the content of introduced compound is lineary followed by an increase in peak area. For the regression equation, the correlation coefficient of linear dependence for the tested compounds was 0.996, i.e. 0.997, suggesting the high sensitivity of abamectin and etoxazole determination by this method.

Repeatability of the injection

Repeatability was determined by injecting of 1 µl standard abamectin and etoxazole solution and etoxazolee in the concentration of 0.1715 mg/ml, i.e. 0.2336 mg/ml six times. The injected volume was 1 µL. Values of relative standard deviation (RSD, %) of 0.41% and 0.02% for abamectin and etoxazole indicate good reproductivity of determination of these compounds by the applied method, which was also confirmed by comparison by the demand of the standard (RSD≤2).

Accuracy of the method

As the parameter of the method accuracy extraction yield (Rec, %) was tested for three levels of enrichment. The average recoveries of the three fortification levels were 92.9% for abamectin and 91.6% for etoxazolee with RSDs of 2.69% and 0.72%, respectively. The high agreement between the values obtained in the process and the actual value confirms the accuracy of the applied method for the determination of abamectin and ethoxazole in the formulated products.

Limit of detection and limit of quantification

The achieved values of the detection limit of 0.05 mg/l and the limit of quantification of 0.12 mg/l indicate the satisfactory sensitivity of the method for abamectin and etoxazole determination in formulated products.

Conclusion

For the determination of abamectin and etoxazole there is no validated standard method. In this study, a simple, precise, accurate and selective method for simultaneous determination of the abamectin and etoxazole in formulated pesticide products was developed. According to IAEA-TECDOC-1612, conditions under which the analysis was performed fully meet the standards of HPLC pesticide analysis in formulations. This method could be successfully applied for the quality control of commercial formulation and proved to be convenient and accurate.

Abstract

The most important lettuce pathogens in our agro-ecological conditions are *Bremia lactucae,* causal of downy mildew and *Botrytis cinerea*, causal of gray rot. Bearing in mind the demanding market, different production requirements of lettuce, as well its varieties, biological assays with fungicides are very important. The experiment was set up in 2015, in the locality of Provo (Mačva, western Serbia), in the crop of lettuce Seter variety, using standard OEPP methods. Fungicide based on fosetyl-aluminum (Aliette 80 WP) has been applied in a concentration of 0.31%. Biostimulant (Megafol; applied doses 2 l/ha), and a mixture of fungicide with biostimulant were also used in the bioassay. Foliar treatment of plants was carried out by backpack sprayer, with a consumption of spray liquid of 400 l/ha. The experimental design was a randomized block design with four replications. The efficacy of the fungicide is determined by Abbott, while the significance of differences for the confidence interval of 95% was done using ANOVA. In the laboratory conditions, the physical and chemical properties (pH, suspendability, surface tension and electric-conductivity) of spray liquid fungicide and the mixture of the fungicide + biostimulant have been tested. Fungicide Aliette 80 WP, as well as a mixture of Aliette 80 WP + Megafol, exhibited a high efficiency (from 79.1 to 91.7%) in control of downy mildew (*B. lactucae*). In all treatments where the fungicide, biostimulant as well as mixtures of fungicide + biostimulants were applied, the average weight of lettuce plants (417.3 to 433.3 g) was at a significantly higher level in comparison to the control (403.6 g). Physical and chemical properties of the spray liquids fungicide and mixture of fungicide + biostimulant were within acceptable limits and there is no significant change after 24 hours of standing. Mixtures of fungicide and biostimulant, based on physical and chemical properties exhibited compatibility.

Key words: *lettuce, B. lactucae, fosetyl-aluminum, biostimulant*

Introduction

In Serbia, lettuce growing has a long tradition. Lettuce belongs to the group of leafy and herbaceous vegetables. In past it has been produced for someone's own needs or for the market, today it is intensive production. Lettuce growing is endangered by an increasing number of mainly fungal diseases. According to its significance and frequency of occurrence, the most important lettuce pathogen in our agro-ecological conditions is Botrytis cinerea, causal of gray rot. However, in years that favor its' development great losses are also affected by downy mildew, caused by Bremia lactuce. Besides, a disease that is regularly occurring in greenhouse lettuce is white mold caused by Sclerotinia sclerotiorum. Development of these diseases favor cool and moist conditions during vegetation period and in the lack of adequate protection, a significant and sometimes even total decay of the crop occurs. One of the risks of fungicide application is also the occurrence of resistant isolates of Bremia lactucae and Botrytis cinerea toward fungicides that are used for control of these pathogens, which certainly represents a huge problem.

The aim of this study was to determine the efficiency of the product based on fosetyl-aluminum (Aliette 80 WP) aimed for control of lettuce downy mildew (Bremia lactucae) in filed products from locality Provo (Mačva, West Serbia), according to the standard EPPO methods applied individually and in a mixture of fungicide with foliar biostimulant (Megafol). In order to provide possible recommendations for their joint application, the aim was also to determine the compatibility of fungicide and foliar biostimulant mixture.

Material and Methods

The trial was set up at locality Provo, Serbia. Lettuce (*Lactuca sativa* L.), variety Seter, was sown in containers made of Styrofoam with 200 of 5 cm^3 volume holes in each; sowing was performed on 15th, February 2015. A substrate Klasman Potgraund H was used for sowing. Lettuce seedlings were planted in open field on 10th April 2015; the inter-row distance was 30 cm, and the distance between plants 25 cm, which provided a canopy of 11 plants per square meter, i.e. 110,000 plants per hectare. Right after planting lettuce was watered by artificial rain micro-sprinklers. During vegetation period, lettuce crop has been regularly irrigated due to the lack of participations during that period. Twenty days after planting, following the development of a leaf rosette, a 400-kg ha^{-1} nitrogenous minerals fertilization was carried out. With the aim of lettuce protection against downy mildew (*B. lactucae*), lettuce was treated by the product Aliette 80 WP (fosetyl-aluminum 800 g kg^{-1}) applied in recommended concentration of 0.31%, i.e. 1.24 kg ha^{-1} . Fungicide application was carried out by back-pack sprinkler Villager 16, of 16 L volume, with working pressure of 3 bars. The quantity of the applied working liquid was 400 L ha^{-1} , with the use of recommended product concentrations. In field trials the fungicide was added a foliar fertilizer, i.e. the biostimulant Megafol in the amount of 2 L ha^{-1} . The experimental design in the field was a randomized block design with four replications per variant (EPPO Standards, 2012). One plot contained 80 plants per repetition.

The first lettuce treatment was carried out six days after planting (16th, April 2015), and the second one 15 days after the first (1st, May 2015). Five evaluations of the intensity of the disease occurrence were performed according to the standard EPPO method (EPPO Standards, 2004). The evaluations were done according to the scale for evaluation of the disease intensity; plants were divided into five groups – to those that had up to 5% damages on leaves caused by downy mildew, plants with 5-10% of damages, 10-25%, 25-50%, and plants with 50-75% of damages. Evaluations were carried out by visual observation of symptoms on lettuce leaves. The first evaluation was conducted before the first treatment, i.e. on 16th, April, 2014, the second was carried out seven days after the first treatment, i.e. on 23rd, May 2015, the third one after the second treatment, i.e. on 1st, May 2015, the fourth fourteen days after the second treatment, i.e. on 15th, May 2015, and the fifth evaluation followed ten days after the previous, i.e. on 25th, May 2015. After application of fungicides, biostimulants and mixtures of fungicides and biostimulants according to the standard EPPO method (EPPO Standards, 2014), eventual occurrence of phytotoxicity on lettuce plants has also been monitored. Disease intensity expressed in % was calculated according to Towsend-Heuberger, and fungicide efficacy according to the formula of Abbott-a (Wentzel, 1963). The achieved results were statistically analyzed by the method of variance analysis (ANOVA). During lettuce picking, individual measurements of each head mass (g) was performed.

In Laboratory for Biological Research and Pesticides of the Faculty of Agriculture in Novi Sad, pH value, suspendability, surface tension and electrical conductivity of fungicide spray liquids, foliar fertilizers and their mixtures in water (from locality Provo) also used in field trials have been determined. All studies of physical and chemical properties of spray liquids were carried out in three replications. Methods for studies of physical and chemical properties of pesticide formulations are prescribed by the Regulations on the methodology and documentation for pesticide testing (Anonimus, 2001).

Results and Discussion

Fungicide efficacy in lettuce protection against *B. lactucae*

Results of the study of the intensity of the occurrence of downy mildew in lettuce crop, as well as the efficacy of the applied fungicide Aliette 80 WP, individually or in mixture with foliar fertilizer Megafol in control of downy mildew causer (*B. lactucae*), are presented in Tables 1-5.

In the first evaluation which was carried out immediately after the treatment, the disease intensity was low, being in average 1.3-1.8%.

In Table 1 are presented results of biological assays seven days after fungicide application. The disease intensity in control was 7.2%, while it was 1.4-1.5% in fungicide treated plots. In variants in which only fungicide Aliette 80 was applied, as well as in a variant in which Aliette 80 WP + Megafol were sprayed, the disease intensity was on the significantly lower level in comparison to the control. The applied fungicide showed the efficacy of 79.1-80.5%.

Table 1. Intensity of the disease on leaf and efficiency of fungicide Aliette 80 WP in suppression of *B. lactucae* (23.04.2015.)

Treatment	Application rate kg, L ha^{-1}	Intensity of the disease (%)	Efficiency (%)
Aliette 80 WP	1.24	1.4 b	80.5
Megafol	2.0	6.5 a	9.7
Aliette 80 WP + Megafol	1.24+2.0	1.5 b	79.1
Control	/	7.2 a	/
LSD (0.05)		0.80	

During the third evaluation, it was ascertained that the average disease intensity in control was 10.5%, and in variants in which Aliette 80 WP and Aliette 80 WP + Megafol were applied it was 1-1.1%, also on significantly lower level in regard to the control. Efficacy of the applied fungicide in control of downy mildew causer in lettuce was 90.5%, while in the variant in which a mixture of Aliette 80 WP + Megafol was applied, it was 91.4%. As it could be expected, in the variant in which the only biostimulant was used, the effect was missing (Table 2).

Table 2. Intensity of the disease on leaf and efficiency of fungicide Aliette 80 WP in suppression of *B. lactucae* (01.05.2015.)

Treatment	Application rate kg, L ha^{-1}	Intensity of the disease (%)	Efficiency (%)
Aliette 80 WP	1.24	1.0 b	90.5
Megafol	2.0	9.5 a	9.5
Aliette 80 WP + Megafol	1.24+2.0	0.9 b	91.4
Control	/	10.5 a	/
LSD (0.05)		1.20	

In Table 3, the disease intensity of downy mildew in lettuce 14 days after the second treatment that was in control 15.1% is given, and in variants in which the fungicide (Aliette 80 WP) was used individually or in a mixture with foliar fertilizer (Aliette 80 WP + Megafol) in comparison to the control it was on significantly lower level of 1.3-1.5%.The applied fungicide showed efficacy of 90.1 – 91.3%

Table 3. Intensity of the disease on leaf and efficiency of fungicide Aliette 80 WP in suppression of *B. lactucae* (15.05.2015.)

Treatment	Application rate kg, L ha^{-1}	Intensity of the disease (%)	Efficiency (%)
Aliette 80 WP	1.24	1.3 b	91.3
Megafol	2.0	13.5 a	10.6
Aliette 80 WP + Megafol	1.24+2.0	1.5 b	90.1
Control	/	15.1 a	/
LSD (0.05)		1.90	

During the fifth evaluation of the effects, the disease intensity in control was 20.5%, while in variants in which Aliette 80 WP and Aliette 80 WP + Megafol were applied it was on the significantly lower level in regard to the control with 1.7-2.0% (Table 4).

Table 4. Intensity of the disease on leaf and efficiency of fungicide Aliette 80 WP in suppression of *B. lactucae* (25.05.2015.)

Treatment	Application rate kg, L ha^{-1}	Intensity of the disease (%)	Efficiency (%)
Aliette 80 WP	1.24	1.7 b	91.7
Megafol	2.0	18.5 a	9.8
Aliette 80 WP + Megafol	1.24+2.0	2.0 b	90.2
Control	/	20.5 a	/
LSD (0.05)		2.70	

Based on the studies of the intensity of downy mildew occurrence in lettuce after use of fungicide Aliette 80 WP and mixture of Aliette 80 WP + Megafol, it can be concluded that fungicide showed satisfactory efficacy in control of *B. lactucae* in lettuce in locality Provo, and there were no negative effects of the use of mixture of fungicide and biostimulant, nor there were recorded phytotoxic changes in lettuce crop of the variety Seter. Susceptibility studies of 134 isolates of fungus *B. lactucae*, collected from lettuce crop from California, showed significantly reduced susceptibility of this fungus to fosetyl-aluminum. Even 50% of isolates exhibited fosetyl-aluminum tolerance, and 40% moderate susceptibility (Brown et al., 2004). During 2012, Stević et al. (2014) studied efficacy of fungicide based on pyraclostrobin + boscalid in control of downy mildew causer (*B. lactucae*) in lettuce. Depending on the locality, the studied fungicide achieved the high efficacy of 93.6-97.4% in control of lettuce downy mildew causer.

Impact of fungicide and biostimulant on yield of salad crop

Based on average lettuce plants weight measured during picking, it was ascertained that the highest plant weight of 433.3 g per plant was recorded in a variant in which a mixture of the fungicide Aliette 80 WP + Megafol was applied, while the lowest plant weight of 403.6 g was in control. In variants in which fungicide, biostimulant, as well as mixtures of fungicide and biostimulant were applied, the average lettuce plant weight was on the significantly higher level in comparison to the control. The achieved results are in accordance with studies of Vinković et al. (2013) who studied the impact of biostimulants, among which was also Megafol, to the index of leaf area of the tomato crop. They concluded that plants treated by biostimulants have a significantly higher index of leaf area in regard to plants from control variant.

Physical and chemical propertiesof spray liquid of fungicides and mixtures of fungicides and biostimulants

The pH value of well water from locality is 6.4 (weakly acid), while the pH of spray liquid of fungicides Aliette 80 WP (4.3), as well as mixture Aliette 80 WP + Megafol (4.7) is acid. Electric-conductivity of well water from locality Provo, immediately after preparation was 1050.0 $\mu S\ cm^{-1}$, while for the other fungicide spray liquids it was about 1425 $\mu S\ cm^{-1}$. The introduction of biostimulant Megafol in fungicide spray liquid increases their electric-conductivity (1838.7 $\mu S\ cm^{-1}$) so it is even higher than the electric-conductivity of the biostimulant itself (1612.3 $\mu S\ cm^{-1}$).

Surface voltage of well water from the locality Provo, immediately after preparation was 65.6 $mJ\ m^{-2}$, of fungicide spray liquid 36.6 -37.8 $mJ\ m^{-2}$, of biostimulant 46.7 $mJ\ m^{-2}$, while the surface voltage of fungicide and biostimulant mixture was 35.3-38.0 mJ/m^2 (Table 5). After 24h of the standing of fungicide and mixtures of fungicide and biostimulant, there were no significant changes of physical and chemical properties.

Table 5. Physico-chemical properties of working fluids of fungicides, biostimulators and their mixtures (immediately after preparation)

Sample	Concentration (%)	pH	Electrical conductivity (μS cm^{-1})	Surface tension (mJ m^{-2})
Aliette 80 WP	0.31%	4.3	1425.0	36.3
Megafol	0.5%	6.5	1612.3	46.7
Aliette 80 WP + Megafol	0.31%+0.5%	4.7	1838.7	35.3
Control (Water well - Provo)	/	6.4	1050.0	65.6

Spray liquid of fungicides, as well as their mixtures with biostimulant in well water from the locality Provo, achieved suspendability in the allowed limits, which in all cases was above 60%. The low prescribed suspendability limit is 60% (Anonimus, 2001).
Based upon the above presented, physical and chemical properties of fungicide spray liquids and their mixtures with biostimulant depend on components in a mixture, as well as on physical and chemical properties of water used for the preparation of spray liquids. (Vuković, 2011).

Conclusions

Based upon studies and achieved results in control of downy mildew causer (*Bremia lactucae*) in lettuce crop, the following can be concluded:
Fungicide based on fosetyl-aluminum (Aliette 80 WP), as well as the mixture Aliette 80 WP + Megafol, showed high efficacy of 79.1-91.7%, depending on time of evaluation, in control of downy mildew causer (*B. lactucae*) in lettuce from locality Provo, and there were no negative effects of fungicide and biostimulant mixture.
After use of fungicide Aliette 80 WP and mixtures with biostimulant Megafol, there were no phytotoxic effects in lettuce crop of the variety Seter.
In all variants in which fungicide, biostimulant, as well as mixture of fungicide and biostimulant were applied, the average lettuce plant weight was on significantly higher level in comparison to the control. The applied fungicide and biostimulant had impact on a significant increase in salad yield.
Physical and chemical properties (pH, suspendability, surface tension and electric-conductivity) of fungicide spray liquid and the mixture of the fungicide + biostimulant (Megafol) were within allowed limits and there has been no significant changes after 24 hours of standing. Based on physical and chemical properties, fungicide and biostimulant mixtures showed compatibility

Abstract

Biological control of plant diseases by using microorganisms provides a possible alternative to the use of chemicals in agriculture. Microbial biopesticides originate mostly from bacteria (78%). The wilt-inducing strains of *Fusarium oxysporum* are responsible for severe damage of many economically important plant species. The aim of this study was to examine effect of indigenous rhizobacteria *Pseudomonas* spp. and *Bacillus subtilis* against *F. oxysporum in vitro*. The antagonistic activities of several *Pseudomonas* strains and different concentration of *B. subtilis* strain obtained from rhizosphere of clover, maize and alfalfa were evaluated for antagonistic activity against *F. oxysporum* originating from potato. The antagonistic activity was studied by using dual culture method on Waksman agar. The results were shown as percentage of inhibition of the fungal growth. All tested bacterial strains possess several biocontrol traits. *Pseudomonas* strain K24 was the most effective, causing 78.97% of fungal growth inhibition. *Pseudomonas* B25, isolated from clover rhizosphere, and M28 isolated from rhizosphere of maize, were less effective (53.33 and 51.11%, respectively). *B. subtilis* strain Bs13 (in concentration of $8x10^{6}CFUmL^{-1}$) inhibited fungal growth up to 73%. The antifungal effects of six lower concentrations (from $1x10^{5}$to $4x10^{6}CFUmL^{-1}$) inhibited fungal growth over 50%. The lower concentrations exhibited a minor levels of inhibition compared to the difenoconazol used as standard, which showed 68% of inhibition. Strains K24 and Bs13, originating from alfalfa rhizosphere, were more effective than difenoconazol. *Pseudomonas* sp. K24 ($1x10^{6}CFUmL^{-1}$) showed higher effectiveness in inhibition of *F. oxysporum* than *B. subtilis* Bs13 ($8x10^{6}CFUmL^{-1}$) and difenoconazol. The results obtained in this study are promising and support the importance of further *in vivo* investigations of the antifungal capacity of indigenous rhizobacteria.

Introduction

The application of fungicides against phytopathogenic fungi in order to reduce the damages has been compromised by evolution of pathogen resistance to many fungicides. Over the past 20 years, biological control has been found to be effective in controlling some plant disease (Peighami-Ashnaei et al., 2009). Control of phytopathogenes by biological agents is environmentally benign in comparison to the classical chemical control methods (Hassanein et al., 2009). The biopesticides characteristics include low-residue, high-performance efficacy and less toxic effects (Mnif and Dhouta, 2015).

The most commonly used microbial biopesticides contain a wide array of bacteria,including Gram positive *Bacillus* spp. and Gram negative *Pseudomonas* spp. *Bacillus subtilis* is commonly found in various ecological niches and does not have any history of pathogenicity. It was shown to be a potential biocontrol agent against phytopathogenic fungi (Ongena et al., 2007), especially *Fusarium* spp. (Chen et al., 2010; Liu et al., 2010; Velho et al., 2011). *Pseudomonas* genus is one of the most heterogeneous and ecologically significant groups of bacteria. Some members of this genus are considered to be phytopathogenic, while other strains and species can have important bioremediation and biocontrol potential. They produce diverse metabolites including mycolytic enzymes and secondary active metabolites which have the ability to reduce plant infections caused by fungal growth.

Fusarium spp. are widespread fungi, which can cause diseases on economically significant plants (Wang et al. 2011). *Fusarium* genus fungi are already reported to cause seed “rot” disease that affect different stages of the host, such as seeds, seedlings and the crowns of developing plants (Moya-Elizando, 2013).

Fusarium dry rot is caused by several species, including *Fusarium oxysporum* Schlech. Potato dry rot usually occurs during storage and can lead to losses in crop quality and yield. It is responsible for severe vascular wilts, and can cause rots of tubers. Yield reduction caused by dry rot has been estimated to 6% in average, with losses up to 25% in some cases (Gashari, Gherbawy 2013). In 2000., almost complete loss of stored commercial potatoes varieties was reported in Turkey (Eken et al., 2000).

In this study, we compare the influence of *Pseudomonas* spp. and *Bacillus subtilis* to the inhibition of *Fusarium oxysporum* growth originating from potato tubers.

Materials and methods

The *Fusarium* strain used in this study is a part of the collection of the Institute for Plant Protection and Environment, Belgrade, Serbia. It is originating from infected potato tuber. The fungus has been already morphologically identified as *F. oxysporum*. The fungus was grown on PDA medium.

Bacterial strains belong to the Project III46007 collection (Institute of Soil Science). *Pseudomonas* strains were isolated from rhizosphere of clover (B25), maize (M28) and alfalfa (K24). *Bacillus subtilis* strain Bs13 was isolated from alfalfa rhizosphere. All strains were chosen for this study based on their biocontrol potential, detected earlier for several phytopathogenic fungi (unpublished data). *Pseudomonas* B25 was isolated from clover rhizosphere, M28 from rhizosphere of maize, while K24 and Bs13 were originating from alfalfa rhizosphere. Bacteria were grown in liquid King’s B medium (KB) for 24h at 26^0C. Concentration of bacterial suspension was determined spectrophotometrically and diluted to appropriate concentration.

Inhibition of the pathogenic fungi *F. oxysporum* was performed on Waksman agar (WA). Ten microliter of each culture was applied near the edges of the WA plate. One hour later, a 5 mm diameter of circular plug, from an actively growing fungal culture on PDA, was placed on the surface of fresh WA at the center, according to Anjaiah et al. (1998). All treatments consisted of three Petri plates, and experiments were repeated three times. Petri plates containing only fungal mycelia were used as a control. The inhibition of the fungal growth was determined after 7 days incubation at 26 ^{0}C. Inhibition was expressed as percentage of radial growth inhibition (PIRG) and was measured by using the following formula PIRG % $=100x(R_1-R_2)/R_1$, where R1 was the radial distance of the fungal growth in control and R2 represented the radial distance of the fungal growth in the direction of the antagonist.

Results and discussion

The inhibition of *F. oxysporum* growth by *B. subtilis* and *Pseudomonas* spp. strains was determined after a week of incubation. The percentage of *F. oxysporum* mycelial inhibition induced by different concentrations of *B. subtilis* and three *Pseudomonas* spp. strains: B25, K24 and M28 is shown in Table 1 and Figure 1. The highest percentage of growth inhibition - 78.97% was observed for *Pseudomonas* strain K24. The highest concentrations of *B. subtilis* showed the strongest inhibition of mycelial growth -73%. All tested concentrations of *B. subtilis* and applied concentration of *Pseudomonas* spp. induced growth inhibition over 50%. *Pseudomonas* K24 and the highest concentrations of *B. subtilis* had better antifungal effect than difenoconazol, used as standard.

Figure 1. Antagonistic effect of *Pseudomonas* sp. strain K24 against *F.oxysporum*

Table 1. Percentage of *F. oxysporum* growth inhibition by using different concentrations of *B. subtilis* and three isolates of *Pseudomonas* spp.

Treatment	Strain	Concentration CFU ml^{-1}/%	Inhibition (%)
Bacillus subtilis		8x10^{6}	73.00
		4x10^{6}	62.16
		2x10^{6}	62.16
		1x10^{6}	60.81
		5x10^{5}	54.05
		2,5x10^{5}	52.70
		1x10^{5}	51.35
Pseudomonas	B25	1x10^{6}	53.33
	K24	1x10^{6}	78.97
	M28	1x10^{6}	51.11
Difenoconazol		0.03%	68.92

Many reports indicatethat different bacterial strains from genus *Bacillus* and *Pseudomonas* can be used as biocontrol agents against *Fusarium* wilt disease of many field crops, including potato (Puopolo et al, 2011; Susilowatiet al, 2011; Crane et al, 2013; Schisler et al., 2016). Recep et al. (2009) tested eight different *Bacillus* and *Pseudomonas* species for antifungal activity in *in vitro* conditions against *Fusarium* spp. causal agent of dry rot disease of potato. The strongest antagonism was observed for one of the *Bacillus* strains, while *Pseudomonas* strains had medium antagonistic activity against *F. oxysporum* originating from potato tubers.
In our previous investigation, several *Pseudomonas* strains reduced disease incidence on cardoon caused by *Alternaria tenuissima* (Jošić et al., 2012). Indigenous *Bacillus* sp. Q3 caused stimulation of marshmallow seed germination and reduction of seed infection by several phytopathogenic fungi (Starović et al., 2013).

The use of bacterial biocontrol agents in controlling potato dry rot disease has aroused great attention, due to its applicability in postharvest conditions which provide an ideal niche for biocontrol agents. In this study, we demonstrated that all tested bacteria show satisfactory activity against the same pathogen *in vitro*. In further research, *in vivo* assay will be performed in order to evaluate the efficacy of K24 strain against pathogen originating fromdifferent hosts.

Conclusion

All tested bacterial strains induced inhibition of *F. oxysporum* growth over 50%. *Pseudomonas* strain K24 had better inhibitory effect than *Bacillus subtilis* Bs13 and other *Pseudomonas* strains, as well as than difenoconazol. This strain will be used in further research of determination of its potential as biocontrol agent for managing *Fusarium* species causing dry rot.

Abstract

In this paper, analyzes were conducted on the false acacia, meadow, and mixed honey and honeydew from the territory of Central Serbia. Honey was obtained from the area which is bordered to the east by Mojsinjske mountains and Jastrebac, from the south and west by the mountains of Kopaonik and Goč, and from the north by Resavske mountains. Quality parameters of honey (ash, water, acid, and total reducing sugars, sucrose and diastase activity) were determined by the methods from the Rulebook of honey quality (Sl. SCG, 2003). Total nitrogen was determined by micro-Kjeldahl method, phosphorus was determined by spectrophotometry, and potassium by AAS method. Most of the analyzed honeys met both domestic (which are somewhat sharper for individual parameters) and EU standards. Deviation was present in two samples of the mixed honey, where total acidity exceeded both standards and in two samples of honeydew, where results for this parameter exceeded the domestic standard. It was found that the type of honey significantly ($p < 0.05$) influences the amount of ash, total acidity, diastase number and amount of reducing sugars. False acacia honey had high P content (73.3 $mgkg^{-1}$) and honeydew had the highest N (937.8 $mgkg^{-1}$) and K (84.1 $mgkg^{-1}$). The amount of N, K and Mg significantly ($p < 0.01$) depended on the type of honey and the differences in the amount of phosphorus did not show statistical significance. False acacia honey had the most of Na and Fe, meadow honey had the highest content of Zn and honeydew had the most of Mn.

