FOREWORD

A Word from the Editor

The successful implementation of the 2030 Agenda for Sustainable Development and the achievement of the Sustainable Development Goals depend on progress in agriculture. Agriculture has far-reaching implications in terms of poverty eradication, food security, health and wellbeing, biodiversity, climate change and economic development.

The most important goal of the 8^{th} International Agriculture Symposium “AGROSYM 2017” – held in Jahorina on 05-08 October, 2017 – was to promote sustainability principles in agriculture. Sustainable agriculture is an important element of the overall effort to make human activities compatible with the demands of the earth's eco-system. Thus, an understanding of the different approaches to ecological agriculture is necessary if we want to utilize wisely the planet's resources. One of the goals of the sustainable agriculture movement is to create farming systems that eliminate, or at least mitigate, environmental harms associated with industrial agriculture. That aim can be realized only with context-specific agro-ecological practices; these depend on regional characteristics, climate conditions, soil types as well as socio-cultural, institutional and political settings.

AGROSYM 2017 made an important contribution to agriculture science and practice. Symposium themes cover all branches of agriculture and are divided into seven sessions: 1) Plant production, 2) Plant protection and food safety, 3) Organic agriculture, 4) Environment protection and natural resources management, 5) Animal husbandry, 6) Rural development and agro-economy, and 7) Forestry and agro-forestry.

During the four-day Symposium approximately 250 papers were presented orally and 1030 as posters. The contributions, representing the current research in different countries, were presented to more than 1300 participants from more than 85 countries. We are encouraged by the great success of this year’s edition of AGROSYM 2017.

This publication is comprised of an edited selection of over 400 papers submitted to AGROSYM 2017. Each paper included in the present Proceedings was positively reviewed by two referees. Full texts of the submitted communications are also available online (http://www.agrosym.rs.ba). Some selected papers will be published in AGROFOR International Journal (http://www.agrofor.rs.ba/), International Journal "Agriculture and Forestry" (www.agricultforest.ac.me) and EcoPersia (www.ecopersia.modares.ac.ir). Many thanks to all the authors, reviewers, session moderators and colleagues for their help in editing the Proceedings. The results reported here will contribute to the dissemination of knowledge to the wider audience about the importance of agri-food science; one of the most important areas of research strategies in Europe and beyond.

AGROSYM 2017 was made possible through the commitment and contributions of a wide range of partners and sponsors. I take this opportunity to thank all of them and I look forward to a successful joint organization of AGROSYM 2018.

1. PLANT PRODUCTION

THE EFFECT OF CUTTING ON GRAIN AND FORAGE YIELD OF TWO OATS SPECIES IN LOWLAND OF ALBANIA

Abstract

The aims of this study were: a) to find the appropriate time of cutting for better grain and forage yield, and b) to determinate the most suitable species for dual use. The experiment was conducted during 2015 and 2016 at ATTC Fushë Krujë, according to the randomized completed block with four replications. In the study, there were species*:* *A. sativa* (cv. "Këmishtaj") and *A. byzantina* (cv. "Flavia"). Variants were: without cutting; a cutting when the plants were 30 cm height; two cuttings, the first when the plants were 30 cm and after renewal at the same height; a cutting when the plants were in the stem elongation stage. The following traits were determined: the number of plants before and after cutting, the height of plant, number of grains/panicle, grain weight/panicle, grain and forage yield. Cutting reduced the values of the studied traits. The most decrease of traits value was found in the variants with two cuttings and one cutting at intensive stem elongation. The number of plants decreased respectively by 5% and 10%, and the weight of grains/panicle at 34% in two variants for the specie *A. sativa,* 45% and 49,7% for the specie *A. byzantina*. Grain yield was higher in variant without cutting and species *Avena sativa* (58.6 kv/ha). The data showed that the better indices for dual use were taken in the variant with a cutting at 30 cm height, in both studied species.

Keywords: *Avena sativa, Avena byzantina species, forage, cutting, grain yield.*

Introduction

In Albania, livestock farming is the main activity in agriculture which provides 56% of the agricultural income (Statistical yearbook 2013). Increasing livestock has increased the need for nutrition in quantity and quality. For this reason, the area planted with forage has been significantly increased.

In the structure of arable plants, the forage occupies 52% of the area or 200,000 ha. From this alfalfa (*Medicago sativa*) occupies the largest area with about 120 thousand ha, while the rest is planted with annual forage crops such as berseem clover (*Trifolium alexandrinum*), ryegrass (*Lolium multiflorum*) and oats (*Avena* sp.). Among them the largest area is sown with oats about 50 - 60 thousand ha (25-30% of the area planted with forage crops) (Statistical yearbook, 2013). The forage production and forage quality of oats are determined by numerous interacting factors, namely, environment, management practices, and genetics (Brundage et al., 1979; Elizalde et al., 1999; Firdous and Gilani 2001). Environmental factors such as temperature, precipitation, location, etc. strongly influence forage production and quality (Kim et al., 2005). In the conditions of Albania, where farm size is small and irrigation opportunities are scarce, farmers are not able to grow spring crops, which have high demand for water. Therefore, autumn crops are one of the best and most economical opportunities to cope the livestock needs for the food not only in critical periods but throughout the year. Oat is an important winter food, mainly as a green food, but the surplus becomes silage or hay for use during periods of food deficit (Suttie and Reynolds, 2004). Also, as a forage crop, it has its advantages compared to other forage crops, because it has faster growth, and provide high quality fodder for all animal categories. In Albania, oats are cultivated both in the continental climate zone and in the mild Mediterranean climate. In mountainous areas, with continental climate, it is cultivated mainly for grain production, while in the lowland area it is cultivated for green fodder, hay and grain production. Also in the lowland area, there is a cultivation practice for dual use, where it is first used for green fodder (grazing or cutting) and then left for grain production. In some cases, the food deficit during the critical winter period and the beginning of spring, leads to misused of oats crop. So, in many cases happened intensive grazing of oats, very low cutting or cutting very late when the plants are at the stem elongation stage. Such practices make that grain production is significantly reduced. There are many reports of work done regarding the oat management practices for fodder production in mild climate areas. Management practices such as harvest time (Kim et al, 1999), fertilization (Johnston et al., 2004; Pradhan, L. and S.N. Mishra 1994) and etc. found that they affect the quantity and quality of oat fodder production. However, in Albania there are no such studies and much more, studies related to its utilization practices for dual use. The aims of this study were: a) to find the appropriate time of cutting for better grain and forage yield, and b) to determinate the most suitable species for dual use.

Materials and methods

The study was conducted during 2015 and 2016, in the experimental field of ATTC Fushë Krujë, Albania, located between 34^{o}28'20 "N and 19^{o}40'38" E in Mediterranean climate conditions. Two species were found in the test: *A. sativa* (cultivar "Këmishtaj" oat landraces) and *A. byzantina* (cultivar "Flavia"). Variants were: (a) no cutting; (b) a cutting when the plants reach a height of 30 cm (tillering stage); (c), two cuttings, the first when the plants have reached the height of 30 cm and the other after renewal at the same height; (d) a cutting when the plants were in the stem elongation stage (at 2-nodes stage). The experiment was conducted according to the completed randomized block design with four replications. Each variant had a size of 10 m^2 (5m x 2 m) and in each variant 10 rows were planted. The spacing between the rows was 20 cm. Planting was done on 07/11/2014 and on 03/11/2015. Planting was carried out by hand the seed rate was 130 kg/ha. In basic fertilization, before planting, granulated superphosphate was used at 80 kg/ha P_2O_5, while nitrogen fertilization at 90 kg/ha N was applied during vegetation. The number of production tillers/m^2 (PT) was done before harvest. Counting was done directly on the field by counting them in two middle rows at 3 m long, and on this basis calculating the number of production tillers/m^2 using the formula: Number of productive tillers/m^2 (PT/m^2) = (total number of productive tillers in two rows in length 3 m)/3x2x spacing between rows. The height of the plants (HP) was measured at the time of harvest in ten random plants for each variant. For the number of grains and the weight of grains/panicle (GP, WGP), at the time of harvest, 10 random plants were taken and analysed in the laboratory. The fodder production was evaluated at the time of cutting by weighing each variant separately. One kg green fodder sample at cutting from each variant was collected at random for dry matter estimation. The samples were weighed, dried in an oven at 60^{o}C for 48 hours and again weighed to calculate the dry matter yield (DMY) for each cutting. Grain yield (GY) was evaluated at harvest time by weighing each variant separately.
Variance analysis (ANOVA) and student test was used to identify the significant differences between species and treatments.

Results and discussion

Plant height

The highest plant height, for both species, is observed in variant (d) when plants are harvested only once in the steam elongation stage (at 2-nodes stage), (Table 1). In the variant (b) with a cutting and variant (c) with two cuttings the height of the plant has been the same, inasmuch as the cutting criterion was set when the plants reached the height of 30 cm. But the cutting time was not the same for two species. The first cutting of species *A. sativa* was made about six days faster than the species *A. byzantina*. This is explained by the fact that their growth habit is different. Cultivars of *A. sativa* species are characterized by the erect growth habit, while *A. bizantina* species are characterized by the prostrate growth habit. Since growth and development are directly influenced by climatic conditions, mainly temperature and humidity, cultivars with prostrate growth habit are likely to require more temperature for growth, hence characterized by later development, while cultivars with the erect growth habit, *A. sativa* species, have fastest initial growth (Kipps, 1970; Poehlman, 1987; Stuart et al., 2002).

Dry matter yield

The data showed that the two species tested had statistically significant difference in forage production (Table 1, Figure 1). Forage and dry matter production increased with advancing stages of plant development. In both species *A. sativa* and *A. byzantina*, the highest fodder production, was reached in the variant (d) with a cutting when the plants were in the steam elongation stage, respectively 45.46 kv/ha and 42.08 kv/ha. The lowest fodder production green mass and dry matter was carried out in the variant (b) with a cutting in tillering stage. Also in the variant (c) with two cutting the forage production was lower than in the variant (d) with a cutting at the stem elongation stage. The lowest production in these two variants (b) and (c) can be explained by the fact that the plants at the time of the cutting were in the early vegetative growth stage (tillering stage).

Table 1. Average plant height and dry fodder yield (average of two years in cutting variants)

Species	Plant height (cm)			Dray matter yield (kv/ha)			LSD	
	b	c	d	b	c	d	0.05	0.01
A. sativa	31	30.5	74.9	19.9	34.42*	60.6**	6.34	14.55
A. byzantina	30	31	81.3	11.85	34.92**	53.17**	6.34	14.55

b- a cutting when the plants reach a height of 30 cm (tillering stage); c- two cuttings; d- a cutting when the plants were at the stem elongation stage.

Number of productive tillers

The largest number of productive tillers/m^2 was recorded in the variant without cutting and, respectively, for the *A. sativa* species 409 tillers and *A. byzantina* 448 tillers per m^2 (Table 2). In variants with cutting, for both species in the study, it was recorded decrease in the number of tillers/m^2. The smallest number of productive tillers/m^2 was recorded in the variant with a cutting in the stem elongation stage, while the decrease in the number of productive tillers with a cutting at the tillering stage was slight. Specifically, in both species, the decrease in tillers numbers compared to the variant without cutting was 5% for the variant with two cutting and 10% for the variant with a cutting in steam elongation stage. This decrease in the number of productive tillers is explained by the fact that, after cutting, some tillers did not renewal.

Number of grains and weight of grains/panicle

The study showed that there were differences in the numbers of grains and the weight of grains/panicle as between species and variants. The largest number of grains/panicle (107grains) and their weight/panicle (2.8g) were recorded in variant without cutting in species *A. sativa* (Table 2). Also, the results showed that the number of grains and the weight of the grains/panicle decreased in the variants with cutting, but the greater this decrease was in the variant (d) with a cutting at the stem elongation stage, and in the *A. byzantina* species. Thus, in the *A. sativa* species, in the variant (b) with a cutting at tillering stage, the number of grains decreased by 8.6% and their weight by 9%, in the variant (c) with two cuttings the number of grains decreased by 18.2% and weight 34% while in the variant (d) with a cutting at stem elongation stage the number of grains decreased by 18.4% and their weight by 34%, compared to the variant without cutting. In the *A. byzantina* species, in the variant (b) with a cutting at tillering stage, the number of grains decreased by 11% and their weight by 12%, in the variant (c) with two cuttings the number of grains decreased by 23% and weight 45% while in the variant (d) with a cutting at stem elongation stage the number of grains decreased by 24% and their weight by 49.7%, compared to the variant without cutting. This is explained by the fact that oats are very sensitive to high temperatures and drought. High temperatures above 30^{o}C, as well as warmer winds during the flowering stage, increase the percentage of aborted flowers, leading to a reduction in production (Kashta et al. 2010). For the variants of cutting, critical stages, such as flowering and maturity, passed through high temperature and lack of optimal humidity due to the fact that the development stages in these variants were delayed by approximately 6 to 7 day for the variants of two cuttings and 9 to 10 days for the variant with a cutting at the stem elongation. This was reflected in the low grain production in these variants.

Table 2. Number of producer tillers/m^2 (PT), number of grains/panicle (GP), weight of grain/panicle (WGP) and grain yield (GY)

Factor	***A. sativa***				***A. byzantina***			
	PT	GP	WGP (gr)	GY (kv/ha)	PT	GP	WGP (gr)	GY (kv/ha)
a	409	107	2.6	58.6**	448	68	2.2	47.5**
b	400	98	2.4	44.1**	443	62	1.9	35.05**
c	388*	87.5	1.7	18.7**	426*	52.4	1.21	14.9**
d	368**	86.6	1.7	18.4**	403**	51.7	1.1	14.55**
LSD 0.05	13.992			4.0704	26.235			4.0704
LSD 0.01	25.696			7.4752	48.18			7.4752

a-no cutting, b- a cutting when the plants reach a height of 30 cm (tillering stage); c- two cuttings; d- a cutting when the plants were at the stem elongation stage.

Grain yield

Statistical analysis showed that in grain yield there were significant differences between species and variants in the study for both levels of probability. The highest yield of the grain was recorded in varieties without cutting and in the *A. sativa* species (58.6 kv/ha) (Table 2, Figure 2), whereas the lowest yield (14.55 kv/ha) for variant (d) with a cutting at the stem elongation stage, in the *A. byzantina* species. Whereas, from the comparison of data for grain yield between cutting variants, the highest yield was made in the variant with a cutting at tillering stage for both species in the study. Decrease of yield in variants with cutting is explained by the fact that the production elements such as the number of productive tillers, the number of grains and the weight of grains/panicle were reduced. The same thing is reported by other researchers. Morris and Gardner (1958) found that clipping, oats, rye, and wheat as late as February 15 decreased grain yields only slightly, but grain yield were reduced by 75 % or more when clipping was extended another month.

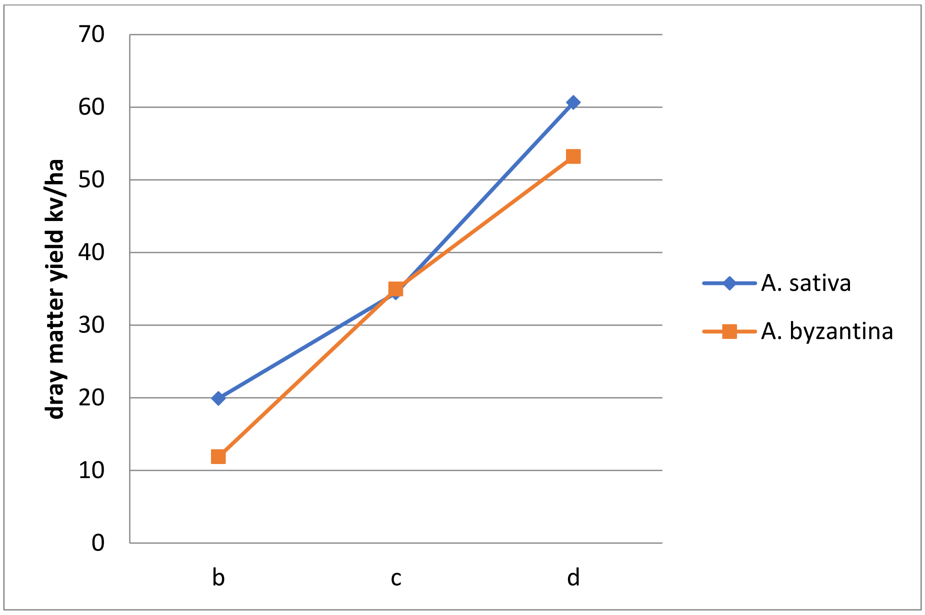

Figure 1. The impact of the species and method of utilization in forage yield

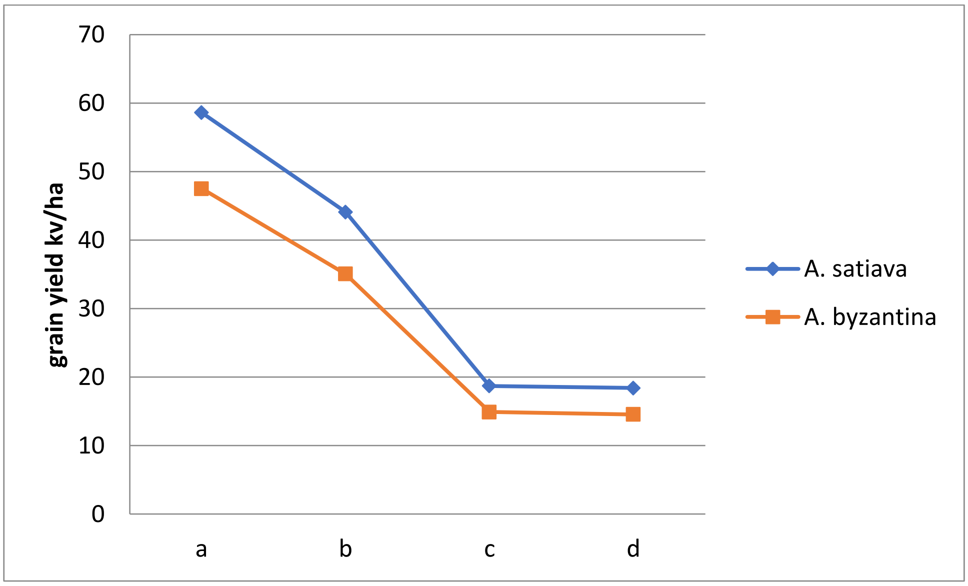

Figure 2. The impact of the species and method of use in grain yield

Conclusion

The results of this study showed that between species there were significant differences for the grain yield, and in forage production. Based on the obtained results, the *A. sativa* species is superior to *A. byzantina* species both in grain and fodder yield. For dual use the best variant for both species resulted the variant (b) with one cutting when the plants are at the tillering stage.

CLIMATIC CONDITIONS, YIELDS AND PLANT PRODUCTION IN ALGERIA

Amel BOUZID*

Centre for Research in Applied Economics for Development, Division of Agriculture, Territory and Environment, Algiers, Algeria.
*Corresponding author: ambzdz@yahoo.fr

Abstract

The Algerian population is growing. We increasing passed from 23 million in 1987 to 40 million in 2016. This population growth induced a significant increase of the in food demand. Despite the fact that Algeria has abundant areas and favorable climatic conditions, the cultivable area is still representing only 3.5% of the total area of the country. Thus, the Algerian agricultural production is still far from covering meeting the local food demand of the population. That makes the country dependent of the international market, especially for sugar, oil and wheat. In the present work, the author intends to contribute to the understanding of the slow growth of the plant production in Algeria and its strong dependence on the climatic conditions and yields.Our analysis will be aimed to give a general review, and also to show the specificity of the three aggregates of the vegetation production: cereals (wheat, oat and barley), pulses (chickpea) and industrial crops and market gardening (industrial tomato, potato). In final, we will conclude by giving some recommendations to improve the efficiency of the public policies aiming to promote agriculture.

Key words: *Algeria, climate, yields and production, cereals, potato, chickpea, industrial tomato*

Introduction

The role of agriculture is crucial in these aspects. First, to offer food to people without constraints and also to provide individuals with an income allowing them to live and buy various products in society. (Bouazouni, 2008). FAO reports indicate that the vulnerability of developing countries will be increased. This is driven by a number of factors, including climate change, international finance and the globalization of certain staple foods. In the present work, we intend to contribute to the understanding of the slow growth of the plant production in Algeria and its strong dependence on the climatic conditions and yields. Our analysis will be aimed to give a general review, and also to show the specificity of the three aggregates of the vegetation production: cereals (wheat, oat and barley), pulses (chickpea) and industrial crops and market gardening (industrial tomato, potato).

Material and Methods

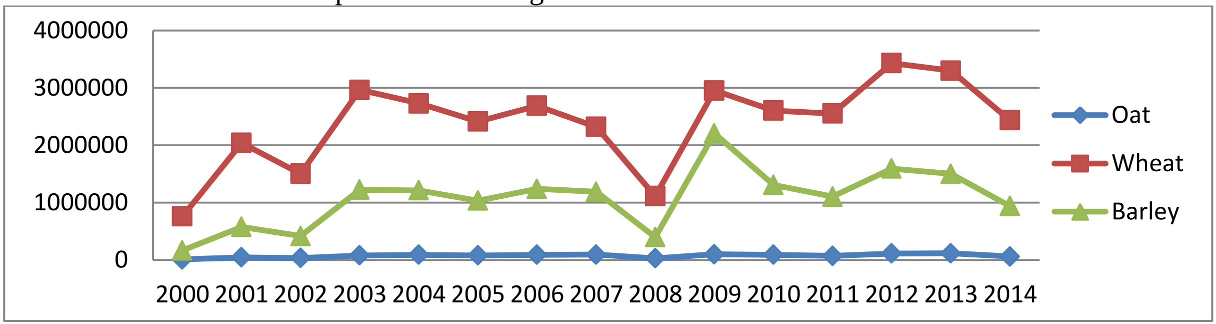
To answer our working hypothesis, data on production, production areas and yields were collected from the Ministry of Agriculture and Fisheries and from the FAO site. A bibliographical search was also carried out to enrich our work with the research that has already been done to explain the variation of productions. On the other hand, it was difficult to collect data precipitation at the National Center for Climatology in order to measure the impact of rainfall on yield increases.

Results and Discussion

1-Cereal production:

Cereals and their derivatives constitute the staple food in many developing countries, particularly in the Maghreb countries. Consumption of cereal products is at a level of about 205 kg / capita / year (Chehat, 2007). The production of cereals, including fallow, occupies about 80% of the utilized agricultural area (UAA) of the country, the area planted in cereals annually between 3 and 3, 5 million hectares. The area harvested annually represents 63% of the area planted. It therefore appears as a dominant speculation. (Djemoum, 2009). According to the RGA, 2001, this crop is practiced by the majority of the farms (60% of the total population associated with the fallow) and it is present on all the bioclimatic stages, including in the Saharan zones.

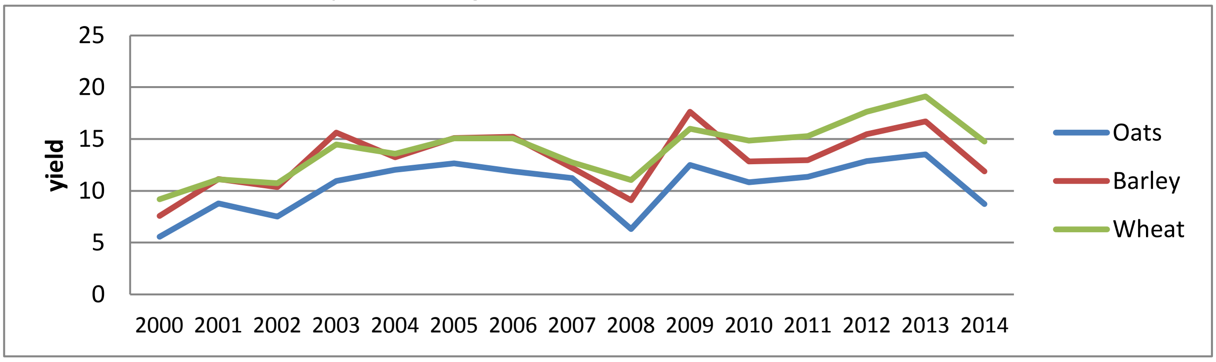
Graf. 1: Evolution of cereal production in Algeria



Source: FAO

Cereal production in Algeria is marked by a strong irregularity, which is conditioned by climatic hazards. Thus, over the last 40 years, recording a gap of 1 to 5 from a calamitous year (9.7 million q in 1994) and a year of abundance (52.5q million in 2009). However, technological and economic progress, if they fail to stabilize production in the sector, has allowed it to increase significantly: the decadal average almost doubled between 1981-90 (18.2 million q) and 2001 -2010 (34.9 million q), With a steady progression which allowed to accompany the demographic progression (from 19 to 38 million inhabitants between 1980 and 2012).(Chehat,2007). The average production of cereals last 5 years (2008-2012), who was just over 32 million quintals according to FAO, consists of 19 million quintals of wheat (60%) and 13 million quintals of barley (40%). Wheat production is divided between durum wheat (70% in 2012) and soft wheat (30%).

Graf. 2: Evolution of cereal yields in Algeria



Source: FAO

Generally well adapted to local conditions, its production is progressing at the same rate as that of soft wheat (+ 47% between the five-year averages 2000-2004 and 2008-

2012).Compared with + 84% for barley, which remains higher than soft wheat, at more than 13 million quintals in 2008-2012, compared with 8 for soft wheat and 19 for durum wheat. Despite undeniable progress, cereal yields remain low and very irregular: 1.35 t per ha for wheat on average for 2001-2010 (durum wheat, better suited to local agro-climatic conditions, enjoys significantly higher yields). And 1.32(t ha^{-1}) for barley, which is far behind the productivity of the Mediterranean countries of Europe and can be explained both by natural causes (soil and climate), techniques (seeds, cultural practices) and human (Organization and training of producers). Algeria also has a strong "regionalization" of production conditions and thus contrasting harvest levels from East to West. (Chehat, 2007)

2. Production of potato:

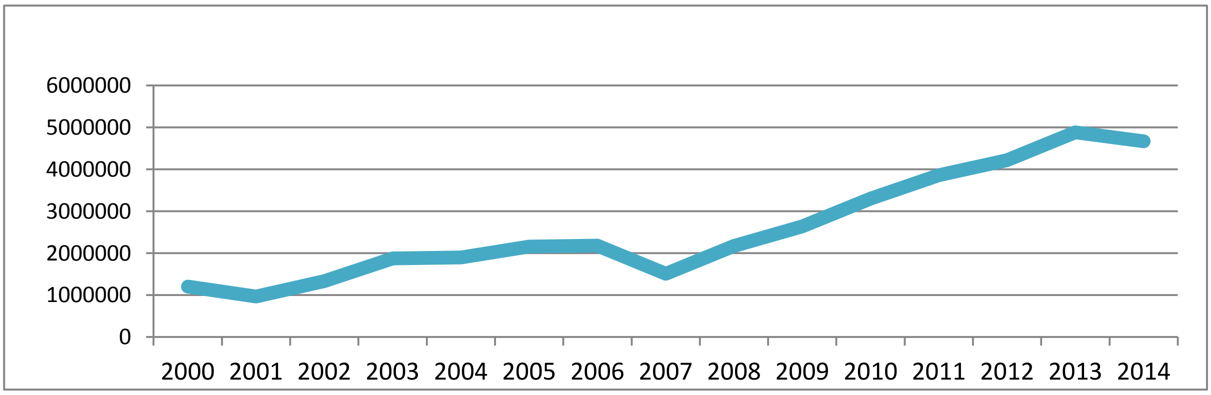
Unlike cereals, potato is cultivated throughout the country, including in the oasis of the south, but if we retain only fifteen department where it occupies more than a thousand hectares, it will be possible to distinguish in the zones of the littoral and the sublittoral three production basins having for wilaya pivot Mascara in the West, Aïn-Defla in the Center and El Oued in the South East (Tria and Chehat, 2013).Tria and Chehat (2013) added that over the past five decades, the potato has gained a place in the food consumption model alongside wheat and milk.

-The seasonal crops (plantation from January to March) dominating both by the area occupied (70 000 ha on average during the last quinquennium or 51% of the areas) and their participation of total production.

- Those of the back season (plantation July - August) which occupies the second place with 47 500 ha, ie 45% of the areas.

-Early vegetables crops (planted from October to November). They occupy only a minor place (less than 5000 hectares) in all the areas and production. Difficulties in setting up and the higher risks incurred by farmers explain the decline in the area used for early potatoes.

Graf. 3: Evolution of potato production in Algeria



Source: FAO

The climate will be the determining factor for the farmer's choice. Thus, the option for the early potato will depend on the rainfall and the severity of the temperatures at the time of the establishment of the crop. The option for backyard potatoes will depend on irrigation possibilities since planting takes place in summer, a dry period in all regions of the country. Only seasonal potatoes are less dependent on climatic hazards, although in most cases irrigation will be required to ensure a good development of the plant.

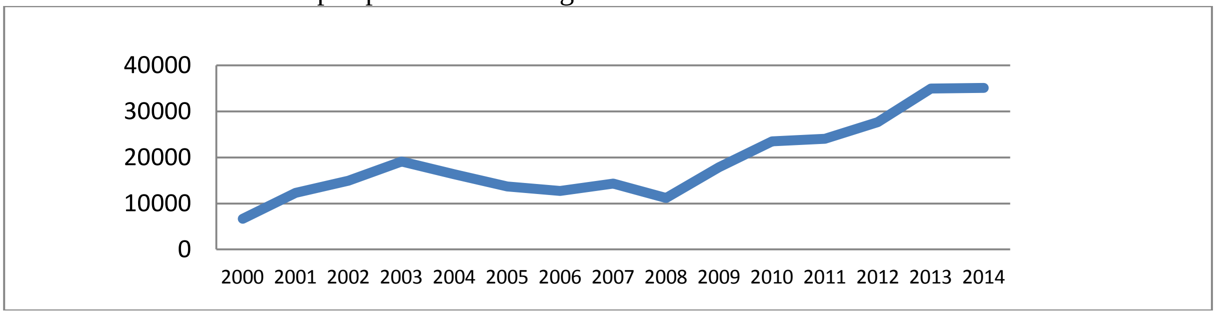
Over the last half-century, yields have initially experienced a long period of almost constant regression, with crops being largely produced on farms in the public sector (D.A.S). If this regression had not been offset by an extension of the area (80 000 ha compared to 18 000 ha), this could have led to serious supply problems on the national market.

The rate of improvement in yields slowed somewhat since 2001 but still high compared to most other vegetable crops. The highest performance (over 25 t / ha) were obtained in the western basin wilaya (Chlef), two departments of the central basin (Ain-Defla and Algiers) and one department of the Eastern basin (Mila). The highest yield is obtained in 2012 or the yield exceeded 30T / ha. (Tria and Chehat, 2013)

3. Production of chickpeas:

For a long time, the chickpea is present in our farming systems associated with cereals which it leaves significant amounts of nitrogen in the soil. However, the local agro-economic constraints mean that the production of this crop remains very low with the area constantly decreasing, while the needs are constantly increasing. This situation results in almost total dependence on imports (Labdi and al., 2007).