Keywords: *honey, Central Serbia, physical and chemical parameters, macro - and micro-elements.*

Introduction

Honey is a sweet, thick, crystallized, viscous product that honey bees make from the nectar of flowers of honey plants or secretions from the live parts of the plants that bees collect, add their own specific substances to it, transform and store in the honeycomb cells to mature (Sl list SCG, 2003). Honey is the natural sweet substance produced by honey bees from the nectar of plants, secretions of living parts of plants or excretion products of insects that live on plant parts, which the bees collect, transform with the addition of their specific substances are deposit in honeycomb, dehydrate, leave stored in the honeycombs to ripen and mature (Codex Alimentarius, 2001). Honey is a high quality food product which quality is determined based on the contents of carbohydrates, water, protein, minerals, pH, vitamins, organic acids, the presence of HMF (Hydroxymethylfurfural) and the enzyme activity (Bogdanov, 2007).
Natural honey represents the most complete and highest quality food for both honey bees and for humans. In addition to the carbohydrate component, honey contains many other

substances that are important in human nutrition. This is primarily related to the proteins (Christov & Silitskaya, 1952), acids (Nelson & Mottern, 1931), mineral materials, i.e. macro and micro elements, and in a small but measurable amount, vitamins (Haydak et al., 1942, Kitzes et al., 1943), enzymes (White, 1975) and other substances that may be found in foods. When it comes to honey bee nutrition, their requirement for carbohydrates are completely satisfied by consumption of honey, while other ingredients that are necessary for normal activity (primarily proteins, minerals, vitamins, etc.) are far less represented in honey and the honeybees meet needs for them by consuming pollen (Adekanmbi & Ogundipe, 2009).

Quality control of honey is very important for the protection of consumers, but also because of the development of production and processing methods and use of honey. Consumers expect to that information on the quality and origin of honey present in the market are available, based on the quality indicators marked on the label, which are analyzed as suggested by the European Union directive (EU, 2002). The lack of certain micro-elements (Mn, Fe, Cu, Zn and Se) can cause serious health disorders people (Fraga, 2005)

The aim of this study was to determine the physical and chemical characteristics and the amount of macro- and micro-elements in honey from Central Serbia. Given the fact that lately there is an increasing demand for honey from Serbia, we wanted to determine whether and how it meets the qualitative criteria set in our country and in the EU.

Materials and methods

In this paper, 60 honey samples (21 of false acacia honey, 15 of meadow honey, 11 of mixed honey and 13 of honeydew) were analyzed which were obtained from beekeepers from Central Serbia. Honey is derived from the area bordered by Mojsinjske mountains and Jastrebac from the east, Kopaonik and Goč mountains from the south and west and with Resavke moutains from the north. The apiary in the Duboka near Pojate had the lowest altitude (150m) and the apiary with the highest altitude in Kriva Reka, Kopaonik (1191m).

Considering the physico-chemical quality of the honey, following indicators were determined: ashes, water content, acidity, diastase activity, reducing sugars and sucrose. All analyzes were done according to the Regulations on quality and other requirements for honey and other bee products, products based on honey and other bee products (Sl. list SCG 45/03, 2003). Total nitrogen was determined by micro-Kjeldahl method, phosphorus by the spectrometric method of the SRP, ISO (6491:2003), and potassium and the macro and micro elements were determined by AAS method (AAS-Perkin Elmer 1100 B USA). Each sample was done in three replications. ANOVA was done using the computer program Statistica 8.0 (StatSoft) in completely randomized design in three replications.

Results and discussion

Quality parameters of honey

The average amount of ash in the analyzed honeys was 0.51% (Table 1). The highest ash content was found in honeydew 0.61%, and at the lowest (0.31%) was determined in acacia honey. The amounts of ash in the meadow and mixed honey were almost the same.

One honeydew sample had 0.96% of ash which is allowed for this type of honey considering EU and national standards. Similar results were listed by many authors (Mendes et al., 1998; Golob & Plestenjak, 1999; Šarić et al., 2005; Kahraman et al., 2010). The high ash content in honeydew was also determined in the research of Thrasyvoulou & Manikis (1995).

The water content in honey is a very important factor when it comes to storing honey, because there is a possibility of its decay (fermentation) due to increased humidity. In addition, the moisture content may influence the crystallization of honey. In the observed honeys average 18.9% of water was determined. The lowest water content was found in false acacia honey (18.3%) while other honeys had a very small difference for this parameter. All observed honeys were very uniform which is shown by a very low coefficient of variation (CV = 4.57 to 6.04%). In the studied samples there were none that deviated from Rulebook which allows the honey to contain up to 20% of water. Most authors agree that naturally matured honey from the hive contains 16-18% water (Devillers et al., 2004; Conti i sar., 2007; Nedić i sar., 2007; Marghitas et al., 2010). By analyzing monofloral honeys, Persano Oddo et al., (1995) determined that false acacia honey and honeydew have less than 18% water.

Honey naturally contains acids, but the problem arises when their quantity increases, which indicates deterioration of honey (fermentation). In the analyzed honeys, the highest acidity was measured in mixed honey (41.1 mmol/kg), and the lowest in false acacia honey, but that honey also had the highest coefficient of variation. A high coefficient of variation for the honey acidity, as well as for HMF content and diastase activity were cited by Esti et al., (1997) in the research of the Italian honey. This amount of total acidity does not meet the national standards which are slightly more stringent and allow 40 mmol/kg, while it is acceptable according to the standards of the EU (allowing the acidity of up to 50 mmol/kg). Honeys from this region can have a higher acidity than the national standards specify (Lazarević et al., 2012) in which the amount of acid in honey can range from 7.8 to 42.7 mmol/kg. Analyzed mixed honeys had a slightly higher acidity due to one sample that significantly exceeded standards (70.9 mmol/kg). The high acidity of honey may be a sign of poor storage or storage in inadequate packaging, so there was degradation of honey. Persano Oddo et al., (1995) stated 8-19 mmol/kg for the acidity of false acacia honey, and 17-57 mmol/kg for honeydew, depending on the origin of honeydew. In studies by Tucak et al., (2000), acidity was very similar to our results. The lower level of acidity was stated by Finola et al. (2007), and higher by Rodriguez et al. (2004).

Diastase activity (diastase number) was in average 14.2, the lowest in acacia honey and the highest in the honeydew. National standards do not allow that the diastase number be lower than 8, which was met by all analyzed samples. There are two samples (false acacia (8.3) and meadow (8.2)) which were very close to the lower limit but they meet the standard. Some authors report a considerably higher diastase number than the one obtained in our studies (Devillers et al., 2004; Kirsa et al., 2011). Very high diastase number (50.42) was found by Dezmirean et al., (2010), in honey from common heather (*Calluna vulgaris*), and even higher value was found by Costa et al., (1999), in some honeys from Brazil.

The amount of reducing sugars ranged from 61.7% to 78.2%. The highest amount of reducing sugars was detected in mixed honey and the minimal was in honeydew. All honeys fulfilled standards that require that a minimum of reducing sugars be 65% in honey and not less than 60% in honeydew. Very similar results were given by Šarić et al., (2005) and Persano Oddo et al., (2004). Mladenović et al. (2012) found a somewhat higher amount of reducing sugars in honey, and Conti et al., (2007) reported significantly higher content (77.60 to 83.80%). Jevtić et al. (2002) have found that the natural honey contains 77.7% of reducing sugars.

Sucrose level depends on the degree of honey maturity, as well as on the origin of nectar. In all samples, the average level of sucrose was 3.43%. Considering that the standards allow for false acacia honey and honeydew of having up to 10% of sucrose, and all other honeys to have up to 5%, the analyzed samples showed no deviation from the standard. Very similar results were reported by Cantarelli et al. (2008) and Kirsa et al., (2011). Devillers et al. (2004) found a significantly lower percentage of sucrose, and Mladenović et al. (2012) found an even lower content than them (0.2%).

Analysis of variance in single-factor experiment showed that all differences between the different types of honey for all of the observed parameters were statistically significant ($p < 0.05$) except for the amount of water in honey, where there was no significance (Table 1).

Macro-elements in honey

The highest amount of nitrogen (N) was found in honeydew, while meadow and forest honey had nearly identical amounts of this element, and it was reduced in false acacia honey (Table 2). The amount of nitrogen had very high interval of variation that ranged from 150 $mgkg^{-1}$ in false acacia to 1120 $mgkg^{-1}$ in honeydew. The highest variation in the quantity of this element was determined in false acacia indicating an extremely high coefficient of variation (CV = 40.9%). For false acacia honey Jevtić et al., (2011) reported an average of 360 $mgkg^{-1}$ of N.

The amount of phosphorus (P) ranged from 48.0 to 73.3 $mgkg^{-1}$. The highest P content was found in false acacia honey, and the lowest was in meadow honey, while the honeydew and mixed honey were quite similar considering this element in both the average and extreme values. Cantarelli et al. (2008) reported an average of 28.20 ± 20.64 $mgkg^{-1}$ of phosphorus, and Atanassova et al. (2009) indicated that the amount of phosphorus in honey from Bulgaria was in the range of 28.4 to 72.8 $mgkg^{-1}$. Sulbarán de Ferrer et al. (2004) found significantly greater amount of P (1642 ± 32 $mgkg^{-1}$) in the Venezuelan honey.

F-test		34.41**	2.07^{ns}	29.62**	3.53*	8.68**

After the nitrogen which was the most represented of the analyzed elements, potassium (K) was found to be in the second place. The highest K content was found in honeydew, and the lowest was in false acacia honey, while mixed and meadow honeys were considerably more varied considering amounts of this element compared with the amount of phosphorus. False acacia honey had the least amount of K but it also showed the highest variation of this element (IV = 62.8 to 602.8 and CV = 75%). Slightly lower value for K, in relation to our research, was determined by Yilmaz & Yavuz (1999). Similar values for this element were found by Chakir et al., (2011), while Tucak et al., (2000) argue that in Croatia, dark honeys have much less K compared to the light honeys, which was not confirmed in our research. Substantially higher amounts of K in false acacia honey were noted by Gulfra et al., (2010).
In the observed honeys, an average of 23.8 $mgkg^{-1}$ of calcium was determined, the highest amount was in false acacia honey (32.67 $mgkg^{-1}$), and the lowest in the meadow honey (15.9 $mgkg^{-1}$). The amount of this element in honeydew and mixed honey was almost identical. The average amount of magnesium was 17.1 $mgkg^{-1}$, the highest was in honeydew, and the lowest was in false acacia honey. Kirsa et al. (2011) found twice as high Ca content while Mg content and intervals of variation of these elements in Lithuanian honey were very similar. Emmeretz (2010) in New Zealand honeydew found significantly lower calcium content (7.41 $mgkg^{-1}$) and a significantly higher content of magnesium (86.33 $mgkg^{-1}$).
Analysis of variance of single-factor experiment showed that the differences in the amount of N, K and Mg were highly significant ($p < 0.01$), while in the Ca ($p < 0.01$) they were significant, and the differences in the amount of P were not statistically significant.

Micro-elements in honey

Considering micro-elements in the analyzed honeys, it was determined that Na had the highest presence of Na (Table 3), and Cu had the lowest, while the amounts of Fe, Mn and Zn were very similar. False acacia honey was full of sodium and iron while the other honeys have almost identical content of these two elements. False acacia and meadow honeys have the same amount of zinc, while honeydew and mixed honey had almost half as much of this element. Manganese amount was the highest in honeydew and the least was false acacia honey. Copper was found in nearly identical amounts in all analyzed honeys. Conti et al. (2007) found average of 6.28 $mgkg^{-1}$ of Fe, 0.59 $mgkg^{-1}$ and Mn of 1.15 $mgkg^{-1}$ Cu in false acacia, mixed honey and honeydew, which is quite different from the results obtained in our studies. While Atanassova (2009) states very similar results for the amount of Na, Fe, Mn and Zn in honey from Bulgaria. Bogdanov et al. (2007) found that mixed flower honey contains 5 times more iron and zinc, and twice as much manganese and copper in relation to the false acacia honey. Stankovska et al. (2008) obtained 0.69 $mgkg^{-1}$ Cu in honey from Macedonia, which is as twice as in honey which was the object of our study. Analysis of variance showed that the differences in the amount of Na and Mg were very significant, and in an amount of Fe, Zn and Cu differences were not significant. Especially important is the amount of Mn in honeydew (about 3 $mgkg^{-1}$), because by the consumption of 100 g of honey per day about 15-20% of a need for this element is satisfied (Food and Nutrition Board, 2000; Food and Nutrition Board, 2001).

Table 3. Micro-elements in honey from Central Serbia

Honey type	Parameter-Element	Na $mgkg^{-1}$	Fe $mgkg^{-1}$	Zn $mgkg^{-1}$	Mn $mgkg^{-1}$	Cu $mgkg^{-1}$

Conclusion

Based on the analysis of the quality of honey (false acacia, meadow, mixed and honeydew), produced on apiaries in Central Serbia the following conclusions can be drawn:

- The vast majority of the analyzed honeys are compliant to both domestic and EU standards that consider the quality of honey.
- Deviation existed in two samples of mixed honey considering total acidity which exceeded EU standards that are somewhat lower than domestic, and two samples of honeydew that exceeded national standards.
- Variance analysis shown that all of the observed parameters, except the amount of water, had significant differences depending on the type of the analyzed honey.
- False acacia honey had the highest amount of phosphorus, while honeydew had the highest amount of nitrogen and potassium.
- An analysis of variance revealed that differences in an amount of N and C in the different honeys were statistically significant.
- Of all observed micro-elements, false acacia honey had the highest amounts of Na and Fe, while meadow and false acacia honeys. Honeydew had the highest levels of Mn, while Cu was almost equally represented in all analyzed types of honey.

Abstract

Virginia type of tobacco is used in the highest percentage in the mixture for making cigarettes. Important factors for the formation of quality features of Virginia are environmental conditions of manufacturing but preferably the well regulated drying process. Drying of these tobacco types is performed in special dryers with controlled conditions (flue curing-FC). Since the price of energy source for drying process participate the greatest deal in total expenses during the production and processing of tobacco, the scope of the experiment was to determine the possibilities of drying tobacco in a natural condition (air curing-AC).
Material for research the first-class middle leaves of Virginia tobacco type, variety Heveshi - 9, were produced in Vojvodina area (Srem - Maradik), vintage 2015.
The experimental results showed that the way of drying affects the appearance and color of leaves, chemical characteristics of tobacco and duration of the drying process. Considerable differences of chemical composition between flue curing and air curing tobacco were found as follows (% in dry matter): 2.03 and 2.25 (nicotine), 1.80 and 2.73 (total N), 0.87 and 2.06 (protein N), 5.46 and 6.60 (total proteins), 19.39 and 1.96 (reducing sugars), 11.61 and 15.43 (ash), 1.48 and 8.91 (sand), 5.19 and 5.92 (pH), respectively. The leaves dried in natural condition (AC) had dark color (dark Virginia) and rough nervature. Although drying in a natural condition brings cost savings in energy, the process is longer by 24 days comparing to flue curing.

Keywords: *drying, flue-curing (FC), air curing (AC), Virginia, chemical composition*

Introduction

First steps in production of Virginia in the Republic of Serbia were taken in1960's (Popović, 2000). More intensive production began in the eighties and has continued until today.
Virginia type of tobacco contains large leafs; it has lemon yellow to golden yellow color, specific flavor and pleasant tobacco smell. This type of tobacco represents a very important component in a blend for the cigarettes. Due to the high content of soluble carbohydrates, Virginia tobacco is the main precursor for the components which contribute to the taste of tobacco smoke. In addition, this type of tobacco has good cutting properties, which makes it a binding material inside the cigarette and makes it prevent falling other components out of cigarette. Mentioned properties are influenced either by genetics or the curing method. Virginia tobacco type, due to its characteristics, is used in the preparation of high quality cigarette blends of American type (in which may comprise up to 60% of mixture), and exclusively as a material for the cigarettes of English (the Virginia type).
Due to increasing yearly demands for this tobacco type on both, domestic and foreign markets, it is important to determine processing parameters influencing significantly on obtaining the raw material of highest possible quality. The significance of Virginia tobacco type resembles in technological properties such as voluminous and combustion properties, percent of fibre and fractions, but first of all in its taste, which makes this tobacco

indispensable raw material in the production of cigarettes (Radojičić, 2016). Based on data of Statistical Office of the Republic of Serbia, the total yield of Virginia tobacco in year 2014 was 9341 tons, in year 2015 it was 8776 tons (Statistical Yearbook of the Republic of Serbia, 2016).

Due to morphological characteristics, Virginia tobacco type has large leaves. In accordance with technological classification it belongs to FC types of tobacco, i.e. type of tobacco that is dried under controlled conditions (in special dryers), in which drying parameters can be regulated.

Tobacco production requires a lot of work from the beginning of seeding, transplanting, cultivating of the crops, harvesting stringing, drying and delivering of yellow leaves. The quantity and the quality of the leaf, after drying, affect its use value. Drying tobacco is often crucial operation that defines quality, and hence the selling price. For all mentioned reasons it is important to apply the optimal drying regime, which for Virginia tobacco type is drying in a stream of conditioned air (Popović, 2000). However, for this method of drying, the largest shares in production expenses are energy costs. They comprise from 26 to 28% of the total costs (Radojičić, N. 2011), which is understandable due to high price of energy sources and high consumption per unit of product (1m^3 of natural gas is consumed for drying of 1 kg of tobacco). Besides, the high price of the dryer is also large expense for the middle size producer. Therefore the scope of this work was to examine the possibilities of other methods of curing Virginia type of tobacco.

In developing countries, due to lack of funds for the purchasing of energy sources, drying in natural conditions (in the sun or in the shade) are widely spread. It is known that Virginia tobacco type can be dried in the sun. Under conditions of this type of drying, the leaf has darker color, and they are mainly used for making the mixture for a pipe or cigar (Voges, 1984). However, the literature review authors found no data about air curing of Virginia tobacco type. Therefore, the aim of this experiment was to determine the possibilities of drying the Virginia in the natural condition (AC), and to compare the chemical properties to properties of a standard tobacco dried in the special dryers. These results may indicate the possible use value of this raw material relevant to the manufacturers.

Materials and methods

As a material in this work the first-class leaves of medium insertion of Virginia tobacco type, the variety Heveshi - 9, produced in the Vojvodina area (Srem - Maradik), of harvest year 2015 were used. The leaves are harvested at the stage of technological maturity, strung and dried in two different ways:

- The first sample was dried in the special dryer T - 42, under a stream of heated air, in a controlled condition (FC).
- The second sample is dried under the influence of the ambient air, in the shade, without the influence of additional sources of heat (AC).

Chemical parameters were determined by methods described in sources as follows: nicotine (ISO, 2881, 2007), total nitrogen, protein nitrogen and total proteins (Radojičić, 2011), reducing sugars (SRPS E.P3.115, 1965), ash (SRPS E.P3.117, 1965), sand (ISO 2817, 2007) and pH (SRPS E.P3.116, 1965).

The experiment was carried out in Maradik, municipality of Inđija. Analysis of chemical quality parameters of dried leaves was carried out in the Tobacco Laboratory, Faculty of Agriculture, and University of Belgrade. Methods used are given in Table 1. All analyzes were done in five repetitions. Data obtained from the experiments were analyzed and the results were expressed as mean value ± SD. Statistics were performed using SPSS 17.0 t - test to compare differences between samples.

Results and discussion

Results showed that the applied methods of drying affect the color of dried leaves, the changes in chemical characteristics of tobacco and duration of the drying process.

- The leaves dried in a special dryer T- 42with heated air, under controlled conditions had a light yellow color (bright Virginia) with a fine and thin nervature.
- The leaves dried in a natural condition (AC) had dark color (dark Virginia), rough nervature.
- The drying process under controlled conditions lasted for 127 hours (6 days) and the air curing process lasted for 30 days.

Table 1 shows the mean values of the studied chemical characteristics of the Virginia tobacco type, dried in two different ways.

Table 1. Chemical composition of Virginia tobacco type (% in dry matter)

Drying	Nicotine	Total nitrogen	Protein nitrogen	Total proteins	Reducing sugars	Ash	Sand	pH
Flue curing	2.03	1.80	0.87	5.46	19.39	11.61	1.48	5.19
Air curing	2.25	2.73	2.06	6.60	1.96	15.43	8.91	5.92

* pH in units

Based on the results shown in Table 1, it is clearly seen that the mean values of six parameters observed (nicotine, total nitrogen, protein nitrogen, total proteins, ash, and sand) are higher in tobacco dried in natural condition (AC) comparing to FC. In contrast, the content of reducing sugars and the pH value are lower for tobacco, dried in natural conditions (AC).

Statistical comparison of the chemical characteristics of tobacco in relation to the method of drying is presented in Tables 2 and 3.

Based on the ANOVA test, it can be concluded that there is a statistically significant difference between the mean values of the chemical composition depending on the applied drying process. In terms of the content of nicotine and pH value there is significant difference at the 0.05 level, while for all other components difference is significant at the 0.01 level.

Among samples, the lowest difference was observed in the content of nicotine (0.22). The difference in the content of total nitrogen is 0.93. This is indication that physiological strength and sharpness of tobacco smoke dried in a natural condition (AC) is different comparing to FC. Beljo et al. (1998) reported that the content of total nitrogen in the Virginia tobacco can be in the range between 1.53%-2.38%. Based on the values shown in Tables 1 and 3 it can be concluded that drying in natural conditions (AC) yields the increased value of total nitrogen. As drying process influences the changes in the content of total proteins in leaf, it means that drying is a critical step in processing. In the dark Virginia content of total proteins is increased by 1.41 compared to bright Virginia. It is considered that the optimum value for the highest quality of flue cured tobacco between 4.5%-5.5% (Stanković, 2000). The data from Tables 1 and 3 indicate more extensive degradation of total proteins affected by drying in a stream of heating air.

Sand	.016	.906	-182.607	4	.000**	-7.43000	.04069
pH	.143	.725	6.614	4	.003*	.27000	.04082

** p< 0.01
*p< 0.05

The most prominent difference among samples is in the content of reducing sugars. For bright Virginia type, sugar content is 19.39%, while for dark it is only 1.96% (Table 1). The difference of 17.44 (Table 3) shows that longer drying process caused an almost complete breakdown of the reducing sugars (Brown, 1990). According to Dixon (2000), pH value for Virginia tobacco is between 5 and 6. Based on values in Table 1, the pH value for the sample of bright Virginia was lower (5.19), in comparison with the sample of dark Virginia (5.92). This result is a direct consequence of the extremely large reduction of reducing sugars compared to a slight increase in the content of nitrogen compounds. Alteration of these parameters indirectly causing a sense of sharpness and a stronger smoke during inhalation.

The difference in ash content is 3.82 (Table 3). A sample of bright Virginia has proportionately smaller amount of mineral matter comparing to the dark Virginia, which means that the decomposition of organic matter during drying in a natural condition (AC) was more complete. The resulting ash content in both experimental samples was within the limits for Virginia type of tobacco (Alić-Džemidžić et al., 2002; Radojičić, 2016). Sand content was significantly higher in the dark Virginia (difference is 7.43), almost beyond all known literature data. It is assumed that the sample had significantly more impurities because drying in an unprotected area.

Conclusion

Based on the results of this research which aim was to figure the possibilities of curing Virginia tobacco type under natural conditions (AC) it can be concluded:
Significant differences in the duration time of the drying process exist, as well as difference between sensory and chemical characteristics among Virginia tobacco type dried in a conventional manner (in a special dryer) compared with tobacco dried in natural condition (AC).
Although drying in a natural condition (AC) brings cost savings in energy, the process is longer by 24 days compared to drying in a special dryer. Leaves dried in special dryers under controlled conditions had light yellow color (bright Virginia) with a fine and thin nervature, whereas those dried in natural condition had dark color (dark Virginia) and rough nervature.
Nicotine, total nitrogen, protein nitrogen, total proteins, ash, and sand were higher in tobacco dried in shadow (AC), but reducing sugars and pH value were smaller. As a general conclusion can be observed that drying of Virginia in natural condition is completely changing its sensory and chemical properties, which is the reason of approaching to the characteristics of dark tobacco.

Abstract

Coriander (*Coriandrum sativum* L.) is an annual herb that belongs to the *Apiaceae* family. This herb is used for treating various diseases and disorders in the folk medicine over the century. The ripe fruits have a distinctive sweet citrus-mint aroma and have been valued as a spice. *Rhizoctonia* sp. is a plant-pathogenic fungus which attacks a wide range of crop and aromatic plants, including coriander. *Rhizoctonia* persists in the soil in a form of resistant sclerotia. *R. solani* causes damping-off disease on coriander; seeds and seedlings are particularly susceptible to this fungus. The aim of this study was to test various *Pseudomonas* strains and their extracellular products on the growth of phytopatogenic fungi isolated from coriander seeds and to evaluate several strains as potential biocontrol agents. *Rhizoctonia zeae* was isolated from infected seeds and characterized based on macroscopic and microscopic morphology. Among 142 strains of *Pseudomonas* spp., only 11 showed inhibition of fungal growth. *P. chlororaphis* strain K24 was the most effective, showing the fungal growth inhibition in all tested fraction: 65.86% for cell culture (10^6 $CFUml^{-1}$), 57.77% for cell-free supernatant (CFS), 55.77% for CFS-EDTA and 50.48% for thermo-stable fraction of cell-free supernatant. Because of its strong inhibition activity toward *Rhizoctonia zeae*, *P. chlororaphis* strain K24 can be used in seeds treatment to enable fungi-clean seeds and to prevent the introduction of the disease into new fields.

Keywords: *Coriandrum sativum* L., *seed infection*, *Rhizoctonia zeae*, *Pseudomonas chlororaphis*, *antifungal activity.*

Introduction

Plan pathogenic fungi are one of the most pronounced issues in modern agriculture. During the last century, different kinds of pests and chemicals were massively used for suppression of plant pathogenic fungi which cause crop deterioration. However the excessive use of pests and chemicals which are necessary for good yield, can induce negative side effects in the field, and can even potentially cause crop failure. Microbiological biocontrol aroused as one of the most promising strategies for suppressing phytopatogenic fungi, without using potentially harmful chemicals (Whipps, 2001).
Coriander is an annual herb, which can be planted during summer or winter. Fruits and green parts of the plant are used as folk medicine for treating external ulcers, halitosis and rheumatism and for improving general health of the digestive tract (Diederichsen A., 1996). Coriander leaves are proven to be a valuable source of polyphenols and as natural antioxidants (Wangensteen et al., 2004). Essential oils isolated from coriander plant have strong antimicrobial activity against pathogenic microorganisms such as bacteria from *Bacillus*, *Clostridium*, *Enterobacter*, *Erwinia*, *Escherichia*, *Klebsiella*, *Staphylococcus*,

Streptococcus genus (Baratta et al., 1998). Coriander is also highly valued as spice due to its pleasant flavour determined by specific essential oil composition.