Graf .4: Evolution of chickpea production in Algeria



Source: FAO

Over the last ten years, production of chickpea has declined significantly with a very good production in 2010 (23 473 t). This decline can be explained in part by the reluctance of farmers to plant this species, due to the poor performance recorded in previous years.

4. Production of industrial tomatoes:

Industrial tomatoes are mainly grown in the north-east of the country: the departments of El Tarf, Annaba, Guelma and Skikda account for 90% of the total area devoted to this crop in Algeria.

Table 1. Average yields and harvested area of industrial tomato in Algeria

Average annual yield (t ha^{-1}) and harvested area (ha) of industrial tomato in Algeria						
Period	1971-1980	1981-1990	1991-2000	2000-2009	2005-2009	2009-2015
t ha^{-1}	8	9	16	22	26	36
ha	8 110	14 498	28 024	19 471	14 618	25 000

Source: Calculated from statistics MARD

A marked improvement in yields was observed during the period 1971-2015, yields increased from 8 tons / ha in 1990 to 32 tons / ha in 2009 and 40 t / ha at the currently. Despite this evolution, Algerian yields are still low compared to those obtained in many other countries.
The low production can be explained by many factors, other than cultivated and the yields obtained, the changes can be explained by other parameters can be identified. Low yields can be attributed to several causes, including:
-Failure to respect the technical itinerary recommended by cultural specialists (Baci, 1993).
-The lack of rigor of the farmers in respect of the technical itinerary is probably due to the lack of effort in the popularization of production techniques.
- The lack of rigor of the farmers in respect of the technical itinerary is probably due to the lack of effort in the popularization of production techniques. The low level of mechanization of transplanting and maintenance operations increases the load per hectare. (Guedmani, 1993)
- Late and inadequate use of high-performing varieties, particularly certain hybrid varieties whose yield is much higher than that of local varieties. The reason is that hybrids have a high price (150 000-230 000 DA kilogram in 2011, according to market supply state) unlike the price of traditional seed whose price does not exceed 3000 DA / Kg. It should be noted that the cost of purchasing hybrid seed accounts for 22 to 27% of the total cost of production of one kilogram of tomato. (Bouzid et Bedrani,2013)
The lack of irrigation until the end of the 1980s, the irrigation was begun with the commissioning of the Hammam Debagh dam (in the Guelma wilaya). But it was not until 2000 that the policy of supporting water-saving irrigation (by sprinkling and localized) allowed the generalization of irrigation. Before the end of the 1980s, culture was practiced "dry" and undergoing the main cause of the weakness and irregularity of yields.

Conclusions

Algerian agriculture, although placed in relatively difficult climatic conditions, has still untapped potentialities whose development would significantly reduce its food dependence. Since 1961 there has been an increase in crop yields but at what price and at what rate of integration?
Recommendations:
Establish an effective system for collecting and disseminating statistics on all aspects of agriculture and rural development (production, financing, foreign trade, employment, land structures, etc.);
Establish independent institutions for the evaluation of agricultural and rural development Agricultural research is the key to future food.
Algeria devotes to research only relatively weak means, dispersed between too many different themes policies,

Abstract

The economic analysis of winter lettuce production comprised three breeding technologies based on localized drip irrigation and using plants with protected root. These types differed in the applied mulch: a) uncovered area; b) mulching with black PVC film; c) covering with agro textile weight 17 g; d) a combination of black PVC foil mulch and agro textile. The research was done during winter (2009, 2010, and 2011) in a greenhouse with no extra heating. The greenhouse is located on the sample field in the area of the Agricultural Faculty in Eastern Sarajevo. The research comprised Santoro RZ variety. The results showed some variation, depending on the observed parameters, but the combination of mulch and agro textile was proved to be the best material. The most efficeint production is with usage of combination of black PVC film and agro textile. Production of lettuce with technology that includes a combination of black PVC film and agro textile is economically viable. This combination has achieved the rate of profitability of 58.22%

Key words: *winter production of lettuce, mulching, efficiency, effectiveness, protected space.*

Introduction

Modern science pays a lot of attention on winter lettuce, not just because of its high nutritional value, but also because this vegetable has a short period of vegetation and modest demands towards its surrounding, which means that it can be produced during winter when there is the lowest offer supply of fresh vegetables.

On the other side, the earliest supply of fresh vegetables is, at the same time, most expensive. The most economical production of vegetables is one that offers harvest during the period of the lowest supply on the market (Coelho et al., 2005). The lack of this production them is the reason why most people use just seasonal vegetables, while they buy other vegetables just for special occasions or do not buy it at all. It is important to find a balance between demands for quality work, achievement of high quality of vegetables and rational usage of energy, in order to warrant your solutions (Barać, 2004). Nowadays when we produce early vegetables we cover our plants immediately after putting them in the ground or immediately after sowing. According to the research of Đurovka et al. (1996), planting of vegetables by covering plants provides better microclimate conditions, which means faster and more equal growing, development and yielding with better quality of fruit and better crop as well. Manufacturing techniques affect growth rate, total yield, earlier yield and yield quality components (El – Shinaway and Gawish, 2006; El-Behairy et al., 2001). The appropriate covering material can affect energy consumption and energy efficiency of production. Dimitrijević (2007) pointed out that the most important factors one should take into consideration when choose covering material are the variety of the plant, period of the year for the production and climate conditions of the region. In view of the above facts, the objective of the research is to determine which variation of the mulch is economically viable.

Material and method

We researched the variety Santoro *RZ* during winter (2009, 2010 and 2011) in a greenhouse without extra heating in a randomized block design. The greenhouse is located on the sample field in the area of the Agricultural Faculty in Eastern Sarajevo. Seedlings with protected root were replanted in the first decade of October. The distance between them was 20 cm in a row and 30 cm between the rows, resulting in about 150.000 plants/ha. We used a drip irrigation system, put at the same time with mulching. We included the following mulch material in our research: black PVC foil, agro textile (17 g), a combination of black PVC mulch and agro textile. For the analysis of climate conditions in the greenhouse we used standard methods and meteorological equipment. The micro climate measurements included monitoring of daily temperature. We calculated the economic efficiency of the production, including the coefficient (Ek) that was established by the following formula:
Ek = Value of production/Total costs
The profitability of the production was established from the relation of the financial results and the value of production:
$R_{п}$ = profit/value of production *100

In the daily temperature chart (chart 1) one can see that the first and second year of the research (2009 and 2010) had similar and favorable climate conditions comparing with 2011, which was considered to be colder. The temperatures in greenhouse space were directly dependent on the outside temperature. The reason for that was that we did not use heating inside the greenhouse. During the warm days, the difference in temperature was 7.64°C, while during the cold days it was from 2.98 to 3.82°C. On the other side, using different cover materials resulted in the variation in the temperatures between the treatments in the project. Ponjičan (2004) states that in his research the temperature difference under different covering material varied from 6.22°C to 12.71°C.

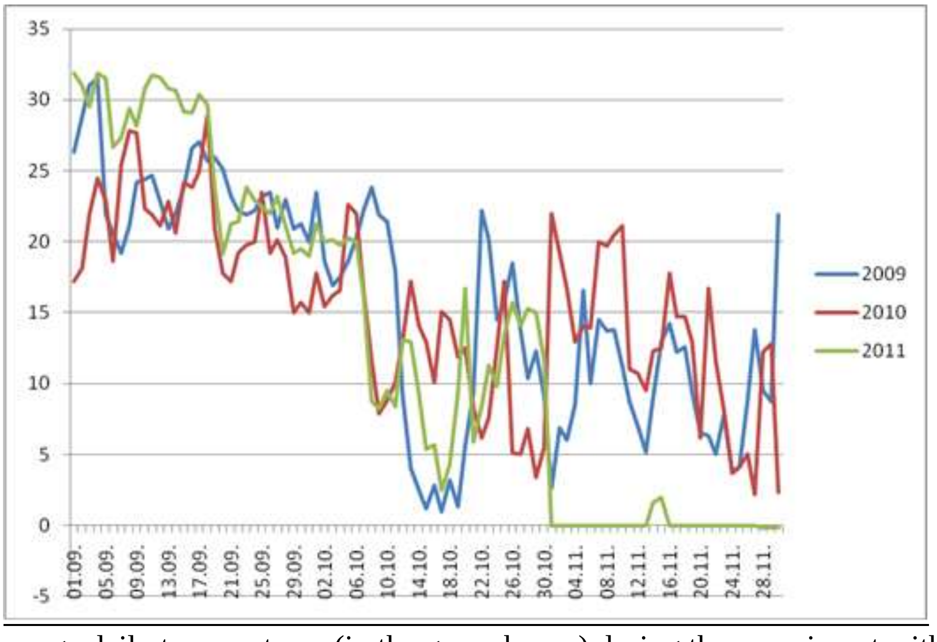

Chart 1. Average daily temperatures (in the green house) during the experiment with production of lettuce

Results and Discussion

Efficiency and profitability of production

The efficiency of production is economical usage of production factors. If the spend of production factors in the process of production for a certain product is lower, then the benefit of this spending is higher and vice versa. It is impossible to express the consumption of different production factors and the volume of the obtained products and services in the same natural units. The efficiency of certain production lines is established on the basis of the ratio of the production value and the value of all consumption factors (Gogić, 2009). Production is more efficient when Ek>1, while it is on the efficiency margin when Ek=1, and it is not efficient when Ek<1. The results are presented in Table 1, showing that the production of lettuce is economically efficient, and if different mulching variants are used, the coefficients are always higher than 1. The most efficient production is with usage of a combination of a black PVC film and agro textile. Using these materials resulted in the highest coefficient of efficiency 2.39.

Table 1. Profitability of production

Mulching material	Production value (BAM/100m^2)	Total costs (BAM/100m^2)	Coefficient of efficiency ***(Eк)***
Land without mulch	854.04	525.32	1.63
Black PVC film	901.14	488.82	1.84
Agrotextile	912.09	478.15	1.91
Combination of film and agro textile	1216.17	508.15	2.39

Table 2. shows the profitability of the production in different methods of lettuce production. The highest rate of profitability was achieved when lettuce was produced with combination of a black PVC film and agro textile, and the lowest rate was achieved on the land without mulch. These results are confirmed by Tošić et al., (2014) who said that the plant growing on the uncovered soil proved to be a bad solution for the total yield achievement. The production of lettuce with a combination of a black PVC film and agro textile achieved the rate of profitability of 58.22%, which means that on every 100 BAM of production the value profit was 58.22 BAM.

Table 2. Profitability of production

Mulching material	Production value (BAM/100m^2)	Profit (BAM/100m^2)	Profitability of production
Land without mulch	854.04	328.72	38.49
Black PVC film	901.14	412.32	45.76
Agrotextile	912.09	433.94	47.58
Combination of film and agro textile	1216.17	708.02	58.22

Economic success with different mulching variants

Chart 2 shows that production of lettuce with technology that includes a combination of black PVC film and agro textile is economically viable. This mulching variant gave the highest profit and income, and when we compare it with other variants it was 40.40% higher than the control, 34.75% than the black PVC film and 33.40% than the agro textile.

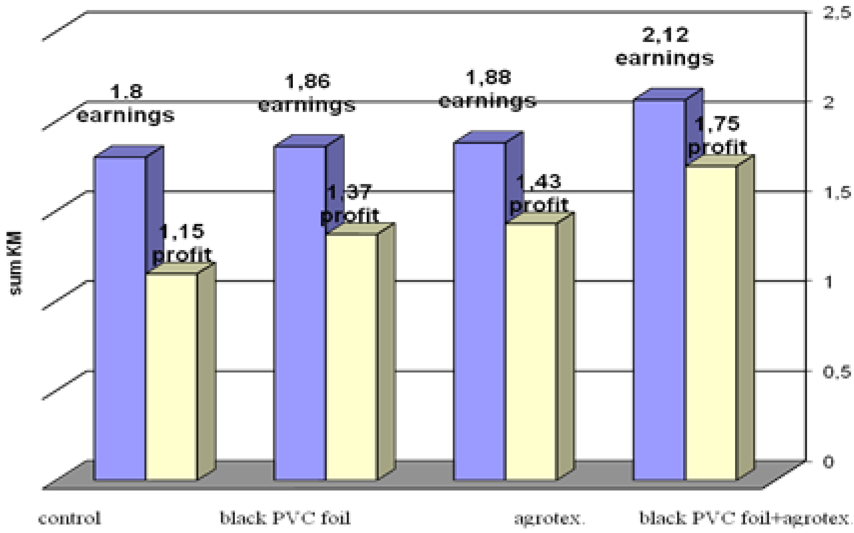

Chart 2. Profit and income per 1kg of the produced lettuce

Conclusion

Based on the three year research (2009-2011), we can recommend the following:

- The production of lettuce is economically efficient, and if different mulching variants are used, the coefficients are always higher than 1.
- A combination of a black PVC film and agro textile is most economical. This variant achieved the highest percentage of profitability and production income.
- The production of lettuce with a combination of a black PVC film and agro textile achieved the rate of profitability of 58.22%.

Abstract

This paper presents the results of the sowing o twine in twin row technology on Family Farm Jovic, Prud, municipality Odzak, Bosnia and Herzegovina, using the MaterMacc Twin row - 2 planter. Two hybrids were used: hybrid P0412 and hybrid BC 525 sown in standard sowing with a row spacing of 70 cm and twin row sowing with a spacing of double rows of 22 cm. Standard sowing was done with the pneumatic sowing machine Gaspardo SP-4, on the April 18th. The standard sowing of hybrid P0412 was performed on a predetermined set of 66355 plants per hectare. The estimated size of the plant was 60705 plants per hectare. The yield of this hybrid, harvested on September 26th, 2016, was 15798 kg with a standard deviation of 303,250 and a coefficient of variation of 1.92%. The yield of corn hybrids P0412 in sowing twin rows made by a set of roasted plants of 60528 plants was 16671 kg / ha or 5.53% more than standard sowing. The standard sowing of the hybrid BC525 was performed on a predetermined set of 66355 plants / ha. The estimate of drowned plants was 62658 plants per hectare. Yield of this hybrid in the berry was 14579 kg with a standard deviation of 1162,311 and a variation coefficient of 7, 97%. The yield of maize hybrids BC525 in sow Twin-row technology with a set of rotten plants of 68515 plants was 16613 kg / ha or 13.95% more than standard sowing.

Keywords: *corn, sowing, twin wheat, yield*

Introduction

Maize (Zea mays L.) is one of the three leading agricultural crops along with wheat and rice, both in the world and in our country. Of all cereals, maize has the greatest fertility potential, that needs to be used in this and future period as well. Maize continues to be traditionally grown on major agricultural areas with different levels of soil fertility, and the reason for that is relatively simple maize cultivation without significant mechanization. Corn sowing in our area is performed at the row spacing of 70 and 75 cm. Recently, scientific research has been conducted for corn sowing in two rows, worldwide known as twin-row technology. Depending on the sowing machine producers, the twin rows are sown on a spacing of 20, 22 or 25 cm, and the central spacing of the adjoining dotted rows is 70 or 75 cm, so that corn harvest can be done with standard maize harvesters. This sowing technology allows better soil and sunlight utilization, and contributes to achieving equal or greater yield per hectare in most experiments. The difference in crop yields in dotted rows is significantly higher because this technology sow 284 rows per ha. Production of maize and other cultures using twin-row technology still represents a great unknown in BiH and the region. According to available current literature of this scientific area, Twin-row technology has been applied at the beginning of the nineteenth century in SAD as an attempt to enlarge yield by increasing the sowing of a larger number of plants (crops) per production area (ha). In the areas of the former Yugoslavia, Lazar Tadić started experiments with corn sowing in double rows in 1976,

according to Čuljat (1989), with the basic aim of enlarging the yield by increasing the plant density.
According to the same author, sowing in strips reduced the shading of plants, and the number of cracked and broken plants did not increase. In that same year, the Agricultural Institute of Osijek and Ph.D Mile Čuljat, along with the Metal industry Osijek and OLT, are developing the sowing machine for the cultural plant in two rows. Their joint work resulted in the first sowing machine in 1986 named PSK-T. According to this author, there was a significant enlarge in yield in all sowings from 6 to 18%. There is a large number of sowing machine manufacturers on the agricultural technology market today, some of which are predominant such as Great Plains, John Deere, Monosem, MaterMacc Crust Buster Speed King Inc., Kinze Manufacturing, Gaspardo and many others. The differences between the offered models of these companies are certainly in the sowing system as well as the spacing between double rows that is 20, 22 or 25 cm. Banaj, A. et al. (2017) presents the results of the application of twin-row technology in the Republic of Croatia using the MaterMacc Twin row -2 planter. Studies were conducted in the eastern part of Croatia where optimal precipitation rates were recorded throughout the whole vegetation (2016) of maize growing. According to Blandino M. et al (2013) a study of the row technology was conducted in Italy in 12 locations on different soils and climatic conditions in the provinces of Alessandria, Cuneo, Ferrara, Milan, Mantovi, Padua, Turin, Udine and Verona. The hybrid DKC 6815, of the FAO Group 600, is sown on various circuits, from 7.5 to 9.5 and even 10 plants / m^2. The results indicate an increase in yields at 8 locations by 5.5% in average. The enlarge in yield was 0.6 t / ha (+ 3.6%) and 0.9 t / ha, which is the increase of 6.2%. According to Mackey G.L. et al. (2016), there is an increased interest in narrow rows (<30 inches) corn production in order to increase yields. Experiments were conducted around the cities of Lexington and Hodgenville in the state of Kentucky during 2011 and 2012 with three hybrids sown at a 15-inch spacing, two rows at 8 inches (20.32 cm) and standard sown at 30 inches (76.2 cm) with circuits of 30,000; 35,000; 40,000; and 45,000 plants per acre. In Hodgenville area in 2011, twin-row sowing has 6.7% higher yield compare to the standard which was not the case in the next year. However, a part of the author presented results with no significant differences in the yield between sowing on the standard row spacing and sowing with twin-row planters. Authors Ogrizović B. (2015) and Robles, M. (2012) quotes that twin-row technology sowing has advantages over the classic corn sowing because it increases the plant's complexity and improves the physical appearance of the plants which increases yield.

Materials and methods

MaterMacc company was founded in the 1980's and became a member of the *Foton LovoI International Heavy Industry Group* in january 2015. The field experiment was conducted for 2016 growing season on Family Farm Jovic (Prud, municipality Odzak,Posavski Canton, Bosnia and Herzegovina). Maize was sown in term April 18 and harvested in October 1, 2016. Yields were calculated on 14% grain mosture basis. Developing the investor system and the sowing sections of the pneumatic sowing machines, lead to the production of double rows also-called Twin row planters. Some technical features of newly developed twin row planter are given in Table 1. The sowing was done on the April 18th 2016, on the surface where the pre-culture was wheat fertilized with 130 kg / ha N, 90 kg / ha P_2O_5 and 110 kg / ha K_2O. Treatment was conventional using Adengo herbicide for weed control.
The average air temperature in the sowing month was 12.9 ° C with the total measured precipitation of 60.7 mm. At harvest time, in mid-September, average air temperature was 17.2 ° C with 67.1 mm precipitation. The average air temperature in June was 21.3 ° C with maximum of 23.1 ° C in July. Significant soil characteristics at the trial site are the humus content of 3,07 %, pH in H_20 8,43 and in KCl 7,11.

Table 1. Basic technical characteristics of the MS 8100 Twin Row planter

Conclusion

Based on the meteorological data, primarily by observing the average monthly air temperature and monthly rainfall, it can be concluded that the vegetation year 2016 was suitable for maize production at the site of OPG Jović. In the standard sowing with the pneumatic sowing machine Gaspardo SP-4, hybrid P0412 with a set of 60705 plants / ha after emergence, obtained the yield of 15798 kg / ha of dry grain with an average humidity of 19.0%. Twin row sowing of the same hybrid with a set of 60528 plants / ha obtained a yield of 16671kg / ha of dry grain with an average moisture of 20.04%, which makes an increase of 5.53%, compared to the standard sowing. The standard sowing of the hybrid BC 525 with a set of 62 658 plants / ha after emergence, obtained the yield of 14579 kg / ha of dry grain with an average moisture of 18.42%. Twin row sowing of the same hybrid with MaterMacc Twin Row-2 planter with a set of 68 515 plants / ha and obtained yield of 16613 kg / ha of dry grain with an average moisture of 22.50%, represents an increase of 13.95% compared to standard sowing. After one year of research, an increase with the Twin Row-2 planter sowing was established.

Abstract

The field experiment of liming (0 and 10 t ha^{-1} of powdered hydrated lime) and phosphorus (P) fertilization (monoammonium phosphate or MAP: 12% N + 52% P_2O_5) started in autumn 2008 on acid soil (pH in 1n KCl: 4.28) of Lijevce polje region (Laktasi municipality, Bosnia and Herzegovina). Three doses of P (0, 500, 1000 and 1500 kg P_2O_5 ha^{-1}) on the conventional fertilization (160 N + 75 P_2O_5 + 75 K_2O kg ha^{-1}) were applied in four replicates (basic plots of liming and P fertilization 640 m^2 and 40 m^2, respectively). The conventional fertilization was applied in the next years of the experiment. Soil of the experiment was low supplied with plant available P and adequate supplied with potassium (AL-method: 2.9 mg P_2O_5 and 23.4 mg K_2O in 100 g of soil). Maize was grown in monoculture from 2009 to 2013. Average grain yield of maize was considerable different among the years, ranging from 2.06 to 9.38 t ha^{-1}. Under less favorable weather conditions (drought and high temperature stress) in the 2011, 2012 and 2013, yields were considerably lower (mean 4.28 t ha^{-1}) than in the remaining two years (mean 9.20 t ha^{-1}). In general, liming effects on maize yields were stronger than P effects with considerable impacts of weather conditions. Affected by liming, yields were increased for 39%, 18%, 47%, 25% and 158%, for 2009, 2010, 2011, 2012 and 2013, respectively. However, P effects ranged, depending on the year, from non-significant differences (2012) to 32% (2013).

Keywords: *maize, liming, fertilization, phosphorus, grain yield*

Introduction

Acidic soil with low a level of humus, reduced accessibility of exchangeable forms of the most important plant nutrients such as phosphorus and calcium, as well as rather poor physical soil properties (poor water-air regime) are limiting factors for achieving higher and stable yields of cultivated plants. Low yields on this soil in recent years, despite the regular application of mineral fertilizers, indicate the blocking of individual nutrients in the soil under conditions of acid reaction. If such a bad agrochemical trait is added to drought, then the production of crop, fodder, vegetable plants and fruits stagnates year after year.

Neutralization of the acidic soil reaction by introducing lime materials is a measure that is regularly recommended for the purpose of repairing physical, chemical and biological properties and increasing the level of fertility of the soil. Numerous studies in our region and in the world indicate that the adequate application of lime materials in combination with organic and mineral fertilizers is the most effective way of removing unfavorable production characteristics of acidic soils (Jelić et al. 2015).

In addition to monitoring the influence of liming and phosphate treatment on maize yield, in this paper is accompanied by an extension effect of these agromelioration rates, ie, the time frame will be liming and phosphate has an effect on the amount of maize yield.
Marković and Supić (2013) are estimating that 25 % arable lands in Bosnia and Herzegovina belong to pseudogley. Acid soils and low levels exchangeable phosphorus (P) as well as unfavourable physical properties are limiting factor of pseudogley fertility (Okiljevic et al., 1997, Resulovic and Custovic, 2002; Markovic et al., 2006). Aim of this paper was testing response of maize to liming and ameliorative phosphorus fertilization under conditions of Lijevce Polje (Lijevce Field) in the northern Bosnia.

Materials and methods

General description of the Lijevce Polje area
Lijevce polje is an area in the northern part of B&H, encompassing the Gradiska, Laktasi and Srbac municipalities. It is lowland area in the lower flow of the Vrbas river, extending from the Sava river to the north and the mountains Prosara to the west, Motajica to the east and Kozara to the southwest. Climate of this area is moderate continental. In general, soil is more fertile compared to the majority of agricultural areas in the country, although serious problems of aluminum toxicity were sporadically found (Okiljevic, 1982; Kovacevic et al., 1988). Climate of wide region area was elaborated by Komljenovic et al., 2014).

The field experiment
This research was carried out on the Djurasinovic Family Farm in Lijevče Polje (Mahovljani willage, Laktasi municipality, Entity of Republic of Srpska, B&H) during four consecutive growing seasons, from 2009 to 2013, on pseudogley soil ($pH_{1nKCl} = 4.28$) low supplied with plant available P and rich in potassium (K). The treatments included liming and P fertilization. P distribution as monoammonium phosphate (MAP: 12% N + 52% P_2O_5) was conducted on November 10th, 2008 before ploughing. The rates of P on basic fertilization (160 N + 75 P_2O_5 + 75 K_2O kg ha^{-1}) were as follows: 0, 500, 1000 and 1500 kg P_2O_5 ha^{-1}. Immediately after P fertilization the experiment plot was ploughed up to 30 cm in depth. Liming of the experiment by 10 t ha^{-1} of powdered hydratized lime (73% CaO + 2-3% MgO + 21% of bound water) was made on November 16th, 2008 (four replicates and basic plots 40 m^2 and 640 m^2 for P and liming treatments, respectively). Maize (the hybrid NS444) was grown in monoculture. Detailed information regarding crop management practice, soil properties, weather characteristics, statistical analysis, grain yield, grain moisture, protein-, starch- and oil- determinations until 2012, were shown in the previous studies (Komljenovic et al., 2013, 2015a, 2015b). Maize was sown in April 30 and harvested in November 2, 2013.

Weather conditions for maize growth in the 2013 growing season

Table 1. Precipitation and air-temperatures in Banja Luka (SY, 2014)

Year	The weather data (Banja Luka* Weather Bureau: LTM = long-term averages 1961-1990)							
	Jan.-April	May	June	July	Aug.	Sept.	Oct.	May-Oct.
	Precipitation (mm)							
2013	362	120	54	27	36	70	68	375
LTM**	298	98	111	95	93	82	72	551
	Mean air-temperatures (^{o}C)							
2013	6.2	16.6	20.4	23.0	23.5	16.7	13.1	18.9
LTM	4.9	15.6	18.9	20.6	19.7	15.9	10.8	16.9

Absolute and average maximum air-temperatures (^{o}C), PET, AET, WD and WS (mm) in Banja Luka**									
Year	Absolute maximal temp.			Average maximal temp.			PET	AET	WD	WS
	June	July	August	June	July	August	June –August (sum)			
2013	36.0	41.6	41.1	26.4	30.7	31.3	101.54	67.52	34.01	0

* air-distance from the experiment site: Banja Luka = about 20 km in S direction
** PET = potential (PET) and actual (AET) evapotranspiration, water deficit (WD) and water surplus (WS)

The 2013 growing season was less favorable for maize growing, mainly due to precipitation deficit in July and August (Fig 1). According data for Banja Luka Weather Bureau precipitation in amount 63 mm was only about third part in comparison with the average 1961-1990. At the same period air temperature was for 3.0 ^{o}C higher and absolute maximal temperatures were above 41 ^{o}C (Table 1).

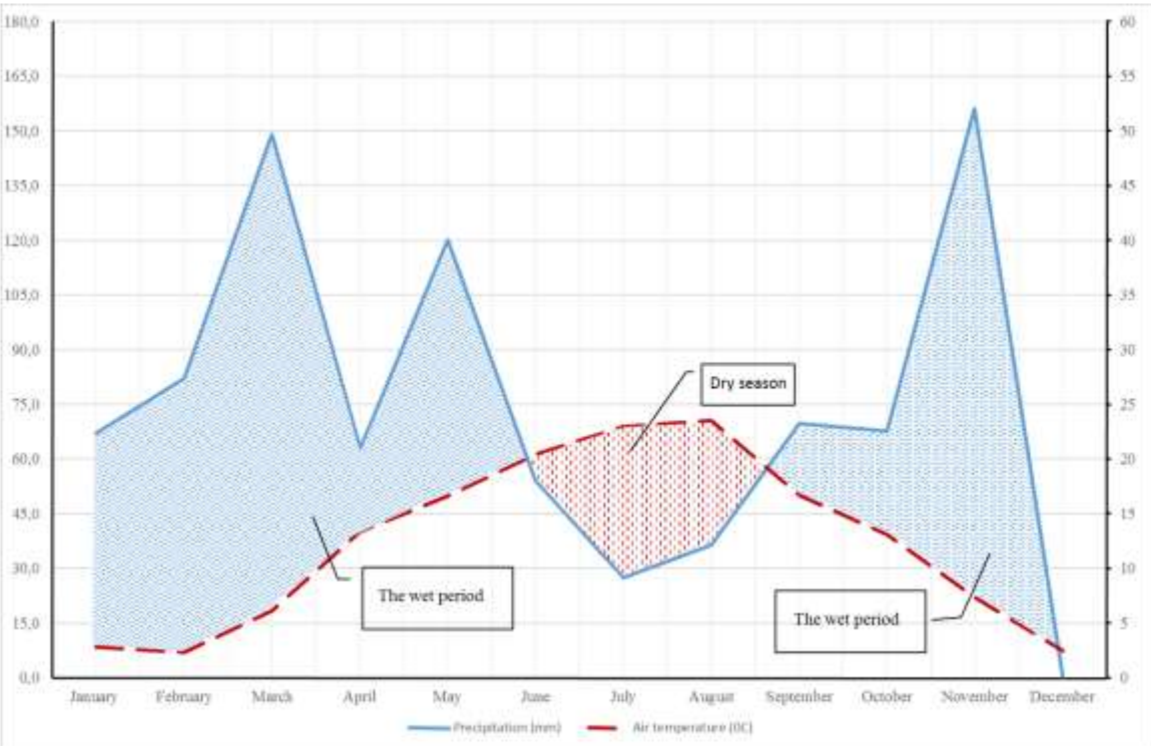

Fig. 1. Climate diagram by H. Walther for 2013 growing season for Banja Luka area

There is a noticeable lack of moisture in the period from the beginning of June to the first half of September in 2013 growing season, therefore in the critical period from the beginning of flowering, fertilization, and filling of grains. This was reflected in the yield of corn grain in the 2013 growing season (Table 1, Fig 1 and Table 3).

Results and discussion

Average grain yield of maize in the experiment for the 2013 growing season was 5.12 t ha^{-1} with considerably liming effects (2.86 and 7.38 t ha^{-1}, for control and limed treatment, respectively. Main reasons of low yield of maize under control treatment compared to lime application were considerable lower realized plant density (averages 70.8% and 94.5%) and the higher rate of barren plants (averages 37.6% and 7.6%) under acid stress conditions. Grain moisture at harvest was independent on liming (Table 2).