Rhizoctonia sp. is plant-pathogenic fungi which attack a wide range of crop and aromatic plants. This fungus is a natural disease-inducing agent of coriander plants which induce crop deterioration. *Rhizoctonia* sp. is known as stalk rot pathogen which induces plant diseases such as seed decay, dumping of seedlings, root rot, hypocotyl and stem cankers (Parmeter J.R., 1970).

Some of the bacteria which belong to *Pseudomonas* genus have been already used as microbiological fungal control agents against wide spectra of fungal species, including *Rhizoctonia*. *P. chlororaphis* produces substances such as antibiotics phenazines (phenazine-1-carboxamine, phenazine-1-carboxylic acid, 2-hydroxy-phenazine-1-carboxylic acid, 2-hydroxy-phenazine), enzymes (chitinases, proteases, etc) and hydrogen cyanide, which probably underlie its strong antifungal activity (Chin-A-Woeng et al., 2005; Pierson and Pierson, 2010).

The aim of this study was to test various *Pseudomonas* strains and their extracellular products on the growth of phytopatogenic fungi isolated from coriander seeds and to evaluate several strains as potential biocontrol agents and to determine whether it can be used in seeds treatment to enable fungi-clean seeds and to prevent the introduction of the disease into new fields.

Material and Methods

Coriander (*Coriandrum sativum* L.) seeds were obtained from Institute for Medical Plant Research "Dr Josif Pančić", Serbia. *Pseudomonas* spp. strains used in this research are a part of III46007 Project collection, Institute of Soil Science, Belgrade, Serbia.

Initial screening of 142 bacterial isolates was performed in order to determine the best bacterial inhibitors to be used in further research. *P. chlororaphis* K24, as the most efficient strain from initial screening, was tested in a form of cell culture (10^6 CFUml^{-1}), cell-free supernatant (CFS), CFS-EDTA and heat-stable fraction of cell-free supernatant (HSAF). Cells-free supernatant fraction was obtained by centrifuging bacterial suspension (10^6 CFUmL^{-1}) at 13000 rpm for 5 min. Supernatant was then re-centrifuged in centrifugal filter tubes with 0.22 μm micro-porous membrane (Millipore). CFS-EDTA was obtained by adding 1 mM EDTA in CFS. Thermo-stable fraction of cell-free supernatant was obtained by heating bacterial supernatant at 70°C for 30 min.

Rhizoctonia zeae was isolated from infected seeds and characterized based on macroscopic and microscopic morphology. Experiment was performed on Waksman agar (Minkwitz and Berg 2001). For the control sample, only fungus was applied on the centre of Petri dish. For test samples, *R. zeae* was also applied on the centre, while 10 μl (10^5 CFUml^{-1}) of different fractions of *P. chlororaphis* were applied in a form of drops, near the edges of Petri dish. Test and control samples were then incubated on 26°C, for 7 days. After incubation, the growth of *R. zeae* was measured in mm, and percentage of inhibition for each bacterial fraction was calculated by the following formula: % Inhibition = [(Control - Treatment)/Control] x 100 (Ogbebor and Adekunle, 2005). Each test was performed in two independent experiments and results were expressed as mean values.

Results and Discussion

Based on the results of initial screening, only 11 out of 142 tested strains showed inhibitory activity against *R. zeae*. Out of 11 strains with antifungal activity, *P. chlororaphis* K24 showed the best results, and was selected for further examination in this research (Figure 1).
All tested fractions of this strain showed strong potential in reduction of fungal growth (Figure 2). Cell culture in concentration of 10^6 $CFUml^{-1}$ showed the best potential and reduced fungal growth for 34.25 cm in comparison with the control. CFS-EDTA and CFS gave similar results, and reduced fungal growth for 29 and 30 cm, respectively. HSAF showed the weakest potential and reduced fungal growth for 56.25 cm, in comparison with control.

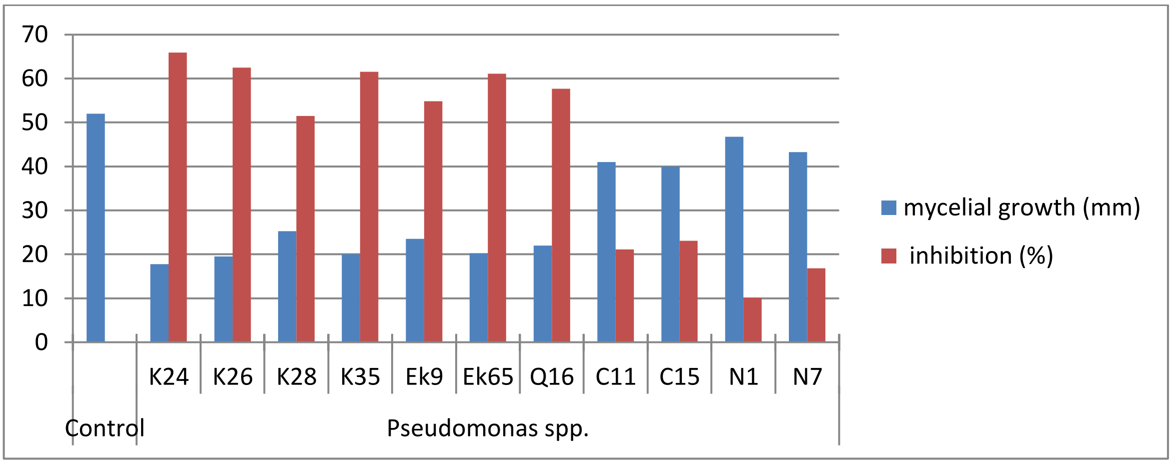

Figure 1. Antifungal activity of *Pseudomonas* spp. strains toward *Rhizoctonia zeae*

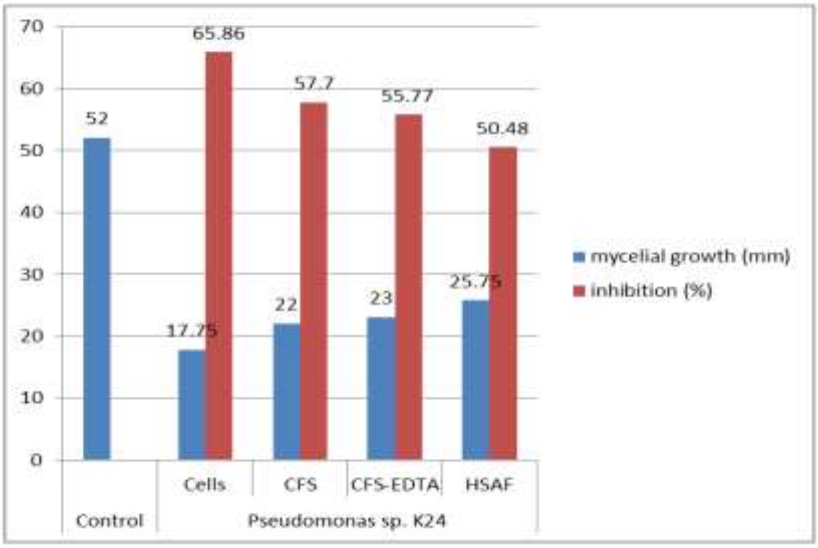

Figure 2. Growth and inhibition of *Rhizoctonia zeae* by cell culture and culture fraction of *Pseudomonas chlororaphis* K24

All tested fractions showed strong inhibition potential against *R. zeae* (Figure 3). Inhibition rate for all fractions was over 50% (Figure 2). Cell culture inhibited the growth of *R. zeae* up to 65.86% and displayed the best activity. Values of inhibition of fungal growth for CFS and

CFS-EDTA were similar (57.7% and 55.77%, respectively). HSAF had the weakest activity of all tested fractions, with inhibition of fungal growth up to 50.48%.

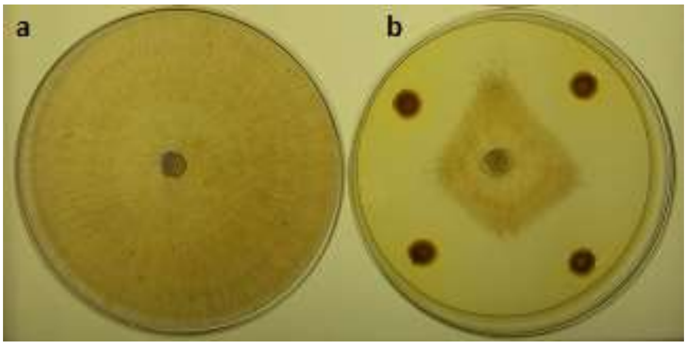

Figure 3. Reduction of fungal growth
a: *Rhizoctonia zeae* ; b: *Rhizoctonia zeae* and *Pseudomonas chlororaphis* K24

There are few studies showing that bacteria from the *Pseudomonas* genus can be used for biocontrol of *Rhizoctonia.* A study conducted on *P. fluorescens* and *R. solani* isolated from rice seeds indicated that the strong antifungal activity of *P. fluorescens* against this pathogen is probably caused by high levels of bacterial metabolites such as *β*-1,3-glucanase, salicylic acid and hydrogen cyanide (Nagarajkumar et al., 2004). Similar results were obtained in another study by using the same strain (Garbeva et al., 2004). It was found that the production of chitinases probably underlies the strong antifungal effects of *P. fluorescens* against *R. solani* isolated from potato. A study conducted by Berta et al. (2005) indicated that *P. fluorescens* can inhibit intraradical root infections up to 92.3% in tomato, caused by *R. solani.* Treating coriander seeds with *Pseudomonas* spp. strains in a form of foliar spray or talk reduces incidence of crown gall up to almost 50% (Kumar et al., 2014). In the same study, it was also shown that treating seeds with *Trichoderma* spp. have slightly better effect on reducing crown gall incidence, in comparison with *Pseudomonas* spp. treatment. Applied to coriander seeds, *P. putida* reduces wild incidence up to almost 90%, and also increases plant height, weight and overall yield (Singh et al., 2010).

Our previous research indicated that *P. chlororaphis* K24 strain is also efficient against *Alternaria* sp., *Phoma* sp. and *Drechslera tetramera* isolated from anise seeds, with inhibition of fungal growth up to 40%, 50% and 69.23%, respectively (Stanojkovic Sebic et al., 2015). Zdravkovic and authors (2015) have also tested inhibitory effects of *P. chlororaphis* K24 strain fractions against *Fusarium acuminatum, Botrytis cinerea* and *Aspergillus niger* isolated from cucumber. K24 strain was the most efficient bacterial strains tested, with inhibition of fungal growth up to 81.49%. Furthermore, K24 had the strongest inhibitory effect against all tested pathogens when tested in a form of cell culture. This strain also had the weakest activity when applied as HSAF against *F. acuminatum, Botrytis cinerea,* which also corresponds to results obtained in our study.

Conclusions

Cell culture of *P. chlororaphis* K24 in a concentration of 10^6 CFUml^{-1} can be considered as a strong inhibitor of *R. zeae* growth. CSF and CSF-EDTA fractions had similar intermediate effect, while HSAF showed the weakest activity against this pathogen. Due to its strong inhibition activity against *Rhizoctonia zeae, P. chlororaphis* strain K24, especially when applied as a cell culture, can be used in seeds treatment for preventing fungal growth, and for prevention of disease introduction into the new fields. Further research is necessary in order to examine all potentially beneficial properties of K24 strain.

Abstract

Tobacco leaf contains more than 3000 compounds that influence the quality of tobacco. The total content of all the constituents of tobacco leaves, and their mutual interactions affects the quality of the cigarettes, as a final product. Addition of sauces made from sugar either fruit components can change the chemical composition of tobacco, with the appropriate temperature regime in order to improve quality. The scope of this study was to examine the effect of casing (sauce application), and toasting regime to the chemical composition of the Burley tobacco, originating from Macedonia. Five groups of samples were made, which were toasted under the different regimes (temperature, time of toasting and thickness of the layer of tobacco). The variations of the chemical composition within the group were followed and compared with a control sample that was not submitted to the process of casing neither toasting. Casing and toasting affected the change of chemical composition of tobacco in terms of increasing the content of moisture, soluble sugars, reducing the content of nicotine and nitrogen compounds as well as decreasing of the total protein levels. Changes in ash content and pH values have no linear character and depend on heating treatment. Changes of any parameter during the toasting process result in changing of the chemical composition of tobacco. They are most pronounced when the toasting of tobacco is carried at lower temperature, but in prolonged time in the toaster, in a thin layer of tobacco.

Key words: *Burley tobacco, moisture content, soluble sugars, nicotine, nitrogen compounds*

Introduction

Tobacco, an herbaceous plant of the Nicotiana tabacum family originates from the tropical part of the Americas. Today, the tobacco plant is cultivated worldwide and primarily used because of its stimulant effect. Burley tobacco is a large leaf tobacco. According to technological classification Burley tobacco is in the AC tobacco group (air cured tobacco), which is dried in the air and in the shade. This type of the tobacco has excellent absorption capacity, thus it is used as a sauce bearer, mostly made from sugar or fruit ingredients. Burley tobacco is used for manufacturing American blend type of cigarettes, where it makes up to 30% of the mixture. The chemical composition of tobacco leaves affects its external appearance and physical properties. Also, the chemical composition of tobacco leaves determines the complex effect of the tobacco smoke on human senses and central nervous system of a smoker. Analysis of tobacco leaf chemical composition shows that it contains more than 3000 components, which influence the tobacco quality. However, the quality of tobacco leaves is determined not only by the sum of its ingredients but also with their mutual ratios. Tobacco contains different nitrogen compounds which significantly impact its quality. The high protein content in tobacco gives an unpleasant taste and smell of the smoke, and it is considered a negative characteristic. Ammonia also adversely affects the quality because it increases the pH value of the smoke. The most important compounds of the tobacco are alkaloids because they determine the tobacco leaves quality, and at the same time alkaloids in the tobacco smoke provide physiological stimulus, which makes smoke pleasant and pleasurable. The main alkaloid is nicotine, but there are nornicotine, nicotirine, myosamine, anabasine and anatabine, as well. However, although the nicotine is an essential factor of the tobacco quality, high nicotine content makes smoke unpleasant, with astringent and bitter taste. Carbohydrates are important components of tobacco leaf as they represent almost one-half of the total organic matter in tobacco. Soluble sugars have a positive effect on the tobacco quality since they prevent the transfer of ammonia or other bases to the smoke, and thereby improving the taste and aroma of the tobacco smoke. The sugar esters are commonly used for this purpose since they are important precursors of aroma. Given that the tobacco leaf has a very complex chemical composition, some of its components could make a problem during the processing. In order to improve the quality of tobacco blends a special group of additives is applied at the tobacco leaves through the casing process. The largest part of casing (sauce) comprise sugars (25–65% of the casing weight), above all the invert sugars. Other components of the sauce are various herbal or fruit extracts, organic acids, amino acids, vegetable oils with unsaturated fatty acid glycerin esters. The sauce added to tobacco during toasting process reacts with tobacco components and provides compounds with favorable sensory characteristics. As noted, Burley tobacco is very convenient for casing process because it has a very porous structure, which can absorb up to 25% of the casing weight. The technological process comprises adding the casing and then tobacco is toasted meaning that tobacco mixture is submitted to a heating temperature (100–150^{0}C) for a short time. Heating the tobacco improves penetration of the casing elements into the leaf tissue, absorption from the surface of the leaves, and the onset of sugars and amino component interaction. This leads to changes in the chemical composition of tobacco blends improving the sensory properties, especially the distinctive tobacco smoke taste. The aim of this paper was to examine the effect of the casing (sauce application), and toasting regimes (temperature, time of toasting and thickness of the layer of tobacco) to the chemical composition of the Burley tobacco.

Material and methods

The starting material for analyses was Burley tobacco from the Former Yugoslav Republic of Macedonia, which a tobacco factory procures for the routine production. The material corresponds to the first class of tobacco (SRPS E.P1.113, 2004), which means that the leaf tissue is soft, with considerable content, brown without defects or damages.

Five groups of tobacco samples were prepared for the experiments. A sauce was applied to each sample group. The sauce was prepared customarily. The composition of sauce represents a factory secret and it is not publicly available. After the sauce addition, all sample groups were toasted on different regimes, as shown in the scheme of the experiment (Table 1). A control sample was not submitted to the process of casing or toasting.

After toasting experimental samples and control sample were chemically analyzed.The moisture content was calculated at two levels: A (starting humidity) and B (final humidity), using standardized methods (Radojičić, 2011).

Table 1. The diagram of the experiment

Sample group	Sample number				Toasting of tobacco samples (treatments): Temperature in ^{o}C - Duration in min - Layer thickness in cm			
					1	2	3	4
I	1	2			115 - 15 - 3	115 - 20 - 4	-	-
II	1	2	3		120 - 20 - 3	125 - 20 - 3	130 - 20 - 3	-
III	1	2	3	4	135 - 15 - 2	135 - 15 - 4	135 - 20 - 2	135 - 20 - 4
IV	1	2	3	4	115 - 20 - 2	115 - 20 - 4	135 - 20 - 2	135 - 20 - 4
V	1	2	3		120 - 15 - 3	120 - 20 - 3	120 - 30 - 3	

Nicotine level was determined using an UV spectrophotometer (SRPS ISO 2881, 2007). Reducing carbohydrates were determined using the method by Bertrand (SRPS E.P3.115, 1965), and ash content by burning samples on 600^{0}C (SRPS E.P3.117, 1965).The pH value was measured directly with the pH meter (SRPS E.P3.116, 1965).Total nitrogen content was determined by the Kjeldalh method (SRPS E.P3.112, 1965; Radojičić, 2011).
Based on these results, we compared the chemical composition of all experimental groups with the control sample. Afterward, effects of temperature, toasting duration, and tobacco layer thickness were examined in all Burley tobacco samples.

Results and Discussion

Table 2 shows the results of examination in the samples.

* pH in units

The results of control sample were confirms results from the literature (Radojičić, 2011). The results of all experimental sample groups showed that when the sauce was added the moisture content increased by 27%–29% compared with the control sample. The increase of moisture was the most prominent in the first and third sample groups. When we analyzed groups separately, the largest increase in moisture by about 29% was observed for samples 1A from the first group. In the second group,the moisture content was the highest in the sample 3A, and it is about 27% greater than in the control sample. In the third group of samples, the largest moisture increase by 29% was observed in the sample 1A. The sample 1A, within the fourth group of samples, showed the largest increase of the moisture content of 28%. In the fifth sample group, the largest increase in moisture content was observed in the sample 3A, being about 27%. Moisture content in the toaster output ranged from 17%–26%, which is consistent with the literature data (Đulančić, 2014). From the results of the chemical analysis of the raw control material and the chemical analysis of every sample group given in Table 2, we concluded that casing and toasting caused an ample change of the tobacco chemical composition. In comparison to the control sample the direct consequence was the evident change of the sugar content in the selected samples within each group. The sugar content increased by approximately 4% for the first and third group of samples, by 3% for the second group, by 2% in the fourth and by 2.4% to 4% for the fifth group of samples. Compared to the control sample, nicotine content decreasedby 0.3% within the first group of samples, by 0.2% within the second group of samples. Nicotine content was slightly decreasedin the samples in the third, fourth and fifth group. The total proteins content decreased by about 1.6% in the samples of the first group, approximately 0.7% in the second group, and by 0.3% in the samples of the fourth group. Changes in the protein content in the samples in the third and fifth group were insignificant. Casing and toasting of the tobacco leaves had a neglible influence on the protein nitrogen content, ash, and the pH value of the samples. The refined information about the effect of temperature, the duration of the toasting, and the thickness of the tobacco layerswas acquired analyzing the individual experimental sample groups. In the first group, the toasting time and thickness of the tobacco were altered, keeping the constant temperature (115°C). When this group of samples was compared to the control sample the distinguishing feature was a slight reduction of the nicotine, the proteins, all the nitrogen components, the ash, and the pH, as well as an increase in sugar content. For the second group of samples, in which weobserved influence of the temperature changes at the constant toasting duration and the thickness of the tobacco layer, it is noted that the increase of temperature reduced content of the sugar, the nicotine, all the nitrogen components, especially proteins, and an increase in the pH. However, increasing the temperature above 125°C did not cause further reduction in protein and nitrogen compounds content. In the samples of the third group of the samples we studied the influence of the changed toasting duration and changed tobacco layer thickness at the two different heat levels. In this case extending the toasting duration combined with a thin tobacco layer lead to a more pronounced reduction in the nicotine content. The protein content decreased with the toasting duration increase, regardless of the thickness of the tobacco layer. A thinner tobacco layer together with a prolonged toasting duration has lead to an increase in sugar content. In the fourth group, we examined the influence of temperature and tobacco layer thickness changes at an unchanged toasting duration. Samples at the higher temperature and in the thinner tobacco layer showed a lower nicotine content. The temperature rise increased theprotein-nitrogenand total protein content, regardless of the thickness of the tobacco layer. The reduction of sugar content responded to the increment of the tobacco layer thickness. In the fifth group of samples, the toasting duration was varied, while the temperature and the tobacco layer thickness were constant. Prolonging the toasting duration time caused a pronounced reduction of the nicotine content, the total protein, and the sugar content, while the ash content and pH value were marginally increased.

Conclusion

Based on the results of this study it can be concluded:
Addition of casing and change in any of the toasting parameters changed the tobacco chemical composition. Changes in the chemical composition of tobacco are most prominent when the toasting of tobacco is carried at a lower temperature, but with prolonged toaster time in a thin tobacco layer. Observing all the parameters of the toasting process, which take into account the energy consumption and time savings due to the thickness of the tobacco layer, according to the quality of the obtained tobacco it can be concluded that sample number 1 from the second group of samples had the best characteristics. The differences of chemical composition between this sample and the control were found as follows (% in dry matter): 1.40 and 1.44 (nicotine), 3.84 and 4.05 (total nitrogen), 2.00 and 2.05 (protein nitrogen), 12.50 and 13.02 (total proteins), 3.12 and 0.01 (soluble carbohydrates), 18.60 and 18.56 (ash), 5.38 and 5.37 (pH), respectively. Reducing the content of nitrogenous substances and increasing the sugar content contributes to better sensory characteristics of tobacco. The nicotine content is slightly reduced which means tobacco will maintain the necessary physiological strength during the smoking process. Contrary to that the soluble carbohydrates content is increased which will improve the taste and smell of tobacco smoke.

Abstract

Knowledge about maize inbred lines response to herbicides could give large advantage in weed control and avoid potential problems with low selectivity in field production. In general, herbicides have lower selectivity to maize inbred lines, when compared to hybrids.
Response of seven maize inbred lines to sulfonylurea herbicides was evaluated in two years field experiment. Years differed, accordingly to meteorological parameters. Two sulfonylurea herbicides - nicosulfuron and foramsulfuron were applied in stage 15-16 (BBCH scale). Herbicides were applied in recommended dose for use in hybrid maize and in double dose. Herbicides did not caused significant visual damages to tested lines (2-3 weeks after treatments), only slight symptoms occurred, typical for applied herbicides, with complete plant recovering observed in second visual evaluation (2-3 weeks after the first). Only in several cases, applied herbicides, mainly foramsulfuron influenced grain yield decrease, especially when it was applied in double dose. On the other hand, according to the regression analyses, significant dependence between inorganic phosphorus content (samples 48 h after treatments) and grain yield were observed in four lines, what can be one of detoxification, i.e. tolerance reactions to herbicide application.

Key words: *herbicides, maize lines, grain yield, inorganic phosphorus*

Introduction

Production of maize hybrids is one of the most profitable branches in agriculture. On the other hand, this production can be limited due to various factors. These factors can be abiotic and biotic. In the case of biotic factors, weeds are one of the most important factors, which could be limiting in maize hybrids production. Another disadvantage of this production is based on its own technology (Pavlov et al., 2008). In breeding process maize plants becomes homozygote. This process is associated with inbreeding, which contributes to the expression of many recessive traits. Homozygote plants are smaller than hybrid, they have slower germination and development and in line crop weeds have more free space for their growth and development (Stefanović et al., 2007). Homozygote plants also have higher susceptibility to biotic and abiotic factors, including higher sensitivity towards herbicides, compared to hybrid crop. High grain yields in maize hybrid production are associated with weed control. Herbicide application is the most important measure for weed control. As it is mentioned, line plants are sensitive to herbicides and their application can cause problems in production. There were notices of crop injuries with leaf deformation, smaller plants, and even total plant destruction (Stefanović et al., 2006; Malidža, 2007). These problems can be avoided in case of previous plants testing to herbicides, at least for two years in field conditions, to avoid yield losses.

The aim of this study was to test seven maize inbred lines to two sulfonylurea herbicides in recommended and double doses, to test possible phytotoxic effect and their influence on grain yield, as well as on changes in content of inorganic phosphorus 48 h after herbicide application.

Material and Methods

Two years field experiment was set up on Maize Research Institute “Zemun Polje” (near Belgrade, Serbia), during 2015 and 2016. In both years, winter wheat was preceding crop. Two sulfonylurea herbicides were applied in recommended and double dose for application in hybrid maize. The experiment was conducted by RBCD design with four replications: main plots encompassed 4 rows of each line, while subplots included two herbicides and control, without herbicide application. The sowing was performed at the end of April in 2015 and at the middle of April in 2016, due to the meteorological conditions, while the herbicides were applied in the 5–6 leaf phase. In period of 2-3 weeks after herbicide application visual plant injuries were determined (scale 1-9), and at the end of vegetation, grain yield was measured and calculated to 14% of moisture. The content of inorganic phosphorus was determined from the plant shoots, 48 h after herbicide application, by method Dragičević et al. (2011). Dependences between grain yield and inorganic phosphorus were obtained by correlation analyses.

Meteorological conditions. The experimental years were similar accordingly to the average temperature and precipitation sum (Table 1). The main differences were expressed between first (April-June) and second (July-October) part of vegetative period, when average monthly temperatures were slightly lower in the first part of 2015 and higher during the second part of 2015, when compared to 2016. 2015 was also characterized with the lower precipitation sum during anthesis period (Jun-July) in regard to 2016.

Table 1. Meteorological condition during experiment (April-October) in 2015 and 2016, at Zemun Polje

Month	IV	V	VI	VII	VIII	IX	X	Aver./Sum
Year	Monthly average temperatures							
2015	12.9	19.1	22.1	26.4	25.7	20.2	12.4	19.8

2016	51.9	47.4	107.4	33.6	43.2	36.6	60.3	380.4

Results and discussion

Applied herbicides caused significant injuries in three maize lines in 2015. The highest damages were recorded in line L3 with nicosulfuron application. Double dose of nicosulfuron caused moderate damages. Lines L4 and L5 had a slight damages induced by herbicides application, while other lines (L1, L2, L6 and L7) did not react significantly on herbicides. In second year of experiment (2016) applied herbicides caused lesser damages in comparison with previous year. It is important to underline that the highest damages were recorded in line L4, especially in double dose of foramsulfuron (Table 2). Maize response to herbicides depends to some extent on meteorological conditions (Brankov, 2016), also genotype plays important role in tolerance to herbicides. Other researchers indicated that sulfonylurea herbicides cause the highest problems with phytotoxicity expression in this production area (Stefanovic et al., 2010).

Table 2. Visual plant damages

2015	Herbicides			
Inbred line	Nicosulfuron RD	Nicosulfuron DD	Foramsulfuron RD	Foramsulfuron DD
L1	1	1	1	1
L2	1.5	1.5	1.5	2
L3	3.25	6	4	3
L4	3	3.25	3	3.25
L5	2	2	3	3.5
L6	1	1	1	1
L7	1	1	1	1
2016	Herbicides			
Inbred line	Nicosulfuron RD	Nicosulfuron DD	Foramsulfuron RD	Foramsulfuron DD
L1	1	1	1	2
L2	1	1	1	1
L3	1	1.5	3.5	5
L4	1	1.5	1.25	1.5
L5	1.5	1	1	2.25
L6	1	1	1.25	1
L7	1.5	1.25	1.25	1

Meteorological conditions affect the grain yield, especially in first year when lower yields were recorded. Due to drought, i.e. interaction of small amount of precipitation and high temperatures during anthesis period, the yield of line L6 was failed. Significant yield reduction was recorded in following treatments: L3 – DD of nicosulfuron, L4 - RD nicosulfuron. In other treatments applied herbicides did not significantly influenced observed parameter. In second year, both doses of foramsulfuron decreased grain yield in line L1. Recommended dose of foramsulfuron decreased grain yield in line L5. Double dose of nicosulfuron significantly influenced grain yield in line L7. In other lines and treatments there was no significant influence of applied herbicides on observed parameter (Table 2). Grain yield is one of the most important traits that could be affected by herbicides. In case of short term stress, plants are able to recover themselves and to continue further development. On the other hand, in case of permanent stress plant are under severe influence of herbicides and they cannot recover easily, so one of the results is grain yield loss (de Carvalho, 2007). Brankov et al. (2015) also indicated that sulfonylurea herbicides caused in the most cases decrease of grain yield in maize inbred lines.

The results presented in table 4 indicated significant correlation between grain yield and content of inorganic phosphorus in maize leaves. The highest significant and negative correlation was obtained in lines L2 (-0.93) and L6 (-0.78), as a lines with the lowest grain yield obtained in 2015. On the other hand, significant and positive correlation between observed parameters was recorded only in line L1 (0.58) with also reduced grain yield values, particularly in 2016 and in foramsulfuron treatment. These results could be good indicators of plants reaction to herbicide stress. Brankov et al., (2015) also indicated role of phosphorus (phytic and inorganic) in their study, claiming that this compounds are important factor in maize tolerance to herbicides.

Conclusions

According to obtained data, application of herbicides from sulfonylurea group can cause some plant injuries on maize inbred lines, so caution is needed to prevent possible yield decrease or loss. Grain yield was reduced in small number or treatments what indicates good maize tolerance to tested herbicides. Analysis of inorganic phosphorus can be a useful tool for better understanding early signs of herbicides in plants leaves.

FIRST REPORT OF THE NATURAL OCCURRENCE OF THE TELEOMORPH OF LEPTOSPHAERIA MACULANS ON OILSEED RAPE IN SERBIA

Petar MITROVIĆ*, Ana MARJANOVIĆ–JEROMELA

Institute of Field and Vegetable Crops, Novi Sad, Serbia
*Corresponding author: petar.mitrovic@ifvcns.ns.ac.rs

Abstract

Leptosphaeria maculans (anamorph *Phoma lingam*) causes blackleg disease of oilseed rape. The teleomorph stage of the blackleg pathogen on oilseed rape in Serbia has been reported for the first time. Plant remains of oilseed rape, with clear symptoms of disease were collected in the locality Crvenka brought to the Institute of Field and Vegetable Crops and placed on the soil surface. Immediately, in the vicinity of plant remains, Burkards spore catcher (Burkard Manufacturing Co.Ltd) was placed. Due to the lack of precipitation during October, the stem was sprayed with water (3 to 5 mm/m^2) every 2 to 3 days. Microscopic examination of tape from Burkards spore catcher was carried out every 7 days. This paper studied the morphological characteristics of pseudothecia, asci and ascospores (size, shape, color and structure). In addition to morphological characteristics, pathogenic properties were investigated by applying a suspension of 10^5 ascospores in the cotyledons. Based on the conducted tests, the presence of a teleomorph stage of fungi *Leptosphaeria maculans* in Serbia was determined.

Key words: ascospore, *Leptosphaeria maculans*, pseudothecia, morphological characteristics.

Introduction

Stem canker or blackleg is economically the most important disease of oilseed rape in Europe, Australia and North America (Fitt et al., 2006). This disease is caused by two types of plant pathogenic fungi belonging to the genus *Leptosphaeria*: *Leptosphaeria maculans* (Desm.) ces. and de Not anamorf *Phoma lingam* (Tode. Fr.) Desmas, which causes severe basal stem canker or the blackleg (Johnson & Lewis,1994) and *Leptospaeria biglobosa* Shoemaker and Brun, which is associated with upper stem lesions, usually causing less damage. However, serious damages may cause in countries with high summer temperatures (Huang et al. 2005; Fitt et al., 2006). Both species also occur in Africa, Central and South America and Asia (Anon. 2004 loc cit Fitt et al., 2006). From the epidemiological point of view, stem canker is the most important disease of rapeseed worldwide (Howlett et al., 2001; Gosende et al., 2003). The intensity of the disease depends on climatic factors, agro-technical practice and varietal tolerance (Howlett, 2004; Sosnowski et al., 2004; Aubertot et al., 2006). Tode (1791) cit. loc. Pound, 1947) described blackleg on the dead stem of cabbage and its causal agent was called *Sphaeria lingam*. Given that the fungus was found on a dead stem cabbage,it was considered a saprophytic organism. However, Desmazières (1849 cit. Loc Pound 1947) found the same fungus during the growing season (on living plants), after which it was renamed to the genus *Phoma*. Afterwords, Rostrup (1894 cit. Loc Pound 1947) in Denmark detected the same disease on a white radish and the pathogen was described as *Phoma napobrassicae* Rostrup. However, Henderson (1918 loc cit. Pound in 1947) stated that there is a considerable evidence that *P. napobrassica* is actually a species of *Phoma lingam*. Smith (1956) found the telemorph stage of *Leptosphaeria maculans* on the stems of rapeseed in New Zealand.The fungus is naturally maintained by pycnidia, mycelium and pseudothecia.The pycnidia are usually transmitted on seed while pseudotheciae are present in plant remaines.Under favorable conditions of temperature and high relative humidity, pycnidia and pseudothecia release a large amount of pycnospores and ascospores (Williams, 1992).Sowing infected seeds, pycnidia under the influence of soil moisture release conidia, which can infect hypocotyl and cause symptoms in the form of lesions on the cotyledons (Barbetti & Khangura, 2000 cit. Loc. West et al., 2001).Pycnospores role in the epidemiology of the disease is slighlty significant/insignificant in Western Europe, but is very important in Western Australia (West et al., 2001).In the UK and other Western European countries, ascospores are the main source of inoculum for the occurrence of stem canker of rapeseed (McGee 1977; Gladders & Musa 1980; Schramm & Hoffmann 1991).After harvest, fungus on infected stems is maintained in the form saprophytic mycelium (Williams, 1992).Shortly after the harvest, pseudothecia may be visible on the lower parts of the stem (area of disease symptoms),while on the upper part of the stem, they are formed a few weeks later (Hammond 1985 cit. Loc. West et al., 1999).The fungus can survive several years in plant residues (Petrie, 1986).However, the greatest release of the ascospores is in the first year after the harvest (McGee, 1977; Sosnowski et al., 2006; Naser et al., 2008).Temperature and humidity are the main factors which influence the maturation of pseudothecia and the release of ascospores (Peres & Poisson, 1997).Pseudothecias are formed at temperatures from 15^0C to 20^0C, and the conditiones are quite similar for both species (*L. maculans*, *L. biglobosa*), while *L. biglobosa* forms a very slowly pseudothecia at a temperature below 10^0C (Toscano-Underwood et al., 2003). In conditiones of Central and Western Europe the release of ascospores is starting in September or October, and the latest 1 to 2 months later (Thürwüchter et al., 1999),while in the arid regions of Western Australia, pseudotecia formation and the release of ascospores begins 18 months after the harvest (Gladders et al., 2006).In Eastern Europe the release of ascospores is recoreded even in April the following year (Fitt et al., 2006). Airborne ascospores fall to leaf surface and in favorable conditions, they infect leaves via stomata or injuries, causing the first visible symptoms (Hammond & Lewis, 1987).

Material and Methods

The presence of teleomorph stage (*L. maculans*) was investigated in the following way:
1.Plant remaines with a clear symptoms of the disease were collected at locality Crvenka (Vojvodina province, Serbia), in plastic bags (Magyar et al., 2006).The material was brought to the Institute of Field and Vegetable Crops and placed on the soil surface. In the vicinity of the plant residues, a Burkard spore catcher (Burkard Manufacturing Co.Ltd) was placed (McGee 1977; Thürwächter et al., 1999) (fig 1).

Fig.1.Burkard spores catcher

The experiment was set on 10th October in 2009.Due to the lack of precipitation during October, the stems were sprayed with water (3 to 5 mm/m^2) every 2 to 3 days (Peres et al., 1999).Binocular view of the tape was carried out every 7 days.Based on the binocular observations (fig.1) 5 stems of rapeseed were placed in plastic bags (a total of 5 bags) at an oblique angle, and 25 to 30 ml of distilled water was added.The bags are partially closed and in the upright position placed in a controlled environment with a 12 h photoperiod. Night temperature was adjused from 8 to 10^0C and daily from13 to 15^0C.Distilled water is added to provide the necessary moisture for the formed pseudothecia, asci and ascospores and for collection of ascospores during their release, which were later used to verify the pathogenicity.The first observation was done after 5 days and subsequent observations were carried out every 2 days. After the appearance of ascospores, pseudothecia, asci and ascospores were measured and structure and forms ascospores were studied. In addition to morphological characteristics, pathogenic properties of ascospores were investigated as follows: in the pots, which were pre-filled with sterile compost, 5 seedlings of rapeseed variety Banaćanka were planted in one pot. One repetition consisted of three pots. Cotyledons from 3 pots were injured with a sterile needle.At the injured area, 5 ml of a suspension of ascospores 10^5 was applied with a micropipette (Koch et al., 1989).In the following treatment, cotyledons from 3 other pots were also injured, but inoculation is done by spraying the cotyledons hand sprayer. In the third group of plants inoculation is done by spraying without harming the cotyledons.The inoculated plants, together with the control treatment, were placed in the controlled environment at 15^0C and 95% RH for 24 hours and then were transferred to the greenhouse.The first review of the plant was carried out after 5 days and the occurrence of symptoms and changes in plants were observed in the next 20 days. Re-isolation of the pathogen from the diseased part is performed after the appearance of symptoms. Ascospores suspension was prepared as follows: under binocularas, pseudotecie were separated together with parts of the plant tissue, from the rest of the stems, using a lance with a needle and placed in distilled water (Mengistu et al., 1993). This mixture was transferred into a test tube and hand-shaken.Then, the contents of the tube together with a spore suspension were filtered through a sieve (140 MESHA) in order to separate pseudothecia and asci from the ascospores. With a hemocytometer ascospores concentration was adjusted to approximately 10^5 per ml. Ascospores suspension was transferred in controlled conditions at temperature of 15^0C for 48 h. After germination of ascospores, the pathogenicity tests was performed.

Results and Discussion

The presence of ascospores of pathogenic fungi *L. maculans* in Serbia was detected in two ways, as described in materials and methods.The first occurrence of ascospores, based on microscopic examination tape (Burkard catcher spores), was recorded on 13th November in 2009.After the first appearance of ascospores (13th November), the observatinos were carried out every 7 days until 20th December 2009.In this period, the strongest release of ascospores was registered in late November and early in December.Due to the low temperature and later snowfalls the monitoring of the release of ascospores was interrupted, and continued in the spring of next year (from 20th May).For the same plat remaines during the spring of 2010 the first release was observedat the end of March and early April.During the autumn and the spring, microscopic examinations revealed that the majority of ascospores is released in the second part of the day.

The first binocular examination of the infected stems of rapeseed from plastic bags, for the presence of pseudothecia, in laboratory conditions was carried out after 5 days, during 2009.Subsequent observatinos were carried out every 48h, and the first occurrance of ascospores was registered after 11 days. Pseudothecia on stem immersed,later becoming erumpent, globose shape, black color with protruding ostioles, with diameter 313 to 532 µm (fig.2). Ostioles occured at the moment of release of ascospores (fig. 3).

Fig. 2. *L. maculans*
Pseudothecia fungus

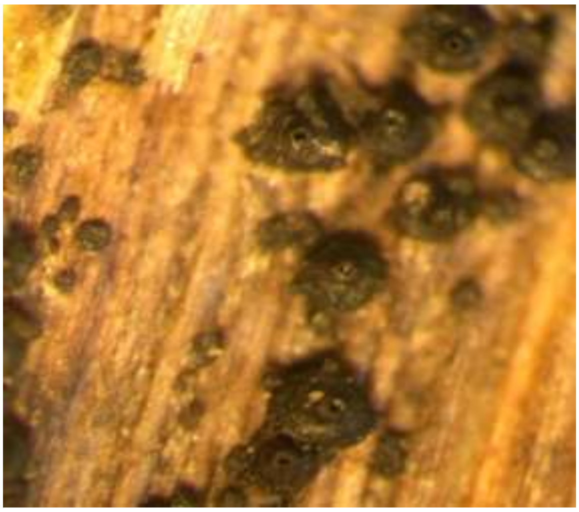

Fig. 3. *L. maculans*
Pseudothecias with form ostioles

Asci cylindrical to clavate,sessile or short stipate,8 ascospora, diameter 16,72–21,39 µm x 90,00–130,00 µm (Fig.4).Ascospores in asci are arranged in two rows. Ascospores biseriate,cylindrical to ellipsoidal,ends mostly rounded yellow brown slightlyor not constricted at the central septum, guttulate 6–10,5 µm x 42–74 µm (Fig.5). With aging septa and oil drops are difficult to spot.

Ascus fungi

Fig. 5. *L. maculans*
Ascosporesfungi

Test of pathogenicity

Pathogenicity of ascospores was tested on cotyledons of oilseed rape, variety Banaćanka.The first occurrence of symptoms could be observed already after 5 days in the form of chlorosis around the injured part.At plants where the conidia suspension was sprayed, spots on cotyledons occurred later.Later, after all three methods of inoculation of the cotyledons were performed, the center spot is assumed grayish color with necrotic edge (Fig.6).The appearance of pycnidia was observed 15 days after the inoculation.Re-isolation on PDA was obtained conidial stage of the fungus which has been described under the name of *Phoma lingam* (Todd Fr.) Desmaz.

Fig. 5. *L. maculans*
Symptoms on cotyledons of oilseed rape (right) – uninoculated control plants (left)

In Serbia (Vojvodina preovince) ascospores of *L.maculans* are released except in the autumn and during spring, usually in April and May, which is in agreement with the results of (Gladolers & Musa 1980; Fitt et al, 2006). Ascospores infected leaves via stomata, or injuries

(Hammond et al., 1985) but in the spring, except leaves, infects stems, branches, flowers and pods, causing characteristic symptoms of the disease. After the harvest, on the diseased part of the oilseed rape stems, during the autumn or the following spring, fungi exists in the form of saprophytic mycelia and in the plant tissue,the pseudothecia is formed. Pseudothecie are roundish in shape, black color with protruding ostioles, diameter 313 to 532 µm, which is in accordance with (Holliday & Punithalingam 1972; Williams, 1992). Asci are cylindrical to clavate, sessile or short stipitate, diameter 16,72–21,39 x 90–160 µm. In ascus, 8 ascospores are found. Ascospores are biseriate, cylindrical to ellipsoidal, ane mostly are rounded yellow brown color with 5 septa, diameter 6–10,5 x 42–74 µm. Similar data were recorded by Punithalingam and Holliday (1972); Williams (1992) and Magyar et al. (2006). The initial symptoms of the cotyledons (infected ascspore) occur in the form of a pale greenish spot (West et al., 1999, 2001). At a later stage, the infected tissue necrosis in the central part of the spot is formed as well as pycnidia. After the occurrence of pycnidia, isolation was carried out on PDA medium and the obtained conidial stage of the fungus is described under the name *Phoma lingam* (Todd Fr.) Desmaz.

Conclusion

Based on this research, pathogenic fungus *Leptosphaeria maculans,* except conidial stage, forms teleomorph stage (pseudothecia with asci and ascospore) in Serbia.

Abstract

During 2016, on agricultural soils of Moravica Administrative District, under irrigation systems were carried out research of the effects to the structural stability of micro aggregates and the risk of crust formation of the irrigation measures applied. Soil samples were sampled in a disturbed condition from the surface horizon at a depth of 0-30 cm from twenty locations. Level of stability of micro aggregates, expressed by Vageler's scale, is determined based on the ratio of total content of the particles of clay in the soil sample prepared with pyrophosphate, and the content of clay particles in a suspension of soil prepared with the water. The risk of the soil crusting was determined according to a Van der Watt & Claassen pattern based on the ratio between the content of organic matter, and total content of the clay and dust particles in soil samples. Based on processed result, it was prepared an assessment of whether and how irrigation affects the structure of soils type fluvisol, vertisol, humogley, cambisol and stagnosol, on which the research were conducted. The obtained results, shows that the tested soil samples, according to the classification by level of stability of micro aggregates by Vagler-in, are belonging to the level of very stable aggregates. In relation to the risk of crust, 50.00% of the samples had a high risk area, 37.50% borderline risk, and at the 12.50% of the samples, a risk of crust was at a low level.

Key words: *irrigation, structural aggregates stability, soil crusting*

Introduction

Each type of soil is characterized by a particular structure and it represents an important morphological and genetic mark of the soil. It is an important factor of fertility of agricultural soil and is gradually created by the complex of physical and chemical processes. The stability of structural aggregates, according to Vučić (1992), is considered to be the key of the fertility of the soil. It is a dynamic determinant especially in the surface horizon, which depends on the characteristics of the soil, climate and processing conditions. As a result of soil processing, stability of aggregates rapidly decreases, while the size of dry aggregates increases. Determination of the stability of the structural aggregates of the soil is important for finding the best solution for maintaining the soil in the most favorable condition for its processing and plant production in general. Creating a structure is a very complex process that depends on the interaction of the type of soil, cement agents, soil management and ecological conditions. A favorable soil structure should be maintained and adversely repaired (Belić et al., 2004).
The factors of stability of the structure of the space are: cohesion, humus content in humus materials, calcium, iron, soil fauna, clay and others, while factors of instability of the structure can be caused by: rain and hail, saturated soil, sodium, acid humus (Pavićević, 1972).

Irrigation, in general, are defecting the structure and this phenomenon is observed in almost all types of soil. Sprinklings are disrupting structures less, while and the most disruptions are by irrigation which considers flooding and overflowing. Structural aggregates are saturated with water and this makes soil particles separated from one another in the swelling process. In a humid state, such soils are glued an in the dry state are prone to grudging.
Soil structure is an important factor of fertility of agricultural soil which is gradually formed by the complex physical and chemical processes. The influence of different cropping systems leads to changes in soil structure (Ćirić et al., 2013).
Soil structure is a key determinant of soil fertility and agricultural productivity, and is thus of great ecological significance. Structural status (shape, size) and stability of structural aggregates are key factors of soil fertility, which significantly affect the sustainability of crop production (Amezketa, 1999; Bronicki and Lal, 2005; Nešić et al., 2014). Creating structures (Tisdall and Oades, 1982; Oades and Waters, 1991) is a very complex process which depends on the interaction between soil types, cement agents, soil management and environmental conditions. Soil structure is very dynamic dimension, especially in the humus horizon which changes under the influence of climatic factors, crops and processing (Vučić, 1964), Favorable soil structure is necessary to preserve and unfavorable to improve (Belić et al., 2004). The most significant properties for the evaluation of soil structure are the content of macro-aggregates, their mechanical strength and water stability, as well as porosity (Sorochkin, 1991). The factors affecting soil structure and aggregate composition are tillage, irrigation and climate (Gérif et al., 2001, Gajić et al., 2006). Soil aggregate stability declines rapidly as the consequence of cropping, and the diameter of dry aggregates increases (Kandelero and Murer, 1993; Shepherd et al., 2001). Soil organic matter (SOM) is an essential, but transient component of the soil that controls many phisical, chemical and biological properties in the soil (Carter, 1996). Soil structure and SOM content are considered important indicator of soil in agricultural soil (Lal and Kimble, 1997, Gajić et al., 2006). The lower stability is usually associated with a decrease in SOM content and significantly affects plant development.
The data obtained by determining the stability of micro aggregates contribute in defining clearer and more complete overview of the soil structure. In soils with less stable micro aggregates it is reduced the share of stable macro aggregates (Belić et al., 2004). Based on the stability of the micro aggregates it can be predicted the risk of erosion (Igwe and Obalum, 2013). Micro aggregates are mainly formed by coagulation of colloids or colloids and opposite-charged ions, and also can be formed by fragmentation of macro aggregates.

Material and Methods

The Moravica Administrative District is located in the central part of the Republic of Serbia and includes the following municipalities: Gornji Milanovac, Čačak, Lučani and Ivanjica. It extends from 43°52' to 44°16' north latitude and from 19° 55' to 20°38' east longitude, covers about 3.016 km^2, and the arable agricultural soil covers about 104.032 ha.
Most of the area are meadows and pastures, then plowed and gardens, and then orchards and vineyards. The total number of locations where observations were performed during July 2016, was twenty. Part of it was under irrigation systems (drop by drop and sprinkling) and part of it was provided for the application of irrigation systems. Soil samples in the disturbed state were analyzed from a depth of 0-30 cm.
Climatic data were processed on the basis of data taken from the yearbooks of Hydro meteorological Institute (RHMZ www.hidmet.gov.rs, accessed May 2017). The data from weather stations Kragujevac and Požega (MS Kragujevac location: 44° 02' latitude and 20°

56' latitude, 185 m above sea level, MS Požega location: 43° 51' latitude and 20° 02' latitude, 310 m above sea level), for a series of 21 years of observation.
The characteristics of the climate of the study area are presented by processing the following indicators (Belanović, 2012):
- Lange's (Kf) rainfall factor, representing the relationship between annual rainfall and mean annual air temperature.
- De Marton's drought index, derives from equitation:

$$\mathrm{Im} = \frac{12 \cdot Pm}{10 + Tm}$$

Where: Im – monthly drought index by De Marton,
Pm – average monthly precipitations,
Tm – average monthly air temperature.
-Climate diagram by Walter, obtained on the basis of average mean monthly air temperature values and average mean monthly precipitation values in relation 3:1.
Preparation of collected soil samples implied processes of drying, grinding and screening following the laboratory analysis. The samples were air-dried at room temperature. A portion of the sample was sieved trough 0.25 mm sieve. The content of organic matter (SOM) was determined by Kotzman, JDPZ (1966).
Determination of physical characteristics of the soil included analysis of the stability of structural aggregates in 20 samples of soil material. The principle of determination was based on an analysis of the relationship between the total content of particles smaller than 0.002 mm (clay) in the soil sample prepared with sodium pyrophosphate ($Na_4P_2O_7$ x 10 H_2O) and the content of these particles in the suspension of soil prepared with water (H_2O).
The stability of the micro aggregate is calculated according to the Vageler's index of their stability (Ss) according to the formula:

$$Ss = (FP - FNP) / FP \times 100,$$

Where: FP (%) - particles smaller than 0.002 mm in the soil material prepared with ($Na_4P_2O_7$ x 10 H_2O);
FNP (%) - particles smaller than 0.002 mm in the soil material prepared with H_2O. Risk of the soil crusting R(%) is determined according to formula Van der Watt & Claassen (1990):

$$R = SOM \times 100 / (clay + silt),$$

Where:
SOM content of organic matter in the soil (%);
Clay + Silt - content of certain mechanical fraction (%).

Results and discussion

Air temperature and amount of precipitation are climatic elements of areas that have a dominant influence on the intensity and ability to perform intensive agricultural production, and are conditioned by geographical position, geographical latitude, altitude, relief formations, and distance from water resources as well as wind influences.
Based on the above criteria, each area has its specificities and diverse climatic characteristics.
None of the above-mentioned climate indicators is sufficient to independently characterize the climate of an area, for better understanding of climate characteristics, it is more convenient to use them together.
The climate of the Moravica region is moderately continental. The collected climatic parameters for the period of observation 1994-2015, due to differences in the configuration of the terrain, were processed for two parts: for the flatland data collected from the meteorological station Kragujevac and for the hilly-mountain part, the data from the metrology station Požega.

The average annual amount of precipitation registered at MS Kragujevac was 627.5 mm, while on MS Požega the value of this parameter was 709.2 mm. Average precipitation during the vegetation period (April-September) at the MS Kragujevac is 366.1 mm and 261.4 mm in the off-season (October-March), and on MS Požega during the vegetation period (April-September) 416.9 mm and 292.3 mm in the extra vegetation period. Within MS Kragujevac, the most probable is the month of June, with an average precipitation of 66.6 mm (MS Požega 80.1 mm). The average annual duration of sunshine during the day at MS Kragujevac is 5.5 hours (MS Požega 4.16 hours), with the highest hours of sunshine in July, 9.49 h (MS Pozega 7.73 h), and at least during December 2.0 h (MS Požega 1.04 h). The average annual air temperature at the MS Kragujevac is 11.48 °C (MS Požega 9.59 °C), with the coldest January (1.41 °C), (MS Požega -0.95 °C) and the warmest July with registered 21.62 °C, (MS Požega 19.54 °C). The average annual wind speed registered within the MS Kragujevac is 1.2 ms^{-1}, with the brightest March (1.7 ms^{-1}) and the smallest August (0.8 ms^{-1}), while in the MS Požega the average annual wind speed 0.6 ms^{-1}, with the brightest March and April (0.9 ms^{-1}) and the smallest December, January and October (0.4 ms^{-1}).

The rainfall factor in Lange, obtained by processing the data from MS Kragujevac is Kf = 54.7, and for MS Požega, Kf =73.9, which indicates that the investigated area at lower altitudes belongs to the climatic field of the semiarid climate, while in the higher regions predominate conditions of semihumidic climate.

De Marton's index from the processed data from MS Kragujevac, points to the conclusion that irrigation in addition to precipitation needs to be included from May to October. Based on the parameters processed, it can be concluded that water is lacking both in winter and summer, almost the whole vegetation period. In higher areas, irrigation in addition to precipitation should be included during August.