However, P effect was considerably lower compared to liming effect. With that regard, significant yield increases for 32% was realized by application the highest rate of P fertilizer.

Realized plant density was independent on P fertilization, while barren plants contribution was significantly decreased (25.0% and 19.8%, respectively) by application of the highest P rate (Table 2).

Impacts of liming on grain quality parameters (protein, oil and starch contents) in 2013 were non-significant, while P use resulted by significant increases only oil contents (Table 3).

Josipovic et.al. (2013) are reported that liming had considerably effects on increase of protein contents in maize grain from 9.9% (the control) to 10.6% (lime 10 t ha^{-1}), while by the using ameliorative PK-fertilization there is tendency to increases of maize grain protein contents. A grain starch content was independent on liming and PK-treatments on very acid soil located near Pavlovac in Croatia.

* basic fertilization of all treatments (160 N + 75 P_2O_5 + 75 K_2O kg ha^{-1}); in the next years (2009-2013) only basic fertilization of the experiment.									

Also, in the 4-year period of 2009-2012 liming considerably affected on grain yield of maize by average yield increase for 31% with differences among years from 18% in 2010 to 47% in 2011. As in 2013 growing season, P fertilization impact was considerably lower because yields were increased in three years from 6% in 2009 to 19% in 2011, while in 2012 differences of yield among P treatments were non-significant. By comparison of yield realized by three ameliorative P rates and the control, P effect on maize yield was only 8% (4-year averages: 6.14 and 6.65 t ha^{-1}, for control and P rates, respectively). With exception of the first year of testing, for significant increase of maize yield was adequate the lowest rate of applied P in amount 500 kg P_2O_5 ha^{-1} (Table 4). Response of maize to liming and P fertilization in 2009-2012 period elaborated in our earlier studies (Komljenovic et al., 2013, 2015a, 2015b).

Conclusions

The results of the study of the impact of liming and P fertilization in 2013 growing season in the Mahovljani (the fifth year of research), clearly show the extended effect of the applied agroemeliorative measures on maize grain yield. On the treatment where is applied 10 t ha^{-1} lime material and phosphorus fertilizer, the yield of maize was 7.86 t ha^{-1} which was higher for 4.52 t ha^{-1} or 258% than the control variant (2.586 t ha^{-1}). However, the same effect was not reflected on the quality properties of corn grains.

Abstract

The aim of this study was to determine the most tolerant winter wheat varieties to the influence of salinity at germination stage and early seedlings growth. The salinity stress was simulated in controlled conditions by adding different concentrations of NaCl solution to the growing media of five winter wheat variety. In all studied varieties the benchmark water potential in which they had germinated and had a good seedlings growth was of -0.3MPa. Under the stronger stress, -0.6MPa, all varieties showed reduction in the all examined parameters. The variety Bosanka, had the highest final germination and germination energy under salt stress. The parameters defining the development or percentage of strong seeds, coleoptile and root length, fresh and DW of root and coleoptile of a seed were more affected by salt stress than germination and germination energy. Biplot analysis showed that wheat cultivars grown under -0.6MPa osmotic had higher values of root/coleoptile ratio in relation to control and -0.3MPa treatment which is the most reliable for screening properties of the genotypes for drought resistance in seedling stage.

Key words: *Winter wheat (Triticum aestivum L.), tolerance, NaCl, osmotic potential, biplot analysis*

Introduction

Wheat (*Triticum aestivum* L.) is regarded as one of the most important cereal crop, grown in different regions that can be characterized with increased salt level in the soil (Rana et al., 2013). It is a cereal grain that belongs to Poaceae family, which has been known as a semi-tolerant plant to drought and moderately salt-tolerant (Tester et al., 2003). Winter wheat is more salt tolerant compaired to other crops such as durum wheat (*Triticum turgidum* ssp. *durum* L.), maize (*Zea mays* L.) and sorghum (*Sorghum bicolor* L.) (Fita et al., 2015). Stresses from the surrounding environment are limiting factor of agricultural production worldwide Roy et al. (2011). Germination is the basic indicator of seed quality and it highly depends on biotic an abiotic factors Vujakovic et al. (2011). The availability of water and its movement in the seed are very important for the process of germination, early growth and root elongation of coleoptile. These processes are under the influence of chemical potential, texture and the contact area of seed and soil. Salinity delays or prevents the seed germination through various factors, such as reduction of water availability, changes in the mobilization of stored reserves and affecting the structural organization of proteins TEMEL et al. (2015). Considering that the germination process is not possible without water, the main negative effect of salt in soils is reflected in creating osmotic potentials that will prevent the seeds from absorbing a sufficient amount of water and sprouts. Plant reaction to increased soil salinity manifests in stopping or reducing rate and duration of vegetative growth and leaf development (Läuchli and Grattan, 2007). Reduction in growth is a consequence of more physiological responses including modifications of ion balance, water status, mineral nutrition, stomatal behavior, photosynthetic efficiency (Tavakkoli et al., 2010). The selection of genotypes that tolerate salt stress in this stage is therefore important, especially if the tolerance in the germination stage correlated with tolerance to salt, with the period of grain filling. The aims of this study were to examine the seed viability of selected winter wheat cultivars in saline stress and to determine the most tolerant cultivars to salinity stress at germination stage and early seedlings growth

Materials and Methods

The experiment

The tests included examination parameters of germination in five different varieties of winter wheat (Jelena, Kristina, Orion, Bosanka and Nova Bosanka) under controlled conditions in the laboratory of the Faculty of Agriculture in East Sarajevo, Bosnia and Herzegovina. Three replicates of 50 uniform, healthy seeds were sterilized in 96 % alcohol for 30 seconds, washed with distilled water several times, and transferred into sterile Petri dishes. A double layer of filter paper was in a dish saturated with solution determined concentration of salt (Table 1) and it is dissolved with water potential close to zero (control), then -0.3 and -0.6MPa. Into each petri dish 15 ml of solution was dispensed. Control petri dishes were filled with distilled water. Sodium chloride to induce stress of salt. Petri dishes were incubated for 7 days, at the temperature of 25°C. During this experiment, the following parameters were determined: germination energy, final germination, Vigor Test or percentage of strong seeds, coleoptile and root length, fresh and DW of root and coleoptile, and root/coleoptile DW ratio. To determine the DW of the root and coleoptile seedlings were dried for 24 hours at 80°C.

Data analysis

Data was processed using two-way analysis of variance, with software Infostat 10. Means were compared using Duncan's multiple range test. Principal component analysis (PCA) was used to determine interdependence between the traits.

Results and Discussion

Results from our study showed that increase in osmotic potential had an adverse effect on wheat final germination and germination energy (Table 1). By increasing NaCl concentration (decreasing osmotic potential), germination energy and germination percent decreased almost linearly in studied wheat cultivars. The variety Orion was the most sensitive variety to the influence of lowest osmotic potential (-0.6MPa) and its germination energy compared to control reduced from 92% to 5%. Percentage of germination decreased by 69% in salt stress compared to the control. Decrease and delay in germination of winter wheat in saline medium, have also been reported by Rahman et al. (2000). The cultivar with highest germination percentage at zero potential, -0.3MPa and -0.6 MPa was Bosanka. Therefore, this cultivar could be grown under decreased osmotic conditions. Similar results were obtained by Braga et al. (1999), in seeds of bean where the potentials between -0.4 and - 0.6MPa, led to a decline in the value of parameters examined as germination percentage and germination.

There was a significant difference in the parameter vigor classification (Table 1) and by decreasing osmotic potential vigor percent declined gradually from 0MPa to -0.3MPa and further drastically at -0.6MPa under salt treatment. Generally, most wheat varieties were sensitive to the influence of osmotic potential of -0.6MPa where their values drastically fall close to zero. Khatun et al. (2013), and Moud and Maghsoudi (2008) also found differential sensitivity of wheat genotypes based on seedling growth in their studies and they suggested that seedling growth is one of the most important characters for screening salt tolerance during an early stage of the growth.

Coleoptile and root length (Table 1) in our experiment interfered differently. At zero potential, both coleoptiles and root lengths reached their highest values. Other treatments gradually reduced seedling growth. At zero potential the highest root length was reported in the variety Orion followed by variety Jelena and Kristina. The Nova Bosanka variety had one of the highest coleoptile length at zero potential. On the other hand, it was among the most sensitive varieties to the influence of decreased osmotic potential since its coleoptiles length significantly decreased at -0.6 MPa. High salt concentration inhibits plant growth (Cuartero et al., 1999) and affects many aspects of plant metabolism, resulting in reduced growth and grain yield. Moud and Maghsoudi (2008) found significant differences among cultivars in terms of coleoptiles and root growth under salt-stress conditions and stated that salt stress inhibited coleoptile growth more than root growth. Related result is published by Qayyum (2011) in investigation of the effect of water deficiency on germination of different wheat genotypes, who found that the length of the coleoptile was significantly decreased in the water potential of -0.8 bar.

Fresh weight of coleoptiles and root (Table 1) were differently affected by water deficits. Under salt treatment, coleoptiles fresh weight decreased with increase of osmotic stress. Under NaCl stress root average fresh weight at water deficit of -0.3MPa showed higher weight (0.059g) than at zero potential (0.047g).
Across treatment, wheat varieties significantly differed in coleoptile dry weight (DW). One of the varieties, with highest average of coleoptile DW, was Jelena, as it had the highest coleoptile DW under conditions of -0.6MPa. Similar results were obtained for root dry weight. There were no differences between control and low salt stress in root dry weight. At -0.6 MPa the variety Kristina had the lowest root dry weight. These results indicate that low salt concentrations stimulate the roots growth. Significant reduction of root growth occurred only at highest NaCl concentration. Our results are in agreement with Machado Neto et al. (2004) they reported that in soybean roots DW decrease under conditions of high salinity in soybean.
Root/coleoptile ratio (RCR) is one of the several ratios which gives estimates of the distribution of DM between the different plant organs (Hunt 1990). It is a measure of distribution of DM between the root and the shoot systems and it is a good indicator for effects on root and shoot dry weights. The RCR was under significant influence of NaCl level (Table 1). Under NaCl treatment RCR across varieties increased from 0.180 (control) to 0.308 (-0.3MPa) and to 1.194 (-0.6MPa). Across treatment wheat varieties significantly differed in RCR. The variety with average highest RCR ratio was Kristina and also had highest RCR under conditions of -0.6 MPa. Our results are in agreement with (Maghsoud et al., 2008) who reported increase of RCR in wheat cultivars under the conditions of salt stress. This kind of an increase in RCR indicates that proportion of DM allocated to the coleoptile was decreased compared to the roots.

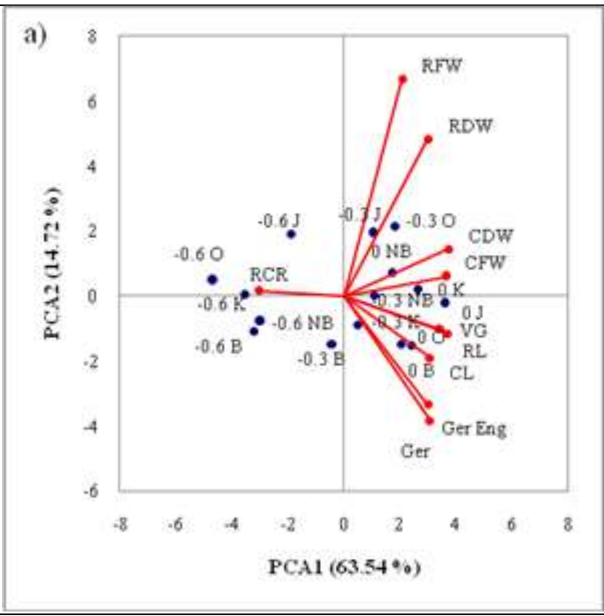

Figure 1. PCA analysis of trait association of winter wheat cultivars (Bosanka – B, Kristina – K, Jelena – J, Nova Bosanka – NB and Orion – O) grown under different level (0 MPa – O, -0.3 MPa – -0.3 and -0.6 MPa – -0.6) of NaCl

The biplot of the principal component analysis (PCA) illustrates the relationships between the means of the studied traits in wheat cultivars grown under different level of NaCl (Figure 1). The cultivar × treatment points and traits vector are placed on biplot according to their PCA scores. Biplot reveled similar interrelationship between studied traits in wheat cultivars at different NaCl levels. Germination (Ger) and germination energy (GerEng) were in high positive association as indicated by acute angles. Moreover, root fresh (RFW) and DW (RDW) and coleoptile fresh weight (CFW) and DW(CDW) were highly associated under influence of different NaCl level. There was positive association between root and coleoptile weight (both dry and fresh). Root length was in positive association with GerEng, indicating an early germination improves root growth. On the other hand, under conditions of NaCl treatment coleoptiles length (CL) was in positive association with Ger and GerEng. Biplot showed that wheat cultivars grown under lowest osmotic potential (-0.6MPa) had higher values of root/coleoptiles ratio (RCR) in relation to control and -0.3MPa treatment. This data indicates that coleoptile growth is more suppressed than root under condition of low osmotic potential.

Conclusion

Based on the results of this study it can be concluded that there are significant differences between the examined cultivars. Although the gradual increase of the NaCl treatment was followed by a reduction in all the analyzed parameters in selected cultivars. Significant decrease occurred only at high salt treatments (-0.6MPa) and it could be an indication of their sensitivity to stressuful conditions. We can conclude that the limit values of water resources when plant,under the influence of sodium chloride, in all varieties can germinate quite well and have a good increase in seedling were at -0.3 MPa , ie. in low stress. Salt tolerance for seedling DW maintained a significant positive correlation with rate of germination, germination vigor index, shoot length, and root length, which indicates that these parameters could be used as selection criteria for screening wheat genotypes against salt stress. Besides the standard techniques and commonly used data analysis, biplot offer additional options, preferably in the portion of a visual representation and understanding of important interactions that shown in the present data sets from surveys seed science research.

Abstract

Interval between appearance of successive leaves (phyllochron, PI) in grasses is determined by timing of leaf initiation at the stem apex and duration of leaf tip elongation through the whorl of mature sheaths. The objective of this study was to evaluate PI of main stem leave (MSL) development during tillering of six spring barley varieties, which differed in origin, earliness, spike type and some other traits. The studies were carried out in the field at the Institute of Field and Vegetable Crops Novi Sad, Serbia (45°20'N, 15°51'E, 86m asl) during 1999-2001 period. The experiments were arranged in a randomized complete block design with three replications and planting rate of 200 viable seeds per m^{-2}. Three random plants in each plot were labeled for monitoring during growing. PI was estimated every 2-3 days using Haun scale. Growing-degree-days (GDD) were used as time scale with base temperature of 0°C. PI was the reciprocal of the slope determined by regression of MSL against GDD using data from each plant within a cultivar. When plotted against thermal time leaf appearance was a strictly linear function of temperature. Across cultivars, the lowest PI was in 2000 – 81 GDD and the highest in 2001 – 89 GDD. Across years and leaves PI arranged from 65.5 in the variety Gustoe to 80.1 in the variety Jelen. All three factors, i.e., year, variety, and their interaction, were included in the PI determination of the first leaf. In all three years, first leaf demanded more days for appearance due to lower temperatures and shorter daylength. Of all six leaves studied, the second leaf was most strongly influenced by genetic constitution of cultivars and 75% of total variation belonged to this component of variation. Variation of PI of the third, fourth and fifth leaf was mainly determined by interaction GxY and year. It seems that in our investigation temperatures had a strong effect on leaf appearance. The linearity suggests that MSL stage can be used as a predictive measure of plant development and it can retroactively show the quality of the preemergent seedbed environment.

Keywords: *Spring barley (Hordeum vulgare* L.*), phyllochron, Haun scale, tillering, growing degree days*

Introduction

Morphological changes of barley plant can be used for the evaluation of both, plant development and growth environment (Klepper *et al*., 1982; Rickman *et al*., 1983). Mainstem leaf (MSL) appearance and proportion of tiller formation are parameters useful for the evaluation of germination and vegetative development. Haun (1973) developed a scale which quantitatively describes the vegetative developmental stages in spring wheat. The time spent for leaf elongation, i.e., the time from leaf appearance to the appearance of the next leaf, measured in growing-degree-days (GDD), is designated as phyllochron interval (PI). Fast emergence is positively related with MSL (Krenzer and Nipp, 1991). Smaller PI, i.e., lower GDD, represents faster development and leaf appearance. PI is influenced by temperature and daylength (Cao and Moss, 1989a; 1989b). Baker *et al*. (1986) found a decrease and Kenzer *et al*. (1991) found an increase in PI in wheat under water deficit conditions, while Bauer *et al*. (1984) did not establish a dependence of MSL appearance on soil moisture content.

Investigations of Dofing (1995) and Sharratt (1999) referred to the subarctic environment, while little is known about MSL growth of spring barley in semiarid conditions of growing. The objective of this study was to evaluate MSL development during tillering of spring barleys, which differed in origin, earliness, spike type and some other traits, grown in a semiarid environment.

Material and Methods

Field trials. Six spring barley varieties were grown in Novi Sad, (45° 20’ N, 15° 51’ E, 86m asl) from 1999 to 2001. The experiments were arranged in a randomized complete block design with three replications with plots 2m long and 1m wide, containing 6 rows 20 cm apart. The planting rate was 200 viable seeds per m^{-2}. Three random plants in each plot were labeled for monitoring during growing. Phyllochron was estimated every 2-3 days using Haun scale (Haun, 1973). Growing-degree-days (GDD) were used as time scale with base temperature of 0°C.

PI, measured as GDD per leaf, was the reciprocal of the slope determined by regression of MSL against GDD using data from each plant within a cultivar (Baker *et al*., 1986). Only MSL measurements greater than or equal to 1.0 were used in the regression because it is difficult to estimate partial emergence of the first leaf since there is no antecedent leaf for comparison.

Statistical analysis. A mixed model was used with varieties considered as fixed and years as random effects (Zar, 1996). Heritability for a single year was estimated as the ratio $\sigma^2_G/\sigma^2_{G+}\sigma^2_E$, (Singh *et al*., 1993).

Weather. At the time of planting in 1999, the mean daily temperature was increased and this year had the highest sum (Σ=52ºC) in pre-emergence period (Figure 1). The amount of available water during that period was appropriate. In the period following first leaf appearance, there occurred a temperature decrease and a water deficit. In the last third of March, the temperatures were moderate, with a slow increasing trend, and a water deficit was recorded. In the year 2000, low temperatures persisted till the last third of March, with the lowest temperature sums for 10-day periods among the three years (Figure 1). From the middle of the last third of March, the temperature continually increased. Water deficit was again recorded in this year. In 2001, low temperatures were recorded till the end of February and after that they continually increased till the end of tillering. The periods of emergence and tillering in this year were well supplied with water.

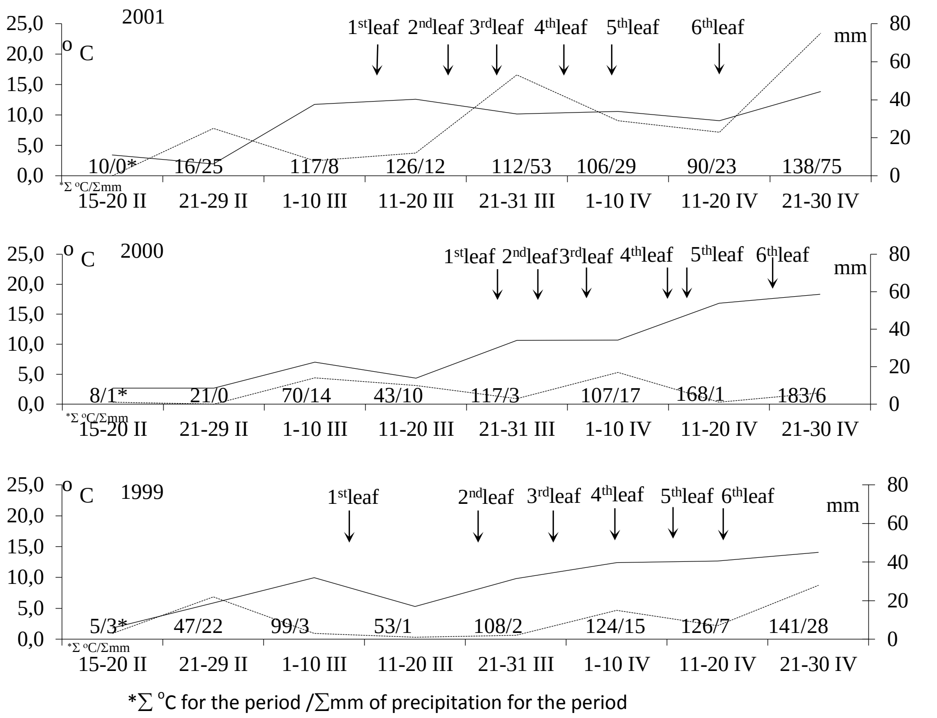

Figure 1. Ten-day average air temperature (——) and total ten-day precipitation (-------) in 1999, 2000, and 2001 growing seasons of spring barley in Novi Sad

Results and Discussion

ANOVA showed that all three factors, i.e., year, variety, and their interaction, were included in the phyllochron determination of the first leaf (Table 1). The phyllochron of the first leaf was not precisely defined, since GDD from sowing to first leaf appearance was supposed to be the phyllochron. Year had a lower range of variation than variety (Table 2), although its component of variance was higher. Across cultivars, the lowest phyllochron was in 1999 and the highest in 2001 (Table 3). The Russian six-rowed variety Avans had the longest phylochron interval for first leaf appearance. Interaction GxY occurred in all cultivars; Jelen, Nora, Alexis, and NS-135 had the shortest PI in 1999 while differences in the other two years could not be established. Avans significantly differed in all three years, while Gustoe had longer PI in 2001 than in the previous two years (data not shown). Significance of variety in first leaf appearance was also confirmed by a high value of heritability (Table 1).

Table 1. ANOVA and percentage of components of variance for phyllochron during tillering of six spring barley varieties in 1999-2001 growing seasons

Source of variation	Df	1st leaf	2nd leaf	3rd leaf	4th leaf	5th leaf	6th leaf
		Square mean					
Year (Y)	2	**	ns	**	**	**	ns

Heritability		96.7	94.1	89.5	64.4	64.0	80.6

*,** Significant at 0.05 and 0.01 level, respectively; ns - not significant

In 1999, high temperatures during emergence caused a faster second leaf development so that it appeared 214.5 GDD after sowing (from Table 4). Low mean daily temperatures and water deficit after first leaf development in that year caused relatively more days for the second leaf appearance in relation to the other two years. Year did not effect second leaf appearance (Table 1) and PI across cultivars ranged from 72.1 in 1999 to 77.8 GDD in 2001 (Table 3). Total sum of GDD from sowing to second leaf appearance was shortest in 1999 (214.5) and longest in 2001 (245.6). Of all six leaves studied, the second leaf was most strongly influenced by genetic constitution of cultivars and 75% of total variation belonged to this component of variation (Table 1). Range of variation for cultivars was from 53.3 (Nora) to 125.2 GDD (Gustoe) (Table 2).

Table 2. Ranges of cultivar and year mean values for phyllochron during tillering in six spring barley varieties in 1999-2001 growing seasons

Leaf	Variety (n=6)	Year (n=3)	Mean
1st leaf	127.5-202.8	142.4-167.8	155,2
2nd leaf	53.3-125.3	72.1-77.8	74,1
3rd leaf	40.3-114.8	62.8-83.3	75,8
4th leaf	49.2-94.1	66.7-81.6	71,8
5th leaf	41.8-79.0	54.5-63.9	60,5
6th leaf	61.3-86.8	73.8-75.0	74,3

The two-rowed cultivars had shorter phyllochron of the second leaf than the six-rowed cultivars. Thermal requirements for the second leaf were consistent among years in the two-rowed cultivars, while significant differences occurred in all three six-rowed cultivars. High heritability values (Table 1) showed that the established variability for second leaf appearance was under strong genetic control.

Variation of phyllochron of the next three leaves, third, fourth and fifth, was mainly determined by interaction GxY and year (Table 1). In the components of variance, year participated from 5 to 30% and interaction from 53 to 75% of total variation (Table 1). Range for variation for these leaves, similar to the previous two, was larger among years than among cultivars (Table 2). The shortest PI for these three leaves was registered in 2000.

Table 3. Means of phyllochron across cultivars and years in GDD during tillering of six spring barley varieties in 1999-2001 growing seasons

Year	1st leaf	2nd leaf	3rd leaf	4th leaf	5th leaf	6th leaf
			GDD			
1999	142.4	72.1	83.3	81.6	63.9	75.0
2000	155.5	72.4	62.8	66.7	54.5	74.0
2001	167.8	77.8	81.5	67.2	63.1	73.8
$LSD_{0.05}$	*2.63*		*3.30*	*3.84*	*3.67*

$LSD_{0.05}$	*3.72*	*5.05*				
$LSD_{0.01}$		*6.78*				

* at 0.05 level of significance

The third and fifth leaf had close phyllochrons in 1999 and 2000, while the fourth leaf had the longest PI in 1999 and similar lengths of PI in the other two years. GxY interaction for these three leaves occurred in almost all cultivars. Variation in third leaf appearance was mainly controlled by cultivar, while about one third of variation in fourth and fifth leaf appearance was due to non-genetic factors. GxY interaction had the highest responsibility for PI of the sixth leaf.

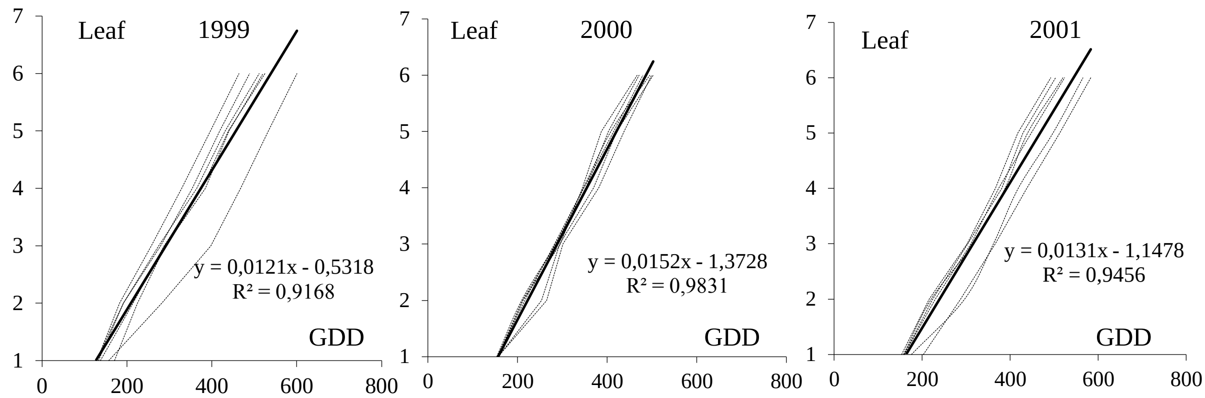

Figure 2. Heat units (GDD) required for the leaf appearance in six spring barley cultivars (── illustrates regression of leaf appearance against GDD for each investigated variety, ------- illustrates regression of average values of the six cultivars against GDD)

Variation across cultivars, i.e., among years, was minor, while across years it varied from 61.3 to 86.6 (Table 2). The cultivars Jelen and Gustoe did not differ in the phyllochron of the sixth leaf, while the other cultivars showed significant differences among the three years (data not shown). There was no consistency in the differences in PI among the cultivars; Alexis had the longer PI in 2000 NS-135 in 1999 and Avans the shortest in 2001.

The differences in the heat units for first leaf appearance suggest that the cultivars responded to accumulated GDD at this phase which agrees with observations of Baker *et al*. (1986) and Bauer ***et al*.** (1984). Avans and Gustoe originated from different ecological conditions in relation to the location of this experiment and it could be partially the reason for longer PI of the first leaf. Fast and uniform seedling emergence is especially desirable in short-season areas (semiartic, semiarid, arid), which provides adequate plant stand and establishment of effective plant canopy structure and yield. Early emerging seedlings have a longer time for growth in relation to late emerging ones. The results of early emergence is higher tillering, i.e., higher grain yield (Gan *et al*., 1992).
In all three years, first leaf demanded more days for appearance due to lower temperatures and shorter daylength. Cao and Moss (1989a), found that decrease in phyllochron interval and increase in the rate of leaf appearance (leaves day^{-1}) was associated with increase in daylength. It seems that in our investigation temperatures had a strong effect on leaf appearance. Indeed, in 1999, temperatures during sowing and germination were rather high and the first leaf appeared soon after sowing; after that, the temperatures dropped and more days were required for second leaf appearance (Figure 1). Water deficit that occurred at the time of sowing in 1999 could also be responsible for the increased rate of first leaf appearance. Baker ***et al*.** (1986) found lower PI values in wheat under non-irrigated field conditions, i.e., a higher rate of mainstem leaf. High air temperature at the time of sowing and emergence is expected to cause longer PI. That was confirmed in this study where high temperatures in the first 10 days of March 2001 (Figure 2, sum of mean daily temperature was 117˚C) caused the longest PI of the first leaf in the three years. Appearance of the other five leaves in 1999 and all leaves in 2001 was in close symmetrical intervals, since temperatures were steady and without large fluctuations. In 2000, temperatures were lowest among the three years and the appearance of the first leaf was latest.
The relation between leaf development and GDD as illustrated in Figure 2 shows the close dependence of leaf development on accumulated GDD. The coefficients of determination (R^2) were 0.92, 0.98, and 0.95 for 1999, 2000, and 2001, respectively, indicating that leaf development was mainly influenced by thermal conditions. Sharratt (1999) also reported high values of coefficients of regression for two spring barleys grown in interior Alaska (R^2=0.98 and R^2=0.95). These results are consistent with Kleper *et al*. (1982), whose results were the basis for suggesting a linear relationship between GDD and leaf emergence. The high dependence of spring barley leaf appearance on temperature found in this investigation confirmed the previously determined thermal requirements for leaf development in small grains.
Leaf appearance is a highly heritable trait and there is a strong relationship with accumulated thermal units. The linearity suggests that MSL stage can be used as a predictive measure of plant development. Also it can retroactively show the quality of the preemergent seedbed environment.

Conclusions

Results from this study showed the high heritability of phyllochron in barley. High temperature and water deficit increase rate of mainstem leaf appearance. Selection for small phyllochron had the desirable indirect effect on reducing time to maturity, but could also reduce grain yield when not accompanied by an increase in leaf number. These results indicate that phyllochron is a good measure of plant development, and that it is associated with time to maturity and other developmental traits.