The Walter diagram points that drought occur in the lower parts of the investigated area in the middle of August. In hilly-mountain areas, data from MS Požega, are determining that the water deficit occurs in mid-July and lasts until the first week of September. Such conditions are unsuitable for fruit and vegetable production, so in the period of deficiency it is necessary to provide some type of irrigation as a complement to precipitation.

In the soil samples it was determined the stability of structural aggregates. The principle of determination was based on an analysis of the relationship between the total content of particles smaller than 0.002 mm (clay) in the soil sample prepared with sodium pyrophosphate ($Na_4P_2O_7$ x 10 H_2O) and the content of these particles in the suspension of soil prepared with water (H_2O).

The stability level of the micro aggregate is estimated by using the classification by Vageler (JDPZ, 1997), shown on Table 1.

Table 1. Classification of stability level of the structure micro aggregate in soil

Index of stability of micro aggregates (Ss)	Level of stability by Vagler
<10	totally unstable
10-20	unstable
20-30	low stable
30-50	slightly stable
50-70	rather stable
70-90	stable
>90	very stable

The risk of soil crust formation is high if the value of R is less than 5%, on the borderline if R is 7% and low if R is greater than 9% (quote Ćirić et al., 2012).

The examined parameter is important, since, for example, by treating soil in a dry condition, structural aggregates are dispersed, and rain or irrigation on the surface of the soil, are formatting of a thick and hard suborach that can affect the uneven growth of cultivated plants, or the absence of plant development. The table 2. shows, locations of the samples, type of soil and existence of irrigation systems.

Table 2.List of locations of samples, type of soil and existence of irrigation systems.

Results of performed analysis of 20 soil samples in disturbed condition are shown in Table 3.

The results of the analysis showed that the soil samples have stable to very stable level of stability micro aggregates, except of the sample No.16 which has very stabile value of this parameter (Ss=60.20).
Soil organic matter is a key attribute of soil quality that affects the aggregation and aggregate stability (Franzluebbers, 2002). In the analyzed samples organic matter content is in the range from low to high content, which is correlation with a certain value of the risk of crust formation. In the analyzed samples the risk of the soil crusting was in limit values 50.00% of the samples had a high risk area, 37.50% borderline risk, and at the 12.50% of the samples, a risk of crust was at a low level.

Table 3. Locations of sampling and examined parameters

No.	Clay (%)*	Clay (%)#	Ss	Index of stability of micro aggregates	Silt (%)	C (%)	SOM (%)	R (%)	Risk of the soil crusting

Ss - Index of stability of micro aggregates;
* - Content of clay (%) determined by preparation with water;
# - Content of clay (%) determined by preparation with $Na_4P_2O_7$ x 10 H_2O;
R (%)-Risk of the soil crusting;
SOM-Content of organic matter in the soil (%).

Conclusion

Based on the results of observations carried out on the soil type fluvisol, vertisol, humogley, cambisol and stagnosol (WRB, 2014), where drip irrigation method is implemented or planed for implementation, in the area of Moravica Administrative District, it is evident that some locations requires the application of complex measures of soil reclamation in order to repair the adverse water- physical Properties (heavy soils such as stagnosol, vertisol and humogley).
Stability of structural aggregate, designated in the subsurface horizon of test profile indicates for all samples tested, that according to the classification by degree of stability of microaggregates by Vagler, all samples belongs to stable or a very stable aggregates. Only one sample with the number of the profile 16, where the micro aggregates are rather stable.
The tested samples of the investigated profiles (surface horizon), compared to the risk of crust formation time, showing 50.00% of the tested samples are in the high risk area; 37.50% marginal risk of crust formation, while in 12.50% of samples tested have low risk of crust formation. Some of the measures to be taken in the event of the identified high-risk and of the border of the crust formation time for reduction of the problems, the soil processing should be performed in the most favorable humidity conditions, by calcification of acidic soils, by application of humus-rich fertilizers and humus substances.

Abstract

European corn borer (ECB) is a pest of maize present worldwide in maize fields. It is a polyphagous pest, but maize (*Zea mayis*) is the main reproductive host. In Europe and North America Z, E and H phero-races are determined. The aim of the study was to identify the presence and flight dynamics of different ECB races in main maize production region in Serbia. In an experimental field (Bečej, northern Serbia) delta pheromone traps and lures of all three strains (Csalomon, Hungary) were placed. Empty traps were the control. Traps were inspected weekly and sticky bases replaced or cleaned, while lures were replaced monthly. Observation indicates the presence of all three pheromone races in northern Serbia. The largest number of caught ECB males belonged to Z strain (total 102 specimens), 12 specimens belonged to H strain and the smallest number (3 specimens) to E strain. The first catches of Z males were registered on 2nd June (3 specimens) and the last on 9th October (34), the largest number was caught on 16th August (54). First specimens of E strain were caught on 16th August (2) and second on 9th October (1 specimen). Catches on H traps were registered on 16th (9) and 27th August (3 specimens). According to these preliminary results, the highest number of caught specimens on the territory of Vojvodina belongs to the Z pheromone strain of ECB. Detailed GSMS analyses will precisely identify which ECB strains are present in northern Serbia and confirm these preliminary results.

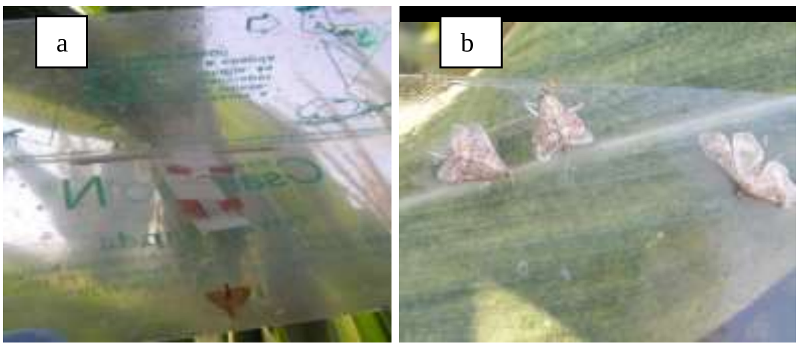
Keywords: *European corn borer, Pheromone traps, Flight dynamics, Pheromone races GSMS analysis.*

Introduction

The European corn borer, *Ostrinia nubilalis* Hübner (Lepidoptera, Crambidae), is of agricultural significance in Northern hemisphere, including Europe, Asia, Africa, America, Japan (Beck, 1987). It is a polyphagous herbivore (Mason *et al*., 1996). It affects maize production, but beside the maize as nutritive and reproductive plant, ECB, can feed and multiply on more than 224 plants including sorghum, cotton, potatoes, paper, hop (Lewis, 1975; Marcon *et al*.,1999; Ponsard *et al*., 2004). The ECB is native to Europe and its presence in European entomophauna was established around the 1500 year (Beck, 1987; Bethenod *et al*., 2005). The first identification of ECB as economically important maize past was in 1835 in France (Coffrey and Worthley, 1927). In maize production, the monitoring of flight dynamics is a usually carried out by light traps, sex pheromone traps or a combination of sex pheromone and attractant multi-baited traps. When sex pheromone baited traps are used for monitoring of moths flight, it is crucial that the pheromone blend used as a bait in the traps is representative blend for the local European corn borer population (Sorenson *et al*., 1992; Bourguet *et al*., 1999). Although moth catches in pheromone-baited traps do not indicate at the intensity of larval infestation that will subsequently develop, monitoring of moth flights provides valuable information on the time of oviposition i.e. indicate precisely at time of moth presence in the field. In that way, these traps could be useful for timely insecticide application in the field and provide efficient control. For insects, sex pheromones represent typically blend of small numbers of volatile organic compound, so even the small change in ratio or identity of the blend can affect the nature of the response (Olsson *et al*., 2010). ECB consists of two sympatric races and each use opposite ratios of components in the similar pheromone blends (Olsson *et al*., 2010). The Z strain uses a 3:97 ratio of E: Z-11 tetradecenyl acetate while the E strain uses a 99:1 ratio of the E: Z isomers (Kluns and Cooperators, 1975; Glover *et al*., 1987). Male response to female pheromone production are identical in each of this races, but E strain males have been shown to respond to a wider range of blend ratios then Z males (Linn *et al*., 1997). In the France, ECB strain development depends on the host and reproductive plants. ECB-Z race feeds and develops exclusively on maize while E race develops on hop (*Humulus lupulus*) and mugwort (*Artemisia absinthium*) (Malausa *et al*., 2007a; Pelozuelo *et al*., 2004: Rak Cizej *et al*., 2013). In the USA, both races develop on maize (Dopman *et al*., 2010). The first presence of ECB, Z races, in the Balkans was identified on the territory of Belgrade and Osijek (Anglade *et al*., 1984). ECB moths live 10 days on average, with the highest activity during the night (Hill, 1987). High humidity and good nutrition have the positive effects on life and fertility of this pest (Leahy and Andow, 1994). Different climatic conditions, vegetation and maize production in different region had the influence to appearances of a different number of generations per year (Bača *et al*., 2002). On the territory of Serbia, from one dominate generation, ECB today can produce more generations per year (Vajgnad, 2010) i.e. up to four.

Material and method

The experiment in the field was carried out from April 18th to October 1st 2016 i.e. from sowing to harvest. It was performed in Bečej, Vojvodina province, Northern Serbia. For the experiment, Serbian cultivar NS-640 was chosen. An experiment was set up in the field with low WCR natural infestation. Pheromone traps for ECB were placed (May 25th, 2016) at the edges of maize field with 15 steps i.e. at least 10m between (Picture 1). Pheromone traps were used for all three different races of ECB (Z, E and H) and empty traps as control traps, labeled with C, were placed as well. Traps are obtained from Institute for plant protection, Budapest, Hungary. They were labeled according to lure i.e. E - strain lures (1:99 Z11-14Ac: E11-14Ac), Z-strain lures (97:3 Z11-14Ac: E11-14Ac), H – strain lures (50:50 Z11-14Ac: E11-14Ac) and C – control or empty traps. On sticky bases for all traps, RAG egér (BIOTOLL) was used as a glue. The field was inspected every week from installment of traps to harvest. In each filed inspection, sticky bases in all type of pheromone traps were inspected as well, the presence of ECB was recorded and sticky surfaces were replaced.



Pictures 1. Delta pheromone trap (a) and ECB males on sticky bases (b)

Results and discussion

According to the obtained data from the field, the number of caught ECB specimens was fluctuating during the vegetation period in 2016. The biggest number of caught specimens was on August 16th in Z pheromone traps with 54 ECB males registered (Figure 1). The first catch in Z traps was on June 3rd (3 specimens) and the latest was on September 10th with 34 specimens registered (Figure 1). The smallest catch was on 9th and 15th June with one registered specimen (Figure 1).

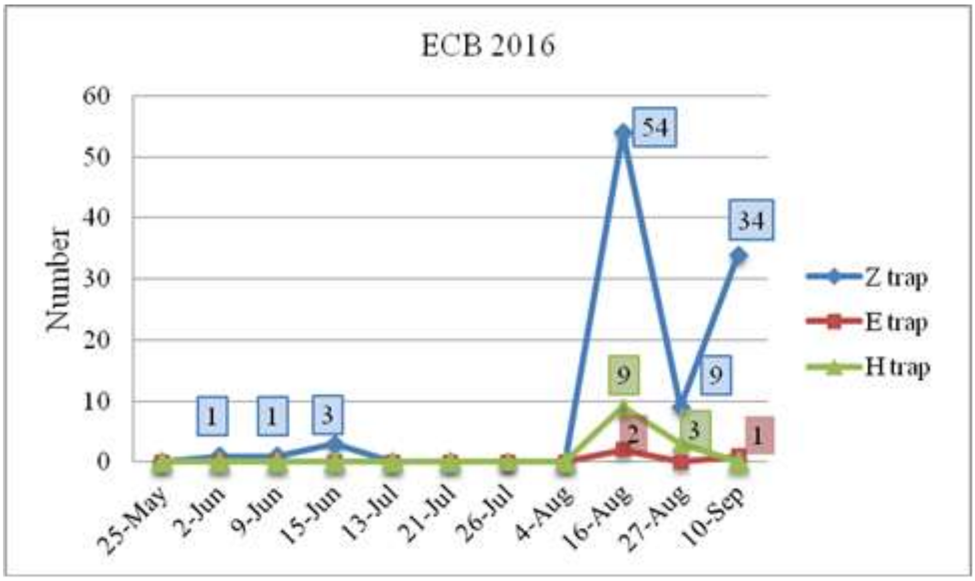


Figure1. Flight dynamic of European corn borer

During the field inspection, caught specimens were also registered on E and H traps (Figure 1). The first registered caught on E trap was on August 16th with 2 specimens and the second and last, on September 10th with only one registered specimen (Figure 1). The first catches on H traps were on 16th August (9 specimens) and the second and last was 27th August with registered 3 specimens (Figure 1). According to Tanasković *et al*. (2017), the first catch during 2014 on the territory of Vojvodina was on 17th July with registered 1 specimen. During 2015 the first catch was registered on 23rd June (four specimens). The same authors record the latest catches in Vojvodina province in 2014 on August 20th (4 specimens) and in 2015 on September 10th (11 specimens). According to the number of caught specimens in all three types of pheromone traps (Z, E and H), the largest number of caught ECB males belonged to Z strain with registered 102 specimens during the vegetation period in 2016 (Figure 2). In E traps, only 3 specimens were registered and in H pheromone traps 12 specimens (Figure 2). According to these preliminary results, the largest number of caught specimens on the territory of Vojvodina belongs to the Z pheromone strain of ECB. These results are in accordance with research of Tanasković *et al*. (2017) regarding the preliminary identification of ECB strains in Vojvodina in 2014 and 2015.

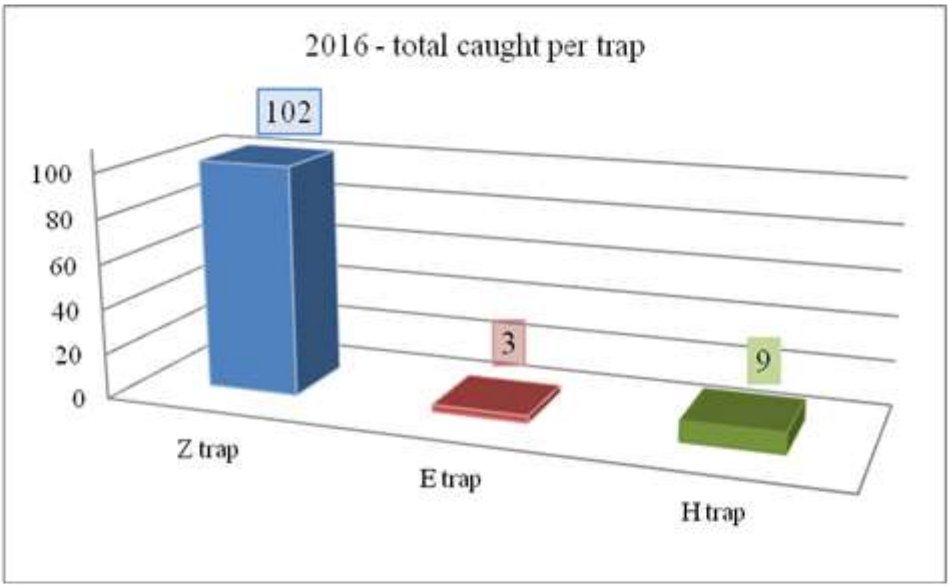

Figure2. Total number of caught European corn borer males per strain in pheromone traps.

Behavior and flight dynamics of ECB depend on temperature, humidity and also nutrition. During research in Poland, authors concluded that average daily temperature, number of rainy and windy days have obvious effect on the flight dynamics of ECB (Bereś, 2011). In the same research, during 2006, 2007 and 2008, a significantly lower number of caught ECB moths was recorded than during our research. Precisely, in Poland, 24, 12 and 9 specimens were caught per year, respectively. In Vojvodina province, according to the data from light traps and research of Čamprag (2002) and Vajgnad (2010), the flight of the first generation was registered on May 1st and the flight of second generation was in mid of July - beginning of August.

During our research period, we the first catch in pheromone traps on 2nd Jun, which is one month later than in research of Čamprag (2002) and Vajgnad, (2010). Also, the flight was prolonged, but ECB flight in cold period was longerthan in warm, rainy period with hot and drought weather (Kania, 1961). Empirical data indicate that climatic factors havethe big influence of population dynamics of ECB flight (Cordero *et al.*, 1998). This is completely accorded with our results.

These results represent preliminary identifications of ECB strains presence in maize field in Bečej region. Detailed GS-MS analysis will confirm preliminary strain identification of caught specimens.

Conclusion

This research and literate data indicate that the use of pheromone traps in the field is a necessary predictive and preventive measure, for confirmation of ECB presence in the field. In further research, we will continue to follow the influence of ECB on plant damages and yield losses in a maize field.

Abstract

(*Vicia villosa* Roth.), is a vining, winter-active legume. It may be annual or biennial. Hairy vetch is a widely grown forage crop, although outside cultivation it is often considered to be a weed. It belongs in the legume family, Leguminosae (also known as Fabaceae). Hairy vetch is very similar to tufted vetch (*Vicia cracca*), the most noticeable difference being that tufted vetch has a smooth stem. It is a legume, grown as a forage crop, fodder crop, cover crop, and green manure. Diseases caused by phytopathogenic fungi every year have a significant impact on yields and quality of the final product to a greater or lesser degree. They can also affect trade plant material and cause the expansion of the disease in new areas where legumes are grown. There has not been a systematic research of hairy vetch mycoflora in Serbia. This research aims to present the results of preliminary research of mycopopulation of 15 different genotypes of hairy vetch. Total of 600 plant parts have been analyzed and 7 genera of fungi are isolated: *Fusarium*, *Phythophthora*, *Rhizoctonia*, *Phoma*, *Verticillium*, *Sclerotinia* and *Botrytis*. On plants from which the fungi were isolated, there were macroscopically clearly visible symptoms of infection. Symptoms in the form of color changes on stems and lateral branches have been identified.

Key words: *phytopathogenic fungi*, *hairy vetch, Serbia*

Introduction

Hairy vetch (*Vicia villosa* Roth.) is annual plant from the legume family (Fabaceae) and originates from the temperate zone of Europe and Asia. It has a special place in the provision of animal fodder in the zone of moderate climate. It belongs to high-quality protein fodder plants (Mišković, 1986). Hairy vetch fixes large amounts of nitrogen (N) that help meet N needs of the following crop, protects soil from erosion, helps improve soil tilth, and provides weed control during its vigorous growth in the spring and when left as a dead mulch at the soil surface. Hairy vetch can also be grazed or harvested as forage. Research has shown that hairy vetch mulch can increase main crop disease resistance and prolong leaf photosynthesis of the following crop (Campiglia *et al*., 2010). The diseases of legumes caused by phytopathogenic fungi occur, in a stronger or weaker intensity, regularly every year in all areas of the world. They have a significant impact on the reduction of potential yield of these cultures, but also the quality of the final product, trade of plant material and expansion of legumes into new areas (Porta-Puglia and Aragona, 1997). Vetch and bean anthracnose is caused by the fungus *Ascochyta fabae* Speg. (teleomorph *Didymella fabae* G.J. Jellis & Punith.) (Tivoli *et al*., 2006). *Uromyces viciae-fabae* (Pers.) J. Schröt. is the causal agent of the rust in hairy vetch and bean and has a wide range of hosts, species from the genera *Pisum*, *Lathyrus* and *Lens* (Sillero and Rubiales, 2014). Two *Fusarium* species were determined on the cultivated legumes seeds, *F. verticillioides* and *F. proliferatum*, respectively (Miličević *et al*., 2013).

Similarly, *Erysiphe pisi*, *Botrytis cinerea*, *Rhizoctonia solani*, *Cercospora medicaginis*, *Pseudopeziza medicaginis*, *Sclerotinia trifoliorum*, *Stemphylium botryosum*, *Verticillium albo-atrum*, *Aphanomyces euteiches* as well as *Phytium*, *Leptosphaerulina*, *Phoma*, *Phythophthora* and *Alternaria* species are significant disease agents in hairy vetch, spread in all production areas (Morgan and Johnson, 1965; Stovold and Walker, 1980; Hughes and Grau, 2007; Villegas-Fernández and Rubiales, 2011; Salam *et al*., 2011; Sillero and Rubiales, 2014). In case of severe infections a serious damage to hairy vetch seedlings could be caused.

Considering the importance of hairy vetch as a fodder crop in Serbia, the aim of this study was to identify phytopathogenic fungi as casual agents of diseases in hairy vetch for a clearer perception of problems (the extinction of plants, reducing yields, deterioration of the quality of feed and other) arising as a result of the presence those fungi.

Material and methods

For the mycopopulations study, samples were collected from the six experimental plant genotypes of hairy vetch (*Vicia villosa* Roth.) originating from Australia, nine wild-genotype originating from Serbia, from the Rasina region. The samples were collected between May and June 2015 at the location of the Institute for forage crops in Globoder. Parts of plants are carefully washed under running water. After washing, the parts of stem and roots are cut to piece of 0.5-1 cm in size. Prepared samples of roots and stems were disinfected with 96% ethanol for 10 seconds and with 1% sodium hypochlorite (NaOCl) for 1 minute and then washed three times in sterile distilled water. They were then dried on sterile filter paper and placed on potato dextrose agar (PDA) with streptomycin. Five pieces of the plant parts (roots and tree) were placed in each Petri dish in four replications. They were kept in a thermostat at 25 °C in 12 h light / 12 h night regime. The observations were performed every 3 days, and the majority of mycelium samples were developed up to 14 days. Developed mycelia were screened to a new PDA substrate and, after an initial grow, the peak part of the mycelium was reseeded on PDA again.

Microscopic examination was performed using microscopes Olympus CX31. Morphological identification of fungi to the genus was carried out using a standard key. Calculated by the frequency of isolation in % according to the formula Vrandečić *et al*. (2011):

$$\textit{(\%) Isolation frequency} = \frac{\textit{Number of segments containing the fungal species}}{\textit{Total number of segments used in the isolation}} \ x\ 100$$

Results

In the study of mycopopulations of hairy vetch genotypes, total of 600 parts of the plant were analyzed. On all plants from which fungi were isolated, there were clear symptoms on stems in the form of spots and necrotic lesions. From these plants, fungi from genus *Fusarium*, *Phytophthora* and *Botrytis* were isolated. Also, in large number of plants, there were necrosis with white airy mycelium in the lower third of stems and fungi from the genus *Sclerotinia* were isolated from those plants. In some plants, black fruiting bodies (pycnidia) were observed on stems, which have been found to belong to the genus *Phoma* (Table 1).

Table 1. *Frequency of fungal isolation on hairy vetch*

Vicia villosa (S)	20	20	*Botrytis* sp. *Sclerotinia* sp.	15 35	*Sclerotinia* sp. *Fusarium*	15 25
Vicia villosa (S)	20	20	*Sclerotinia* sp. *Fusarium* sp.	25 5	*Sclerotinia* sp.	30
Vicia villosa (S)	20	20	*Sclerotinia* sp.	25	*Rhizoctonia* sp. *Sclerotinia* sp.	15 10

The symptoms of a light to dark brown necrosis on the root system of the plants are observed and from these plants fungi of the genera *Fusarium*, *Phythophthora* and *Rhizoctonia* were isolated. Decolorisation of the conduction tissues on root system was observed in a large number of plants and from these plants fungus of the genus *Verticillium* was isolated (Table 1). The results indicate that hairy vetch is vulnerable to the attack of a large number of phytopathogenic fungi that can have a significant impact on reducing its yield and quality.

Discussion

In all the plants from which isolations were conducted there were clearly visible symptoms of the disease present. In these studies, there was difference in frequency of isolation of some genera of phytopatgenic fungi in both Australian and Serbian populations. It was observed that in the genotypes that originated in Serbia fungi of genus *Botrytis, Rhizoctonia*, *Fusarium* and *Sclerotinia* were frequently isolated. Also genera *Verticilluim*, *Sclerotinia*, *Fusarium, Rhizoctonia* and *Phythophthora* were frequently isolated from Australian genotypes. Genera *Fusarium*, *Phythophthora*, *Rhizoctonia*, *Phoma*, *Verticillium*, *Alternaria*, *Sclerotinia*, *Botrytis* and *Ascochyta* were dominant in annual and perennial legumes worldwide (Tivoli *et al*., 2006; Villegas-Fernández and Rubiales, 2011; Salam *et al*., 2011; Sillero and Rubiales, 2014, Vasić *et al*., 2015). Miličević *et al*. (2013) determined two *Fusarium* species *F. verticillioides* and *F. proliferatum* on vetch seed in Croatia. While Salam *et al*. (2011) cited genera *Ascochyta* and *Botrytis*, especially species *Ascochyta fabae* Speg. (teleomorph: *Didymella fabae*) and *Botrytis fabae, Botrytis cinerea* as significant pathogens on fava bean in Australia. It is important to mention that the parasites of the genus *Botrytis* overwinter in the form of sclerotia or mycelium into plant residues in the soil (Davidson *et al*., 2004). So, for these reasons, it is recommended to utilize crop rotation of four years, when it comes to the sowing of vetch after the fava bean and pea (Salam *et al*., 2011). Salam *et al.* (2011) also cited *Phoma medicaginis* var. *pinodella* and *Ascochyta pisi* as significant pathogens in pea. *Phytophthora medicaginis* was recorded on chickpea in Australia and it was also found that this parasite can infect other types of legumes (Salam *et al*., 2011). *Sclerotinia trifoliorums* Eriks. often causes serious problems in many legumes in Greece (Lithourgidis *et al*., 2005). *Rhizoctonia solani* Kühn is soil parasite that can cause serious problems in many legumes, especially on fava bean (Assunção *et al.*, 2011). In Canada, 304 fava bean genotypes were tested on the resistance to *R. solani* and only five of them were identified with high resistance (Rashid and Bernier, 1993). Ligoxigakis *et al*. (2002) determined the *V. dahliae* as a parasite on vetch and other legumes in Greece.

Conclusion

This paper presents the preliminary results of mycopopulations of 20 experimental hairy vetch genotypes. Hairy vetch is very important forage crop and its importance as animal feed is growing within our country. This work is the beginning of a more comprehensive study of phytopatogenic fungi on hairy vetch. So far, there were no significant researches in this direction in Serbia, so the future researches related to hairy vetch will go in the direction of selection of genotypes with increased tolerance to fungal diseases.

Acknowledgments

This work was funded by the Ministry of Education, Science and Technological Development Republic of Serbia, project TR 31057.