Abstract

The paper presents the results of a two-year study of flowering dynamics and fruit morphological characteristics of autochtonous sweet cherry (*Prunus avium* L.) the variety "Alica" within the period 2013-2014 in the area of Mostar in Bosnia and Herzegovina. The study included monitoring of phenological characteristics such as bloom phases, fruit setting and maturation, and morphological characteristics such as weight, length, width and thickness of the fruit, stone weight, stem length and randman. Results showed earlier vegetation on set, so phenophases lasted longer in 2014, which can be directly related to more favourable climatic conditions in that year. The bloom phase in 2014 lasted longer (11 days), due to the high precipitation period which caused prolonged blossom in comparison to shorter bloom phenophase in 2013, that lasted 7 days only. Shorter period of fruit development (34 days) was recorded in 2013, comparing to the period of fruit development in 2014 (42 days). The most of morphological characteristics such as average fruit weight, stone weight and fruit skin weight showed statistically significant differences depending on the year, so their values were higher in 2013, comparing to 2014. Higher values of fruit width, thickness and length of the fruit stalk were recorded in 2013 as well, while randman of fruits showed no significant variations in relation to the year. Based on the research results, it may be concluded that this, once very respectable variety, over the years has acquired adaptability to climate conditions and that it should be further on investigated as a valuable genetic potential.

Keywords: *Phenological and pomological characteristics, autochtonous, sweet cherry, Alica.*

Introduction

Cherry belongs to the genus *Prunus* of the *Rosaceae*, or rose family. The genus *Prunus* includes other stone fruits such as almond, apricot, plum, peach, and nectarine. There are many cherry species, but only a few have been domesticated. The sweet cherry (*Prunus avium* L.) produces large trees (3 metres to 4 metres tall), usually shaped somewhat like a pyramid. Autochthonous genotypes of fruit species are very important source of genetic variability and valuable material for breeding work.

Traditional cherry cultivation is present in the area of Bosnia and Herzegovina (BiH) for a long period, it has been extensive without special use of agrotechnics or plant protection. Though, this area has favourable ecological conditions for cultivation of this type of fruit, cherry production is on the sixth place of total fruit production in BiH.

Cherries cultivation is mostly present in the area of Mostar with varieties "Alica" and "Hrust" introduced during the period of Turkish and Austrian governing.

Domestical varieties are, according to Šoškić (1994), those that originate from BiH or they are cultivated in these ecological conditions for a long time, origin is unknown and they are important because of their natural characteristics, so they represent plan resource of general and national importance. Due to the sudden and unprecedented industrialization, war operations, as well as natural disasters, autochthonous cherry varieties are threatened with extinction. Old local populations are increasingly being replaced by new, highly productive varieties, which is the basis of the progress of agricultural production. However, the fact that autochthonous varieties are characterized by many desirable characteristics should not be ignored, no breeding program can be effective without a wide variety of initial plant material. In addition, these varieties are not yet sufficiently pomologically or economically evaluated, nor have the degree of their inter variety variability been determined. The most valuable genotypes will find their place in breeding programs, so conserving the individuals that currently do not have the current production value, their positive characteristics have would come to light (Jarebica and Kurtović, 1997). For these reasons, the preservation of germplasm should provide the possibility for the creation of new genotypes (varieties and rootstocks of fruit trees), which will be able to fulfil the needs for the fruit of today's and future human generations (Mišić, 1987). A small number of authors dealt with studying of autochthonous cherry varieties in the territory of Herzegovina so, we can emphasize the researches of Stančević et al.(1983) and Pirnat et al. (1980). The aim of this research was to determine phenological and morphological characteristics of autochthonous variety of the variety "Alica" in the area of Mostar.

Material and Methods

The research was carried out during 2013 and 2014, on the location of Mostar, in the private cherry orchard in Vrapčići in BiH. Materials used for research was autochthonous variety of sweet cherry the variety Alica.

Flowering was followed by recommendations of the International working group for pollination (Wertheim, 1996). The date of beginning of bloom was taken when 10% of flowers were open, full bloom– when 80% of flowers were open, the end of bloom – when 90% of petals were fallen.

Duration of bloom phase was determined by the number of days from the beginning to the end of bloom. Abundance was assessed according to a scale from 1 (no flowers) to 9 (abundant bloom). The date of harvest is taken as the time of maturation. Characteristics of fruit are determined on a sample of 30 fruits for variety. Standard morphometric methods were used to determine the weight of fruit, dimensions of the fruit, the length of the stalk . The results are processed by the statistical method of the analyses of variance. The significance of differences between mean values is determined by Tukey test at P=0,05.

International cheery descriptor "Descriptor list for IBPGR (Schmidt et al., 1985) was used for determination of qualitative fruit characteristics.

Results and Discussion

Phenological observations comprehended the flow of phenophases: swelling of buds, beginning of bloom phase, full bloom, end of bloom, leafing, formation of first fruits, rash, and fruit maturation.

Table 1. Flowering phenophases of the cherry variety "Alica"

	Phenophases		*Bloom*				
	Swelling buds	*Green Tip*	*Beginning*	*Full*	*End*	*Duration (days)*	*Full leafing*
2013	19th of March	28 th of March.	10 th of April	14 th of April	17 th of April	7	20 th of April
2014	6 th of March	11st of March	20 th of March	31st of March	31st of March	11	3rd of April

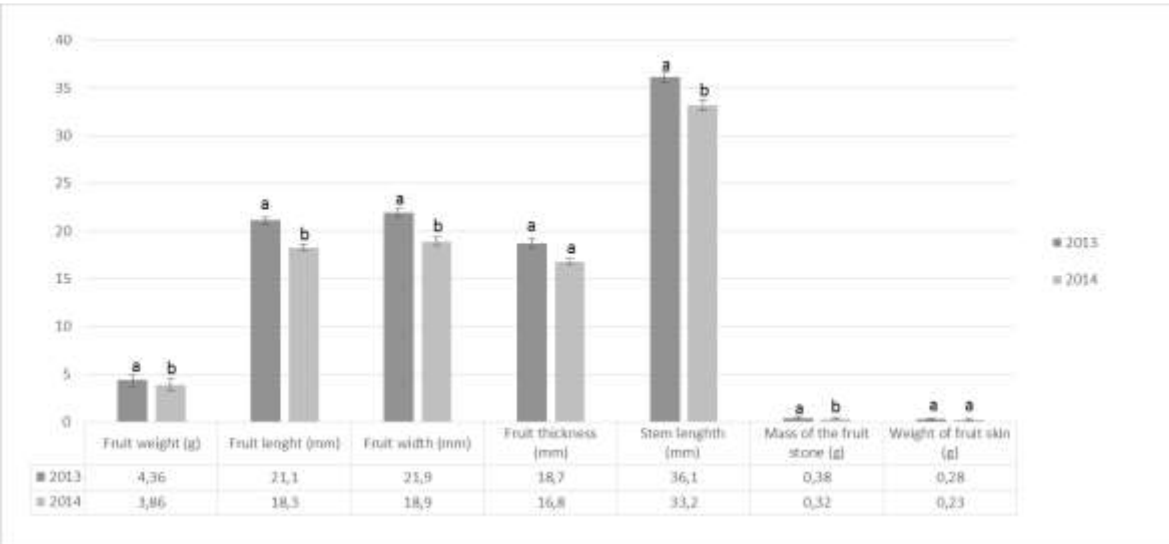
On the observed the variety "Alica", the phenophase from swelling buds to the phenophase of green heads occured within the period from the 19 th of March in 2013 and 6 th of March in 2014, till the 28 th of March and 11 th of March (Table 1). So, the phenophase of green tips started nine days after swelling buds in 2013 and in 2014 this period was five days.
Beginning of bloom phase of the variety "Alica" in 2013 "Alica" started on the 10 th of April, while the beginning of bloom in 2014 was recorded on the 20th of March, this was caused by significantly higher temperatures in that period. The phenophase of full bloom was recorded on the 14th of April in 2013, while in 2014 it was recorded much earlier on the 31st of March. The end of bloom of "Alica" variety in the period 2013-2014 was recorded on the 17th of April in 2013 and 31st of March in 2014.
It may be concluded that all phenophases were moved forward in 2014, influenced by higher temperatures in the period from February to May and significantly higher precipitation in the same period.
Duration of bloom phase is an important category in bloom phase and it has been influenced by genetical characteristics of the variety and meteorological conditions during the bloom. Bloom phase duration for the observed period of 2013-2014 was 7 and 11 days.
Full leafing in the observed period of "Alica" variety occurred significantly later the bloom which was quite favourable in the cases of late frosts avoiding fruit tree damages. Full leafing was recorded on the 20th of April in 2013 and on the 3rd of April in 2014. Stančević (1967) emphasises that the flowering duration for 48 varieties of cherries was 11-17 days,
Pirnat et al., (1980) concluded that this period is 12 days, while in this research similar data have been collected, so this period was 7 days due to the warm weather during bloom phase period.
Aliman et al., (2009) presented their research results including data on swelling buds of "Alica" variety on the 23rd of March in 2006, and on the 4th of March u 2007, bloom g beginning was recorded on the 2nd of April and on the 18th of March, full bloom was recorded on the 7th of April and on the 25th of March, and the end of bloom on the 14th of April and on the 5th of April.
Aliman et al., (2009) in this research presented results on full leafing in 2006 which was recorded on the 16th of April, and on the 10th of April in 2007.

Table 2. Frutting phenophases of the variety "Alica"

	Fruit formation	*Straw*	*Fruit maturation*	*Duration period of fruit development*
2013	21st of April	15th of May	25th of May	34
2014	6th of April	10th of May	1st of May	42

Forming of fruits the variety "Alica" was recorded on the 21st of April in 2013 and on the 6th of April in 2014. Straw phenophase in 2013 was spotted on the 15th of May and on the 10th of May in 2014. Fruit maturation was recorded earlier in 2014, on the 18th of May and on the 25th of May in 2013, which can be directly related to the climate conditions in the period 2013-2014 (Table 2).
Duration period of fruit development from the fruit setting to maturation is influenced by ecological and genetical variety characteristics and it is the time period of 22-62 days, averagely 44 days according to the previous researches (Jovanović, Miletić, 1988), which confirms the results of this research. It may also been noticed that duration of fruit development of "Alica" variety lasted 34 days.
Aliman et al., (2013) stated that their results show that fruit formation for "Alica" variety was recorded on 19th of April, straw on the 24th of May, fruit maturation on the 31st of May. According to the same authors, duration period of fruit development lasted 42 days, which is slightly different from results of this research.
Following the duration period of fruit development of the variety "Alica" in the studied period 2013-2014 it may be concluded that duration period of fruit development in 2013 lasted 34 days, while it was 42 days in 2014.

Graph 1. Fruit properties of the variety "Alica"



Remark: Average values are presented ± SD (standard deviation). Different letter on average values show that years are significantly different in studied characteristic - Tukey test p≤0,05

Fruit weight of studied the variety "Alica" showed statistical differences that depended on a study year. The average fruit weight in 2013 was 4,36 g, while in 2014 it was 3,86 g. Analasying the mass of the fruit stone the variety "Alica", it may be concluded that it varied from 0,38 g in 2013 to 0,32 g in 2014 godini. Weight of fruit skin was 0,28 g, in 2013, and 0,26 g in 2014. The biggest average fruit width, thickness and stem lenghth was recorded for "Alica" variety in 2013. Randman was within 85% in 2013 up to 83% in 2014.
Various analyses showed that fruit mass, length and width of fruit, stem length and mass of the fruit stone expressed statistically significant differences for the studied period 2013-2014, while thickness and skin of fruit did not express statistically significant differences in reference to the studied years.
The results of fruit properties the variety "Alica" are presented in Graph 1.

Important pomological characteristics of cherry fruit are: shape, largeness and dimensions (height, width and thickness) (Nikovski, 1998).
In this period whit rich selection of fruit types and varieties, there is an idea to bring back into production certain types and varieties with domestic origin which are fighting against its disappearance in the areas of Bosnia and Herzegovina. These individual trees carry on the long fight without human help so they become immune to pests and diseases which is of large importance since it reduces use of pesticide and produce healthy fruit. This means a lot for the health of humans but economic significance should not be underestimated.

Conclusions

So, based upon the research on morphological and phenological characteristics of autochthonous "Alica" variety in the period 2013-2014 in the area of Mostar, the following conclusions can be made:
The phenophase of green tip started nine days after swelling buds in 2013 and while in 2014 it occurred five days later. Bloom phenophases of "Alica" variety started earlier in 2014 in comparison to 2013 due to the higher temperatures from February to May and significantly higher precipitation in 2014.
Bloom duration for the studied period 2013-2014 was 7 and 11 days, respectively. Fruit formation, straw and maturation of "Alica" variety was recorded much earlier in 2014 comparing to 2013. Varience analyses showed that fruit mass, length and width of fruit, stem length and mass of the fruit stone expressed statistically significant differences for the studied period 2013-2014 , while thickness and skin of fruit did not express statistically significant differences in reference to the studied years.
Based upon these results it may be concluded that this is highly valuable autochthonous variety which needs to be preserved from disappearance since its positive characteristics can serve as valuable genetic potential in breeding programmes.

Abstract

In modern plant production usage of pesticides is necessary in order to obtain good quality of yield. In corn production, Adengo is one of the most used systemic herbicides for control of grasses and broadleaf weeds. Usage of inadequate concentrations of herbicides may have negative consequences for microbial diversity. The aim of this paper was determination of Adengo influence on microbial diversity in soil under corn. Experiment was performed in Ilidža municipality (Sarajevo canton, Bosnia and Herzegovina) by sowing seeds in spring 2016, followed by Adengo application in three various concentrations (0.22; 0.44; and 0.88 l/ha). Control treatment was untreated soil. Sampling for microbiological analyses was performed 15. 30. and 130 days after sowing. Microbial diversity of soil was determined using standard agar plate method. Total number of bacteria was determined on 0.1xTSA, ammonification bacteria on nutrient agar, nitrogen fixation bacteria and *Azotobacter* sp. on Fyodorov agar, fungi on Rose Bengal streptomycin agar, and actinomycetes on starch-ammonia agar. Microbial activity of soil was expressed as colony forming units per g of dry soil. The highest total bacterial number was detected at the end of experiment. Similar results were obtained for *Azotobacter* sp. and nitrogen fixation bacteria and fungi while highest abundance of ammonification bacteria was obtained in the start of experiment. Number of actinomycetes was highest after 330 days from sowing. These results may be useful for further application of herbicide Adengo in corn production, as well as other crops planting.

Key words: *Herbicide, microbial diversity, corn, Adengo*

Introduction

Application of agrochemicals are irreplaceable part of traditional agriculture production (Carvalho, 2006). These chemicals have various impacts on soil characteristics (Gaherwal *et al.*, 2015). One of them is pesticide; this term covers a various compounds, such as insecticides, fungicides, rodenticides, herbicides etc. (Aktar *et al.*, 2009). Pesticides are important part of integrated pest management and may have a huge influence in agricultural production (Talebi *et al.*, 2011). Application of pesticides is often linked with high crop productivity and protection from pests (Singh and Datta, 2006). With the increased use of pesticides in agriculture, impact of these agrochemicals on soil processes has received more global attention (Andrea *et al.*, 2000). Every year, about $3x10^9$ kg of pesticides is applied worldwide (Pan-UK, 2003). Unfortunately, long-term dispersion of pesticides has negative consequences for ecosystem (Castro *et al*., 2005) and food chain, causing malfunction in living organisms (Arias-Estevez *et al*., 2008). Also, pesticides affect microbial activity of soil, as well as structure of microbial communities (Cycon *et al*., 2005), which are important parameters in transformation of organic matter, N and P cycling and crop productivity (Devare *et al*., 2007). The pesticides are accumulated in surface layer of soil, where microbial activity is highest (Sethi *et al*., 2015). The influence of pesticides on microbial diversity of soil may be various, depends on various factors (Monkiedje and Spiteller, 2002), such as chemical structure of pesticide, concentration of pesticide, structure of microbial population in soil, different soil characteristics etc. (Digrak and Ozcelik, 1998); in some cases, pesticides stimulate the microbial activity, but other pesticides have deleterious effects on soil microflora (Lo, 2010). Microorganisms play important role in agricultural ecosystem functioning, especially during the corn cultivation, which is one of the most cultivated crops in Bosnia and Herzegovina. Research of microbial activity is considered to be an adequate parameter of estimation of soil disturbance caused by various agricultural practices (Nannipieri *et al*., 2003). Thus, the aim of this research was determination of soil microbial activity after application of herbicide Adengo.

Material and methods

The experiment was performed at Butmir location (Ilidža municipality, Sarajevo canton, Bosnia and Herzegovina). In May 2016, sowing a corn seeds (Pioneer hybrid PR37NO1) was performed. After seeds sowing, treatment of soil by herbicides Adengo (Bayer AG, Germany) obtained from local distributor was conducted in order to prevent the growth of broad-leaved weeds and grasses. This herbicide was applied in three concentrations: 0.22; 0.44; and 0.88 l/ha. In control treatment, herbicide was not applied.
Soil sampling was performed 15; 30; and 130 days after sowing. Samples were taken from the depth 0 to 30 cm at several points in the field. In second and third sampling, samples were taken from the nearness of plants at several points. After preparation of composite sample, microbiological analyses were performed.
Total number of bacteria was determined using 0,1xTSA, ammonification bacteria on nutrient agar, nitrogen fixation bacteria and *Azotobacter* sp. on Fyodorov agar, fungi on rose bengal streptomycin agar (Peper *et al*., 1995), and actinomycetes on starch-ammonia agar. Incubation for fungi was performed at 25°C for 5 days, while for *Azotobacter* sp., and other bacteria at 28°C for 2, and 6 days, respectively. After incubation, microbial activity of samples was expressed in colony forming units (CFU) per gram of absolutely dry samples.

Results and discussion

Usage of pesticides and other agrochemicals affects the crucial functions and activity of soil microorganisms (Milošević and Govedarica, 2002). Enzyme systems of microorganisms comprise up to 90% of soil metabolic activity (Lee, 1994), and its number and activity may serve a good indicator of soil quality after pesticides application (Konstantinović *et al*., 1999). In our study, microbial activity depends on type of microorganisms, time of sampling and herbicide concentrations.
Total number of bacteria may be used as an important parameter of soil fertility (Jarak and Čolo, 2007). In all treatments, at the end of experiment highest total number of bacteria was recorded. Similar trend was noticed in *Azotobacter* sp. number in most of treatments (tab. 2) In most of treatments, in first sampling higher number of bacteria was noticed compared with second sampling (tab. 1), while abundance of *Azotobacter* sp. was higher in second sampling.

Highest number of bacteria and *Azotobacter* sp. was noticed in treatment with 0.44 l/ha of herbicide after 130 days of sowing ($122.3 x 10^5$, and $103.7 x 10^2$ CFU/g, respectively).

Table 1. Total number of bacteria in soil under corn (CFU x 10^5/g)

Treatments	Time of sampling		
	15 days	30 days	130 days
Control	26.6	25.7	100.6
Adengo 0,22 l/ha	48.6	12.8	78.4
Adengo 0,44 l/ha	19.4	24.2	122.3
Adengo 0,88 l/ha	46.3	13.2	82.9

Nitrogen fixation bacteria are diverse and play important role in reduction of atmospheric nitrogen to ammonia (Orr *et al*., 2011). In all treatments (except of control), the number of nitrogen fixation bacteria was lowest at the end of experiment. Increase of herbicide concentration was followed by increase of bacterial activity (tab. 3). In first sampling, highest activity of nitrogen fixation bacteria was noticed in treatment with highest herbicide concentration ($276.9 x 10^2$ CFU/g), in second sampling in treatment with 0.44 l/ha ($166.7 x 10^2$ CFU/g) and in third in control treatment ($122.5 x 10^2$ CFU/g).

Table 2. *Azotobacter* sp. in soil under corn (CFU x 10^2/ g)

Treatments	Time of sampling		
	15 days	30 days	130 days
Control	87.7	67.0	94.3
Adengo 0,22 l/ha	53.8	54.1	46.3
Adengo 0,44 l/ha	45.1	49.0	103.7
Adengo 0,88 l/ha	37.3	40.4	54.4

Table 3. Nitrogen fixation bacteria in soil under corn (CFU x 10^2/ g)

Treatments	Time of sampling		
	15 days	30 days	130 days
Control	92.0	150.4	122.5
Adengo 0,22 l/ha	250.0	79.0	40.3
Adengo 0,44 l/ha	73.7	166.7	53.1
Adengo 0,88 l/ha	276.9	146.9	55.7

Ammonification bacteria use proteins as an energy material (Miletić et al., 2012) and its presence is one of the indicators of soil fertility (Sargsyan et al., 2013). Abundance of ammonifiers is highest in soil with high level of nutrients (Marinković et al., 2008). In all treatments (except of control) highest number of ammonifiers was recorded in first sampling. Inhibitory effect of herbicides was noticed 30 days after sowing, followed with increase of ammonifiers number in third sampling compared to second (tab. 4). Lowest number of ammonifiers was recorded in treatment with 0.22 l/ha of herbicides after 30 and 130 days of sowing (4.1; and 10.3x105 CFU/g, respectively), while highest activity was noticed in first sampling of 0.88 l/ha treatment (30.5x105 CFU/g).

Table 4. Ammonification bacteria in soil under corn (CFU x 10^5/ g)

Treatments	Time of sampling		
	15 days	30 days	130 days
Control	12.2	21.6	25.1
Adengo 0,22 l/ha	21.4	4.1	10.3
Adengo 0,44 l/ha	16.8	12.1	15.2
Adengo 0,88 l/ha	30.5	10.6	14.8

Fungi are important systematic group of microorganisms which play a crucial role in decomposition of organic matter (Vieira and Nahas, 2005). They are more acid tolerant organisms compared to bacteria, thus, fungi are dominant microorganisms in acid soils (Rousk *et al*., 2009). Actinomycetes are also involved in significant processes in soil (Ghorbani-Nasrabadi *et al*., 2013); they may survive under various soil conditions and stimulate the plant development (Hamdali *et al*., 2008). As can be seen from table 5, in most of samples, higher number of actinomycetes compared to fungi was recorded. In treatments with herbicide, highest number of fungi was noticed in first sampling, while abundance of actinomycetes was highest in second sampling. In control treatment fungal and actinomycetes activity was highest in second sampling.

Table 5. Fungi and actinomycetes in soil under corn (CFU x 103/ g)

Treatments	Fungi			Actinomycetes		
	Time of sampling					
	15 days	30 days	130 days	15 days	30 days	130 days
Control	9.5	26.6	13.7	105.9	274.0	108.0
Adengo 0,22 l/ha	66.8	9.4	15.4	51.3	87.7	18.0
Adengo 0,44l/ha	57.3	11.1	24.8	85.9	135.7	104.5
Adengo 0,88l/ha	70.3	19.0	7.8	54.6	159.0	48.0

Results of previous researches showed the various impact of herbicides on soil microflora. In general, its application can cause decrease of beneficial microorganisms number (Aktar *et al*., 2009). For example, application of triclopyr inhibits activity of several bacterial populations (Pell *et al*., 1998), glyphosate has negative influence on nitrogen-fixing bacteria (Santos and Flores, 1995), while 2,4-D reduces the growth of cyanobacteria (Singh and Singh, 1989). These results are similar with our observation (tab. 3), where inhibitory activity of herbicide can be seen after 130 days from sowing. On the other side, some researchers suggest that some herbicides have stimulatory effects on microbial activity. Jena *et al*. (1987) found that butachlor had stimulatory effect on growth of anaerobic nitrogen fixation bacteria. Glyphosate applied at high concentration produces a short-term stimulation of bacterial growth (Ratcliff *et al*., 2006).

Conclusion

These results confirms that herbicide Adengo has various effects on soil microbial activity. Its impact depends on applied concentrations and microbial populations. Our results may be useful for further application of herbicide Adengo in corn production.

Abstract

In contemporary crop production, several techniques were developed for protection from weeds. One of methods is herbicides application. Herbicide Lumax (Syngenta) can be used for control of annual grasses and broadleaf weeds in corn and sorghum. The usage of herbicide may influence the microbiological properties of soil, which is important parameter of soil fertility. The aim of this paper was determination of influence of herbicide Lumax on microbiological properties of soil. Experiment was set up in May 2016 in Ilidža municipality (Bosnia and Herzegovina) by sowing corn seeds and application of herbicide Lumax in three concentrations (2, 4, and 8 l/ha). Soil sampling for microbiological analyses was performed 15, 30, and 130 days after sowing. Determination of microbiological properties of soil was performed using standard methodology and agar plate method. Microbial activity was expressed as colony forming units per g of absolutely dry soil. Highest total number of bacteria and *Azotobacter* sp. was noticed at the end of experiment, while ammonification and nitrogen fixation bacteria in most of samples were most abundant 15 days after sowing. Fungi were most abundant in the start of experiment, while actinomycetes number was highest 30 days after sowing seeds. These results showed good adaptation of total bacteria and *Azotobacter* sp. in the presence of Lumax, while number of fungi, ammonification and nitrogen fixation bacteria in most of samples decreased during the growth of corn. This research may be useful for further experimental designs considering the impact of herbicides on microbial diversity in corn production.

Key words: *microorganisms, soil, corn, herbicide, Lumax*

Introduction

Microorganisms play an important role in decomposition of organic matter in soil and cycling of nutrients (Pandey and Singh, 2004). In soil-microorganism-plant system, microorganisms, mostly bacteria and fungi, are considered as nutrient pool to crops (Subhani *et al.*, 2000). They affect the physical, chemical and biological characteristics of soil (Gulhane *et al.*, 2015). Activity and number of microorganisms in agricultural ecosystems depend on various factors. One of them is application of pesticides (Cycon and Piotrowska-Seget, 2007). They were introduced in agricultural production to protect crops from pests and pathogen microorganisms (Gaherwal *et al.*, 2015). In several last decades, application of pesticides has become a crucial parameter for high crop productivity (Singh and Datta, 2006). Unfortunately, repeat and long-term usage of pesticides has negative consequences for soil characteristics (Sethi and Gupta, 2013) and global environment (Castro *et al*., 2005). On the other side, researches focusing impact of pesticides on microbial population of soil reported stimulatory or inhibitory effect (Devare *et al*., 2007). Pesticides interact with soil microorganisms and change physiological characteristics of microbial populations (Weber *et al*., 2004). Microbiological characteristics are good parameter of soil quality (Winding *et al*., 2005) because of early responses to disturbance of soil caused by agricultural crop production (Sethi and Gupta, 2013), especially in corn production, which is very intensive in central part of Bosnia and Herzegovina. Based on official report of Ministry of foreign trade and economic relations of Bosnia and Herzegovina (2016), corn production participates with 58% of total grain production in Bosnia and Herzegovina. Because of importance of high quality of corn and consequences caused by pesticide application, it is necessary to find methods for determination of soil quality disrupted by agricultural practices. The aim of this work was determination of influence of herbicide Lumax on microbiological activity of soil under corn.

Material and methods

The experiment was performed in May 2016 at Butmir location (Ilidža municipality, Sarajevo canton, Bosnia and Herzegovina). After sowing a corn seeds (Pioneer hybrid PR37NO1), treatment of soil by herbicides Lumax (Syngenta) obtained from local distributor was conducted in order to prevent the growth of broadleaf weeds and annual grasses. This herbicide was applied in three concentrations (2, 4 and 8 l/ha). Control treatment was untreated soil.

Soil sampling was performed 15, 30 and 130 days after sowing, from the depth 0 to 30 cm at several points in the field. In second and third sampling, samples were taken from the nearness of plants at several points. After preparation of composite sample, microbiological analyses were performed using standard methodology. Total number of bacteria was determined on 0,1xTSA, ammonification bacteria on nutrient agar, nitrogen fixation bacteria and *Azotobacter* sp. on Fyodorov agar, fungi on rose bengal streptomycin agar (Peper *et al*., 1995), and actinomycetes on starch-ammonia agar. Incubation for fungi was performed at 25°C for 5 days, while for *Azotobacter* sp., and other bacteria at 28°C for 2, and 6 days, respectively. After incubation, microbial activity of samples was expressed in colony forming units (CFU) per gram of absolutely dry samples.

Results and discussion

Agricultural land management has significant influence on soil microbiological activity (Garcia-Orenes *et al*., 2013). Various practices in agriculture, such as pesticides application, influence microbial structure and microbiological processes (Morugan Coronado *et al*., 2015). Also, growth of soil microflora depends on plant-soil interactions (Grayston *et al*., 1998) and soil type (Girvan *et al*., 2003).

In our research, microbial activity was affected by type of microorganisms, time of sampling and herbicide concentrations. In all treatments, total number of bacteria was highest after 130 days from sowing (Tab. 1). In most of samples, application of Lumax had stimulatory influence on total number of bacteria compared to control, especially at the end of experiment. Busse *et al*. (2000) suggest that glyphosate stimulated microbial activity when was applied directly to soil. These authors found increase in total number of bacteria and *Pseudomonas*, *Bacillus*, *Arthrobacter* and *Xanthomonas* populations. In carbon-limiting soils, bacteria are able to use herbicides as carbon and energy sources, which can be linked with increase of bacterial activity (Radosevich *et al*., 1995).

Ammonification is important process of proteins transformation into mineral form (Jarak *et al*., 2003). Because the proteins are commonly originated from microorganisms, number of ammonification bacteria represent an important parameter of soil microbial activity (Golic *et al*., 2014). In treatments with 2 and 8 l/ha, highest number of ammonification bacteria was noticed in the first sampling and lowest at the end of experiment (Tab. 1), while in control and in treatment with 4 l/ha of herbicide, during the experiment, increase of number of ammonification bacteria was recorded. Studies of Hart and Brookes (1996) show that glyphosate application increased the intensity of ammonification compared with control. On the other side, using atrazine and alachlor, decrease of ammonifiers was noticed (Konstantinović, 1999).

Table 1. Total number of bacteria and ammonification bacteria in soil samplesTotal number of bacteria (x10^4 CFU/g)

Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	419.3	482.6	625.0	266.5
	30 days	191.5	353.9	249.0	256.8
	130 days	1701.8	1504.6	1079.37	1005.6

Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	349.8	212.7	291.7	121.5
	30 days	156.2	213.0	128.9	215.6
	130 days	114.0	263.3	84.0	251.2

Nitrogen fixation bacteria are responsible for fixing of atmospheric nitrogen and its transformation into available forms (Bogdanović, 1990). From these bacteria, *Azotobacter* sp. is recommended as a parameter of soil fertility and important factor of atmospheric nitrogen fixation (Golic *et al*., 2014). In first sampling number of nitrogen fixation bacteria was higher in treatments with herbicide compared to control, while at the end of experiment, number of this important physiological group of microorganisms was higher in control (Tab. 2).

Table 2. Nitrogen fixation bacteria and *Azotobacter* sp. in soil samples

Nitrogen fixation bacteria (x10^2 CFU/g)					
Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	170.0	137.1	197.0	92.0
	30 days	121.1	225.9	121.2	150.4
	130 days	69.5	115.7	46.3	122.5
Azotobacter sp. (x10^2 CFU/g)					
Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	88.5	79.0	62.5	87.7
	30 days	71.3	59.3	55.8	67.0
	130 days	115.7	115.7	87.4	94.3

On the other side, in most of samples, number of *Azotobacter* sp. in first sampling was lower in control compared to treated soil, while after 130 days from sowing its number was higher in soil treated with low herbicide concentrations. Also, at the end of experiment, lowest number of nitrogen fixation bacteria and *Azotobacter* sp. was detected in treatment with highest herbicide concentration (tab. 2). High concentrations of herbicides reduce the nodules number, nitrogenase activity and ATP synthesis (Govedarica *et al*., 1993). The herbicide 2,4-D showed growth inhibition of nitrogen fixation bacteria (Gaherwal *et al*., 2015). In contrast, growth of nitrogen fixation bacteria were stimulated after application of Anilofos coupled with 2,4-D (Patnaik *et al*., 1995).

Table 3. Fungi and actinomycetes in soil samples (x10^3 CFU/g)

Fungi (x10^3 CFU/g)					
Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	97.3	28.6	41.6	9.5
	30 days	34.3	20.6	20.6	26.6
	130 days	17.2	10.3	8.5	13.7
Actinomycetes (x10^3 CFU/g)					
Treatments		2 l/ha	4 l/ha	8 l/ha	Control
Time of sampling	15 days	59.0	92.0	49.5	105.9
	30 days	207.0	134.0	95.3	274.0
	130 days	62.6	64.4	60.0	108.0

Fungi are group of microorganisms responsible for litter decomposition and its number depends on litter composition and various abiotic and biotic factors (Taylor and Sinsabaugh, 2015). Actinomycetes plays an important role in organic matter decomposition, degradation of pollutants and production of bioactive compounds (Dilip *et al*., 2013). In first sampling, number of fungi was lowest in control treatment. In all treatments, highest number of fungi was recorded in first sampling, followed with decreasing of fungal number until the end of experiment (Tab. 3). Various effects of different Lumax concentrations on fungal number were noticed in this study. Reduction of fungal number using glysphosphate was recorded in previous research (Ubuoh *et al*., 2012), but some *Mucor* and *Aspergillus* species were tolerant to herbicide application. Herbicide application had negative consequences for actinomycetes development in soil in all treatments compared to control (Tab. 3). In researches of other authors, significant inhibition of actinomycetes number was recorded using Paraquat (Zain *et al*., 2013) and nicosulfuron, metribuzin and glyphosate (Šantrić *et al*., 2016).

Conclusion

Our results suggest the various influence of herbicide Lumax on microbial diversity in soil under corn. Total number of bacteria and *Azotobacter* sp. showed good adaptability in the presence of different Lumax concentrations. On the other side, in most of samples, number of fungi, ammonification and nitrogen fixation bacteria was highest 15 days after sowing and decreased during corn growth. These results can be useful for further research of Lumax application considering the importance of beneficial soil microflora in corn production.

Abstract

Forage pea is becoming more and more important plant species as the source of proteins in fodder foods. Although the surfaces on which this plant is grown have been increasing in Bosnia and Herzegovina still the farmers' needs have not been satisfied. A biannual experiment (period 2016- 2017) were set up on the Agricultural institute of Republic of Srpska with five sorts of spring pea (NS Dukat, NS Junior, Bakara, Saša and NS Javor) and different varieties of fertilization (control, NPK fertilization and NPK fertilization+nitrogen fertilization) so we could recommend the best variety to the farmers. Saša variety (29.72 t ha^{-1}) because of its yield stands out as the best one, but it also had high proteins content (19.99%), which is compared to the Baccara variety Baccara (20.04%) slightly lower. For economic reasons it is not viable to perform nitrogen fertilization together with NPK fertilization because it doesn't affect the yield increase, but it makes production more costly. Nitrogen fertilization negatively affects the proteins content so for these reasons basic fertilization with NPK fertilizators is recommended.

Keywords: *forage pea, variety, yield, proteins, green mass*

Introduction

Forage pea is, like other legumes, rich in proteins, which makes it an important source of forage food (*Tawaha & Turk*, 2004; *Rapčan et al*., 2009; *Corre-Hellou & Crozat* 2005, *Lauk &Lauk* 2008). The pea is used as a green forage, silage, hay, milled beans are used as a protein concentrate, for green fertilization and it leaves 80-160 kg ha^{-1} of active nitrogen.
The forage peas green mass represents cheap and quality source for ruminants nutrition. It contains 17, 5 to 18, 3% of raw proteins in its dry matter in average, and its digestibility ranges between 77 and 88 % (*DLG*, 1997; *Stjepanović et al*., 2008). The protein content in the above ground mass and grain varies depending on genotype, year and location (*Lhuiller-Sondélé i et al*., 1999; *Lecoeur & Sinclair*, 2001; *Santalla et al*., 2001; *Rapčan et al*., 2006). Forage pea, compared to others legumes, has shorter vegetation, bigger green mass and bean yield, and is a good pre-crop for most cultivars (*Rapčan et al.,* 2004).
In Bosnia and Herzegovina pea is, as cattle food, produced in low quantity for usage in green mass, while it has been produced in symbolic amounts as a bean for animal nutrition. Pea is primarily grown as spring pea for bean and green mass (*Ćota & Čamdžija*, 2010).

Matherial and work methods

The experiment is set in 2016 and 2017 at an experimental field of Republic of Srpska Agricultural Institute in Banja Luka (160 meters above sea level). Field experiment was set in a random block system in four repetitions. Sowing was conducted with 12, 5 cm spacing between rows and 8 cm in the inside of a row in the basic parcels with combined surface of 5 m^2. Seeds of five different spring varieties of forage pea were used for sowing: NS Dukat, NS Junior, Baccara, Saša, NS Javor. For the research of mineral feeding effecting on raw proteins content in peas above ground mass, together with control variety, the variety with basic fertilization of 350 kg ha^{-1} with $N_8P_{24}K_{24}$ fertilizer was also used, as well as the variety with basic fertilization of 350 kg ha^{-1} with $N_8P_{24}K_{24}$ fertilitzer+top-dressing of 27 kg ha^{-1} (27% KAN was used) . In 2016 the sowing was conducted on April 15th, and harvesting on July 15th, while in 2017 the sowing was on March 23rd, and harvesting on July 6th. The samples of above ground mass were taken in the inflorescence stage from a surface of 1 m^2 from every repetition. After weighing the mass of the samples was recalculated into amount of above ground vegetative mass expressed with t ha^{-1}. The content of raw proteins was determined by Weende (Kjeltec autosampler 1035-Tecator) in the laboratory of the Faculty of Agriculture in East Sarajevo. The obtained data were processed by multivariate analysis of variance (MANOVA) and tested with LSD test (STATISTICA 7.1 for Windows (Stat Soft 2005).

Agroecological conditions

Total monthly rainfall and average air temperatures for years in which the research was conducted and perennial average in Banja Luka are showed in Table 1.

Table 1. Average monthly air temperatures (°C), monthly rainfall (mm) and perennial averages for Banja Luka

Month		I	II	III	IV	V	VI	VII
2016.	Temperature (°C)	2.3	7.6	8.0	13.5	16.2	21.5	23.3
	Rainfall (mm)	109.7	108.5	122.2	0.5	100.6	117.8	125.9
2017.	Temperature (°C)	-3.6	5.5	9.7	11.8	17.5		
	Rainfall (mm)	87.2	100.4	124.0	148.4	92.1		
Average 1981-2010	Temperature (°C)	0.6	2.3	6.8	11.5	16.5	19.8	21.8
	Rainfall (mm)	69.7	59.1	87.5	84.3	89.4	112.4	81.4

Regarding the temperature, the conditions were favorable for pea growth. Average monthly temperatures were above the perennial average in both years during the experiment, with only May 2016 having slightly lower average temperature compared to the perennial average. In the vegetation period, the rainfall varied year to year and month to month. In 2016, May vas the extreme month with the rainfall of only 0, 5 mm, and in 2017, June and July were the dry months. Uneven rainfall affects the yield and quality of forage pea.

The soil on which the experiment was conducted is of good physical properties with plow depth up to 35 cm. According to agrochemical analysis performed in the Faculty of

Agriculture in East Sarajevo, the soil contains 0,13% of nitrogen, 8.6% of calcium, 2,05% humus, >40 mg/100 g phosphorus and 38,48 mg/100 g potassium. The soil reaction is neutral with pH in nKCl at 6,97.

Results and discussion

The average green mass yield for all forage pea varieties was 20,83 t ha^{-1} , regardless of experimental years and fertilization varieties. (Table 2).

Table 2. The effect of year, fertilization and variety on green mass yield

NPK amount	Variety	Year		Average
		2016	2017	
Control	NS Dukat	15.50	13.75	14.62

AxBxC (year x fertilization x variety)	0.961	6.056	8.024

In 2016, the average green biomass yield was statistically significantly higher, compared to 2017 (19,35 t ha^{-1}). In 2017, there was an unfavorable rainfall schedule, which significantly affected the green mass yield. Forage pea requires a lot of moisture, so the amount and the

schedule of rainfall during the vegetation period are crucial for bean and green mass formation. The amount of rainfall in May and the first ten days of June are significant for the spring peas yield (*Kovac*, 1994; *Rapcan et al*, 2006). The control variety, compared to others where mineral fertilizers were applied, had statistically significant smallest yield of green mass, while the differences in varieties with mineral top-dressing had no statistical significance.
The Saša variety (29,72 t ha^{-1}) compared to other varieties had significantly higher yield, and the NS Junior variety (23,03 t ha^{-1}) had higher yield when compared to NS Dukat, Baccara, NS Javor varieties, while there were not significant differences between these varieties. *Hoffman i Dér* (2003) established in their research that variety had a significant influence on fresh mass yield in pea, which is in accordance with our results. In every variety in the year 2016, there was a bigger yield in green mass compared to 2017. Unfavorable weather conditions in 2017 had an effect on significant decrease in the Saša variety because the difference between the researched years was 7,93 t ha^{-1}. Year significantly affected the green mass yield in NS Junior variety also (3,4 t ha^{-1}), while the differences in other varieties varied between 0,55 and 1,77 t ha^{-1}.

The average raw proteins content for all tested varieties regardless of experimental years and fertilization varieties was 18,03% (table 3).
The proteins content in above ground green mass, from a statistic point of view, was significantly higher in 2016 (19,235), when compared to 2017. (16,74%). The fertilization did not have a significant effect on proteins content, as even in NPK fertilization+ nitrogen top-dressing variety there was determined the smallest protein content, which is in accordance with results gathered by *Štafa et al.* (1999). In the year+fertilization interaction we determined highly significant differences in proteins content. Larger proteins content was found in 2016 in all fertilization varieties, compared to 2017. The Baccara variety (20,04%) had the largest proteins content, and the NS Dukat (14,04%) had the smallest. The determined differences were highly significant from the statistical point of view, as well as the differences between the NS Dukat variety and varieties NS Junior, Saša and NS Javor. Significant difference in proteins content was determined between varieties NS Javor and Saša, and highly significant between Saša and NS Junior. Although all varieties had larger proteins percentage in 2016 than in 2017 it is interesting that there was a significant decrease of proteins percentage in the NS Dukat variety in 2017. In the control variety there in NS Dukat, NS Junior and Baccara there were more proteins, when compared to NPK fertilization+ nitrogen top-dressing variety.

Table 3. The effect of the year, fertilization and variety on pea's raw proteins percentage

NPK Amount	Variety	Year 2016	Year 2017	Average
Control	NS Dukat	18.59	10.59	14.59

AxBxC (year x fertilization x variety)	0.701	2.558	3.389

Conclusion

Although the agroecolegical conditions were favourable for forage pea growth, unfavourable rainfall schedule during the experiment in 2017 affected the yield of green mass and the proteins content in above ground pea mass. During the usage of different mineral top – dressing treatments, the smallest yield of green mass was found in the control variety, while the usage of NPK fertilizers and the combination of NPK fertilizers and top – dressing did not significantly affected the differences in the yield. The use of mineral fertilizers, especially nitrogen, had a negative effect on the proteins content. The biggest green mass yield in both years of the experiment had the NS Saša variety, but the variety had a significant fluctuation depending on agroecological conditions. The smallest green mass yield had the NS Javor variety. The Baccara variety had the highest protein content and the Dukat variety had the lowest.

Abstract

Maize is main field crop on the arable lands of Bosnia and Herzegovina (B&H). In the 2011-2015 period, maize was grown on average 189 137 ha or close to 20% of arable land. The majority of maize growing area was situated in the northern lowland region and in Republic of Srpska (RS). Considerable variation of the yearly yield was found in this period from 2.7 t ha^{-1} (2012) to 4.7 t ha^{-1} (2014), mainly under influence of weather conditions. With that regard, precipitation and temperature regimes, particularly in July and August, had considerable effects. 2011, 2013 and 2015 growing seasons were more close to usual values. However, 2012 and 2014 were considerably deviated and characterized by drought and hot stress (2012) and excessive, but for maize more favorable, precipitation and the lower temperature (2014). Six meteorological stations were selected for weather characterization as follows: Bijeljina (BI), Tuzla (TZ), Gradacac (GR), Banjaluka (BL), Prijedor (PR) and Bihac (BH). Precipitation and mean air temperatures in the period 2011-2015 were compared to the long-termmeans1961-1990 (LTM). In general, precipitation in the April-September period (LTM) was lower and temperatures higher in the eastern part (BI: 417 mm and 17.8 ^{o}C) than in western part (BI: 664 mm and 16.6 ^{o}C) of the country. These values for two deviated growing seasons were as follows: 288 mm and 20.0 ^{o}C in BI, 693 mm and 18.9 ^{o}C in BH (2012), 731 mm and 18.5 ^{o}C in BI, 1135 mm and 17.1 ^{o}C in BH (2014).

Keywords: *precipitation, temperature, maize yield, climatic change.*

Introduction

Maize is main field crop on the arable lands of Bosnia and Herzegovina (B&H). In the 2011-2015 period, maize was grown close to 20% of arable land of the country. Average yield in the mentioned period was 3.92 t ha^{-1} (AS, from 2012 to 2016) and it is low with the aspect of possibilities, the existence of high-yielding hybrids and environmental conditions under different systems of soil tillage (Jug et.al., 2014). Weather conditions are also important factors of maize yield and weather excess accompanied with drought and high air temperature, particularly in July and August, are often in connection with low yields (Kovacevic et al., 2013, 2016; Kovacevic and Rastija, 2014; Majdancic et al., 2016). In the recent period there are considerable variations annual yields of maize among years mainly as affected by climatic change, particularly extreme drought during summer months (Kovacevic and Rastija, 2014). Aim of this study was testing maize yields in B&H for the recent 5-year period with emphasis on climatic change.

Material and methods

The FAO database (FAO), releases of Agency for Statistics (AS) of Bosnia and Herzegovina (Agriculture, Environment and Regional Statistics: harvested area, total production and yield of main crops), statistical yearbooks Republic of Srpska (SYRS) and Federation of B&H (SYFB&H) were used as source of the arable land, harvested area and maize yield data. Publications of Hydrometeorological Institute of the Republic of Srpska in Banja Luka and Federal Hydrometeorological Institute in Sarajevo were perused for used the meteorological data as follows: monthly values of precipitation and mean air temperature, means of minimal and maximal air temperatures and their absolute values. B&H is administratively divided into two political entities (Federation of B&H or FB&H and Republic of Srpska or RS) and Brcko district.

Six meteorological stations (MS) situated in the northern part of the country - three from RS and three from FB&H - were selected for analyzing of weather data with the aspect of maize growth (Fig 1). The most western and the most eastern positions of Bihac and Bijeljina are air-distanced 320 km. Choice of this part of B&H is resulted by the fact that by these localities are covered majority growing area of maize in B&H.

Fig. 1. Situation of MS in B&H

Results and discussion

B&H has on disposal about 1 million ha of arable land and gardens and even close to 50% are fallow and uncultivated land. Maize harvested area in the 2011-2015 period was average 189 137 ha and close to decade 2000-2010 average. However, average maize yield 3.92 t ha^{-1} is about 12% lower compared to the decade average. About 70% of maize harvested area are situated in RS. High variation of yields are mainly affected by weather conditions (Table 1).

Table 1. The harvested area and yields of maize in B&H and in level of the entities

	Statistical data from 2011 to 2015 (FAO, AS, SYRS and SYFB&H)						
	Average	Year					Average
	2001-2010	2011	2012	2013	2014	2015	2011-2015
Arable land and gardens (000 ha): total, fallow and unfarmed land							
Total		1 009	1 006	998	1 011	1 029	1 010
Fallow and unfarmed		478	476	478	508	510	490
Harvested area (ha) and yields of maize for grain (t ha^{-1})							
Bosnia and Herzegovina

However, the mean air temperature in 2011 -2015 period (April-September) was 18.9 ^{o}C or for 1.9 ^{o}C higher than in 1961-1990 with variation among years from 17.8 ^{o}C in 2014 to 19.7 ^{o}C in 2012 (Table 3). In general, precipitation quantities have increasing trend and temperature decreasing trend in the direction from the east toward the west (1961-1990: Bijeljina 417 mm and 17.8 ^{o}C and Bihac 664 mm and 16.6 ^{o}C). Average minimal and average maximal temperature in the 2011-2015 period (Table 4) was 13.4 ^{o}C and 25.6 ^{o}C in Bijeljina, 11.9 ^{o}C and 24.9 ^{o}C in Bihac (averages 1961-1990: 13.7 ^{o}C and 24.4 ^{o}C, 10.5 ^{o}C and 22.8 ^{o}C, for Bijeljina and Bihac, respectively). Absolute minimal air temperature in 2011-2015 period (Table 5) was recorded in April of 2012 (Bijeljina -2.8 ^{o}C and Bihac -4.0 ^{o}C (1961-1990: Bijeljina -0.6 ^{o}C and Bihac -4.6 ^{o}C), while values for absolute maximal temperature were for 2011-2015 period were recorded in August of 2012 (Bijeljina 40.3 ^{o}C) and 2013 (Bihac 42.0 ^{o}C). Comparison these values with 1961-1990 period (34.7 ^{o}C in Bijeljina and 38.6 ^{o}C in Bihac) indicating global warming (Chi-Chung et al., 2004, FAO, 2007). The 2012 growing season was unfavorable for maize growth because of lower precipitation and the higher temperature in April-September period (means of 6 stations: 427 mm and 19.8 ^{o}C). Especially unfavorable weather conditions were observed in August for all tested sites with exception Bihac (from 0 to 2 mm precipitation and mean air temperature between 24.1 ^{o}C in Prijedor to 25.8 ^{o}C in Gradacac; Bihac 39 mm and 22.9 ^{o}C: Tables 1-2). Absolute maximal air temperature in Bijeljina was in three 10-day periods of August 2012 from 35.6 ^{o}C to 40.3 ^{o}C and by these stress conditions was also exposed maize in the eastern parts of Croatia and Hungary, as well as in the northern part of Serbia in Vojvodina province (Table 6). As affected by these conditions maize yields in 2012 were low in B&H (2.74 t ha^{-1}), in the neighbouring Croatia (4.34 t ha^{-1}) and Serbia (2.78 t ha^{-1}), as well as in Hungary (3.98 t ha^{-1}) and yield decrease in 2012 compared to normal weather conditions in 2010 were between 38% (Croatia and Hungary: in B&H 40%) and 53% in Serbia (Kovacevic et al., 2013).

Alleviation of unfavorable weather stress for maize growth is possible by application corresponding soil and crop management practice, for example, soil ploughing in autumn instead of spring and incorporation before ploughing phosphorus and particularly potassium mineral fertilizer according soil test, liming of acid soils and growing of drought more tolerant hybrids (Kovacevic and Rastija, 2014; Komljenovic et al., 2010, 2015; Kovacevic and Loncaric, 2014; Markovic et al., 2008).

Conclusions

Weather conditions, particularly long drought period and high air temperature adversely affected on maize yields. With that regards, the 2012 and 2014 growing season are typical examples of recent climatic change characterizing by global warming and extremely oscillation of weather in short period. The first mentioned year was unfavorable and the second mentioned year very favorable for maize growth. By adequate soil and crop management is possible to alleviate stress provocated by weather and stabilizing yields of maize among years.

Abstract

The studies on genetic control of productivity are impotant for the breeding of new productive cotton varieties. Six varieties (*G. hirsutum* L.), differing in productivity were included in a half diallel cross, in 2010-2011, with the aim to investigate the inheritance of productivity. In 2012 another half diallel cross, including other six parents was made. The study was carried out in the experimental field of the Field Crops Institute in Chirpan. One set of F_1 hybrids and their parents were studied. The components of variability caused by the additive and dominant effects and their ratios, the variability due to the conditions of the environment were determined. Based on these, the indexes of inheritance of productivity were calculated. It was found that the productivity in the studied sets of crosses was controlled by a complex genetic system, in which the overdominance action of genes predominated especially in F_1–2011 and F_1-2012 without $P_{5.}$ Statistically significant were both additive and dominant effects. Dominant gene action was superior to additive one for both diallel crosses and reflects the importance of dominant variance in the inheritance of productivity. The parents had different dominance (recessiveness) in F_1 – 2010-2011 during the two years of the exploration probably due to their specific reaction to the year conditions. Because of high degree of dominance, weakly genetic variability and different expression of genes observed in F_1 – 2010-2011 quick and successful selection can not be expected.

Keywords: *cotton, G. hirsutum L., diallel analysis, productivity*

Introduction

Diallel analysis has been frequently used method in the selection of different cultures, including cotton, to obtain valuable information about the genetic components and parameters of inheritance for a particular set of parents, and an assessment of their general and specific combining ability (Hayman, 1954, Griffing, 1956, Mather and Jinks, 1982).
A number of authors, using various schemes of complete and incomplete diallel crosses, have been established the breeding value of a large number of cotton varieties and the effects of gene action on the characteristics related to yield and fibre quality (Dukre *et al.*, 2009; Khan *et al*., 2011; Batool, 2011). Singh *et al*. (2011) concluded that additive and non-additive gene effects played a parallel role in the inheriting of seed cotton yield. Others, Gamal *et al.* (2009), Ali *et al.* (2009), Makhdoom (2011) reported the superiority of non-additive gene action. The Abbass *et al*. (2008), Khan *et al.* (2011), Igbal *et al.* (2011), Sarwar *et al.* (2011) studies supported the greater importance of additive genes.
The aim of this study was to establich through diallel analysis the parameters of some genetic components and indexes of inheritance of productivity in F_1 cotton hybrids (*G. hirsutum* L.).

Material and Methods

The hybrid populations of two diallel crosses were investigated. In 2010-2011 in one diallel cross 6 upland cotton varieties (4 Bulgarian and 2 foreign) were included: Beli Iskar - P_1;

Barut 2005 (Turkish) - P_2; Darmi - P_3; Mytra (Greek) - P_4; Helius - P_5 and Dorina - P_6. In 2012, in another diallel cross, 6 other varieties, except Helius, were included: Chirpan-539 - P_1; Helius – P_2; Rumi - P_3; Boyana - P_4; Natalia - P_5 and Nelina - P_6 (Bulgarian selection). An incomplete diallel scheme was used, including the parents and one set of F_1 hybrids from direct crosses. The study was carried out in the experimental field of the Institute of Field Crops in Chirpan. The trials were set in three replicates, the parents and their F_1 hybrids were sown in 2 rows of 2.4 m in a 60×20×1 sowing scheme. Ten plants from each replication were accounted. Dispersion and diallel analyses, adequate of diallel scheme, were applied to the data processing (Mather and Jinks, 1982). The data suitability for diallel analysis was evaluated with the regression coefficient b and t (Wr-Vr) (Mather and Jinks, 1982).

The following components of genotypic variation along with their standard errors were calculated: D – additive genetic variance; H_1 and H_2 – dominance variances; F - shows the ratio of dominant to recessive genes in parents; E - variability due to the influence of environmental conditions. On the basis of the above components, the following indicators were calculated: $(H_1/D)^{1/2}$ - average degree of dominance in each locus; $H_2/4H_1$ - ratio of the positive and negative alleles in the loci showing dominance in the parents; K_D/K_R $[(4DH_1)^{1/2}+F/(4DH_1)^{1/2}-F]$ - shows the ratio of dominant to recessive genes in parents; $k = (h^2/H_2)$ - number of effective factors; H^2 and h^2 – coefficients of heritability in a broad and in a narrow sense, calculated by Mather and Jinks (1982). The strong and significant variation of Wr-Vr of the parental arrays and deviation of regression coefficient b from 1 (b≠0; b=1) were used to check the existence of epistasis. In the model b<1 indicates the presence of complementary epistasis.

Results and Disussion

Diallel analyses of the productivity per plant were made for F_1 - 2010-2011 (1st diallel cross) and F_1 - 2012 (2nd diallel cross), with and without exclusion of parents from the diallel schemes. Due to the specific reaction to the conditions of years, the parents from F_1 - 2010-2011 changed their ranking by years and the change of grading was more significant for the varieties Mytra, Darmi and Dorina. Parents with high (P_5 - Helius) and low (P_2 – Barut 2005) values of the studied trait generally retained their positions. The differences between P_5 - Helius and P_2 – Barut 2005 were large - 32.5 g and 20.7 g/plant, respectively, average for the two years. The preliminary analysis of the variance (ANOVA) showed significant differences among the genotypes (data are not given here). In F_1-2012, the differences between P_5 - Natalia and P_4 - Boyana, with highest and lowest productivity, respectively, were small - 20.8 g and 16.4 g per plant.

The regression coefficient - b for the F_1-2012 was significantly less than unity, indicating the presence of complementary epistasis (Table 1). The variation of parental arrays under the Wr-Vr criterion for the F_1 - 2010-2011 and F_1-2012 was statistically insignificant and do not indicate the presence of non-allelic interactions. In all analyses, however, the regression coefficients were low (with low values) and it is considered that the regression lines in diallel graphs do not adequately represent the Wr/Vr relationship because of existence of epistasis. Many authors reported incomplete or partial adequacy of characters contributed to the seed cotton yield and fiber quality (Abbass *et al*., 2008; Ali *et al*., 2008; 2009). According to Jinks (1954) and Jana (1972) the exclusion of one or more parents, bringing epistatic effects, from diallel scheme could improve the adequacy of the data with the additive-dominance model. After exclusion of one of the parents - P_6 (Dorina) from the F_1 -2010-2011 diallel scheme, the resulting set improved the results adequacy for diallel analysis. The F_1-2012 diallel scheme from which P_5 (Natalia) was excluded provided the most constant values of the Wr-Vr which improve the data adequacy to the additive-dominance model.

Table 1. Additive-dominance model and epistasis tests for the productivity/plant in two diallel crosses - F_1-2010-2011 and F_1-2012

Diallel cross Year	Excluded parent	$b_{Wr/Vr}$	0>b>0	1>b>1	t (W_r-V_r)
F_1 – 2010	-	0.690 ± 0.211	3.270^{++}	1.469	0.948
	P_6	0.851 ± 0.167	5.096^{++}	0.892	0.663
F_1 – 2011	-	0.614 ± 0.242	2.537^{+}	1.595	0.929
	P_6	0.715 ± 0.217	3.295^{++}	1.313	0.920
F_1 – 2012	-	0.568 ± 0.211	2.692^{++}	2.047^{+}	1.368
	P_5	0.719 ± 0.304	2.365^{+}	0.924	0.389

The diallel results were significantly improved with the exclusion of P_6 in F_1-2010-2011 and P_5 in F_1-2012, but the regression test, as a more accurate, showed incomplete adequacy of results in F_1- 2011 without P_6 and in F_1-2012 without P_5 because of low values of regression coefficients, suggesting that other parents were also carriers of non-allelic interactions. Both parents (P_6 and P_5) were removed after successively exclusion of each parent.

Both additive and dominance gene effects were statistically significant (Table 2). The parameter *D* had relatively lower values revealing that the additive gene action had less importance for the variation of studied trait. Dominance gene action was superior to additive, both H_1 and H_2 dominance components, except H_2 in F_1-2010 without P_6, were greater than additive component (*D*) during all years of research, indicating greater importance of dominance variance in the inheritance of productivity. The parameter H_1 shows a high degree of dominance. The indicator H_1/D expresses overdominance in both crosses, and $H_1/D^{1/2}$ - overdominance in each individual locus showing non-additive type of gene action and that the dominant genes were in increasing position, confirmed by positive values of h^2 which were significant in F_1- 2010-2011 and insignificant in F_1- 2012. From M_{L1}-M_{L0} it is visible that on average for the entire diallel crosses, the overdominance was in direction of increasing productivity. The second dominant parameter H_2 had also high values close to those of H_1 in F_1-2012. The $H_2/4H_1$ ratio showed unequal distribution of positive and negative alleles in the loci exhibited dominance in the parents, which was well expressed in F_1-2010 and F_1-2011 with a full set of parents, and less in F_1-2011 with the excluded parent P_6 (Dorina), as well in F_1-2012. The parameter F had a positive sign in all years, but its values were significant only for F_1-2010, which means that the dominance alleles exceeded recessive ones, while for F_1-2011 and F_1-2012 these values were insignificant and it should be assumed that dominance and recessive alleles had relatively equal frequencies. The K_D/K_R ratio reflects superiority of dominance alleles over the recessive alleles, less pronounced for F_1-2011. The coefficient of heritability in a narrow sense (h^2) was very low to moderate due to the large influence of dominance gene action in the inheritance of this trait. This means that an effective improving the productivity could only be achieved in later hybrid generations - F_3-F_4 when dominance gene effects have declined. Significant negative correlation coefficients between (*Wr+Vr*) values and parental mean meanings reveal that the parents containing dominant genes were responsible for increased productivity per plant. The *k* values (number of effective factors) indicate at least 2 to 3 genes or groups of genes controlling productivity.

The varieties Darmi (P_3), Helius (P_5), Beli Iskar (P_1) and Dorina (P_6) (F_1 - 2010-2011), Rumi (P_3) and Chirpan-539 (P_1) (F_1-2012), showed high productivity, had low *Wr+Vr* values. This means that their high productivity was determined by dominant genes with unidirectional enhancing productivity effect (Table 3).

The varieties Darmi(P_3), Dorina (P_6), Beli Iskar (P_1) (F_1 - 2010-2011), Rumi (P_3) and Natalia (P_5) (F_1-2012) were the parents containing most dominant genes and were best suited for including in crosses, while the varieties Barut (P_2), Mytra (P_4) (F_1 - 2010-2011), Boyana (P_4) and Nelina (P_6) (F_1-2012) had most recessive genes. Helius variety had a non-permanent dominance, high in 2010 and 2012, and low in 2011. Foreign varieties Mytra and Barut also had a non-permanent dominance/recessivity. These varieties were unable to realize their productive potential under our conditions due to a delay in ripening and have given unstable yields. In some cases degree of dominance varied with the change in diallel scheme after the exclusion of one of the parents.