Abstract

Bacterial soft-rot disease caused by *Pectobacterium carotovorum* subsp. *carotovorum* is a very destructive disease with a diverse host range in agricultural crops, during the plant growth in the field and in storage. Control, usually based on the use of chemical products, is not satisfactory because of their harmful effect on human health and environment, as well as the possibility for pathogen resistance development. Therefore, developing of new natural products (such as essential oils-EOs, plant extracts etc.) with a sufficient efficacy in control of the disease was imposed. The current study included *in vitro* testing of bactericidal activity of 51 different oils against *P. c.* subsp. *carotovorum*, using an agar-diffusion assay. Bacterial suspension was mixed in Nutrient Agar to final concentration of 10^7-10^8 cells/mL and poured in sterilized Petri plates (ø 90 mm). After media solidified, sterile filter paper discs (ø 5 mm) were placed on the surface of the Petri plates and supplemented with 20 µL of each tested oils. The experiment was performed in a completely randomized design. The results were expressed as a width of inhibition zone (mm) and analyzed by one-factor analysis of variance by using the software package Statistica 7.0 (StatSoft, Inc.). Results showed that the 7 most efficient EOs against *P. c.* subsp. *carotovorum* (*Thymus vulgaris*, *Cinnamomum cassia*, *Cassia angustifolia*, *Origanum vulgare*, *Boswellia serrata*, *Eucalyptus globulus*, *Satureja montana*, respectively) achieved inhibition zone greater than 20 mm. Inhibition zones in the range of 15-20 mm were achieved by 8, 10-15 mm by 9, and less than 10 mm by 6 EOs. The rest of 21 Eos did not show any bactericidal effect.

Keywords: *in vitro, bacteria, inhibition, essential oils.*

Introduction

Soft rot phytopathogens are responsible for several macerating diseases that can occur during the plant growth in the field but is more common during transport and in storage (Babadoost, 1990; Des Essarts *et al*., 2016). The *Pectobacterium* bacteria (*Pectobacterium carotovorum* subsp. *carotovorum*, *P. atrosepticum*, *P. wasabiae*, *P. carotovorum* subsp. *brasiliense*) are among the most important responsible for these disease on a wide range of crop and ornamental plants (Babadoost, 1990). The damage caused by these pathogens remains an important issue in many countries worldwide (Des Essarts *et al*., 2016). The bacteria attack succulent, tender tissues of storage organs (tubers, fruits, roots, bulbs, corms, rhizomes), as well as buds, stems, petioles and leafstalk tissues. The disease initially starts on leaves and stems in form of small, water-soaked, translucent lesions that rapidly enlarge in diameter and depth. The infected tissue becomes watery. Slimy bacteria exudates and cellular debris frequently ooze out from cracks in the tissues. Within one to three days, fleshy organs may rot and collapse. Decaying tissue gives off a characteristically putrid odour which comes from saprophytic bacteria that are growing in the decomposing tissues (Babadoost, 1990).

Control of soft rot pathogens is based on agricultural practices (eradication of diseased plants, removal and destroying of crop residues, crop rotation) and chemical control commonly based on the use of copper based products. The increasing interest in natural products as an alternative in disease control is mainly due to their low impact on the human health and environment (Jeong *et al*., 2009; Mohan *et al.*, 2011). Natural substances such as essential oils (EOs) often function as antibacterial, antiviral, antimycotic, antitoxigenic, antiparasitic, and insecticidal or inducing resistance in plants through activation of biochemical defence pathways (Deans and Ritchie, 1987; Mihaliak *et al*., 1991; Isman, 2000; Burt, 2004; Freeman and Beattie, 2008). EOs are aromatic and volatile oily liquids as products of secondary metabolism of aromatic plants, formed in special groups of cells and commonly concentrated in one particular region such as leaves, bark or fruit (Gutierrez *et al*., 2008). They present complex mixtures of natural components among which predominate terpenes, terpenoids, aromatic and aliphatic components (Pichersky *et al*., 2006; Bakkali *et al*., 2008). These are particularly present in families: *Lamiaceae, Asteraceae, Lauraceae, Zingiberaceae, Myrtaceae, Rutaceae, Apiaceae* and *Pinaceae* (Gorunović and Lukić, 2001). The antibacterial effect of EOs and their components against soft rot pathogens was reported by some authors (Kalemba and Kunicka, 2003; El-Zemity *et al*., 2008; de Lira Guerra *et al.*, 2014; Umunna and Anselem, 2014). Considering that soft rot disease is a one of limiting factor in the many crop production worldwide and the fact that effective control measures are insufficiently, the aim of this work was to evaluate the inhibitory potential of some EOs on the growth of soft rot pathogen, *P. c.* subsp. *carotovorum* by *in vitro* assay.

Material and Methods

For the experiment the EOs of *Abies alba, Ables sibirica, Anethum graveolens, Boswellia carteri, Boswellia serrata, Cananga odorata, Cassia angustifolia, Cedrus atlantica, Cinnamomum cassia, Cinnamomum verum, Citrus bergamia, Citrus x limon, Citrus x sinensis, Coriandrum sativum, Cupressus sempervirens, Curcuma longa, Cymbopogon flexuosus, Cymbopogon martinii, Eucalyptus globulus, Foeniculum vulgare, Gaultheria procumbens, Jasminum grandiflorum, Juniperus communis, Juniperus virginiana, Laurus nobilis, Lavandula angustifolia, Lippia citriodora, Melaleuca alternifolia, Melaleuca quinquenervia, Mentha x piperita, Myristica fragrans, Nigella sativa, Ocimum basilicum, Origanum vulgare, Pelargonium graveolens, Petroselinum crispum, Pimpinella anisum, Pinus nigra, Pinus mugo, Pinus sylvestris, Piper nigrum, Pogostemon patchouli, Ravensara aromatica, Rosmarinus officinalis, Salvia sclarea, Santalum album, Satureja montana, Syzygium aromaticum, Thymus vulgaris, Vanilla planifolia* and *Zingiber officinale* were used. The strain of *P. carotovorum* subsp. *carotovorum* (KFB85) was obtained from the culture collection of the Faculty of Agriculture in Belgrade (Serbia). For use in the experiment, the strain was grown onto Nutrient Agar for 48 h at 26°C.

The inhibitory effect of the EOs on the growth of *P. c.* subsp. *carotovorum* was evaluated by Agar-diffusion assay. Bacterial suspension was mixed in Nutrient Agar to final concentration of 10^7-10^8 cells/mL and poured in sterilized Petri plates (ø 90 mm). After media solidified, sterile filter paper discs (ø 5 mm) were placed on the surface of the Petri plates and supplemented with 20 μL of each of 51 tested oils. There were four replicates for each tested oil. As positive and negative controls served plates with and without bacterial culture in medium treated with sterile distilled water, respectively.

The experiment was performed in a completely randomized design. The presence/absence and the diameter of inhibition halos (mm) were determined 72 hours after incubation at 26°C.

Data were analyzed by one-factor analysis of variance by using the software package Statistica 7.0 (StatSoft, Inc.).

Results and Discussion

Results showed that the 7 most efficient EOs against *P. c.* subsp. *carotovorum* (*Thymus vulgaris, Cinnamomum cassia, Cassia angustifolia, Origanum vulgare, Boswellia serrata, Eucalyptus globulus, Satureja montana*, respectively) achieved inhibition zone greater than 20 mm (Table 1). Inhibition zones in the range of 15-20 mm were achieved by 8 (*Melaleuca alternifolia, Rosmarinus officinalis, Anethum graveolens, Syzygium aromaticum, Laurus nobilis, Ravensara aromatica, Pimpinella anisum, Cinnamomum verum*), 10-15 mm by 9 (*Gaultheria procumbens, Cymbopogon martinii, Lavandula angustifolia, Cedrus atlantica, Citrus bergamia, Ocimum basilicum, Pinus sylvestris, Mentha x piperita, Lippia citriodora*), and less than 10 mm by 6 EOs (*Boswellia carteri, Pelargonium graveolens, Foeniculum vulgare, Pinus nigra, Cymbopogon flexuosus, Myristica fragrans*).
The rest of 21 EOs (*Cananga odorata, Nigella sativa, Santalum album, Coriandrum sativum, Petroselinum crispum, Citrus x limon, Citrus x sinensis, Zingiber officinale, Piper nigrum, Salvia sclarea, Abies alba, Juniperus communis, Ables sibirica, Pinus mugo, Cupressus sempervirens, Juniperus virginiana, Melaleuca quinquenervia, Pogostemon patchouli, Curcuma longa, Jasminum grandiflorum, Vanilla planifolia*) did not show any bactericidal effect.

Table 1. Inhibition zone in mm ($\overline{X}$ ±SE) caused by the influence of the tested EOs. F relation and P value from ANOVA; df – number of degrees of freedom. Experimental groups with the same letter in column are not significantly different (Duncan Multiple Range Test, P < 0.05)

There are a lot of reports on the use of EOs on several pathogenic bacteria. Deans and Ritchie (1987) cited ten most inhibitory EOs against 25 bacterial genera and the most comprehensively inhibitory extracts were angelica (against 25 genera), bay (24), cinnamon (23), clove (23), thyme (23), almond (bitter) (22), marjoram (22), pimento (22), geranium (21) and lovage (20). Recently, many studies have been specified the bactericidal activity of thyme as a promising active ingredient effective against a wide range of plant pathogenic bacteria (Deans and Ritchie, 1987; Kalemba and Kunicka, 2003; Alamshahi *et al.*, 2010; Lucas *et al*., 2012; Rojas *et al*., 2014; Alamshahi and Nezhad, 2015). Kalemba and Kunicka (2003) reviewed that besides thyme, EOs of cinnamon, clove and mint were found to possess the strongest antimicrobial properties among many tested bacteria.
Potential antibacterial properties of EOs against *P. carotovorum* in *in vitro* trials were described by some researchers; c. *Thymus vulgaris*, *Rosmarinus officinalis*, *Coriandrum sativum*, *Cuminum syminum* by Alamshahi *et al*. (2010); cinnamon, clove, chenopodium, caraway, rosemary and thyme oils by El-Zemity *et al.* (2008); *Thymus vulgaris*, *Artemisia kermanensis, Lavandula officinalis, Rosemarinous officinalis, Eucalyptus caesia* by Mehrorosh *et al.* (2014); *Syzygium cumini* by Elansary *et al*. (2012); *Ziziphora clinopodioides* by Ozturk and Ercisli (2007). *Thymus vulgaris* compared to other extracts, possess the best inhibitory effect on *P. carotovorum* in the lowest concentration (Mehrorosh *et al.*, 2014). Results given by Nezhad *et al.* (2012) distinguish thyme as a most active for antibacterial activity against soft rot pathogen (*P. carotovorum*) and bacterial wilt pathogen (*Ralstonia solanacearum*); in the next positions were *Coriandrum sativum*, *Cuminum cyminum* and *Rosmarinus officinalis*; oil from *Eucalyptus globulus* was insignificant. Jeong *et al.* (2009) showing that EO from *Cymbopogon citrates* effectively inhibited the growth of *P. carotovorum* in a dose-dependent fashion, and 0.5% of the oil inhibited the growth of bacteria completely.
Variation in the potency of the EOs as well as in the sensitivity pattern of the test organisms was found by Umunna and Anselem (2014). Authors report *Zingiber officinale* oil to be most effective in the inhibition of *Erwinia* pathogen in the *in vitro* trials, but oils of *C. citratus* and *Azadirachta indica* in the *in vivo* experiment. *In vivo* trials given by Alamshahi and Nezhad (2015) showed that greenhouse experiments treatment by thyme EO caused a significant reduction in soft rot (*P. carotovorum*) and bacterial wilt (*R. solanacearum*) incidence on potato by 41 and 44%, respectively. Pradhanang *et al.* (2003) were found that *R. solanacearum* populations declined to undetectable levels in thymol, palmarosa oil, and lemongrass oil treatments showing that tomato seedlings transplanted in soil treated with EOs (700 mg/L of thymol oil, 700 ml/L of palmarosa oil, and 700 ml/L of lemongrass oil) were free from bacterial wilt and 100% of plants in thymol treatments were free of disease. De Lira Guerra *et al.* (2014) evaluated the action of 11 EOs in reducing soft rot in Chinese cabbage by spraying plants and found that spraying with the oils of bergamot, copaiba, *Eucalyptus citriodora*, spearmint and sweet orange has potential in the control of this disease.

Soft-rot or blackleg disease on potato could be controlled by using of EOs such as garlic (Nassar *et al.*, 2013) or thyme (Alamshahi *et al.*, 2010), respectively. Considering that thyme showed strong antibacterial activity against the *P. carotovorum* in our study and studies given by other authors it should be considered as a promising active ingredient for developing a new product for the disease control. Also, it should be remark that antimicrobial, antioxidant or other biological activities of natural EOs may be subject to change, based on vary in the chemical composition of the oil that may be observed due to the origin, their locality, the environmental conditions, and the stage of development of the collected plant material (Gulluce *et al.*, 2003).

Conclusion

According to the obtained results, EOs of *Thymus vulgaris*, *Cinnamomum cassia*, *Cassia angustifolia*, *Origanum vulgare*, *Boswellia serrata*, *Eucalyptus globulus and Satureja montana* potentially might be used as antibacterial agents against plant pathogenic bacterium *P. c.* subsp. *carotovorum* for further analysis *in vivo* studies. Development of EOs as natural antimicrobial agents has a potential for further developing in agricultural pest management.

Abstract

The aim of this experiment was to determine the possibility of drying Burley tobacco type in a solar drier, monitoring the parameters of the drying process and determination of the physical, chemical and sensory characteristics of tobacco. As a material we used Burley tobacco, the lower middle leaves from the production areas of Šabac (Serbia), vintage 2013. Drying was carried out in a solar passive-active drier F-1 at the Faculty of Agriculture, University of Belgrade. The results represent that drying was 16 days shorter comparing to the standard process of air curing Burley tobacco type. It has been found that the physical, chemical and sensory properties of the solar dried tobacco differ in relation to standard Burley. In general, the increase of equilibrium moisture content and quantity of soluble sugars, pH reduction, reduction of nitrogen components and ash quantity can be marked as a positive results. Such tobacco, due to acidic reaction, will be more pleasant to smoke compared to standard air curing Burley. In contrast, increasing the thickness of the leaf, the specific mass and the body fullness is a negative outcome, because such tobacco has worse cutting properties, lower filling power during cigarette making, which all result in an increased amount of smoke. According to the criteria for classification of Burley tobacco, and sensorial characteristics it is classified in third quality group. Burley tobacco type obtained in the experiment described could find its use in cigarettes blends, which opens up opportunities for further research.

Keywords: *solar dryer, Burley tobacco, chemical properties, physical properties, sensory properties*

Introduction

Drying is the first technological operation during tobaco processing, which, in most cases is done by the manufacturer. It is the most important step, because it determines the direction of the transformation of substances present in tobacco leaf and directly affects the quality of the final product (Wiernik et al., 1996). The process of tobacco drying and the changes which will take place in the tobacco leaf depend on the mode of drying and the state of the material. In order to perform drying of tobacco leaves properly, it is necessary to provide conditions which will enable the removal of the excess moisture in a way to get a final product with the desired sensory characteristics, as well as with relevant chemical and physical properties (Radojičić, 2016). Burley has big leaves that are naturally dried by air curing. Drying is slower, and due to the more extensive oxidation process the leaf gets deeper brown color, which is preferred for this type of raw material. This drying process should give the tobacco wich has medium or full tissue, with a thin and soft nervature, with superior elasticity (Đulančić, 2014). Although exhibition and desiccation are not strictly separated by the terms of the embodiment of the process, dry Burley can be divided into the following stages: the stage of yellowing, the color fixation stage and the stage of the final drying of leaf and midrib (Tomić, 1973; Voges, 1984).

The aim of this experiment was to determine the possibility of drying Burley tobacco type in a solar dryer, through monitoring the parameters of the drying process and determination physical, chemical and sensory characteristics of the tobacco. Possibility use solar energy is becoming more attractive in industry and the crop materials processing. The reason for this is the fact that solar energy represents inexhaustible, economically viable, and at the same time the cleanest source of energy. Previous experiments on fruit, vegetable and herb drying in a solar dryer indicate that, except form the shortening of the drying process period, acceptable results could be achieved.

Materials and methods

Material that we used is Burley tobacco type, the lower middle leaves, from the production area of Šabac (Serbia), vintage 2013. Tobacco was dried in a solar passive-active dryer F-1, at the Faculty of Agriculture, University of Belgrade. Preparation of the tobacco for drying was as it follows: each tobacco leaf was cut in half following its lengthand the midrib so that we obtained the same number of halves with or without the midrib. After that, the tobacco is strung so that each and every set (bandelier or string of tobacco) represented the same number of the above mentioned halves. Prepared strings were hung indoors for two days to perform the process of yellowing. On the third day strings were hung in a solar dryer. During the experiment the following parameters of the process were measured:

IDK (W m^{-2}) – the intensity of the direct solar radiation in the level of the collector
Idk (W m^{-2}) – the intensity of the diffuse solar radiation in the level of the collector
IGK(W m^{-2}) – solar radiation in the level of the collector
IDH(W m^{-2}) – the intensity of the direct solar radiation in the horizontal level of the collector
Idh(W m^{-2}) – the intensity of the diffuse solar radiation in the horizontal level of the collector
IGH(W m^{-2}) – global solar radiation on a horizontal level of the collector
φ ok. – relative humidity of the outside air at the entrance to the absorber
φ iz. – relative humidity at the outlet from the chamber dryer
W(%) – moisture in materials

Measuring of the intensity of direct and diffuse solar radiation is conducted with a solarimeter Kipp und Zonen 683132 with a pyranometer Microva AL 4CM-683297. When the diffuse radiation was measured we used a cover. The temperature and the relative humidity of air at the entrance in the absorber and the outlet of the chamber, as well as the temperature in the material were controled with a thermometer K-TYPE 5115; microprocessor - moisture meter, model No. RS7825PS, CE ISO-2178 mini meteorological station Kestrel 4000, Nielsen - Kellerman. Moisture in the material was determined by the standard method of periodic sampling (Radojičić, 2011). Physical properties that were determined in this experiment were: leaf thickness, tissue fullness, equilibrium moisture content and specific weight relative to the standard (Radojičić, 2011). On the other hand, measured chemical parameters were the following ones: pH, nicotine, total nitrogen, protein nitrogen, starche, soluble sugars and ash content according to the current ISO standards. All analyzes were done in five repetitions. Sensory characteristics and quality were evaluated according to classification criteria for tobacco leaves (JUS.E.P1.113: 2004). Statistical analysis were carried out with SPSS 17.0 software.

Results and discussion

As shown in Table 1 and Table 2, the total duration of the drying process of the Burley tobacco type in a combined passive-active solar dryer F-1 lasted for a total of 12 days.

Table 1. Parameters followed during the first stage of tobacco drying

Before the begining of drying process, tobacco was standing for 2 days (48 hours) in a closed room in order to finish the yellowing process. During this time the leaves crinkled and became bright green with yellow hues. In the classical method of drying yellowing stage lasts up to 15 days, and the leaves have a light brown color at the end. After that, tobacco had been placed for 12 more days (288 hours) in the solar dryer. During these days, the active dry (insolation duration) lasted for 58 hours. Compared with the classical drying of the Burley tobacco type in natural conditions (air curing-AC), which takes an average of 30 days, this process lasted significantly shorter (16 days less).
On the first day after placing of the tobacco strings in the dryer, the tops and edges of the leaves began to receive yellow color, while the next day they turned dark yellow and started to curl. On the third day, the color of the leaves was uniform dark yellow. On the fourth day of the drying process, some parts of the leaves obtained light brown color. During that day the leaves evenly darkened and continued to curl. On the fifth day we noticed that the leaves on the upper strings got darker more intensively than those on the lower strings. The reason for this might be the higher air temperature in the upper part of the dryer, because air that is heated in the absorber when passing through the dryer is additionally heated by direct sunlight through the transparent walls of the dryer. On the sixth day leaves completely curled, lost its shine and continued to darken. There was an increase in the percentage of dark spots on the leaves.

The next three days (seventh, eighth and ninth day), we did not performe measuring due to unfavorable weather conditions (cloudy with a chance of rain). Dryer was only occasionally

uncovered. During this time, most of the leaves got a brown color, while the midrib obtained a dark yellow color.
On the tenth day of the drying process we continued measuring (Table 2). We noted that side of the leaf facing the front of the dryer, which is exposed to direct sunlight squander, got more intensevely darker than those facing the door at the back of the chamber. The midrib dryed slowly and with difficulty. At the end of the twelfth day the drying process was completed. The leaves got brown. The midrib breaks under pressure.
The initial humidity of the tobacco leaves when entering the solar dryer was 86.6%. During the first four days of drying, moisture had been gradually and smoothly decreasing to 68.81%. After that, the process of moisture reduction intensified. At the end of the sixth day of drying, the moisture content in tobacco decreased to 30.57%. The next three days, due to adverse weather conditions (low temperature and increased relative humidity of the outside air), the moisture in the material increased to 43.71%. When drying process continued and weather conditions were appropriate, moisture content in the material decreased with greater intensity, so at the end of the twelfth day of drying it resulted in 8.12%.
Physical characteristics of tobacco Table 2 shows mean values of the examined physical characteristics of the Burley tobacco type dried in a solar dryer, as well as standard values for the tobacco dried in natural conditions (air curing-AC).

Table 2. Physical characteristics of Burley tobacco type

Mode of drying	Leaf thickness (mm)	Tissue fullness (g/cm^3)	Specific weight (g/cm^3)	Equilibrium moisture content (%)
Solar dryer	0.15	0.87	1.69	19.11
Air curing	0.12	0.37	1.55	16.84

Our results imply that significant changes did occur in physical characteristics of the leaf. Leaf tissue of the test sample was thicker than the standard one, which means that the decomposition of the material did not happen. Thickness of the leaf is inversely proportional to its quality and refers to its woody part. Such tobacco will be harder to cut and will have lower filling power compared with the tobacco dried in natural conditions. Furthermore, the tissue fullness and the specific weight in the solar dried tobacco was also higher than the standard. This differences are important because they cause higher tobacco density, which leads to increased draw resistance of cigarette smoke. This is due to high temperatures and shortened process of yellowing. Tobacco with higher specific weight provides more products in the process of cigarette burning. Taking all previously mentioned into account, the increase in the leaf thickness, tissue fullness and specific weight can be regarded as negative features.
In contrast, the increase in equilibrium moisture content can be considered as a positive result. The reason for this might be the shorter duration of yellowing, as well as the faster drying of the Burley tobacco in a solar dryer. All of this has prevented degradation of colloidal components, in particular pectins, which are responsible for this quality parameter (Davis and Nielsen, 1999).
Chemical characteristics of tobacco
The Table 3 shows the mean values of the measured chemical characteristics of the Burley tobacco type dried in a solar dryer, as well as standard values for the tobacco dried in natural conditions.

Table 3. Chemical characteristics of Burley tobacco type (%)

Mode of drying	pH	Nicotine	Total nitrogen	Protein nitrogen	Starch	Soluble sugars	Ash
Solar dryer	5.71	2.71	3.88	1.52	2.97	3.96	17.49
Air curing	5.80	2.91	3.96	1.77	0.60	0.21	21.53

*pH in units

According to data in presented in Table 3, the pH value, nicotine, total nitrogen, protein nitrogen and ash content of the solar dried Burley tobacco was lower compared with the standard. These results are in agreement with the literature data (Radojičić, 2016), that the nicotine loss is greatest when dried in the sun. The ash content was also significantly reduced due to the drying process. According to the literature, if the drying takes longer, processes that alter the material are deeper, and will result in higher ash content (Burton et al., 1983). In contrast, the amount of starch and soluble sugars was higher than the standard. The increase in the amount of starch is a result of the shorter duration of yellowing. During this process, starch is decomposed completelly under the influence of hydrolytic enzymes, which was omitted in this experiment. On the other hand, the increased soluble sugar content is a result of shorter drying process in the solar dryer. According to its genetic characteristics, Burley tobacco type has the least amount of carbohydrates compared with other tobacco types (Radojičić and Đukić, 1999). Because the drying in natural conditions lasts the longest, even this small amount can be almost completely decomposed. Since Burley contains a very small amount of sugar (literally in trace), the amount of 3.96% is significant.

Sensory properties of tobacco

According to the standard JUS.E.P1.113: 2004 and after the completion of the drying process in the solar dryer, we evaluated the sensory characteristics of tobacco leaves and classified it in the third class. In case we dry the medium insertions of Burley in natural conditions, and follow all the process parameters during different phases of the drying operation, we could obtain I class tobacco leaves. Such a result would be a financial loss of about 5 euro per kg of tobacco.

Conclusion

According to the results of the research we conducted on investigating the possibility of drying Burley tobacco in a solar dryer, we can conclude:

1.The duration of the drying process in a solar dryer was 16 days shorter compared with the standard process of drying in natural conditions (air curing-AC).

2.The capacity of the dryer we used was relatively small. Given the size of the leaves of Burley tobacco, we managed to dry only two strings of tobacco leaves.

3.The intensity of solar radiation varies during the day and depends on weather conditions and the position of the dryer. An active drying step lasts for only 8 hours per day. Parameters of the outside air (temperature, relative humidity) are also variable. It is therefore impossible to establish constant conditions in the dryer.

4.Changes in the physical characteristics of the tobacco are as it follows: tissue fullness, leaf thickness, specific weight and equilibrium moisture content were higher compared with the standard.

4.We also observed changes in chemical characteristics: the pH value, nicotine, total nitrogen, protein nitrogen and ash content was lower of the solar dried Burley tobacco compared with the standard. In contrast, the amount of starch and soluble sugars was higher.

In general, as positive results, we can outline the following ones: the increase in the equilibrium moisture content, as well as the increase in soluble sugars, the reduction in pH and the reduction in nitrogen components.

5.Based on the the classification criteria for Burley tobacco according to its sensory characteristics, it was classified in the III quality group.

Abstract

The Aloe vera plant (Aloe barbadensis Mill.) has been used in functional nutrition for decades. The plant produces a colorless extract composed of three fractions of different molecular sized mucopolysaccharides, and two aloin fractions (Aloe-emodin and barbaloin/ isobarbaloin). While the first three are beneficial for human health - they stimulate the immune system - the last two produce diarrhea symptoms and, possibly, nephritic problems. The aim of this work was to chemically analyze the fresh juice contained in the plant, so as to identify and quantify the mucopolysaccharide (AVMP) and the aloin (the anthrachinon Aloe-emodin, barbaloin and isobarbaloin) on a regular and temporary basis (monthly, for a year). An analytical method capable of identifying and quantifying has been developed, based on the HPLC technique. For this, an OHpak SB-806 HQ Shodex column was installed in a VWR-Hitachi, Elite La Chrom liquid chromatograph, equipped with a pump, an automatic injector, a refraction index detector and an UV detector. Fresh Aloe vera leaves were collected monthly at the home property of Antonio del Rosario (Arinaga, Gran Canaria, Canary Islands). The concentration of AVMP fluctuated throughout the year between 940 ± 40 and 21600 ± 700 ppm, and yielded an annual average of 5500 ± 700 ppm, whereas the aloin fluctuated during the same period between 130 ± 15 and 776 ± 17 ppm, yielding an average value of 464 ± 17 ppm.