Summarized results show that the productivity/plant in both diallel crosses was determined by a complex genetic system, in which the overdominance action of genes predominated. The overdominance reveals the presence of nonallelic interactions, which were more strongly pronounced in F_1-2011 with and without P_6 and in F_1-2012 without P_5. Due to overdominance some parameters (H_1 and H_2) and indicators (K_D/K_R), as well as heritability values (h^2), in F_1-2011 without P_6 and in F_1-2012 without P_5, were more strongly influenced by dominant effects. In both crosses the inheritance was incompletely dominant to overdominant, some crosses showed significant specific combining ability (data not given). The model worked correctly in F_1-2010 without P_6 (with the highest value of regression coefficient and very weak overdominance) and showed that the genetic control of productivity per plant was largely non-additive and this was obseved in all diallel analyses. Overdominance type of inheritance of productivity was reported by Ahmad *et al*. (2005), Iqbal *et al*. (2005) and Khan *et al*. (2009). In the relatively complexity of this feature, low additive variation, and influence of the year conditions on genetic control, a rapid and successful selection could not be expected. In all cases, non-additive gene effects predominated and the selection for productivity has to be conducted in later hybrid generations. The results obtained from this study were in accordance with those by Gamal *et al*. (2009), Ali *et al*. (2009), Khan *et al*. (2009; 2011) and Makhdoom (2011), who also reported that the seed cotton yield/plant was more strongly influenced by the non-additive gene effects.

Conclusion

Genetic control of productivity in both studied diallel crosses was largely non-additive. The overdominance action of genes predominated with manifestation of complementary epistasis. Greater participation of non-additive genetic variation and relatively low coeficients of heritability suggested that a rapid and successful selection could not be expected, effective selection for improving the productivity could achieved in later hybrid generations - F_3-F_4.

Abstract

Response of 16 new introduced sweet cherry cultivars and one hybrid from Poland and China to winter hardiness and late spring frost was evaluated, and their phytosanitary status was determined. The research was conducted in the experimental sweet cherry orchard planted in the spring of 2012 at the Institute of Agriculture – Kyustendil. The study on the resistance of cultivars to low winter temperatures was conducted under natural conditions in 2016 and 2017, and in 2016 for the late spring frosts. Young leaf or petal samples were taken from 84 trees and were analysed by ELISA for the presence of PNRSV (*Prunus necrotic ring spot virus*), PDV (*Prune dwarf virus*), CLRV (*Cherry leaf roll virus*) and RpRSV (*Raspberry ring spot virus*), PPV (*Plum pox virus*) and ACLSV (*Apple chlorotic leaf spot virus*) infection. In 2016 (-19.9°C), all investigated cultivars had a higher resistance to winter cold than the standard Van. In 2017 (-29.5ºC) with the highest cold resistance was cultivar Kozerska, in which the damage of flower buds was 79.2%. It was found that 13 of studied cultivars had higher cold hardness than Van. Young fruit sets were damaged completely without cultivar difference after the late spring frost on 27th April, 2016 (- 4,0°C). The most significant damages with deep longitudinal cracks on the stem of the trees were found in cultivars Kristin, Van, Van Compact, Rucsandra, Techlovan, Tieton, Huldra and Bigalise pozna. The total infection rate in the investigated orchard was 52.4%. Among the viruses, PDV infection was the most frequent (29.8%), followed by mixed infection - PNRSV + PDV (11.9%), PNRSV (5.9%) and ACLSV (4.8%). The different cultivars were infected to a different degree. PPV, CLRV and RpRSV were not present in the sweet cherry orchard.

Keywords: *Sweet cherry, Winter hardiness, Late spring frost, Resistance, Viruses.*

Introduction

The Kyustendil region is one of the main producers of sweet cherry fruits in Bulgaria. The climate in the region is moderate continental, characterized by cold winters and conditions for late spring frosts. One of the high-priority breeding goals in the selection of sweet cherries are cold hardiness and late bloom; the late bloom is to prevent from damage caused by spring frost in the northern districts and low chill requirement in the southern districts (Sansavini and Lugli, 2008). Significant attention is paid to this problem abroad (Lang et al., 1997; Blažková, 2004; Szewczuk et al., 2007; Kask et al., 2009), as well as in Bulgaria (Georgiev et al., 2001; Lichev and Papachatzis, 2009; Christov et al., 2015).

To date, seven virus species have been identified in sweet cherry trees in Bulgaria. They include *Prunus necrotic ring spot virus* (PNRSV), *Prune dwarf virus* (PDV), *Apple chlorotic leaf spot virus* (ACLSV) (Milusheva and Borisova, 2005; Borisova et al, 2013), *Cherry leaf roll virus* (CLRV), *Arabis mosaic virus* (ArMV), *Raspberry ring spot virus* (RpRSV), *Apple*

mosaic virus (ApMV) (Milusheva and Zhivondov, 2009; Milusheva et al., 2014). Among them, the *Ilarvirus* species PDV and PNRSV have been reported as the most common and economically important in sweet cherry orchards in the Kyustendil region (Borisova and Christov, 2012; Borisova et al., 2013), while the most distributed virus in Plovdiv region of Bulgaria is proved to be CLRV (Milusheva et al., 2014). It is very important to know the phytosanitary status of the investigated new sweet cherry cultivars and elites, because virus contaminations can reflect on the evaluation of their biological and economic properties.
The aim of this study was to evaluate 16 newly introduced sweet cherry cultivars and one elite to winter hardiness, spring frost, along with their phytosanitary status and potential to grow in the Kyustendil region.

Material and Methods

The research was conducted in the experimental sweet cherry orchard at the Institute of Agriculture – Kyustendil, planted in the spring of 2012 with newly introduced cultivars from Poland and China. The objects of the study were the cultivars Rucsandra, Kristin, Victor, Bigalise pozna, Bigalise, Black pearl, Sweetheart, Techlovan, Charna z turwil, Vasiliča, Tieton, Santina, Sparkle, Huldra, Star z Chech, Van compact and hybrid 8-102. As controls were used the cultivars Van and Kozerska. The trees were grafted on *P. mahaleb* rootstocks, with planting distances of 6 x 5 m.
The study on the resistance of the investigated cultivars to low winter temperatures and late spring frosts was conducted under natural conditions in 2016 and 2017. The air temperatures were measured in standard meteorological cell (2 m in height). The percentage of damage was calculated based on generally accepted methodology by longitudinal cross-section of buds and their observations under a binocular. After the late spring frost from 27 April 2016, observation of damage of young fruits and multiannual wood was made. The results concerning damages after winter frosts were processed by the method of analysis of variance using the LSD-test to prove statistical significance of the differences found between the control and the variants. The evaluation was made at levels of significance P <0,05, P <0,01 and P <0,001 (Maneva, 2007).
Leaf samples in phenophase "slicing the leaf bud" were tested for PNRSV (*Prunus necrotic ringspot virus*), PDV (*Prune dwarf virus*), CLRV (*Cherry leaf roll virus*) and RpRSV (*Raspberry ring spot virus*) infection, while completely formed petals or young leaves were tested for PPV (*Plum pox virus*) infection and ACLSV (Apple chlorotic leaf spot virus). The double antibody sandwich-ELISA (DAS-ELISA) (Clark and Adams, 1977) was applied to test PPV, PNRSV, PDV, CLRV, RpRSV; whereas DAS-simultaneous ELISA (Flegg and Clark, 1979) was performed to detect ACLSV, using commercial kits (Loewe Company, Germany).

Results and Discussion

On 24th January 2016, the absolute minimum air temperature had fallen to -19.9ºC. The duration of the impact of the temperatures under -18.0°C was 2.5 hours. The absolute maximum temperatures in these days were with low negative values. In the concrete conditions, all investigated cultivars had a higher resistance to cold than the standard cultivar Van, with 66.7% of damaged flower buds (Table 1). The cultivars Santina and Bigalise pozna had the highest cold resistance, with respectively 3.2% and 4.3 % of damaged flower buds. Very good resistance to this stress factor had also the cultivars Kozerska (7.2%), Krustin (8.3%), Huldra (9.5%), Sparkle (9.8%) and hybrid 8-102 (15.9%). In previous studies carried out at the institute, it was found that cultivar Kozerska had very good winter hardiness, after -27.5 ºC it was reported 65.9% of damaged flower buds, while for Van they were around

92.0% (Georgiev et al., 1990). The highest percentage of damage to the generative organs was found in cultivar Van (66.7 %), followed by cultivars Black pearl (61.3%), Star z chech (56.9%), Van compact (52.7%) and Rusandra (41.6%). This temperature value is relative border at which the damages are low and it is possible to get a normal yield. After the statistical analysis the differences between control and investigated cultivars are positively proven, except for the cultivars Black pearl, Star z chech and Van compact in which the differences are insignificant to the control (Table 1). On 8th January 2017, the absolute minimum air temperature reached -29.5 ºC. The duration of the impact of the temperatures under -18.0°C was 13 hours. In these critical temperatures, the highest cold resistance had the cultivar Kozerska, in which the damage of flower buds was 79.2%. For the other cultivars, the damages were from 87.8% to 99.7%. This shows that for most of the studied cultivars this temperature is fatal to their generative organs. 13 of the investigated cultivars had proven higher cold resistance than the control cultivar (Table 1).

** (0) - stems without symptoms; (+) – slight swellings with cracks on the bark of the stems; (++) - longitudinal cracks on the stems*

On 27th April 2016, it was registered late spring frost with an absolute minimum temperature of -4.0°C, with long duration of impact (5.0 h). In this period, all the tested cultivars had fruits with the size of a pea. All the fruits were 100% damaged at this critical temperature. No differences between the cultivars were found. According to Georgiev (2001), the most sensitive to frosts are pistils and young fruit sets. In some cultivars, it was found damages to the stems of the trees in the form of slight swellings with cracks on the bark and longitudinal cracks. The most significant damages with deep longitudinal cracks to the stem of the trees was found in the cultivars Kristin, Van, Van Compact, Rucsandra, Techlovan, Tieton, Huldra and Bigalise pozna (Table 1). With low swellings and slight surface cracks on the bark were the cultivars Charna z turwil, Victor, Santina, Sweetheart and Vasilica. In the rest investigated cultivars, there were not established damages to the stem of trees caused by the late spring frost. In order to understand the sanitary status of the cherry trees grown in the investigated new experimental sweet cherry orchard, a total of 84 sweet cherry trees were tested for the presence of six RNA plant viruses by ELISA. The total infection rate in the investigated orchard came up to 52.4%. Among the viruses, PDV infection was the most frequent (29.8%), followed by mixed infection - PNRSV + PDV(11.9%), PNRSV (5.9%) and ACLSV (4.8%) . PPV, CLRV and RpRSV were not present in the sweet cherry orchard (Table 2). Similar results were reported about sweet cherry plantations of Central-Western Spain (Sanchez et al., 2015). The ELISA results revealed that 72% of the sweet cherry trees were infected by at least one of the viruses, PDV was in the highest infection rate.

Table 2. Viruses detected by ELISA in experimental sweet cherry orchard planted in the spring of 2012 with newly introduced cultivars at Institute of Agriculture – Kyustendil, Bulgaria

Cultivars	**Tested samples**	**Infected samples No. (%)**	**PNRSV**	**PDV**	**PPV**	**CLRV**	**RpRSV**	**ACLSV**	**PNRSV + PDV**
Rucsandra	8	0	0	0	0	0	0	0	0

Victor	5	1	0	1	0	0	0	0	0
Bigalise pozna	7	3	0	2	0	0	0	0	1
Van compact	11	11	0	11	0	0	0	0	0
Black pearl	1	1	1	0	0	0	0	0	0
Sweetheart	3	3	3	0	0	0	0	0	0
Techlovan	5	0	0	0	0	0	0	0	0
Charna z turwil	4	0	0	0	0	0	0	0	0
Vasiliča	2	2	0	1	0	0	0	0	1
Tieton	6	6	0	3	0	0	0	0	3
Kozerska	6	4	0	0	0	0	0	4	0
Santina	3	3	1	1	0	0	0	0	1
Van	6	1	0	1	0	0	0	0	0
Sparkle	3	3	0	0	0	0	0	0	3
Huldra	1	0	0	0	0	0	0	0	0
Star z Chech	1	1	0	0	0	0	0	0	1
Bigalise	2	0	0	0	0	0	0	0	0
8-102	5	0	0	0	0	0	0	0	0
TOTAL	84	44 52.4%	5 5.9%	25 29.8%	0	0	0	4 4.8 %	10 11.9%

The data from the tests has shown that different cultivars were infected to a different degree. A single infection of PNRSV was found in tree trees of cultivar Sweetheart, one tree Black pearl and one Santina. PDV was detected in 100% of the trees of the cultivars Kristin and Van compact, in 50% of the trees of the cultivar Tieton, two trees of the cultivar Bigalise pozna and in one tree of the cultivars Victor, Vasilica, Santina and Van. In 100% of investigated trees of the cultivar Sparkle, 50% of Tieton and one tree of the cultivars Bigalise pozna, Vasilica, Santina and Huldra was found mixed infection of PNRSV + PDV. There was also found a single infection of ACLSV in 4 trees of the cultivar Kozerska.

In field observations, in our study were not identified symptoms of the virus infection on leaves of the studied cultivars, although ELISA tests confirmed the presence of viral infection in some of them. These results are in confirmation of the results of other authors, according to which after natural infection PNRSV, PDV and ACLSV are symptomless in most cultivars in some years (Smith et al., 1988; Hadidi et al., 2011).

The aim of this experimental sweet cherry orchard was to introduce new cultivars to the region of Kyustendil and to evaluate their adaptation to the regional conditions by fruit quality and quantity. It would be hard to have reliable data from the trees carrying virus infections which can affect these aspects. This material is inappropriate for propagation purpose.

Conclusions

All investigated cultivars had a higher resistance to winter cold than the standard cultivar Van, at air temperature -19.9° C. When temperatures fell to -29.5° C, the damage was severe. At this temperature, the highest degree of cold resistance had the cultivar Kozerska, with 79.2% damaged flower buds.

The young fruit set was damaged completely without cultivar difference after late spring frost on April 27^{th} 2016 (-4.0°C). The most significant damages with deep longitudinal cracks to the stem of trees were found in the cultivars Kristin, Van, Van Compact, Rucsandra, Techlovan, Tieton, Huldra and Bigalise pozna.

The total infection rate in the investigated orchard was 52.4%. Among the viruses, PDV infection was the most frequent (29.8%), followed by mixed infection - PNRSV + PDV(11.9%), PNRSV (5.9%) and ACLSV (4.8%). PPV, CLRV and RpRSV were not present in the sweet cherry orchard.

Abstract

The aim of the present study was to evaluate 15 new introduced apple cultivars and 5 hybrids to spring frost tolerance and the occurrence of main pome fruit viruses. The research was conducted in two experimental apple orchards planted in the spring of 2002 and 2007 at the Institute of Agriculture – Kyustendil, Bulgaria. The study on the tolerance to late spring frosts was conducted under natural conditions in 2016. On 27th April, it was registered an absolute minimum temperature of -4.0°C, with long duration of the impact (5.0 h). The best resistance to late spring frost showed young fruit sets of hybrid 1/5 and cultivars Fuji Nagafu 6, Oregon Spur, Teser T219, Super Chief, Scarlet Spur. There were no symptoms caused by spring frost on their fruits. The cultivars Ginger Gold, Arkcharm and the standard Prima were the most susceptible, in which the damages were about 90.0%. All samples were tested by DAS - ELISA for the presence of Apple mosaic virus (ApMV) and by Cocktail – ELISA for Apple chlorotic leaf spot virus (ACLSV) and Apple stem grooving virus (ASGV). Of the total 104 tested trees, 67.3% were infected with ACLSV and 3.8% with ASGV. A mixed infection by both ACLSV and ASGV was identified in 3.8% of tested trees. ApMV was not detected in investigated cultivars and hybrids.

Keywords: *Apple, Cultivar, Late spring frost, Resistance, Virus status.*

Introduction

The specific agroecological conditions of the region is one of main determining factors for the right choice of the most appropriate species and cultivars. A limiting factor when choosing a place for apple orchards is the absolute minimum and maximum temperatures during different seasons, as well as the frequency of early autumn and late spring frosts, summer heats, the amount of vegetation rainfall, relative air humidity, strength and direction of wind, etc. (Bergamini and Faedi, 1984; Cline, 1998; Dzhuvinov et al., 2002; Blagov, 2011).

The reaction of apple cultivars to extreme winter colds and late spring frosts is the subject of many studies, because they can cause significant damage to the fruit yield (Zhelev, 1991). The frequency of occurrence of spring frost in some areas and the damage that they cause to the fruit harvest is the reason why spring frosts are limiting factor in apple cultivation.

Among biotic factors, apple is susceptible to infection by bacteria, fungi, phytoplasma, viruses and viroids. Among viruses the major ones are *Apple chlorotic leaf spot virus* (ACLSV), *Apple mosaic virus* (ApMV), *Apple stem grooving virus* (ASGV) and *Apple stem pitting virus* (ASPV) (Desvignes et al., 1999). All of them are economically important and common pathogens in commercial cultivars (Campbell, 1963; Posnette et al., 1963; Hadidi et al., 2011). ApMV is the most important virus, while the other three viruses ACLSV, ASPV and ASGV are latent (Nemeth, 1986). Latent viral infections in many apple (*Malus domestica* Bork.) cultivars and rootstocks can cause significant yield reduction up to 60%, particularly when occurring in mixed infections (Posnette, 1989). Economic impact and economic value of viral diseases, of virus-free and infected apple cultivars was investigated by many authors (Maxim et al., 2004; Kviklys and Stankienė, 2005; Cieszlinska and Rutkowski, 2008, Öztürk et al., 2015). Virus-infected plants are more susceptible to various environmental stresses (Zawadzka, 1989).

The aim of the presented study was to evaluate 15 new introduced apple cultivars and 5 hybrids to spring frost tolerance and the occurrence of main pome fruit viruses.

Materials and Methods

The research was conducted in two experimental apple orchards at the Institute of Agriculture – Kyustendil. The Institute is located 5 km east from the town, at the altitude of 450 m above sea level in the southwest part of Bulgaria. The meteorological conditions in this region for 2016 were: average yearly temperature + 12.0°C, the coolest month – December with average monthly temperature –1.2°C, the warmest month – July with average monthly temperature + 23.0°C, average sum of rainfall – 548 mm, date of the first autumn frost – October 29nd, date of the last spring frost – April 27 th.

The first orchard was established in the spring of 2002. The objects of the study were new introduced cultivars Cadel, Ginger Gold, New Jonagold, Braeburn, Rosana, Rubinola, Fuji Nagafu 6, Oregon Spur, Arkcharm, Charden, Belgolden, Redstar, Scarlet Spur, Super Chief, Teser T219. Prima and Golden Delicious cultivars were used as controls. The second orchard was planted in the spring of 2007 with 5 apple hybrids 1/3 (Molly's Delicious - open pollinated), 1/5 (Malus robusta x Liberty), 1/26 (Melrose x Kent), 2/28 (Prima x Florina) and 2/30 (Prima x Sekai-ichi), selected at the same institute. The trees were grafted on MM 106 rootstock and planted at a distance of 4.5 x 2.5 m.

The study on the hardiness of the investigated apple cultivars to late spring frosts was conducted under natural conditions in 2016. On 27 th April it was registered an absolute minimum air temperature of -4.0°C, with long duration about 5.0 hours.Twelve days after the late spring frost it was made the observation and the percentage of damage on young fruits was calculated. At this time the fruit size of all investigated cultivars and hybrids was about 20 mm in diameter (BBCH-72).

In total, 104 accessions of apple from 18 cultivars and 5 hybrids were tested using randomly collected samples of fully developed leaves and petals and processed using Enzyme Linked ImmunoSorbent Assay (ELISA) in two consecutive years – 2015 and 2016. All samples were tested by Double Antibody Sandwich- ELISA for the presence of *Apple mosaic virus* (ApMV) (Clark and Adams, 1977). DAS-ELISA for ACLSV and ASGV were conducted according to the modification suggested by Flegg and Clark (1979). Diagnostic kits of Loewe Phytodiagnostica GmbH (Sauerlach, Germany) were used.

Results and Discussion

The late spring frost caused injuries both in the leaves and fruits. In leaves of all stydied cultivars and hybrids, besides the separation of the epidermis from the other tissues, they became wrinkled and deformed. The injuries to young fruits were different in shape and intensity (Table 1). On the surface of fruits of Cadel, New Jonagold, Braeburn, Golden Delicious cultivars, and the hybrids 2/28, 2/30 and 1/3 were observed corking deformations called frost rings (Fig.1). The cultivars Ginger Gold, Rosana and Charden reacted with longitudinally cracking on fruits (Fig. 2). On the fruits of Arkcharm, Prima, Rubinola and hybrid 1/26 mixed damages from frost ring, cracked and russeting were observed. These symptoms were not observed in the rest cultivars - Fuji Nagafu 6, Oregon Spur, Scarlet Spur, Super Chief, Teser T219 and hybrid 1/5.

Figure 1. Corking deformations (frost rings) on fruit of hybrid 1/3 affter late spring frost

Figure 2. Longitudinal cracking on fruits of Ginger Gold cultivar after late spring frost

Table 1. Damages on apple cultivars and hybrids from spring late frost (- 4.0°C)

Cultivar /Hybrid	**Symptoms on the fruits**	**Damaged fruits, %**
Cadel	frost rings, without cracking	70.0
Ginger Gold	longitudinal cracking	90.0
New Jonagold	frost ring and russeting	41.5
Braeburn	frost ring, without cracking	43.8
Rosana	longitudinal cracking and resination	81.7
Rubinola	frost ring, cracking of a cross and resination	83.5
Fuji Nagafu 6	no	0
Oregon Spur	no	0
Arkcharm	frost ring and longitudinal cracking	90.2
Charden	longitudinal cracking	10.4
Belgolden	russeting	89.3
Redstar	russeting	45.8
Scarlet Spur	no	0
Super Chief	no	0
Teser T219	no	0
Prima	frost ring and longitudinal cracking	91.2
Granny Smith	slight surface russeting	20.3
Golden Delicious	frost ring, without cracking	72.3
2/28	frost rings, without cracking	52.4
2/30	frost rings, without cracking	60.5
1/3	frost ring, without cracking	71.4
1/5	no	0
1/26	cracking and russeting	50.3

The results showed that the most sensitive to late spring frosts were the young fruits of the cultivars Ginger Gold, Arkcharm, Belgoden and Prima, in which about 90% of the fruits had the described symptoms. High levels of damages were also found in cultivars Cadel, Golden Delicious, Rosana, Rubinola and hybrid 1/3 - from 70 to 83%. The relatively resistant were young fruits of cultivars Charden and Granny Smith. The best resistance to late spring frost showed young fruit sets of hybrid 1/5 and cultivars Fuji Nagafu 6, Oregon Spur, Teser T219, Super Chief, and Scarlet Spur.

The symptoms on the fruits were maintained till the harvest. Although serious change in the taste of the damaged fruits was not found, they were non-marketable and used only for procesing in juices and jams.
The incidence of ACLSV, ASGV and ApMV in the tested apple trees of investigated cultivars and hybrids are reported in Table 2.

Table 2. Viruses detected in the investigated apple cultivars and hybrids by ELISA.

Cultivar /Hybrid	Samples			Viruses detected			
	Tested	Infected	Infection rate (%)	ACLSV	ASGV	ApMV	ACLSV + ASGV
Cadel	5	3	60.0	3	0	0	0
Ginger Gold	5	5	100	5	0	0	0
New Jonagold	5	5	100	5	0	0	0
Braeburn	5	5	100	5	0	0	0
Rosana	5	5	100	5	0	0	0
Rubinola	5	5	100	5	0	0	0
Fuji Nagafu 6	5	5	100	4	0	0	1
Oregon Spur	4	4	100	3	0	0	1
Arkcharm	5	4	80.0	4	0	0	0
Charden	5	2	40.0	2	0	0	0
Belgolden	4	1	25.0	1	0	0	0
Redstar	5	5	100	5	0	0	0
Scarlet Spur	5	5	100	5	0	0	0
Super Chief	5	4	80.0	2	0	0	2
Teser T219	5	3	60.0	3	0	0	0
Prima	1	1	100	1	0	0	0
Granny Smith	5	4	80	1	3	0	0
Golden Delicious	5	2	40.0	1	1	0	0
2/28	5	1	20.0	1	0	0	0
2/30	4	3	75.0	3	0	0	0
1/3	2	1	50.0	1	0	0	0
1/5	5	2	40.0	2	0	0	0
1/26	4	3	75.0	3	0	0	0
Total	104	78	75.0 %	70 (67.3%)	4 (3.8%)	0	4 (3.8%)

Of the total 104 tested trees from18 apple cultivars and 5 hybrids, 67.3% were infected with ACLSV and 3.8% with ASGV. A mixed infection by both ACLSV and ASGV was identified in 3.8% of tested trees. ApMV was not detected in investigated cultivars and hybrids. The distribution of these viruses was recorded as more or less frequent in all cultivars. Some of them were 100 % infected with ACLSV - Ginger Gold, New Jonagold, Braeburn, Rosana, Rubinola, Redstar, Scarlet Spur. A mixed infection was found in two trees of Super Chief, one tree of cultivars Fuji Nagafu 6 and Oregon Spur. The detection of these viruses in apple orchard agrees in our previous observation on ACLSV and ASGV incidence in field –grown apple orchards regardless the age of orchards (Borisova et al., 2014). ACLSV was more frequent than ASGV in the tested orchards. No ApMV infection was found. A quite high level (about 75%) of incidence of ACLSV, based on detection by ELISA was reported by Kryczyński et al. (1995) of several apple cultivars in Poland and some cultivars were infected 100%.

Similarly severe ACLSV infection in main cultivars of intensive orchards was reported by Polk et al. (1997) in the Czech Republic. In Turkey, 126 out of 174 tested samples of apple in orchards and commercial gardens were infected with at least one virus (Caglayan et al., 2006). 36.8% of virus-infected plants were found in the apple collection in Romania (Popescu et al., 2004). The study of apple cultivars collection in Albania showed a very high level of virus contamination: ASPV (98.6%), ACLSV (97.8%), ASGV (91.4%) (Myrta et al., 2003). In our investigation although ACLSV and/or ASGV were detected in 75 % tested trees, no indications were obtained on the sesceptibility of these cultivars. These viruses were in latent infections.

Conclusion

The studied cultivars and hybrids reacted in a different way to late spring frost. Symptoms of young fruit were most pronounced in the Ginger Gold, Arkcharm and Prima cultivars, and damages were about 90%. Although their fruit were not seriously altered in taste, they were non-marketable and can only be used for processing in juices and jams. Hybrid 1/5 and cultivars Fuji Nagafu 6, Oregon Spur, Teser T219, Super Chief, Scarlet Spur had the best resistance to late spring frost, and they are the most suitable for the specific climatic conditions.

The results obtained in the present work show high level of virus contamination – 75.0% in average. The high incidence of ACLSV in the tested orchards calls for an evaluation of the health status of nursery trees before their cultivation in the field.

Abstract

Blackberry is one of the main berry crops. It is not particularly demanding on soil and climate conditions. Foothill regions are suitable area for its cultivation, where plants develop to a large extent their biological and economic potential. The experiment was conducted during the period 2014-2016 in a plantation of the Research Institute of Mountain Stockbreeding and Agriculture (Bulgaria) at altitude of 400 m on grey forest soils. The experimental setting consists of interrow grass cover with common bird's-foot-trefoil, bird's-foot-trefoil of Aegean region and vetch.The influence of grass cover on some indicators of the biochemical composition and flowering characteristics of fruits was studied of 'Black Satin' blackberry cultivars. Higher values were registered in the content of anthocyanins and pectin. The grass cover with bird's-foot-trefoil and vetch had no influence on the colour characteristics of fruits. There were no significant differences in relation to the average weight of different fruit variants.

Keywords: *blackberries, cultivars, chemical composition, fruit weight*

Introduction

Blackberry is one of the traditional crops with proven economic and social efficiency in the foothill and mountain regions of Bulgaria. Most of the plantations are located on slopes, which require anti-erosion systems for maintaining of soil surface. The soils in the mountain and hilly areas are among the most infertile in Bulgaria – with poor drainage, overdamping surface, low in organic matter, digestible forms of phosphorus and poorly supplied with mobile forms of nitrogen. These regions are catchment areas, where the use of pesticides is not desirable. What has been pointed so far requires the study of artificial grass cover as an adequate and effective practice for maintaining of soil surface in plantations of small-sized fruit species in the region of Troyan (Petkov, Petrov, 1998; Gergov et al., 2004). It is also necessary for the development and approval of environmentally friendly technologies for organic production of blackberries. Blackberry fruits are distinguished by a specific taste, aroma and rich biochemical composition (Boycheva et al., 1999). The very good balance of sugars and acids makes them attractive both for fresh consumption and for processing into various derivatives/products. Nowadays the interest to small-sized fruit species has been increased and especially to introduced varieties (Stoyanova et al., 2015). The aim of study was to follow the influence of some legumes on the biochemical composition and colour characteristics of fruits of 'Black Satin' blackberry cultivar.

Material and Methods

The experiment was conducted in the period 2014 – 2016 in the collection plantation of Research Institute of Mountain Stockbreeding and Agriculture – in Troyan.

The object of the present paper is 'Black Satin' blackberry cultivar. 'Black Satin' is American cultivar that was introduced in Bulgaria in 1984. The bush has a moderate growth, with average number of shoot, thornless. It is relatively resistant to high temperatures and drought, but it is susceptible to winter frosts. Fruits are globose-conical to oblong, with intensive black colour, with a glance (Velchev § Boycheva, 1983; Hristov et al., 1988; Ivanov, 2003).

The following variants of grass cover for soil surface were studied: control, common bird's-foot-trefoil, bird's-foot-trefoil of Aegean region and vetch.

Biochemical composition of fruits of the studied cultivar was conducted in the chemical laboratory in the institute, as the following indicators were observed: dry matter weight (%), refractometric determination of dry matter, total sugars % (total, inverted and sucrose) according to the method of Schoorl and Regenbogen; acids % (malic acid); ascorbic acid according to method of Fialkov; tanning according to Levental method; anthocyanins according to method of Fuleki and Francis; pectin according to Melitz method. Analyses were conducted in the chemical laboratory of RIMSA.

The fruit colour was determined according to Gardener in the Food Research and Development Institute – Plovdiv.

The colour was determined according to Gardner – using the laboratory apparatus 'GOLORGRAD2000' of BYK-GARDNER INC. USA. The blackberry samples were grounded in laboratory apparatus МРІЯ–2М with 4 mm diameter of grid holes. The sample was deaerated in a vacuum chamber at vacuum of 0.85 kPa for 10 min.

The indicators were given according to the system CIE Lab. Chromaticity coordinates L, and b were taken for the measurement: L - colour brightness; + a - red; -a green; +b - yellow, -b - blue.

Precipitation amount in the period from April – September were significantly higher than the annual average for that area.

In 2014 were reported 820.4 l, for 2015 – 594.2 l and for 2016 484.8 l, as for a ten-year period there were 528.51 l.

Results and Discussion

Data from biochemical composition of fruits are presented in Table 1. The analysis of results shows varying in the values of the individual indicators of the biochemical composition of fruits throughout the period, probably due to different agro-meteorological conditions.

The highest average dry matter weight was recorded in the variants with common bird's-foot-trefoil - 16.06% and bird's-foot-trefoil of Aegean region - 15.93% (Table 2). As in 2015, its amount reached up to 18.16% in the control fruits, and it was the least in the vetch variant – 11.28% in 2014.

There were no large differences in the average refractometric dry matter of different experimental settings that were in the range from 9.33% (variant with vetch) to 10.40% (control). There was no significant variation in that indicator amount either during the years of study.

In 2015, a higher content of total sugars was found in control fruits and the variants with bird's-foot-trefoil, which were in the range from 6.35 % to 7.85 %. In the variant with vetch, the values were almost identical for s three-year period. There were no significant differences in the amounts of total sugars among the variants average for the period.

Values were almost identical also in the case of inverted sugar. They were higher in the control (7.20%) and the common bird's-foot-trefoil (7.85 %) in 2015. There were no significant differences for the other two variants. They were the least average for the period in the variant with bird's-foot-trefoil of Aegean region - 5.40%

There was no sucrose in the control and variant with vetch. For the other variants, there were minimum amounts only in one of the years.

Organic acids were in close values among variants in the experiment. The average amounts were in the range 0.5 %-0.6 %.The content of ascorbic acid varied over the years in all variants. On the average, this indicator was higher for the common bird's-foot-trefoil – 20.53 mg/% and bird's-foot-trefoil of Aegean region – 22.88 mg/%. Similar results were reported by Skrovankova et al. (2015). Tanning substances were recorded in different values for each year of the variants. The highest amounts were determined for bird's-foot-trefoil of Aegean region – 0.333 % (2016) and vetch – 0.333 % (2015). They were the most for the above mentioned variants average for the period. Over the years the values of anthocyanins reached 129.35 mg /% (bird's-foot-trefoil of Aegean region) and 97.58 mg /% (common bird's-foot-trefoil) in 2015 and the lowest were reported in variants with vetch - 40.16 mg /% in 2014. Average for the period, they were the most in the variant with bird's-foot-trefoil of Aegean region – 98.92 mg /% (Figure 1). There was a significant variation of pectin in the study period. Its values increased twice and even more in different years.

The highest amounts were reported in the variants with vetch – 2.320% and with common bird's-foot-trefoil – 1.400% in 2016. The highest average value of the indicator was also obtained for these variants for the period.

The parameters of the fruit color characteristics are presented in Table 3.

In terms of fruit brightness, there were no significant differences for all variants. There were higher values in the control and common bird's-foot-trefoil variant. Red colour shade was higher in the control and for vetch variant. Yellow colour had the highest values for the same two variants.

Table 3. Colour characteristics of fruits for grass cover variants

Grass cover variants		Indicators	
	L	a	b
Control	14.98	31.74	8.67
Common bird's-foot-trefoil	14.83	29.33	7.39
Trefoil of Aegean region	13.27	30.30	7.87
Vetch with barley	14.02	31.04	8.16

The highest average fruit weight was recorded for the variant with bird's-foot-trefoil of Aegean region – 3.30 g and the control – 2.85 g, and it was the lowest for the vetch variant – 2.50 g. Variation of that indicator is great for all variants.

Table 4. Fruit weight (g) of 'Black satin' cultivar for different variants of grass cover

Grass cover variants	Year	Min	Max	Average	STDEV	VC
Control	2015	2,00	5,33	3,20	0,97	30,16
	2016	2,00	5,00	2,85	1,50	52,63
Common bird's-foot-trefoil	2015	2,92	4,33	2,92	0,69	23,50
	2016	1,75	5,00	2,65	1,63	61,32
Trefoil of Aegean region	2015	3,18	4,50	3,18	0,67	20,96
	2016	3,00	5,00	3,30	1,00	30,30
Vetch with barley	2015	2,67	3,67	2,67	0,72	26,98
	2016	2,00	4,70	2,50	1,35	54,00

Conclusion

An analysis was conducted of the influence of interrow grass cover with some legumes over the biochemical composition and colour parameters of 'Black Satin' blackberry fruits.
Higher anthocyanin values were recorded for grass cover with bird's-foot-trefoil of Aegean region, and pectin in the three variants in comparison with control.
The grass cover with bird's-foot-trefoil of Aegean region had a positive influence over the fruit size of 'Black Satin' cultivar.

Abstract

A comparative investigation of the growth and reproductive parameters of trees of the cherry cultivars: Kozerska, Stella, and Stefania with five different cutting heights of the stem and summer pruning was conducted during the period 2008–2014 in the experimental field of the Institute of Agriculture – Kyustendil, Bulgaria. The cultivars were grafted on mahaleb rootstock and planted at a spacing of 5 x 5 m. The growth of the trees of all cultivars was most vigorous at heights of the stems of 70 and 110 cm. The application of summer pruning led to suppression of the growth, which was with the lowest value among the treatments tested. During the period of full fruit-bearing, the highest fruit yields and largest fruits were obtained in the treatments with trees whose stems were shortened at 70 and 110 cm above the soil surface. Summer pruning and cutting of the stems at 25 cm above the soil surface retarded the transition of the trees into full fruit-bearing. Cultivar Stella shortened to 70 cm had the best economic performance (1,534 euro/ha), followed by Stefania at 110 cm (1,498 euro/ha); the lowest values of this parameter were observed in Kozerska at a stem height of 70 cm and summer pruning applied (264 euro/ha). Stella and Stefania had better growth and economic properties than Kozerska.

Keywords: *cherry, cultivar, growth, yield, height of the stem.*

Introduction

Technology improvement is one of the most important priorities in cultivating species and varieties (Micic et al., 2008; Rozpara et al., 2008). In addition to the variety features, the growth factor and the height of the crown are an exceedingly important element contributing to a more efficient fruit harvesting (Radomirska et al., 2010). In a study of five varieties and four rootstocks during the fruiting period, formed as a spindle with a supporting structure, it was found that in the trees with the spindle shape were more vigorously growing (Blazkova et al., 2010). In Hungary, a cherry rootstock that is suitable for hand picking and in accordance with the requirements of the European market has been proposed (Hrotko et al., 2008). The formation system has a significant impact on cherry tree growth and yield (Radunic et al., 2011), eventually reflecting on the economic efficiency of production.
In this respect, it is critically important to study the growth and reproduction behavior of individual cherry varieties, which was the aim of this study.

Material and Methods

The investigation was conducted in the experimental field of the Agricultural Institute - Kyustendil (Bulgaria) during the period 2008-2014. The studied cultivars: Kozerska, Stella, and Stefania were grafted onto a mahaleb rootstock and grown at a distance of 5 m in the row and between rows.

The experiment was conducted in accordance with the standard method in four replications, with three trees in each replication, or 12 trees per treatment of pruning. We studied five treatments of stem-cutting height in each variety representing different heights of the stem from the soil surface achieved by application of summer pruning: I - 25 cm; II - 70 cm; III - 110 cm; IV - 150 cm; and V - 70 cm.

A free-growing tree crown was used, and the orchard was maintained in fallow using shallow cultivations (at a depth of 8–10 cm) and autumn deep plowing. All other agro-technical measures were the same for all varieties and treatments of pruning.

We obtained and analyzed:stem diameter, tree height, diameter of the crown, average yield (kg/tree), gross output (euro/ha) and production costs (euro/ha).

Results and Discussion

After planting, the stem diameters of all the studied cultivars and pruning variants were approximately the same, ranging from 1.06 cm to 1.42 cm.

Over the seven years of study, there was a tendency for increasing of stem diameter, which was more expressed at the lower stem height. We assume that phenomenon was due to a better balance between the over-ground and underground part of the trees (Table 1). Stem diameter in cv. Kozerska varied from 8.6 cm to 11.76 cm; in Stella, from 8.5 to 10.26 cm; and in Stefania, from 8.0 cm to 12.8 cm. The differences were statistically significant for 2012, 2013, and 2014. Therefore, during the studied period, the smaller stems grew more rapidly.

The growth of stem depended on variety, and the stems of Stefania trees grew faster, followed in descending order by those of Kozerska and Stella. With the exception of Kozerska, the stems on which summer pruning had been applied exhibited the least vigorous growth. This can be explained by influence summer pruning exerts on the dynamics of tree growth processes.

The treatments with stem reduction influenced the height and the average diameter of the crowns, and hence the volumes of the crowns, which was also statistically confirmed (Table 2). In all studied varieties, with the exception of Kozerska from variant I, the crowns of the trees of variants II and III grew faster, which we attribute to the better proportion of their underground and above-ground parts. These differences were also statistically significant for 2012, 2013, and 2014, with the exception of Kozerska. The crowns of the trees on which summer pruning was performed had the lowest growth. Therefore, the experimental trees of Stefania and Stella demonstrated the most vigorous growth (excluding Kozerska) when the stem was cut on 70 cm and 110 cm of height. Therefore, summer pruning reduces the growth of experimental trees.

In 2013 and 2014, the trees were in their full fruit-bearing period (Table 3). It is clear from the table that for the Kozerska variety in 2013, the lowest quantity of fruits were obtained from summer-pruned trees (3 kg), and the highest in the third-variant (18 kg). This tendency was not sustained in 2014. The lowest fruit yields were obtained in the variant with summer pruning of Stella, from 7 to 23 kg in 2013; this trend remained in 2014. The fruit production received from Stefania ranged from 3 kg in 2013 to 16 kg in 2014. Regardless of the pruning variant, the variety and the year, the highest yields were obtained from the Stella variety, which was the weakest growing. Therefore, yields depend on, and are inversely proportional to, the vigor of the variety.

	LSD 0.05	**1.232**	**6.128**	
Stefania	I	12	73	85
	II st	12	70	82
	III	37	103	140
	IV	6	14	20
	V	2	16	18
	Sd	**0.352**	**1.577**	
	f	**30.224**	**14.089**	
	LSD 0.05	**0,8137**	**3.642**	

Depending on the variety, the highest yields in 2013–2014 were obtained from Stella trees, followed in descending order by Stefania and Kozerska. The highest yield during the study period was obtained from the third variant in Stefania variety, amounting to 140 g per tree, whereas the lowest was obtained by the trees of the summer pruning variant of the Stefania variety.

Regardless of the variety, the lowest yield for the study period was obtained in the V variant, whereas the highest was established in variants II and III. As a result, the summer fruit harvest at the beginning of the fruiting period was growing more slowly compared to variant II and III, which shows that the trees shortened to 70 cm and 110 cm were faster garnished with fruitwood.

In 2013 and 2014 the average fruit weight varied according to the variants of the pruning and the variety. Kozerska variety produced the largest yield among all III variants (8.0 g), whereas it was the smallest in variant V (6.9 g) in 2013. In 2014, for the same variety, the fruits of the II variant were the largest and the smallest in the IV variant - 7.8 g. By 2013, in all variants were formed larger fruits were, although the yield was much higher. This means that the trees had not reached their maximum potential. The largest fruits in the year 2013 from the variant II (8.9 g), and the smallest among the IV variants were obtained from Stella variety. There was no significant difference in the size of the fruits in 2013 and 2014. In 2013, the fruits of variants I and II were the largest, whereas V variant was the smallest from the Stefania variety. In 2010, the fruits of variant II (9.9 g) were the largest, whereas the smallest were from variant V (8.9 g). It is obvious that, despite the higher yields of Stefania variety in 2014, larger fruits were obtained on lower stems at the beginning of full fruiting. The fruit size depended on the specific variety, and those of Stefania were the largest, followed in descending order by the ones produced by the trees of Kozerska and Stella.

The obtained and analyzed data in the experimental cherry orchards with different stem-cutting heights indicate that the variant shortened to 110 cm expressed the best economic results in 2013 among all three varieties. Nevertheless, Stefania had an advantage over the other cultivars examined (Figure 1). The lowest values were obtained in the variants in which the trees were shortened to 70 cm and summer pruning was implemented. In 2014, the gross output was significantly higher than that in 2013, which was caused by the higher yields. The indicator values ranged from 757 to 2,774 euro/ha. Values of the indicator were the highest in the variants shortened to 150 cm for Kozerska (1,028 euro/ha), 70 cm for Stella, and 110 cm for Stefania –(2,774 euro/ha). In two of the varieties, the lowest results were obtained again in the variants whose height was reduced to 70 cm by summer pruning. In all variants, Stella had better results than the other two varieties, except variant III, where Stefania performed better. In 2015, in individual variants, no yield and no gross output was obtained. For the Kozerska and Stella varieties, the values of the indicator were the highest in the variant where the trees were cut to 70 cm, respectively 1,176 and 1,610 euro/ha, and for Stefania at 110 cm (1,274 euro/ha). The trend for the lowest results for the cuts of 70 cm and summer pruning was retained. Average for the period 2013–2015, the highest value is the gross production of the Stella variety, shortened to 70 cm –(1,534 euro/ha), followed by Stefania at 110 cm (1,498 euro/ha), and the lowest was obtained in Kozerska at the height of 70 cm and summer pruning applied (264 euro/ha). Stella and Stefania had higher results than the corresponding variants of Kozerska.

Conclusions

The growing characteristics of cherry varieties are influenced by the height of stem reduction. They are best realized when the stem is cut at 70 and 110 cm, whereas the weakest growth is observed in trees that have been subjected to summer pruning.

At the beginning of full fruiting, the highest total yield was obtained from cherry trees with a stem height reduced to 70 and 110 cm (from 60 kg to 140 kg per tree). The fruits harvested in these treatments were also the largest (from 8.3 to 9.9 g).

In addition, we found that the summer pruning and cutting of the stems at 25 cm from the soil surface leads to later fruiting of the cherry varieties and formation of smaller fruits. The height of the cherry stem shortening does not significantly affect the content of dry matter, sugars, and acids in the fruits as well as the chemical composition of the leaves. The highest value of gross production was established in the trees of Stella variety that had been shortened to 70 cm and those of Stefania reduced to 110 cm.

Abstract

The influence of two types of pruning, a voluminous crown with different numbers of skeletal branches (5–6 and 15–18), of trees of the sour cherry cultivar Erdi Bötermö on the growth characteristics, chemical composition of the fruits and leaves, and the economic performance was examined. The investigations were carried out during the period 2006–2015 in the experimental field of the Institute of Agriculture – Kyustendil, Bulgaria. The orchard was established with sour cherry trees grafted on mahaleb rootstock and planted at distances of 5 x 4 m (500 trees/ha). The free-growing crown with 15–18 branches induced a better growth than that in the trees with 5–6 branches. The trees with 5–6 branches entered earlier the period of full fruit-bearing and had higher yields compared to those of the trees with 15–18 branches. The latter trees were more vigorous, and their yield and average fruit weight were greater. The number of skeletal branches exerted no effect on the content of dry matter, sugars, and acids in the fruits and leaf chemical composition. The resulting balance value amounted to 2,430 €/ha. The economic evaluation confirmed that a crown with 5–6 skeletal branches provided higher economic returns.

Keywords: *cherry, forming a crown, economic impact*

Introduction

Sour cherry is an economically valuable fruit species with production traditions in our country (Mitov et al., 1990; Vasilev et al., 1982). The biological and economic qualities of sour cherry allow it to take a worthy place in the fruit-growing of Bulgaria. Valuable nutritional, medicinal, and dietary qualities make it a desirable fruit on both the domestic and the outside market. In the last 30 years there has been a decline in the production of sour cherry despite the favorable conditions for the cultivation of this species in our country (Sotirov and Radomirska, 2012). A number of factors influence the economic efficiency of fruit production in perennial fruit crops - choice of the appropriate site for orchard establishment, the variety-rootstock combinations used, agrotechnical measures applied, material and labor costs, demand and supply of fruits and their conversion price (Bashev, 1990; Zimbrek et al., 1995). Unfortunately, the studies conducted to identify and analyze the factors affecting the economic efficiency of sour cherry fruit production in Bulgaria are scarce. A previous comparative study was performed of six variety-rootstock combinations. Sour cherry trees of the varieties Schatten Morelle and Meteor, grafted on seedlings of the cherry variety Drogan's Yellow and mahaleb rootstocks SL-64 and T-36 were used in the experiments. A good economic effect was obtained for the experimental trees, which were cultivated under identical agrotechnical conditions, expressed. The combination of cv. Meteor on T- 36 mahaleb rootstock had the highest economic efficiency and additional profit obtained. The profitability of the costs of yielding the additional fruit production is 614%, which is a guarantee of a high return of each cost (Saeva and Koukov, 1998).

Sour cherry production in Bulgaria is characterized by many problems that require purposeful and hard work to improve yield quantity and quality. Therefore, the purpose of the present study was to investigate the productivity and economic performance of two types of the crown pruning of the sour cherry cultivar Erdi Bötermö.

Material and Methods

The experiment was established in 2006 in the experimental field of the Institute of Agriculture – Kyustendil in Bulgaria. Experimental Erdi Bötermö trees, grafted on a mahaleb rootstock and planted at a distance of 5 m between the rows and 4 m in the rows or 500 pcs / ha, were used for the experiments.

The field trial was based on the long- plot method in four replications with four trees in each replication.

We studied a tree shape with a different number of skeleton branches:

Variant I - free crown with 15–18 branches;

Variant II - free crown with 5–6 branches (standard).

The orchard interrows were maintained in fallow, with 6–8 shallow treatments and autumn deep plowing. Irrigation was carried out by over-crown sprinkling and plant protection through ground-mounted devices.

The balance value of the plantation, used as an economic indicator in the study, includes all production costs associated with the establishment and cultivation of the plants until fruit-bearing. During the fruit growing period, the main economic indicators were calculated annually: gross output, euro/ha; production costs, euro/ha; net income, euro/ha; rate of profitability, %. The necessary funds for obtaining fruit production were established on the basis of actual costs incurred in accordance with the standardized norms and tariffs for labor and mechanized works used in the Institute of Agriculture - Kyustendil as well as taking into account the market prices of the raw materials and other materials utilized. The valuation of production was determined using the actual realization prices in the individual years.

Results and Discussion

The balance value of one hectare of sour cherry plantation amounts to 2,369.35 euro/ha (Table 1). In the year of planting, the material costs significantly exceed labor costs. In the structure of material costs, the expenses for planting material and fertilizers account for a major share. Koprivlenski and Krinkov (2002) obtained similar results, who found that in the establishment of permanent crops, 50% of the material costs incurred were for planting material and 40% for fertilizers. In our investigation, the labor costs in both variants were identical because of the implementation of the same technology of establishment. Mechanized services required the largest part of the financial resources spent (71.32%) due to the relatively high degree of mechanization of the labor processes during planting. Labor costs accounted for the remaining 28.68%.

Differences in costs were hardly observed during the growing period until initiation of fruiting, except for those incurred only in the first year, when replanting of a small part of the trees was carried out.

Table 1. Balance value, euro/ha.

Types of costs	Establishment and First growing season	Second growing season	Third growing season	Total costs for the period
Labor costs	469.90	286.25	253.95	1,010.10
Mechanized	335.10	180.25	197.50	712.85
Labor	134.80	106.00	56.45	297.25
Materials	1,190.30	95.95	73.00	1,359.25
Production costs	1,660.20	382.20	326.95	2,369.35

The average stem diameter of the test plants was almost the same (1.03 cm in the treatment with 15–18 branches and 1.00 cm in the trees with 5–6 branches), (Table 2). Altogether, for the 10-year study period, there was a slight, but statistically significant predominance in the increase in stem thickness of the experimental plants formed with 15–18 branches over that of the standard treatment (5–6 branches). We consider that the stronger pruning had led to a better plant growth response in the trees formed with 15–18 branches characterized by greater leaf mass and a higher number and length of the annual shoots.
In the first year of measurement (2010), the height, the diameter of the crowns, and hence the volumes were equal (Table 3). In 2011, there was a tendency for a faster crown growth in the trees formed with 15–18 branches, which is explained by their larger leaf weight. These differences in crown size were also observed in 2013 and 2015, but were statistically significant only in 2015.
For the first time, the trees of both varieties yielded in 2009, producing from 3.1 to 3.9 kg/tree with a slight predominance of the standard (Table 4). In 2010, these tree yields doubled, maintaining the same trend, but less pronouncedly expressed. In 2011, the fruits obtained were three times more than in 2009 (from 9.8 to 10.8 kg/tree). However, in 2012 and 2013, this difference was variable. In 2014 and 2015, a larger quantity of fruit was harvested in the standard variant. The difference between the yields of the different variants was insignificant, but every year the trees of the standard treatment produced larger fruit quantities, which can be explained by the weaker pruning of the crown, hence the weaker tree growth.

Table 4. Average yield per tree, kg

Variety	Variant	2009	2010	2011	2012	2013	2014	2015
Erdi Bötermö	I	3.1	7.2	9.8	12.7	28.0	28.0	30.0
	IIst	3.9	7.8	10.8	13.8	26.8	28.6	31.0
	Sd				2.428	3.250	2.196	2.171
	f				0.196	0.131	9.444	0.245
	LSD 0.05				7.72	10.33	6.984	6.903

The average weight of the fruits shows a slight tendency opposite to that of the quantities of fruits obtained. Somewhat larger were the fruits of trees of variant I (15–18 branches), which is explained by the greater growth but a lower fruit yield from the trees. We also found that the annual climatic conditions had an impact on the size of the fruit.

Importantly, the annual climatic conditions during the period of study had a greater influence on the contents of dry matter, sugars, and acids in the fruit than the treatments with varying pruning intensity.

Laboratory analyses were carried out 3th year, revealing that the pruning aimed at forming the crown shape exerted no influence on the chemical composition of the leaves.

The data obtained and analyzed for the seven-year fruiting period (2009–2015) show that the gross output in value terms in the examined variants, broadly follows the tendency of changes of the average yield (Table 5). The gross output obtained for both variants is the highest in 2014. The average gross production is the largest for trees with 5–6 skeleton branches, 3,011.0 euro/ha, which is 3.5% higher than that of the trees formed with 15–18 skeletal branches.

The production costs required to grow a one-hectare sour cherry orchard of the studied variants ranged from 1,307.5 euro/ha for V1 in 2009 to 3,323.7 euro/ha for V2 in 2014 (Table 6). Since an identical cultivation technology was employed in the two treatments, their material costs were the same in the respective year, and the average for the period amounted to 292.4 euro/ha. The differences in labor costs are determined by the different average yields and the associated costs of harvesting additional fruit production. In 2010 and 2011, the labor costs were significantly higher than those in 2009 and 2012 due to the need to perform sanitary pruning in both variants. In the remaining years, the higher yields had an impact on the value of the production costs.

The magnitude of the average yields had a significant impact on the amount of the net income received. On average for the survey period, treatment V2 formed a higher net profit of 752.7 euro/ha (Fig. 1). Thus, the net income per hectare obtained was 8.9% higher than that of treatment V1. The profitability rate was 33.3% for the variant V2 (5–6 branches) and 30.9% for the V1 (15–18 branches).

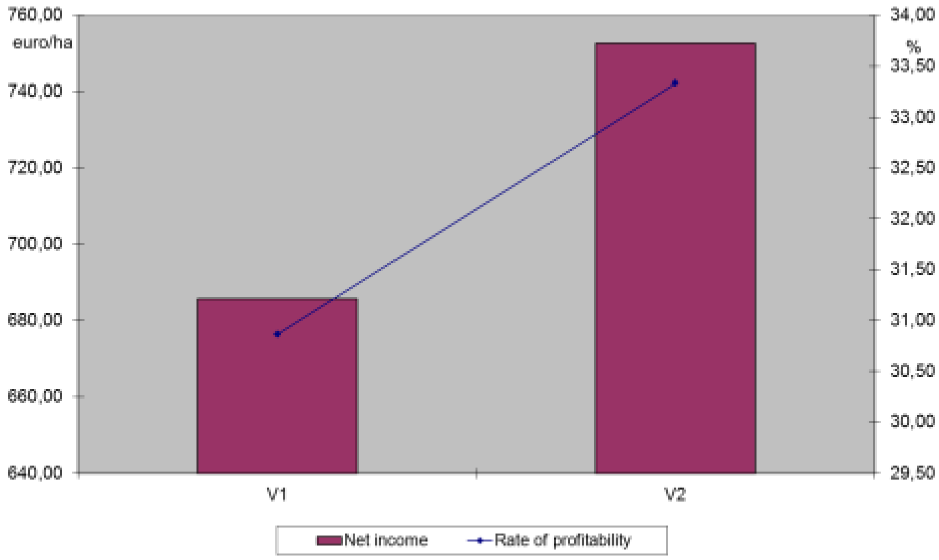

Fig. 1. Average net income (euro/ha) and rate of profitability (%) for the period 2009–2015

Conclusions

The balance value per one hectare of sour cherry orchard amounts to 2,369.35 euro/ha. The free crown with 15–18 branches induces a more vigorous growth of Erdi Bötermö trees than the free crown with 5–6 skeletal branches. Furthermore, the crown with 5–6 skeletal branches initiates earlier and more abundant fruit-bearing than that with 15–18 branches. The more vigorous tree growth and yield increased are associated with the rise in the average weight of the fruit. This finding indicates that trees possess the potential for even higher fruit yields. The formation of the crown does not affect the contents of dry matter, sugars, and acids in the fruit as well as leaf chemical composition. The economic assessment of the experimental treatments confirmed that the crown with 5–6 skeletal branches produced higher economic results.

Abstract

Path-coefficient analysis is very important statistical technique that can be used to quantify the interrelationship of different yield components. It was applied to study the interaction of applied agronomic activities on productivity of mid-early Bulgarian garden peas *Pisum sativum* cv. Promethei seeking to minimize pesticide use and to maintain sustainable quality and quantity of yield, and to prevent underground water pollution caused by using Dual 930EK/930g/l-s (metachloras) minimized herbicide doses from vegetative herbicide Basagran-200g/l (Bentazon) and Fusillade-200g/l (Fluasifop-P-Butil). Data was collected from long years trials on plants treated with different combinations of foliar suspension fertilizer Lactofol® with insecticides and herbicides. Results showed that grain yield (0.997), dry matter of the grain (0.996), Chlorophyll "a" (0.993), Zn (0.992), N (0.991), grain/whole pod ratio (0.984), total nitrogen (0.982), K (0.975), weight of 50 grains (0.973) fresh weight of 50 beans (0.962), fertile pollen (0.961), plant density/ m^2 (0,873), the length of beans (0.871), sterile pollen (0.837) had positive impact on yield. Dry matter, grain yield, dry matter of grains, chla, N, weight of 50 pods, fertile pollen, and plant density/ m^2 showed positive direct and indirect effects on yield. Other factors such as sugars (0.797), chlorophyll “b” (0.739), and starch (0.620) had an indirect effect on total yield. Grain yield should be given prior attention in field pea improvement programmers due to its major influence on yield. This research gave valuable information about which steps of agro techniques needs more attention to enhance best quality and quantity of sustainable yield.

Keywords: Correlation; path-coefficient, garden peas, growth, yield.

Introduction

Garden peas are highly valued crops worldwide with multiple uses in food consumption. Grain peas are highly nutritious and are rich in protein (27%), complex carbohydrates (42.65%), vitamins, minerals, dietary fibers and antioxidant compounds (Urbano *et al.,* 2003). Yields and production areas have increased during the last years (Shaban *et al.,* 2014). The total harvested area in Bulgaria is of 882 ha, with a total production of 17358 tonnes (FAOSTAT, 2014). One of the best methods to ensure high quantity and quality of garden peas is to apply new agro technical solutions while protecting ecosystems from pollution (Shaban, 2007). Grain yield of peas is a complex character and is the product of several contributing factors affecting yield directly or indirectly. Correlation analysis provides information about association of plant characters and therefore, leads to a directional model for yield prediction. Path coefficient analysis quantifies the interrelationships between different components in

their direct and indirect effects on grain yield (Aashfaq *et al.,* 2003).
In agricultural production, higher interaction between different parameters and the presence of contrasting developments in their effects on the yield is often not possible to separate the effects with significant impact on mathematical modeling- water efficiency and its contribution to the yield (Chowdhry *et al.,* 2000). Application of Path- analysis in determining the independent variables in the construction of production function allows to identify the most significant of them and the nature of their interaction in forming the productivity of individual plants (Jedynski, 2001) (Narwal *et al.,* 1999). Path- analysis has advantages in terms of assessment of the factors and influences the prognostic results than classical statistical methods. Production function analysis has advantages in the yield of agricultural crops not only because it allows establishing relationships but is also valued and key indicators such as average and marginal efficiency coefficient of elasticity and production rate alternative variables (Nayeem and Baig, 2003). It explores the dependence of the rate of change in volume of the factors forming yield (Steel and Torrie, 1984). For instance, on peas, it was found that plant height showed positive direct effect on seed yield and that No. of pods/plant is a highly reliable component for yield indications (Tiwari *et al.,* 2001; Singh *et al.,* 2001; Arya *et al.,* 2004; Singh J.D. and Singh I.P., 2005 and Singh J.D. and I.P. Singh 2006). In the same trend, Ceyhan *et al.* (2005) found that the correlation between seed yield with plant height, No. of pods/ plant and biological yield/plant and No. seeds/pod was highly significant and positive. Correlation studies showed that the grain yield was positive correlated with plant height, No. of pods/plant and No. of seeds/pod.
The present study was conducted in order to investigate the interrelationship of yield components and applied new techniques (mixed foliar fertilizer with decreased pesticide doses) and their contribution to yield of peas.

Material and Methods

Data was collected through long years field trial with mid-early garden peas of the cultivar Promethei. Seeds were sown with the help of a trible with a distance of 30 cm between rows and 5 cm between plants. The experimental design adopted was RCBD (Randomized Complete Block Design) with four replications. All agronomic practices were kept uniform. Plants were treated with different combinations of foliar suspensions fertilizer Lactofol® with insecticides and herbicides. At maturity, ten monitored plants were chosen from each replication for measuring the number of pods, number of grains per pods, grain weight per pod (g), weight of 50 pods(g) and grain yield per plant (g). Moreover, plant physiology was analyzed through three measurements of photosynthetic and transpiration intensity, and through analysis of photosynthetic pigments (chl.a, chl.b and carotenoids). Chemical composition of plants was evaluated by testing the micro and macro-nutrients contents. Weed density was monitored and recorded as well during the consecutive experimental years.
Correlation coefficients were calculated for fixing the degree of association of the different investigated parameters and pea yield as well as among themselves. Correlations were calculated based on Singh and Chaudray (1985) and path coefficient analysis was carried out as suggested by Dewey *et al.* (1955), Singh and Chaudray (1985), Soomro (2010) and Arbuckle (2009). Analysis was done using AMOS Ver. 18 Software.