Keywords: *Aloe vera, Chemical analysis, Mucopolysaccharide, Aloin, Spain.*

Introduction

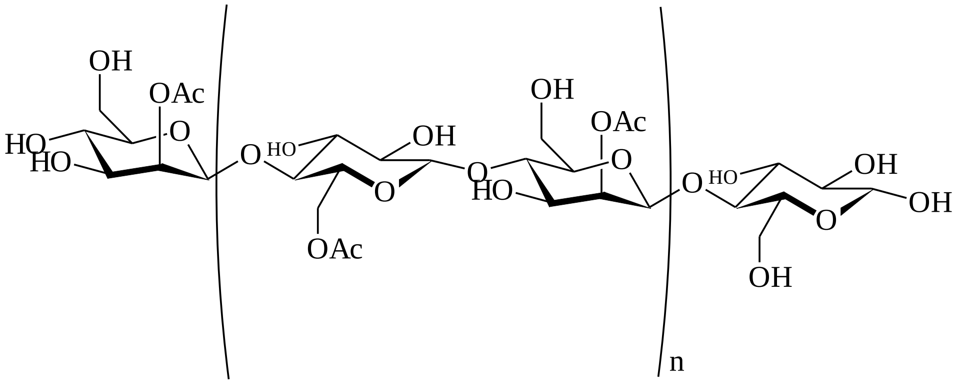
Aloe vera (L) Burm. f. (Liliaceae) or *Aloe barbadensis* Miller is a medicinal plant used in folk medicine for the treatment of diverse illnesses. It is also used in the cosmetic industry and in dietary supplements. “Aloe Vera Gel”, “Latex” or “Juice”, and “Aloe” are different commercial products that can be obtained from the leaves of *A. vera* (WHO, 1999). These and other *A. vera* preparations contain aloin, polysaccharides, monosaccharides, organic acids, and other minor compounds (WHO, 1999). There are a few reports of Aloe preparations inducing elevations in hepatic enzymes (Yang *et al.*, 2010). On the other hand, in kidney disorders, excessive doses could theoretically cause nephritis (Maschio, 2006). The correct individual dose (posology) is the smallest amount required to produce the desirable physiological effect, not overcoming the higher doses recommended of 10-30 mg aloin per day (WHO, 1999). Some countries have established control tests. For example, the risk assessment of the *A. vera* plant for food supplements is listed in the document “Drogelisten” (Gry *et al.*, 1998). “Drogelisten” is a list of risk assessments performed by the Danish Food Institute. The maximum dosage of Aloin permitted in Denmark is 16.7 ppm in gel form, or 0.1 ppm in food and beverages. On the other hand, the EEC Council Directive 88/388 fixed their maximum allowable concentration values for aloin in food and beverages (0.1 ppm) and in alcoholic drinks (50 ppm). This indicates that it is necessary to establish control measures for the *A. vera* plant's active substances, as much for the plant itself as for the numerous preparations that are currently available on the market. It's with this perspective that we have endeavored to undertake the project of reviewing the analytical methods that are currently applicable, as well as developing a new analytical method based on the size-exclusion chromatography technique (SE-HPLC).

Materials and Methods

Sodium azide, Aloe-emodin and barbaloin were supplied by Sigma-Aldrich (Biosigma, Spain). Manapol was supplied by Carrington Laboratories (USA). HPLC grade water was supplied by Scharlau (Melcan, Spain) and was used to prepare samples, standards, and eluents. To samples/standard solutions, sodium azide was added (0.5% w/v). A column was then installed to perform size exclusion chromatography (SEC), specifically, the Shodex OHpak SB-806 HQ, in a UHPLC VWR-Hitachi, Elite La Chrom model, equipped with a pump, an automatic injector, a refraction index detector (IR, T = 35 ºC) and an ultraviolet detector (UV, λ = 355 *nm*). The fresh *A. vera* leaves were then collected from Mr. Antonio del Rosario's farm (in Arinaga, Gran Canaria, Spain). Once their skin was removed, their flesh was put into a blender and diluted with water (1:1), then filtered with membrane filters of 0.80 - 1.2 μm (Sartorius stedim biotech, Minisart model). The resulting viscous liquid [0.5 x (juice + gel)] was injected directly into the chromatograph. An authentic sample of *Aloe vera* mucilaginous polysaccharide (AVMP) in its Manapol version, was used as a model to deduce the calibration curves for the three fractions of the same, corresponding to three median molecular sizes (tr = 7.7, 11.2 y 11.3 minutes) (Table 1). To prepare the AVMP dissolution model at 0,2%, we weighed 20,0 mg of Manapol and dissolved it in 10 mL of water (with sodium azide, 0.5 % w/v). For the dilution, successive dissolution models were prepared. The dissolution models were injected in triplicate. Other models (mannose, glucose, ascorbic acid, guar, Aloe-emodin and barbaloin) were prepared at the initial concentration level of 2.0 $mgxmL^{-1}$.

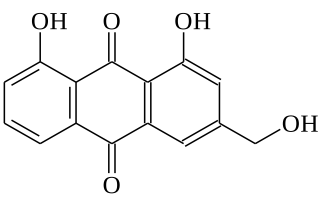
Results and Discussion

Aloe vera mucilaginous polysaccharide (AVMP) is the component that creates the characteristic viscosity of the "*Aloe vera* Gel" that's freshly extracted from the fresh plant, which presents a concentration that fluctuates around 5000 ppm. This initial concentration of AVMP falls quickly because of a process of depolymerization, due to the acidic condition of the gel (Toledo Marante, 2003). Since the AVMP is an active ingredient that's very important in the composition of the gel (Song *et al.*, 2001), its rapid decomposition creates the so-called "stabilization problem" (Yaron, 1991, 1993; Yaron *et al.*, 1992; Toledo-Marante, 2003). Numerous American researchers have proposed a method for measuring the quality of products derived from the *A. Vera* plant (Pelley *et al.*, 1993). They consist of comparing the product to a "standard". That *Standard A. vera*, was proposed according to the recommendations of the International Aloe Science Council (IASC). As soon as this procedure was adopted, it became possible to confirm suspicions that the quality of *A. vera* is frequently manipulated. AVMP, in reality, is not a unique polysaccharide, but is rather a mixture of them (Gowda *et al.*, 1979; Madis *et al.*, 1989; Yaron, 1991, 1993; Yaron *et al.*, 1992; Lee *et al.*, 1997; Song *et al.*, 2001). In said mixture, multiple elements were identified such as glucomannans, acemannan, and others. These compounds differ in their glucose-to-mannose ratios and acetyl contents. The structure of acemannan (Figure 1) consists of a long chain of polydispersed β-(1 $\rightarrow$ 4) linked mannan polymers. The sugar and acetyl group in the molecule were linked by molar ratio of 3:1 (Lee *et al*., 1997).

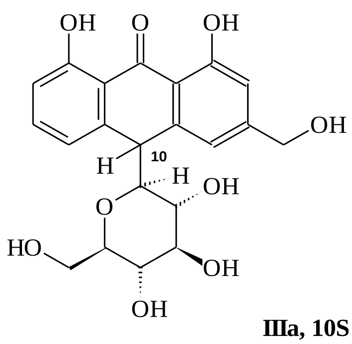


I
Figure 1.- Acemannan

A spectrophotometric analytical method for the determination of total polysaccharides was described (Eberendu and McAnalley, 1994; Leyes *et al.*, 2000). A quantitative method using size exclusion chromatography (SEC) analysis was performed to determine the concentration of AVMP in *A. vera* extracts (Toledo-Marante, 2011). Nuclear magnetic resonance spectroscopy (^{1}H-NMR) was applied to secure the quality and the presence of natural components, e.g., acemannan in commercial *A. vera* products (Diehl and Teichmuller, 1998). This analytical technique is so powerful that it permits us to identify and majorly natural products present, as well as diverse chemical compounds that are produced and present, and accumulate through enzymatic and microbial degradation during the post-harvest period (Table 3). Other artificial additives can also be identified and analyzed, having usually been added as preservatives (benzoic acid sodium salt, sorbic acid potassium salt), antioxidants (ascorbic acid), acidulents (citric acid) or thickeners (maltodextrin, glycerine) (Bozzi *et al.*, 2007; Toledo-Marante, 2010).
On the other hand, the different mono- and di-saccharides that are present in their free form in the plant, or those that result from the depolymerization of the polysaccharides can be analyzed by high performance anion exchange chromatography with pulsed amperometric detection (HPAE-PAD) (Bozzi *et al.*, 2007).



II



IIIa, 10S
IIIb, 10R

Figure 2.- Aloe-emodin (**II**), barbaloin (**IIIa**) and isobarbaloin (**IIIb**)

Aloin is composed, as its major and active principles, by Aloeemodin (**II**, $2x10^{-3}$ % w/w) and barbaloin/ isobarbaloin (**IIIa** + **IIIb**, $44x10^{-3}$ % w/w). These polyphenols are laxative/ cathartic compounds (Ishii *et al.*, 1998; Murray, 2013) and are quite stable in their solid phases (Reynolds, 1994); Nevertheless, they undergo rapid decomposition when in solution (Zonta *et al*., 1995).

Thin-layer chromatography and microchemical analyses are employed for the qualitative analysis for the presence of these phenols, and quantitative analysis of total anthracene glycosides, calculated as barbaloin, is performed by spectrophotometry (WHO, 1999); this can also be analysed by reversed-phase high-performance liquid chromatography (RP-HPLC) and similar techniques (Zonta *et al.*, 1995; Bozzi *et al.*, 2007).

With the objective of reducing the number of instruments used to analyze *A. vera*, we applied the High-Performance Liquid Chromatography (HPLC) with columns of the "Size Exclusion Chromatography" (SEC) type. Those columns separated the analytes from the sample depending on their molecular size. Yet, within the column, the analytes suffered from intermolecular forces in their stationery phase. This is why we consider that by using two aligned detectors, one that's UV-visible and the other a refraction index (IR), we could separate, with a single chromatographic analysis, that is, with a single injection, the different fractions of the AVMP as well as the different components that make up the aloin. For this, an OHpak SB-806 HQ Shodex column was installed in a VWR-Hitachi, Elite La Chrom liquid chromatograph, equipped with an automatic injector, a refraction index detector (IR) and a UV detector. The analytical method was easy to calibrate thanks to commercial models or patterns (Table 1), and even the x axis of the resulting chromatogram (tr<12 minutes) could inform us regarding the molecular size of each AVMP fraction. To calibrate said x axis, there are various gel permeation chromatography standards that exist on the market. The obtained analytical results are indicated in Table 2.

Table 1. Analytical data of the method applied (HPLC-UV/IR)

Compound	***Tr (minutes)**	**Calibration equation**	**Detector used**
AVMP, fraction A ($n=n_1$)	7.7	C (ppm) = $2.3287x10^{-3}$xA – 11.0760 (R^2=0.9997)	IR
AVMP, fraction B ($n=n_2$)	9.9	C (ppm) = $2.3348x10^{-3}$xA – 7.5463 (R^2=0.9998)	IR
AVMP, fraction C ($n=n_3$)	11.2	C (ppm) = $2.4906x10^{-3}$xA – 28.4463 (R^2=0.9930)	IR
Monosaccharides (Man + Glc + …)	11.5	**C (ppm) = $1.3904x10^{-3}$xA +2.3326 (R^2=0.9998)	IR
Aloe-emodin (II)	14.8	C (ppm) = $2.2651x10^{-5}$xA + 4.7377 (R^2=0.9969)	UV
Barbaloin (IIIa) + Isobarbaloin (IIIb)	19.1	C (ppm) = $2.2140x10^{-5}$xA + 5.7822 (R^2=0.9996)	UV

*The retention times of fractions A/B/C of AVMP can fluctuate with the n value.

Conclusion

Aloe vera produces a juice (latex+gel) that's composed of three fractions of muco-polysaccharides (**I**) of different molecular sizes, and two aloin fractions, constituted by aloeemodin (**II**), barbaloin (**IIIa**)/ and isobarbaloin (**IIIb**) compounds. An HPLC–UV/IR method was set up to verify the presence of both fractions (AVMP and aloin). It has the necessary specificity, precision, accuracy, and linearity to resolve the major industrial problems. Fresh *Aloe vera* leaves were collected monthly and analyzed. The concentration of AVMP fluctuated throughout the year and yielded an annual average of 5500 ± 700 ppm, whereas the aloin fluctuated during the same period yielding an average value of 464 ± 17 ppm.

Abstract

Among the most commonly consumed meat in the Morocco, lamb meat plays an important role as both a fresh or like a processed product. Kourdass is a traditional meat product made with lamb intestines, liver, lung and fat. The meat is sliced, salted, spiced and coated in the rumen before exposed to the sun for drying. Currently, a lot of works show the quality of several dried meat products through the studying of different parameters, such as the amine content. These compounds are produced naturally by animal, plant and microorganism metabolism. Furthermore, there are not enough data about kourdass. The aim of this work was to study changes in the content of biogenic amines during the ripening of kourdass. Trials of kourdass-making were carried out in a laboratory with a traditional procedure. Batches of six kilograms, each containing fresh sheep meat, were purchased directly from a slaughterhouse. The batches were sampled at different times to follow up the modifications in the amine contents. During ripening, the total amine content increased significantly ($P < 0.05$). The results indicated that spermine and tyramine were the most abundant biogenic amines in the fresh meat. Together with tryptamine, these compounds make up the majority at the end of the manufacturing process. Histamine and agmatine levels remained very low throughout repining, and exhibited no quantitatively relevant changes. Total content of biogenic amines was 101.72 mg/kg. It is low in comparison with other meat products. In conclusion biogenic amines quantification indicates the hygienic quality of manufacturing processes.

Key words: *Lamb meat, Biogenic amines, Kourdass, Food quality.*

Introduction

It is well known that the North African countries have an important and ancient tradition in food technology. And although the diet in these countries is typically Mediterranean (Benkerroum, 2013; Alexandratos, 2006; Padilla *et al.*, 2005), it is very influenced by religion. The halal food market has grown strongly over recent decades (ITC, 2015). But the relation between halal product, with respect to slaughter ritual, and the economic difficulties to some small producers, makes doubt about the quality and safety of this kind of food. Traditional meat products represent an important group among Halal products. They are characterized by handmade manufacturing usually in small-scale units, following spontaneous fermentation by their particular microbiota. Salting, sun-drying and using spices and herbs were added to these traditional meat products, initially to provide flavour and aroma. But they also contribute to the improvement of food safety and keeping quality (Benkerroum, 2013).

One of them is the Kourdass. It is a traditional meat product made in Morocco. The biochemical and microbiological phenomena that take place throughout the manufacturing process are responsible for the organoleptic quality of the final product. The lack of knowledge about these changes, the heterogeneity of the product and the questionable quality of some units prevent its diffusion to wider markets. Biogenic amines are basic nitrogen compounds usually formed by decarboxylation of free amino acids. Elevated concentrations of biogenic amines must be avoided, not only because of the unfavourable effects on flavor. They are dangerous for human health. Biogenic amines affect blood pressure, and excessive quantities in food can trigger migraines, gastric and intestinal problems and allergic responses in sensitive people (Stratton *et al*., 1991; Taylor, 1985; Smith, 1981). During ripening of meat products, the proteins undergo degradation processes. Large peptides are first generated and then degraded into oligopeptides, and these are in turn degraded to free amino acids. And these last degradation products are then catabolised, giving rise to different compounds such as ammonia, α-ketoacids, methylketones and amines. In meat products, formation of biogenic amines is largely associated with the activity of microorganisms present in meat (Paulsen and Bauer, 1997; Shalaby, 1996). In raw-cured sausages, microorganisms of the *Enterobacteriaceae* family have been revealed to have a high capacity for producing biogenic amines, particularly putrescine and cadaverine (Bover-Cid *et al.*, 2001; Silla Santos, 1998). Ripening of sausages provides conditions that are very favourable for the production of biogenic amines, due to the active growth of microbial populations, acidification and proteolysis. Different measures have been taken with the aim of preventing or minimizing formation of biogenic amines during the manufacture of raw-cured sausages, such as improved hygiene in production plants, the use of starter cultures formed by lactic acid bacteria with acidifying capacity, and the use of certain preservatives (Bover-Cid *et al*., 2001). Although such practices usually reduce the production of biogenic amines, they do not totally prevent the production, and moreover, the increased proteolysis that results from the use of starter cultures may actually increase the availability of amino acids precursors. Complete inhibition of biogenic amine formation during production of sausages, without any adverse effects, is desirable. However, production of biogenic amines is an extremely complex phenomenon that depends on several variables such as the growth kinetics of the microorganisms and their proteolytic and decarboxylase activities. In order to design strategies for specific inhibition of the production of these compounds, it is essential to obtain information about the potential production of biogenic amines by the microorganisms present in fermented meat products and about the growth phase during which maximum production takes place. This work forms part of a wider study of both the microbiological and biochemical processes that occur during the manufacture of kourdass. And the main objective of the present paper was to obtain information about the changes in biogenic amine content during the manufacturing process.

Materials and methods

Samples

Fresh sheep loins and rib meat were purchased from the slaughterhouse of Tangier (Morocco). A total of 6 kg of meat was used in the elaboration of two batches of kourdass. All meat was allowed to mature for 24 h at room temperature (around 25°C). After this time, the meat was cut into small pieces, were salted and spiced with garlic, pepper, paprika, coriander and cumin. Finally, it was allowed to macerate for 24 h. Firstly The seasoned meat was, wrapped with the rumen and then were sealed with the intestine. Each roll was sun-dried for 20 days. All the determinations were performed within 20 days of drying.

In each batch, samples were taken before beginning of the ripening process and after 2, 4, 8, 12, 16 and 20 days of sun-ripening. Each sample consisted of one whole kourdass piece. Once in the laboratory, outer casing was removed and the rest of the meat product was minced.

Biogenic amines determination

Separation, identification and quantification of the biogenic amines were carried out by HPLC, following the procedure described by Eerola et al. (1993), with a Spectra System chromatograph (Thermo Finnigan, San José, CA, USA) equipped with a SCM 1000 degasser, a P4000 pump, an AS 3000 automatic injector and a Photodiode Array UV6000LP detector. Separation of the different biogenic amines was carried out on a reverse phase C18 mod Kromasil 100 column (25 cm, 4 mm ID) (Teknokroma S. Coop. C. Ltda., San Cugat del Vallés, Barcelona, Spain). The temperature of the column was 40 ± 1 °C and the wavelength of the detector 254 nm. The chromatographic conditions used are described in Table 1; a solution of 0.1 M ammonium acetate was used as eluent A, and acetonitrile as eluent B.

Table 1. Chromatographic conditions used in the determination of the biogenic amines.

Time (min)	**Flow (mL/min)**	**% Eluent A**	**% Eluent B**
0	1.00	50	50
19.00	1.00	10	90
20.00	1.00	50	50
30.00	1.00	50	50

A standard solution containing appropriate amounts of agmatine, tryptamine, 2-phenylethylamine, putrescine, cadaverine, histamine, tyramine, spermidine, spermine and 1,7-diaminoheptane (as internal standard) was used to quantify the biogenic amines present in the samples.

All the samples and standards were injected at least in duplicate in different days. Repeatability tests were performed by injecting a standard and a sample consecutively six times in a day. Reproducibility tests were also carried out by injecting the standard and the sample twice a day for three days, under the same experimental conditions. There were no significant differences ($P < 0.05$) in the results obtained in these tests.

Samples were analysed in triplicate and the results were expressed as an average value in mg/kg. All statistical analyses were performed using the Statistica 5.1 computer program for Windows (Statsoft Inc, Tulsa, OK, USA). Significant differences between samples were determined using an analysis of variance (ANOVA) followed by Fisher's least-significant difference (LSD) test.

Results and discussion

The changes in the content of biogenic amines during manufacture of kourdass are shown in Table 2. The main biogenic amines in the fresh pieces were spermine, followed by tyramine and tryptamine. The average total biogenic amines content increased significantly ($P < 0.05$) from 28,0±3,53 mg/kg in the fresh pieces to 101,7±10,2 mg/kg at the end of the sun-drying stage In general, the accumulation of biogenic amines at the end of the ripening was low. The content of each biogenic amine showed great variability at each sampling time. And the total amine concentration (101.7 mg/kg) was lower than other meat products evaluated for different authors. For example, Dos Santos *et al.* (2015) studied some Italian-type salami brands sold in Niteroi (Brazil) and they found total levels over 303 mg/kg.

Tyramine and spermine were the main biogenic amines in all samples. This result coincides with the profile of amines reported by Trevino *et al.* (1997) in cervelat sausage, but with a lot differences about their contents. Tyramine is one of the most relevant vasoactive amines present in food (Paulsen *et al*., 2012). In kourdass, it increased during the sun-drying. Although, the concentration after 20 days of sun-drying were 30.5 mg/kg. And it is lower than contents of Spanish sausages, such as “chorizo” (76.5-477.8 mg/kg) and “salchichón” (67.5-465.2 mg/kg) (Hernández-Jover *et al*., 1997).
The sum of vasoactive biogenic amines (VBA) is considered as a good indicator of practical and high-quality handling in the preparation of meat products. The limit of VBA is considered 200 mg/kg (Eerola *et al.*, 1998). In the case of our study, no samples exceeded this limit and the final product showed values around 60.6 mg/kg.

Table 2. Changes in biogenic amine content (expressed as mg/kg) during the sun-drying process of kourdass (average values ± standard deviation).

Biogenic Amines	0	2	4	8	12	16	20

a–g Values in the same row (corresponding to the same parameters) not followed by a common letter differ significantly ($P < 0.05$); ND: No Detected; VBA: Sum of tyramine, histamine, tryptamine, and 2-phenylethylamine

Spermine appears naturally in fresh meat (Lorenzo *et al.*, 2007). It is the second more concentrated in Kourdass (25.62 mg/kg). This result was in accordance with the reported by Eerola *et al.* (1998) in finish dry sausages (19-48 mg/kg).
Histamine and agmatine were not detected at the first sampling point. Agmatine not was found until 12 days of ripening, with final content around 0.28 mg/kg. While, histamine was detected after two days of sun-drying. Although, its content was not raised too much in the final product (0.90 mg/kg). Histamine is toxic when large doses enter the circulatory system (FAO/WHO, 2013). Nevertheless, there is no regulation on the limit content of histamine.
Cadaverine and putrescine are two other biogenic amines found in fermented meat products. Lorenzo *et al.* (2008) found important concentrations of putrescine and cadaverine in Spanish traditional sausages, such as “androlla” (215.4 mg/kg and 232.4 mg/kg, respectively). Their results were significant higher than the contents obtained in kourdass. On the other hand, the cadaverine content is similar to the range values reported for Hernández-Jover *et al.* (1997) in “chorizo” (3.9-34.9 mg/kg) and for Shalaby (1993) in Egyptian dry sausages (5.6-38.5

mg/kg). Putrescine contents, showed by these authors, were higher than the results in kourdass.

Conclusion

Meat sausages, free of biogenic amines and without any adverse effects, are desirable. However, the synthesis phenomenon of these compounds involves several variables difficult to control. In order to design strategies for specific inhibition of the production of amines, it is essential to obtain information about the presence of these compounds in fermented meat products and about the ripening phase during which maximum production takes place. In all case, the amine content in kourdass is lower than values reported for a more meat products with a high consumption. These results indicate that kourdass, made with ribs and loins of lamb, meets the safety and quality requirements demanded by the consumer.

Abstract

The essential oils of seeds of anise, cumin, fennel and parsley provided from Saudi Arabia were extracted by hydrodistillation, and analysed by GC and GC-MS. The percentage yields of the essential oils from seeds were 0.81%, 1.28%, 0.64 % and 0.52% v/w, respectively. The major constituents varied depending on species. The oil was colourless to pale-yellow in colour. More than 90% of the studied essential oils constituents were identified. It seems that there were partly similarities among chemical compositions of the four essential oils. In some of essential oils, the main constituents accounted for more than 60% of total oil, e.g., anise and fennel (E-anethole 93.00% and 62.63%, respectively). The main components were E-anethole (93.00%), γ-himachalene (2.85%), methyl chavicol (1.13%) and appiol (0.22%) in anise oil; E-anethole (62.63%), fenchone (13.27%), methyl chavicol (11.19%) and limonene (7.98%) in cumin oil; β-pinene (36.46%), γ-terpinene (36.29%), p-cymene (10.43%), terpinene-7-al-γ (3.48%), sabinene (2.02%) and α-pinene (1.92%) in fennel oil and α-pinene (39.27%), β-pinene (29.61%), limonene (9.73%), myristicin (6.70%), appiol (4.75%), myrtenal (1.82%) and sabinene (1.59%) in parsley oil.

Key words: *spice seeds, essential oil, composition, methyl chavicol, E-anethole,* anise (*Pimpinella anisum*), cumin (*Cuminum cyminum*), fennel (*Foeniculum vulgare*), Parsley (*Petroselinum crispum* Mill.)

Introduction

Parsley (*Petroselinum crispum* Mill.) is a biennial plant growing to 0.3-0.6 m long. It is frequently used as a garnish or as a flavoring in salads and many cooked dishes and also used for medicinal purposes (Akgül, 1993; Özcan, 2004). The dried leaves known as parsley flakes are particularly used in the instant food sector as an ingredient to flavor soups and sausages (Soysal, 2004). Fennel (*Foeniculum vulgare*) is a perennial or annual herbaceous and a typical aromatic plant that grows in several regions all over the world (Özcan et al. 2006; Özcan & Chalchat, 2006). Fennel oil is used in cooking and for correcting less pleasant odours and flavours in oral and medicinal preparations (Baytop, 1984; Akgül, 1986). Fennel has been prescribed as a muscle relaxant, a weak diuretic, carminative and a mild stimulant (Duke, 1988). There are usually considerably variations in the major components of *Foeniculum vulgare* Mill. subsp. *piperitum* (Ucria) Count fruits in north of France were reported to be limonene (52.4 and 56.9 %), piperitenone oxide (21.5 and 14.2%) and γ-terpinene (12.1 and 5.1 %) (Badoc et al. 1994). In previous investigation on the essential oil of *F. vulgare* subps. *piperitum* fruits, methyl chavicol (47.09 %), limonene (29.07 %), fenchone (13.43 %) and fenchly acetate (exo) (1.95 %) were found to be the major

components (Özcan & Akgül, 2001). Many species of *Pimpinella* L. (Apiaceae) are agronomically important, particularly those with distinctive aromas and flavours. The most widely known and cultivated *Pimpinella* species is *P. anisum* (Crellin & Philpott, 1990; Tabanca et al. 2003). In addition, essential oils of some *Pimpinella* species have been used to treat sedative, antidepressant, carminative, antiseptic, diuretic, mutagenic, pectoral, tonic and stimulant properties (Ross et al. 1980; Twaij et al. 1987; Miller & Murray, 1998). Different species of *Pimpinella* can be annuals, biennials and perennials and are generally characterised by the presence of fibrous collars at the top of the root stock (Matthew, 1972).
The aim of this study was to determine the essential oil compositions of *P.anisum, P.crispum, F.vulgare and C.cyminum* growing in Saudi Arabia.

Material and Methods

Plant fruits (anise, cumin, fennel (sweet) and parsley) were provided from Saudi Arabia in June 2013. The plant was identified by Dr Dural and a voucher specimen (SA1, SA2, SA3 and SA4) was deposited at the herbarium of Selçuk University, Faculty of Agriculture, Department of Food Engineering, in Konya, in Turkey. The aerial parts of anise, cumin, fennel (sweet) and parsley plant seeds were extracted by using a Clevenger type apparatus for 4 h. The obtained essential oils (0.81%, 1.28%, 0.64 % and 0.52%, respectively; v/w) were dried over anhydrous sodium sulfate, and stored at -18 ^{o}C until GC/MS analysis. The essential oil were analysed on a Agilent gas chromatograph Model 6890, equipped with a DB5 MS column (30 m X 0,25 mm, 0,25 µm), programming from 50°C (5 min) to 300°C at 5°C/ min, 5 min hold. The essential oil is diluted in hexane: 1/30. The essential oil were analysed on a Agilent gas chromatograph Model 7890, coupled to a Agilent MS model 5975, equipped with a DB5 MS column (30 m X 0.25 mm, 0.25 µm), programming from 50°C (5 min) to 300°C at 5°C/ mn, 5 min hold. Helium as carrier gas (1,0 ml/min); injection in split mode (1: 100); injector and detector temperature, 250 and 280°C respectively. The essential oil is diluted in hexane: 1/30. The components were identified by comparing linear Kovats indices (KI), their retention times (RT) and mass spectra with those obtained from the authentic samples and/or the MS library. The percentage composition of the essential oil was computed from GC peak areas without correction factors (Adams, 2001).

Results and Discussion

The essential oils analysed by GC/MS for determination of their components and results are given in Table 1 as a relative peak area of each constituent.

The oil yields of the seeds of anise, cumin, fennel (sweet) and parsley were 0.81%, 1.28%, 0.64 % and 0.52%, v/w, respectively. A total of 18, 19, 22 and 24 compounds which account for about 99.70%, 99.95%, 99.26 % and 99.48 % of the essential oils of anise, cumin, fennel and parsley, respectively. The oil was colourless to pale-yellow in colour. More than 90% of the studied essential oils constituents were identified. It seems that there were partly similarities among chemical compositions of the four essential oils. In some of essential oils, the main constituents accounted for more than 60% of total oil, e.g., anise and fennel (E-anethole 93.00% and 62.63%, respectively). The main components were E-anethole (93.00%), γ-himachalene (2.85%), methyl chavicol (1.13%) and appiol (0.22%) in anise oil; E-anethole (62.63%), fenchone (13.27%), methyl chavicol (11.19%) and limonene (7.98%) in cumin oil; β-pinene (36.46%), γ-terpinene (36.29%), p-cymene (10.43%), terpinene-7-al-γ (3.48%), sabinene (2.02%) and α-pinene (1.92%) in fennel oil and α-pinene (39.27%), β-pinene (29.61%), limonene (9.73%), myristicin (6.70%), appiol (4.75%), myrtenal (1.82%) and sabinene (1.59%) in parsley oil. Romeilah et al., (2010) reported that parsley oil contained 18.23% apiol, 16.16% alpha-pinene, 11.16% beta-pinene and 3.23% limonene. The same researchers determined 60.01% cuminaldehyde, 6.12% caryophyllene oxide, 4.89% β-pinene, 4.11% geranyl acetate and β-caryophyllene in *Cuminum cyminum* seed oil (Romeilah et al. 2010). Arslan et al. (2004) determined that essential oil content of *P.anisum* leave varied from 1.3 to 3.7%. The major compounds of *Pimpinella tirupatiensis* are beta-bisabolene (9.2%), delta-3-carene (8.9%), cis-carveol (6.7%), elemol (5.8%), delta-cadinol (4.4%), methyl-geranate (4.3%) and gamma-nonalactone (3.4%) (Bakshu and Raju,2002). The major component of the essential oil of *P.anisum* was *trans*-anethole (78.63-95.21%) (Arslan et al. 2004). Başer et al. (1992) reported that cumin seed oil contained 19.25-27.02% cuminaldehyde, 7.06-14.10% alpha-terpinene, 4.61-12.01% p-cymene and 2.98-8.90% beta-pinene. Arslan et al. (1989) reported the percentage of anethole to be 86 to 88% in sweet fennel oil and 74% in bitter fennel oil while limonene was only 4 and 2% respectively in sweet and bitter fennel oil. These results are in agreement with many authors like the following; the E-anethole was found as the main component in anise and fennel oils (Damayanti and Setyawan, 2012); the main compound of parsley seeds was alpha-pinene in cumin oil was determined as a dominant compound (Başer et al. 1992; Li and Zi-Tao, 2004; Behera et al. 2004). It was reported that the chemical composition of oils are very variable according to seed oils. The environmental conditions and nutritional status of the plant caused to this fact. Plant varieties effected oil chemical contents, composition of oils.

Conclusion

The seeds of anise, cumin, fennel and parsley contained 0.81%, 1.28%, 0.64 % and 0.52% v/w essential oils, respectively. The main components were E-anethole (93.00%) in anise oil; E-anethole (62.63%), fenchone (13.27%) in cumin oil; β-pinene (36.46%), γ-terpinene (36.29%) in fennel oil and α-pinene (39.27%), β-pinene (29.61%) in parsley oil.

Abstract

Antifungal activities of *Salvia sclarea* L. on *Fusarium oxysporum* f. sp.*radicis-lycopersici* Jarvis & Shoemaker and *Verticillium dahliae* (Kleb.) were investigated in 2017 year. The plant essential oil was hydro-distilled in Clevenger's apparatus from the air-dried aerial parts. Plant essential oils at 0.5, 1, 2, 4, 8 µl/petri dishes concentrations were applied to determine their inhibition effects on mycelium growth of plant pathogenic fungi under laboratory conditions. Petri dishes were incubated at 25±2 ^{o}C for 7 days. Mycelium growth was measured by digital calipers and the inhibition rates were calculated. The *S. sclarea* essential oil caused inhibitory effects on mycelium growth of plant pathogenic fungi. Antifungal activity displayed differences according to increasing essential oil concentration and fungi. According to the results, mycelium growth of *Verticillium dahliae* and *Fusarium oxysporum* f. sp.*radicis-lycopersici* was decreased with increase in dose of *S. sclarea* essential oil. The mycelium growth of *Verticillium dahliae, Fusarium oxysporum* f. sp.*radicis-lycopersici* was decreased at 8 µl/petri dishes concentration, 46.49%, 39.06% respectively. In conclusion, this study has been shown that *S. sclarea* essential oil has a phytotoxic effect on plant pathogenic fungi.

Keywords: *Antifungal activity, essential oil, Salvia sclarea, sage.*

Introduction

V. dahliae is a soil borne wilt disease which possess economic importance for various agricultural products (Demirci and Genç, 2009). The disease gets more fundamental because no fungicide exists to recover the plant infected with *Verticillium* and no specific symptoms have been determined (Rus et al., 2015). An additional disease which limits the production on the total cultivated area is the fungal disease caused by soil borne *Fusarium* spp. *Fusarium* spp. not only causes paleness in several products, but also produces mycotoxin in stored wheat. Even if pathogen is not a host plant for long periods of time, it can conserve its endurance. Chemicals are not preferred because soil borne diseases do not have an effective chemical control and its negative impact of the used chemicals on soil, human and non-target organisms in the surrounding (Sharma et al., 2017).

Thus, various applications are implemented in addition to alternative cultural precautions instead of synthetic pesticides used for chemical control. Studies are conducted on plant metabolites and plant based medicines which are considered to be less harmful to human health and the environment than synthetic pesticide which is one of these applications (Shaaya et al., 1991; Kordali et al., 2007; Kordali et al., 2009; Urzúa et al., 2010; Onaran 2016). Therefore, studies on the effect of different plant extracts and essential oils embodied in the flowering aerial parts on plant diseases are prioritized. Plant essential oils and extracts are of

potential use in the control of plant diseases because they have not shown a negative effect on human health and environment, and no problems on residues of the products were observed.
Comprised of distinctly different components and having a complex mixture, plant essential oils can be found in several plant families (Karasu and Öztürk, 2014). Lamiaceae is one of the families which includes fundamental medical flavour plants (Mamadalieva et al., 2017). The Lamiaceae family comprises of 236 species, including the Salvia species, and 7133 types (Harley et al., 2004). Possessing rich essential oil content, the Salvia species contain 900 types (Tohma et al., 2016). 95 types of the Salvia species exist in Turkey with an endemism rate of 51%. *Salvia sclarea* L., which is two-year, shortlived or perennial and can grow up to 1 m (Özer, 2016), is one of the most demanded Mediterranean plant types (Dogan et al., 2015). Salvia species are commonly used in cosmetics perfumery, food industry and medicine (Yilar and Kadioglu, 2016). Previous biological studies have reported that the Salvia species are antibacterial, antifeedant, antioxidant, antiviral, antimicrobial, antifungal and herbicidal (Kawahara et al., 2004; Fraga et al., 2005; Lakhal et al., 2013; Tada et al., 1994; Karcıoglu et al., 2011; Abu-Darwish et al., 2013; Uremis et al., 2009).
The present study explored the potential of antifungal *S. sclarea* essential oils on *Fusarium oxysporum f. sp.radicis-lycopersici* jarvis&shoemaker and *Verticillium dahliae* (Kleb.) which are significant plant pathogens.

Material and Methods

Plant Material and Extraction of Essential Oils: S. sclarea plants were obtained during their flowering stage in the 2015 vegetation period in the Province of Tokat. The essential oil of the shadow-dried plants was retrieved with the use of the neo-clevenger device and hydro-distillation method. The obtained essential oils were preserved at +4 °C until the activity work.
Fungus Cultures: The fungi of plant pathogen used in the study (*Verticillium dahliae* and *Fusarium oxysporum* f. sp.*radicis-lycopersici*) were obtained from the stock cultures in Phytopathology laboratories of the Department of Plant Protection, Faculty of Agriculture, Ahi Evran University.
Antifungal Testing: The prepared PDA’s were poured into 60 mm plastic petri, 10 ml per petri. Sterile blotting paper were attached on the petri capsules and the specified doses (0.5 µl, 1 µl, 2 µl, 4 µl, 8 µl) of essential oil were soaked by the blotting paper with the help of micropipettes. 10 µl sterile purified water was soaked as the control group. The petri were sealed with paraffin film and left for incubation at 25 ^{o}C. The development of mycelium of the diseases was measured with a digital caliper seven days after the application. The application was replicated three times and repeated two times. The percentage of interference rate of the essential oils was calculated according to the formula below.

$$MGI=100\times(DC-DT)/DT$$

I: Blocking percentage compared to the control (Mycelium development)
DC: Mycelium development in the control
DT: Mycelium development in essential oil applications

Results and Discussion

The results of the antifungal effect of *Salvia sclarea* essential oil on *Fusarium oxysporum f. sp.radicis-lycopersici* Jarvis & shoemaker and *Verticillium dahliae* (Kleb.) were presented in Table 1.
An antifungal effect was found in the tested fungi of plant pathogen from *Salvia sclarea* essential oils. The negative effect on the development of mycelium was positively related to the dose of the oil applied. No effect was observed of *S. sclarea* essential oils on mycelium development of *V. dahliae* in 0.5 and 1 µl/petri doses. However, the *V. dahliae* mycelium development was inhibited in the doses of 2, 4 and 8 µl by 26, 16, 37.50 and 46.50 %, respectively (Table 1).
Similar results were noted with the plant pathogen *Fusarium oxysporum f.sp. radicis-lycopersici*. Yet, it was found that this pathogen is more sensible to plant essential oils than *V. dahliae.* The lowest antifungal effect of the S. *sclarea* essential oil on the *Fusarium oxysporum f.sp. radicis-lycopersici* mycelium development was observed to be in the 0.5 µl/petri doses with an interference rate of 1.81, and in the 8 µl doses with an interference rate of 39.06 (Table 1).

Table 1. The effect of *Salvia sclarea* essential oil on the mycelium development of *Fusarium oxysporum f. sp.radicis-lycopersici* jarvis&shoemaker and *Verticillium dahliae* (Kleb.)

Plant essential oils and essential oil components possess antimicrobial activities which enable their use as biofumigant against several pre- and post harvest diseases of economically important plants (Siripornvisal, 2010). Consequently, the present study revealed the antifungal activities of S. *sclarea* essential oil of important plant pathogens.
Similar studies were conducted by various researchers on *Fusarium oxysporum f. sp.radicis-lycopersici* and *V. dahliae*, and the antifungal effects of plant essential oils were reported. Besides the change of plant essential oils and extracts of *Salvia officinalis, S. cryptantha* and *S. tomentosa* on the mycelium development of *Fusarium oxysporum f. sp.radicis-lycopersici* based on the increasing doses, extracts and essential oils, antifungal activities were observed (Yilar and Kadioglu, 2016). Yilar et al. (2016) stated that the *Vitex agnus-castus* L. and *Myrtus communis* L. essential oils interfered the development of mycelium of *Fusarium oxysporum f. sp.radicis-lycopersici* and *Verticillium dahliae* by 70.70%-100%; 93.00%-100%, respectively, compared to the control group. In a similar study, the *Heracleum platytaenium* Boiss essential oil inhibited the development of mycelium of *V. dahliae and Fusarium oxysporum f. sp.radicis-lycopersici* in the 10 µl doses by 73.25% and 100%, respectively (Bayan et al., 2016).
Additionally, Arslan and Dervis (2010) revealed that the *Origanum onites, O. syriacum, O. minutiflorum, O. vulgare, O. marjorana, Thymus vulgaris, T. serpyllum, Rosmarinus*

officinalis, *Salvia officinalis* and *Micromeria fruticosa* essential oils inhibited the mycelium development of *Verticillium dahliae*. Likewise, it was reported that the *Origanum majorana* L. essential oil inhibited the development of mycelium of *Verticillium dahliae* in the 0.5 $mg \cdot L^{-1}$ and 1 $mg \cdot L^{-1}$ doses, and the MIC concentration of this disease was 5 $mg \cdot L^{-1}$(Rus et al., 2015).

Conclusions

The results of the present study revealed that the *S. sclarea* essential oil possesses an antifungal effect on *Fusarium oxysporum f. sp.radicis-lycopersici* and *V. dahliae.* These and similar results of studies is of great importance in today's development of the negative effects of pesticides, which are commonly used in the control of fungal plant pathogens in agricultural products, on the environment and human health.

Abstract

Soil-born fungal diseases cause significant losses in strawberry culture and *Fusarium* is one of the most important among them. The present study was conducted to investigate *Fusarium* species causing wilting in strawberry plants. Morphological and molecular detection of different *Fusarium* species related to wilting diseases in strawberries was objective of the study. The fungal isolates were collected from the main strawberry growing areas in Anamur and Silifke districts of Mersin province, Gazipaşa and Aydıncık districts of Antalya province, and Sultanhisar district of Afyon province. Total of 300 samples were analyzed morphologically and 39% of them found infected with *Fusarium* species. The pathogenicity of six morphologically distinct *Fusarium* isolates were tested utilizing root dipping to spore suspension method using strawberry variety ''Festival''. After pathogenicity tests, total DNA from mycelial cultures of six *Fusarium* isolates were extracted and ribosomal DNA ITS region was amplified using ITS6/4 primers by PCR. The amplicons were sequenced and obtained DNA sequences were blasted in NCBI and Fusarium ID GeneBanks. The sequences of all morphologically identified *Fusarium* isolates showed 99-100% identity with the *Fusarium* species deposited in NCBI. Furthermore, the investigated *Fusarium* species were identified as *Fusarium oxysporum,* and *F. proliferatum* according to NCBI but *F. incarnatum-equiseti* species complex and *F. concolor* according to Fusarium ID.

Key words: *Fusarium* spp., ITS, Molecular diagnosis, Pathogenicity, PCR, Strawberry.

Introduction

The strawberry (*Fragaria* spp.) belongs to family *Rosaceae*. It is a perennial plant with an herbaceous characteristic. It can be grown in a wide variety of ecological conditions of the world due to their high adaptability (Stewart and Folta, 2010). Since 1960's, strawberry is grown as economical crop in Turkey. Maas (1998) reported that soil-borne fungal pathogens are the most destructive diseases causing quality and quantity decrease in strawberry production in the world, and the most detrimental ones are i.e., *Colletotrichum, Pythium, Rhizoctonia*, *Phytophthora* and *Verticillium* genera and *Fusarium oxysporum* f. sp. *fragariae* is considered responsible for causing wilting in strawberries. Black root rot disease caused by *Rhizoctonia*, *Pythium*, *Cylindrocarpon* and *Fusarium* species is also known as a root disease complex affecting strawberry production worldwide and causes significant yield losses (Martin 2000, Manici *et al* 2005). *Fusarium* species can adapt various kinds of climatic conditions and are responsible to cause various diseases in targeted crop. In case of severe infection, yield losses can reach up to 50 percent in strawberry (Maas, 1998).

The correct identification and diagnosis of targeted pathogen is one of the important steps towards management practices (Khiyani *et al*., 2014). Although, the conventional fungal identification methods are also significant but also have various limitations. Because achieving the results in such techniques requires both experience and time, and the results could vary according to the investigators (Garcia *et al*., 2013). The recent advances in molecular biology helped in developing new identification methodologies and simultaneously have also enabled the rapid and reliable identification of fungi. Nowadays, PCR and DNA sequencing based techniques are being widely used for fungal identification (Arvanitis *et al*., 2014).

In molecular studies of fungal genomic system, 18S rDNA and Internal Transcribed Spacer (ITS) in ribosomal DNA (rDNA) are the most preferred genomic regions. ITS, is a non-encoded region, that evolves more rapidly and is suitable for comparing fungal species within same races of species (Schoch *et al*., 2012). Such advancement in molecular methods has enabled accurate disease diagnosis of fungi in a short period by minimizing the chances of misidentification. For this reason, present study was designed to diagnose *Fusarium* species from the collected strawberry samples by using PCR technique.

Materials and Methods

The *Fusarium* isolates have been isolated from strawberry plants showing wilting symptoms. The plants were collected from Anamur and Silifke districts of Mersin province, Gazipaşa and Aydıncık districts of Antalya province, and Sultanhisar district of Afyon province during 2014 (Figure 1). The roots of wilted plant samples were washed under tab water and root samples (1-2 cm) were taken using sterile blades. The root samples were kept in 0.5% sodium hypochlorite solution for 5 minutes and washed three times with distilled water for surface sterilization, after drying of the samples they were incubated at 27°C for 5-7 days on Petri dishes containing potato dextrose agar (PDA) media having 100 mgL^{-1} streptomycin sulfates. Microconidia or macroconidia were collected from developed colonies and transferred to new petri dish containing (PDA) for purification purpose. Pure cultures were obtained from the colonies of *Fusarium* isolates by the single spore isolation method (Choi *et al*., 1999). The samples from pure culture were preserved in tubes containing PDA at 5°C for further studies.

Figure 1. *Fusarium* isolates studied in this research

Pathogenicity Test

The pathogenicity test was conducted on strawberry plants (variety Festival) by using 6 *Fusarium* isolates possessing different morphology. The selected isolates developed on PDA at 25 °C for 7 days before pathogenicity test. The spore suspension was adjusted to 1×10^6 conidia by counting hemocytometer. The roots of strawberry plants were cut to 6 cm length and immersed in spore suspension for 30 mins. The control plants were immersed in sterile water. Following inoculation, plants were planted with a pot of 15 cm in diameter containing a mixture of peat:perlite (1: 1). The pots were maintained under controlled conditions at 27 ± 2◦C and 12:12 h light:dark photoperiod and irrigated regularly. The experiment was set up in three repetitions and repeated two times. The pathogenicity was evaluated using 0-5 scale (0 = no symptom, 1 = 1-2 leafs yellowed, 2 = all leaves deformed, 3 = chlorosis and early plant wilt, 4 = necrosis and all plant wilted, 5 = dead plant) two months after inoculation (Nam *et al*., 2009). The scale data was evaluated by Oneway- ANOVA statistical analysis. Re-isolation of the fungi was carried out from the roots and crowns of the inoculated plants.

Molecular analysis

The fungal DNA extraction was performed using the DNA extraction kit according to the manufacturer defined protocols (Qiagen). The concentration of DNA was measured using spectrophotometer (Thermofisher®) and adjusted to 20 ng/µl. A total of 50 µl PCR reaction mixture included 5 µl of 10 mM dNTPs, 3 µl of 50 mM $MgCl_2$, 5 µl of 10 µM Primer ITS6 and ITS4, 0.5 µl of Taq DNA polymerase (Invitrogen) and 3 µl of DNA. The amplification condition was pre-denaturation at 94 °C for 3 mins, 35 cycles consisting of 30s at 94 °C, 30s at 55 °C and 60s at 72 °C, followed by 10 mins at 72°C for final extension. The PCR product was electrophoresed on 1.5% agarose gel. The staining was performed using Ethidium Bromide solution. The visualization was performed under UV.

The obtained DNA amplicons were directly sent to a DNA sequencing company (Medsantek, Istanbul) for DNA sequencing from both ends. Sequence assembly of forward and reverse contigs of DNA sequences were performed by Mega 7 software (Kumar *et al*, 2016). The final obtained consensus sequences were searched by Basic Local Alignment Search Tool (BLAST) option of National Center for Biotechnology Information (NCBI).

Results and Discussion

The *Fusarium* isolates were confirmed according to the shape and color of mycelium developed in culture. These isolates were; A39- dark, thick vein and purple color, A28-light, thin vein and pinkish purple color, E27-fine vein and purple color, G02-fine vein and purple color, E26-thick vein and purple color, E30-thick vein and purple color (Figure 2). Spore size of *Fusarium* isolates prepared in Lam-lamel preparation was determined by micromicroscope. A39 - 6x3 µm, E26 - 5x2 µm, E27 - 7x3 µm, E28 - 5x3 µm, E30 - 9x3 µm, and G02 - 6x2 µm (Figure 3).

Figure 2. *Fusarium* culture and fungi isolated root samples.

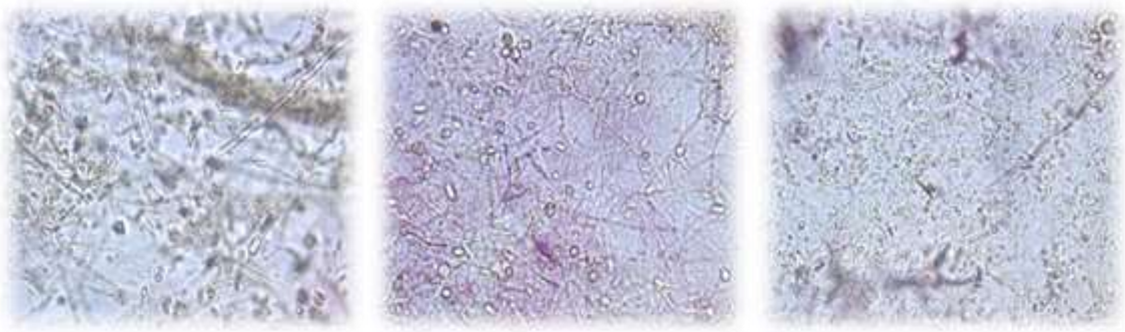

Figure 3. *Fusarium* microconidia and macroconidia.

In pathogenicity tests, the strawberry plants inoculated with *Fusarium* isolates were dead in two months. Root rot and discoloration of sectional cross of crowns were observed on diseased plants (Figure 4). According to statistical analysis, there is no significant differences among the variations because the significance value was lower than 0.05. The experiment is homogenous and the all isolates were pathogenic due to causing the disease on experimental plants.

Figure 4. Pathogenicity tests of *Fusarium* isolates (left) and root and crown symptoms of *Fusarium* isolate (right).

The DNA concentrations of the *Fusarium* isolates obtained from DNA extraction were varied as 22-107 ng/µL. After the PCR analysis, 600 bp length amplicons were obtained on agarose gel (Figure 5). The consensus nucleotides were A39 463 bp, E26, E27 and E28 542 bp, E30 and G02 556 bp after trimming and contig assembly. Among these isolates A39, E28, E26 and E27 were 99.94%, E30 and G02 were 99.82% identical by multiple alignment analysis. The all six sequence multiple alignment analysis exhibited 96.33% identity. As a result of the blast analysis of the consensus sequences in NCBI database, A39, E28, E27, E30 isolates exhibited 99% identity with *F. oxysporum*, E26 and G02 isolates had 99% identity with *F. proliferatum* isolates (Table 1). However, blast analysis in Fusarium ID database diagnosed our isolates as a different *Fusarium* species from NCBI database. By this analysis, A39, E28, E27, E30 isolates matched with *F. incarnatum-equiseti* species complex in 94.84-95.59% range of identity. E26 and G02 isolates had 96.95% and 97.22% identity with *F. concolor* isolates, respectively.

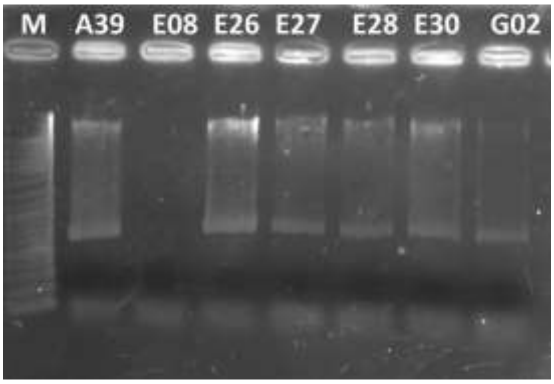

Figure 5. PCR amplification of Fusarium isolates using ITS6 / ITS4 primers.

Isolate name / sequence length	NCBI Blast Analysis	Sequence coverage / Identity (%)	Fusarium ID Blast Analysis	Sequence coverage / Identity (%)
A39, 463 bp	*F. oxysporum*	(1-463 bp) 100	*F. incarnatum-equiseti* species complex	1-463 bp 94.84
E26, 542 bp	*F. oxysporum*	(1-542 bp) 99	*F. incarnatum-equiseti* species complex	(1-542 bp) 95.59
E27, 542 bp	*F. oxysporum*	(1-542 bp) 99	*F. incarnatum-equiseti* species complex	(1-542 bp) 95.41
E28, 542 bp	*F. oxysporum*	(1-542 bp) 99	*F. incarnatum-equiseti* species complex	(1-542 bp) 95.59
E30, 556 bp	*F. proliferatum*	(1-556 bp) 99	*F. concolor*	(1-359 bp) 96.95
G02, 556 bp	*F. proliferatum*	(1-556 bp) 100	*F. concolor*	(1-359 bp) 97.22

Table 1. The results of Blast analysis in two different database.

Conclusions

The rDNA genes have been commonly used in identification and taxonomic studies. In this study these genes were confirmed to be particularly appropriate for the purpose of providing target sequences for molecular detection. So this study is helpful to understand the actual cause as well as the causal organism of the disease and can further support and strengthen the fact that *Fusarium* sp. is the actual causal organism of this disease. As we provided different results by blasting different databases, the further studies have to be conducted on focusing the other gene sequencing such as Beta tubulin, translation elongation factor 1 –alpha, and calmodulin.