Results and Discussion

Results of correlations between the yield of green peas and each of the studied parameters of direct and indirect Path-factor are given in Table 1. The model of research indicated that the total impact of the studied indications on the yield of peas was variant and ranged between strongly positive to strongly negative. The strongest overall positive impact on the yield of peas was exerted by the grain yield (5.4%) and the absolute dry matter content in whole pods (ACB*) (5.4%) followed by dry matter of the grains (5.3%), Chla (5.3%), total Zn (5.3%), grain/pod rate (5.2%), total nitrogen (5.2%), total K (5.1%), weight of 50 grains (5.1%), weight 50 pods (5%), pollen fertility (5%), ACB B in grain (5%), plants/ m^2 (4.1%), length of pods (4.1%), pollen sterility (3.8%) and transpiration at third measurement E3 (3.6%). A lower significant effect on yield was observed for the parameters sugar content (3.4%), Chl.b (2.9%), E2 (2.9%), disorder post first treatment (2.6%) and starch content (2.1%). Finally, yield was also influenced by other factors (2.9%)

Table 1. Partial function of studied parameters on yield structure of green peas.

General variability of yield					
Partial function of studied parameters 97.1%. from:					
No		100.0	No		100.0
1	Plants/m2	4.1	12	Weight of 50 grains	5.1
2	Disorders post first treatment	2.6	13	Grain /pod rate	5.2
3	Absolute dry matter in whole pods ACB*	5.4	14	Absolute dry matter in grains ACB	5.0
4	Sugars	3.4	15	Pods length	4.1
5	Total nitrogen	5.2	16	Grain yield	5.4
6	Starch	2.1	17	Pollen fertility	5.0
7	Dry matter/ grain	5.3	18	Pollen sterility	3.8
8	N	5.3	19	E2- Transpiration at second measurement	2.9
9	K	5.1	20	E3 Transpiration at third measurement	3.6
10	Zn	5.3	21	Chla	5.3
11	Weight of 50 pods	5.0	22	Chlb	2.9
	Other factors: 2.9%				

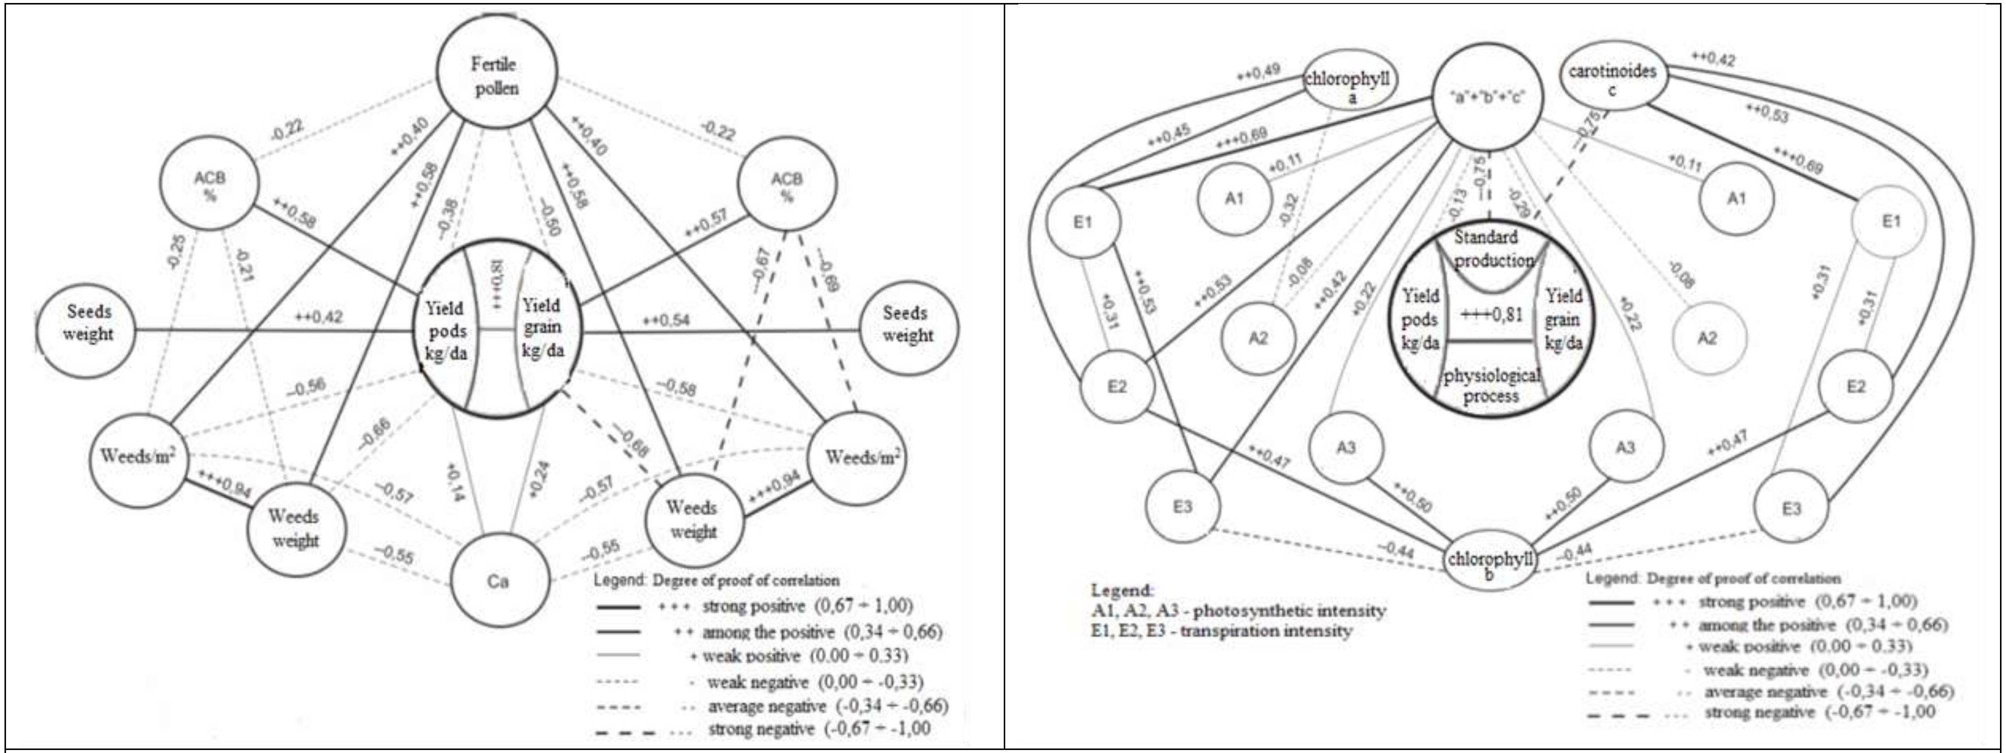
Correlations in figure 1 reflected a moderate positive correlation between pollen fertility and weed density (0.4) as well as with weeds weight (0.58). On the other hand, total Ca was negatively correlated with those two parameters (-0.57 and -0.55 respectively).

Results in figure 2 illustrated the existing correlations between physiological parameters and yield. When considering the physiological activity of plants it seemed that photosynthetic pigments (chl.a, chl.b and carotenoids) were positively correlated with transpiration rate and with photosynthetic intensity with some exceptions: chla was negatively correlated with A2 (-0.32) and chl. b was negatively correlated with E3 (-0.44). In general, correlations between photosynthetic pigments formation with transpiration intensity were stronger than those with photosynthetic intensity. For instance, the correlation coefficient of chl.a, chl.b and carotenoids (a+b+c) with E1 was +0.69 while with A1 it was of +0.11.

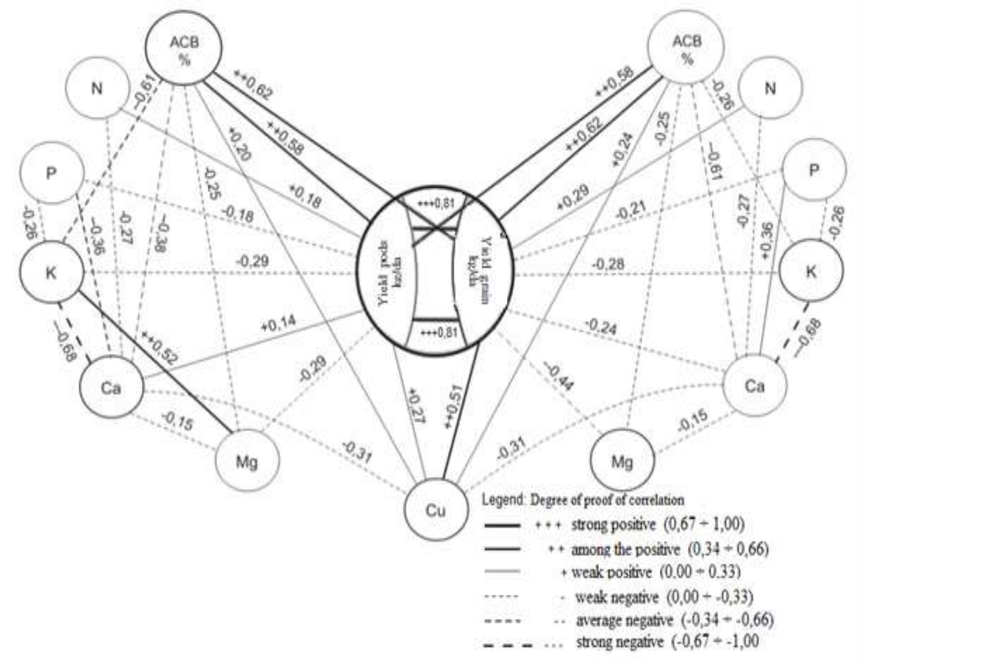
Moreover, the parameters ACB (%) had a strong positive influence on grain yield (0.62) and pods yield (0.58). Total Cu content had a strong positive influence on grain yield (0.51) and a weak positive influence on pods yield (0.27). In addition, total N and total Ca content had a weak positive influence on yield, while total P content showed an indirect positive influence (Fig. 3).

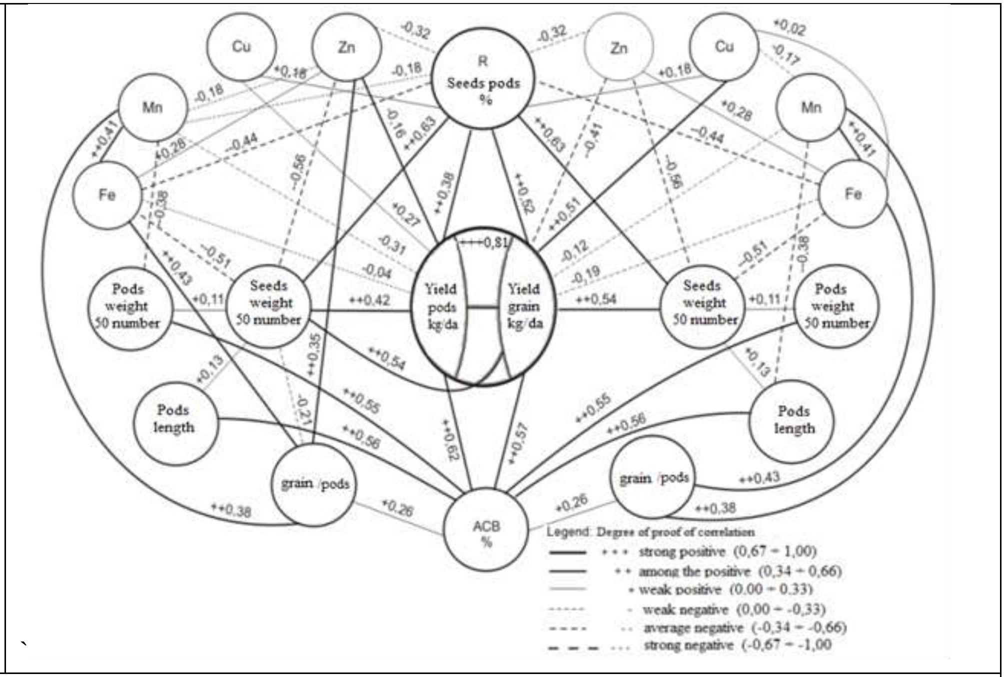
Results in the figure 4 showed that in general, pods characteristics such as the number of grains per pod, weight of 50 grains, and weight of 50 pods had always a strong direct positive influence on each other as well as on pods yield and grain yield consequently on productivity. For example, the weight of 50 seeds was positively correlated with grain yield and pods yields with 0.54 and 0.42 respectively. In addition, the figure 4 illustrated the direct and indirect effects of different chemical parameters (Fe, Mn, Cu and Zn) on all the previously cited pods characteristics as well as on pods length. For instance, Zn, Fe and Mn had a moderate positive direct influence on number of grains per pods with respective correlation coefficients of 0.35, 0.43 and 0.38. On the other hand, Mn influenced directly and negatively the pods length (-0.38).

The figure 5 represented the correlation between the photosynthetic intensity, transpiration intensity, pollen viability, pods yield and grain yield. In specific, pollen fertility has a moderately direct positive influence on grain yield (0.5), and a moderately negative influence on pods yield (-0.38). Additionally, this parameter was negatively correlated with photosynthetic intensity (A1: -0.2 and A2: -0.35). On the contrary, pollen sterility was positively correlated to photosynthetic intensity (A1: 0.39 and A2: 0.45).



Impacts of treatment with Lactofol® and pesticides on correlation coefficients between yield and peas parameters (Fig 1: left) and between yield and plastid pigments content and photosynthetic and transpiration intensity (Fig 2: right)





Impacts of treatment with Lactofol® and pesticides on correlation coefficients between yield and biological values (Fig 3: left) and productivity parameters (Fig 4: right) of peas.

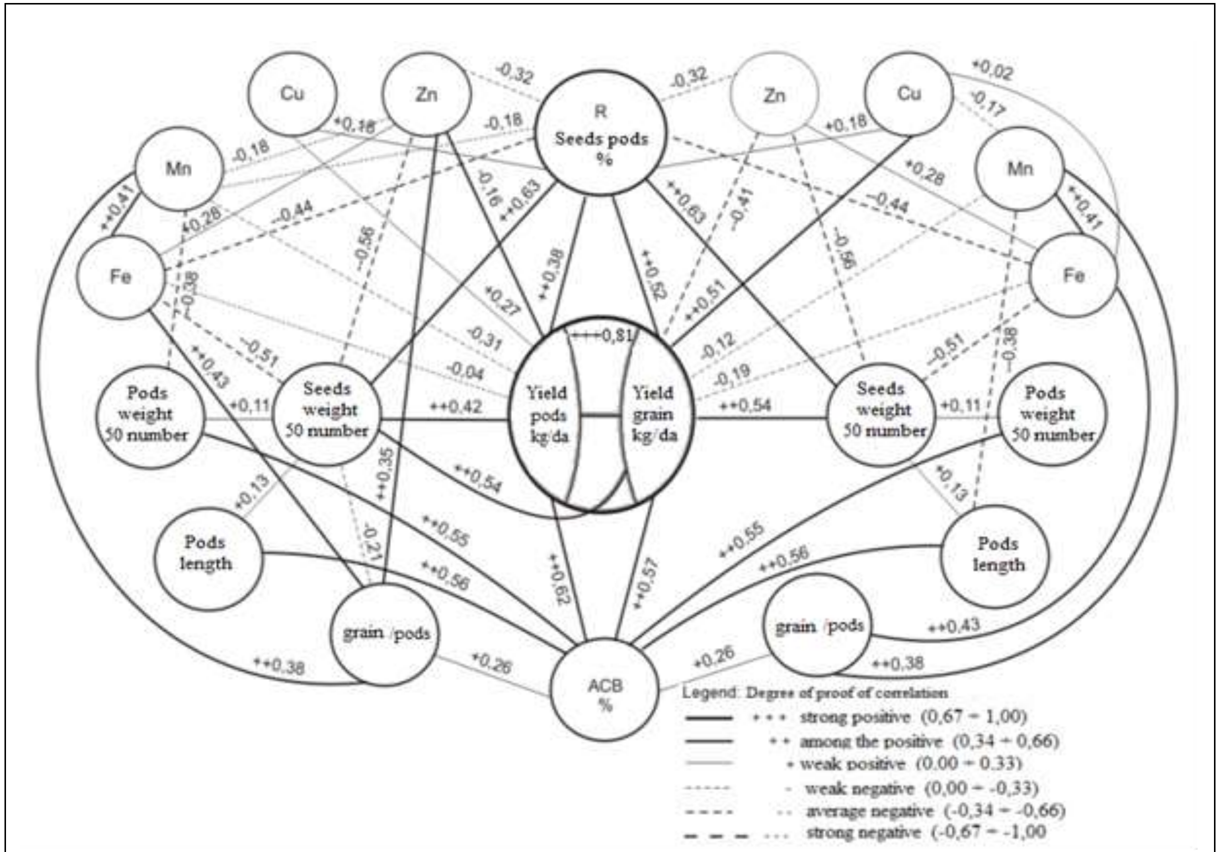


Fig 5: Impacts of treatment with Lactofol® and pesticides on correlation coefficients between yield and photosynthetic and transpiration intensity of peas.

Grain yield should be given prior attention in field pea improvement programmers because of its major influence on yield. Those results came in conformity with those of earlier studies where a positive association of seed weight and grain yield / plant was reported (Manhata *et al.,* 2001, Arya *et al.*, 2004, Singh V. and S.P. Singh, 1999, Singh J.D. and I.P. Singh, 2005, Gul *et al.*, 2005, Patel *et al.*, 2006). Also, it was found previously by Arya *et al.*, 2004, Singh J.D. and I.P. Singh, 2005) that No. of pods / plant exerted highest direct effect on seed yield in field pea. This indicates that No. of pods / plant is highly reliable component on yield. It was also found in the study of Sarawat *et al.* (1994) that there is significant positively correlation between grain yield with, No. of pods / plant and 100 seed weight in pea. No. of pods / plant were also reported to be positive correlated in pea

Conclusions

The application of foliar suspension fertilizer Lactofol® combined with insecticides and herbicides has induced different effects of the studied parameters (morphological, physiological and reproductive) on the yield. In general, this type of treatment has amplified the effects of macro and micro-nutrients in plants, dry matter accumulation and those of pods characteristics on plant yields. Moreover, crop performance was more correlated to the transpiration intensity and less to the photosynthetic intensity while yields were the most affected by grain and pods productions. It seemed that the use of Lactofol had an indirect negative effect on photosynthetic pigments however it caused a direct beneficial impact on quantity and quality of the produce. Also, the negative correlation that was observed between weed incidence and yields could lead to the assumption that Lactofol might help controlling weeds while maintaining high quality yields. Also, the impact of post-treatment disorders on yields was lowered since results clearly demonstrated a low correlation between this parameter and yields.

Lactofol could be applied with decrease pesticide doses as a potential method in GAP (Good Agricultural Practices) as a new element of growing technology of green peas in order to reduce the excessive random application of chemicals, consequently to help sustaining the ecosystem by preventing underground water pollution.

BRIEF POMOLOGICAL DESCRIPTION OF PERSPECTIVE SWEET CHERRY ELITES (*PRUNUS AVIUM L.)*

Nicolai CHRISTOV, Simeon KRUMOV*

Institute of agriculture – Kyustendil, 2500, Bulgaria
*Corresponding author: sd_krumov@abv.bg

Abstract

It was performed a brief pomological description of sweet cherry elites № 32/25 (Van x Stela), № 5750 (Kordia x self-pollination), № 3419 (4C–1821 x self-pollination), № 5752 (Kordia x self-pollination), № 1890 (Germersdorf x self-pollination) and № 6374 (Stella x Germersdorf), created at Institute of agriculture - Kyustendil. It was found that all elites, except for № 1890, have later flowering compared to the standard Van. According to the duration of ripening, the studied elites belong to the following 2 groups: middle medium ripening (the second decade of June) - elites № 5752, № 6374, № 3419, № 1890, № 32/25 and late ripening (early July) - elite № 5750. The biometric analysis showed that all sweet cherry elites have large fruits. In the different elites the form of fruit is cordate to wide-cordate, with dark red to black color of the skin. The flavor of all elites is sweet-sour with the exception of elite № 3419 which taste is defined as a sour-sweet. The coloring of the fruit juice is pink in standard Van and elite № 1890 to ruby-red in elite № 5752. The results of the annually conducted tastings show that the researched sweet cherry elites in the region of Kyustendil have high taste qualities.

Key words: *Sweet cherry, Elites, Pomological description*

Introduction

Sweet cherry (Prunus avium L.) is a fruit species with large ecological plasticity and is one of the main fruit crops in Bulgaria. A premise for this is the favorable soil and climatic conditions in the country.

For increase in the fruit yield, it is important to select a self-fertile, fruitful and highly resistant to diseases and stress conditions cultivars (Georgiev et al., 2001).

Intensive breeding work for the creation of new sweet cherry cultivars is conducted in all countries with well developed production of sweet cherry fruits in accordance with the contemporary quality requirements for the cultivars to be marketable, as well as with increased resistance to stress factors (Sansavini and Lugli, 2008; Kankaya et al., 2005; WangYulinq, 2002; Long et al., 2008; Kappel, et al., 2002; Grandi et al., 2013; Vercammen et al., 2008; Milatović et al., 2013). Worldwide have been created more than 140 perspective new sweet cherry cultivars over the past decade (Sansavini and Lugli, 2008).

As a result of intensive breeding work in the last years, in Bulgaria have been created and approved several sweet cherry cultivars such as Stefania, Daneliya, Dima, Alekston, Vasinika, Kosara, Rosita, Rozalina and others (Georgiev et al., 2001; Zhivondov et al., 2011; Christov et al., 2015). The purpose of this research is to make a brief pomological description of perspective sweet cherry elites, presented in different stages of selection good biological and economic properties.

Material and Methods

The research was conducted during the period 2013-2015 at the experimental sweet cherry plantation of the Institute of Agriculture – Kyustendil in Bulgaria. The object of the study were elites № 32/25 (Van x Stela), № 5750 (Kordia x self-pollination), № 3419 (4C – 1821 x self-pollination), № 5752 (Kordia x self-pollination), № 1890 (Germersdorf x self-pollination), № 6374 (Stela x Germersdorf). The cultivar Van was used as control. The trees were planted in the spring of 2002 at distance of 6 x 5 m in the rows and formed in free growing crown. They are grafted on P. mahaleb rootstock IK-M9, grown without irrigation. Each sweet cherry elite was represented by 5 trees.

The soil in the experimental plantation is highly leached, slightly sandy clay, cinnamon forest soil with a neutral reaction. The availability of assimilable phosphorus is low to moderate, while the assimilable nitrogen is very low. The research of sweet cherry elites was performed according to the established methodology for the study of the plant resources in the fruit growing (Nedev et al., 1979). The taste evaluation of the fruits was done organoleptically on the 5-grade scale (Nedev et al., 1979).

The obtained experimental results were processed by the method of analysis of variance, using the LSD-test to prove statistical significance of the differences found between the control and the variants. The evaluation was made at levels of significance $P <0,05$, $P <0,01$ and $P <0,001$ (Maneva, 2007).

Results and Discussion

The phenological observations showed that the beginning of full flowering occurred the earliest in the control Van and elite № 1890 (10.04) and the latest in elite № 5750 for the period of the survey (2013-2015). The beginning of the full flowering for the other elites began almost at the same time - from 14.04 to 15.04 (Table. 1).

The relatively later flowering is an advantage for the region in view of the fact, that the probability of passing the last spring frost in the five-day period from 7th to 11th April is 52% and from 12th to 16th April - 82%.

Depending on the climatic conditions, the phenophase varied from 12 to 16 days over the years, the earliest occurred in 2014 and the latest in 2015. According to the period of ripening of the fruits in the region of Kyustendil, the elites refer to the following groups: medium ripening - № 5752, № 6374, № 3419, № 1890 and № 32/25 (the second ten days of June) and late ripening - № 5750 (the first days of July). The standard cultivar Van refers to the group of medium ripening. During the period of investigation the cultivar Van ripened 2 to 4 days later than the other elites in the group (Table 1).

The harvest was done in a consumable maturity of the fruits, after which biometric and chemical analyses were performed (Table 2). It was found that the comparatively highest average mass of fruit exceeding the standard Van (7.4 g) had the elites № 6374 (8.5 g) and № 32/25 (7.5 g). The lowest value of the indicator had № 3419 (5.8 g). The rest elites took an intermediate position. The same trend was observed in relation to the size of the fruit. The largest diameter (measured in the widest part of the fruit) had the fruits of the elite № 6374 and № 32/25 (24.3 mm), and the smallest were of the standard cultivar Van (21.5 mm) (Table 2).

The average fruit mass was the highest in 2014, which we suggested was due to the heavy rainfalls during the fruit growing period. The other years were characterized by very high average air temperatures and prolonged droughts, which affected the size of the fruits.

The mechanical analysis showed that the average stone mass was approximately the same for all sweet cherry elites - from 0.22 g for the standard Van, № 5752 and № 3419 to 0.28 g for

№ 6374. The mass of the fruit stem is from 0.09 g in elites № 3419 and 5750 to 0.13 g in Van and № 5752 (Table. 2).

**average for the period*

The sweet cherry elites № 6374 and № 32/25 statistically proven exceeded the control cultivar in terms of diameter of the fruit. Differences in other biometric indicators were insignificant.
Under the experiment conditions, all sweet cherry elites had good fertility. The highest average yield per tree had elite № 5752 (32.8 kg), followed by № 1890 (31.7 kg). The lowest yield, average for the study period, was reported in № 6374 (22.7 kg). Elites № 32/25 (28,5 kg) and № 3419 (25.2 kg) also exceeded the value of the standard Van (24.0 kg).
The established differences to the control in terms of the average yield were positively proven in elites № 5752 and №1890. For the other elites, the differences were insignificant to the control.
The combination of sugars and acids in the fruit juice is very important for the quality of the sweet cherry fruits. The quantitative content of these chemical components is directly related to the biological properties of the cultivar and the weather conditions during the ripening period.

The average results of the chemical analysis showed that the soluble dry matter was the highest in the fruits of elite No 1890 - 20.1%. In the other studied elites, the dry matter content value was lower than the standard Van - 19.3%. The ratio is similar in terms of the total sugar content of the fruits. The highest percentage of total sugar had elite № 1890 - 10.1%, and the lowest had № 6374 - 7.7%.

The highest percentage of titratable acidity had the standard cultivar Van - 0.49%, followed by elite № 5752 - 0.46%. In the other elites titratable acidity was in the range from 0.37% in elite № 1890 to 0.44% in elites № 5750 and № 3419 (Table 2).

Table 2. Comparative biometric and chemical analysis of sweet cherry elites for the period 2013 - 2015

**average for the period*

Beside the content and the ratio of the chemical components, the appearance and the proportions of the fruits are also important for their quality - shape, dimensions and coloring of the skin. Different sizes, shape and coloring are preferred depending on the purpose of the fruits - for fresh consumption or for processing.

All investigated sweet cherry elites had large fruist. The shape of the fruit was from cordate to wide cordate, with dark-red to nearly-black colored skin. The taste of all of them was sweet-sour, with the exception of elite № 3419, which taste was defined as sour-sweet. The coloring of the fruit juice was from pink for Van and elite № 1890 to ruby red for № 5752 (Table 3).

The results of the annually conducted organoleptic degustations show that the studied sweet cherry elites in the Kyustendil region had high taste qualities. In the three years of study, the highest (maximum) taste qualities/properties had standard cultivar Van (5.0 grade) and the lowest - elite № 5750 (3.75). For the other cultivars, the organoleptic evaluation showed very high results - from 4.0 to 4.5 grades (Table 3).

Table 3. Shape and organoleptic qualities of the fruit in sweet cherry elites

Sweet cherry elites	Fruit shape	Flavor	Fruit skin color	Fruit flesh color	Fruit juice color	Organoleptic taste valuation (5 grade scale)
№ 32/25 (Van x Stella)	Wide cordate	Sweet-sour	Dark red	Pink-red	Wine red	4,5
№ 5752 (Kordia x self-pollination)	Cordate with round tip	Sweet-sour	Dark red to black	Dark red	Ruby-red	4,0
№ 5750 (Kordia x self-pollination)	Cordate	Sweet-sour	Dark red	Red	Light red	3,75
№ 6374 (Stella x Germersdorf)	Cordate	Sweet-sour	Dark red	Red	Red	4,0
№ 1890 (Germersdorf x self-pollination)	Cordate	Sweet-sour	Dark red to black	Pink	Pink	4,0
№ 3419 (4C – 1821 x self-pollination)	Wide cordate	Sour-sweet	Nearly black	Red	Dark red	4,5
Van (standart)	Wide cordate to spherical	Sweet-sour	Dark red	Pink	Pink	5,0

Conclusions

The studied sweet cherries, except for elite № 1890, have a later flowering than the standard cultivar Van. According to the period of the ripening of the fruits in the region of Kyustendil, the elites refer to the following groups: medium-ripening - № 5752, № 6374, № 3419, № 1890 and № 32/25 (the second ten days of June) and late-ripening - № 5750 (the first days of July). All sweet cherry elites have good fertility. According to the adopted classification, they have large fruits. The shape of the fruit is from cordate to wide cordate, with dark-red to nearly-black colored skin. The taste is sweet-sour, with the exception of elite № 3419, which taste is defined as sour-sweet. The coloring of the fruit juice is from pink at Van and elite № 1890 to ruby red at № 5752. In consumable maturity, the sugar content of fruits in the studied elites is between 7.7% and 10.1% and titratable acidity - from 0.37% to 0.49%. Organoleptic taste evaluations show high results - from 3.75 grades for № 5750 to 5.0 grades for the standard Van.

Abstract

Aim of this study was to evaluate the allelopathic effect of 10 invasive weeds in forage crops (*Abutilon theophrasti* Medik., *Amaranthus blitoides* S. Wats, *Amaranthus retroflexus* L., *Aristolochia clematitis* L., *Cirsium arvense* Scop. (L.), *Chenopodium album* L., *Matricaria perforata* Merat., *Setaria viridis* (L.) P. Beauv., *Sonchus arvensis* L. and *Sorghum halepense* (L.) Pers.) on the germination and the initial development of *Lactuca sativa* L. cultivar Great Lakes. Ex-situ experiment was carried out as follows: 20 ml (0.75%) agar were pipetted into Petri dishes and the dried weed biomass was added at concentrations 0.05, 0.1, 0.2, 0.4, 0.8% w/v. Samples were stored at 18 ± 2°C for 72 h, then 10 seeds of test plant were placed into agar. Distilled water was used as a control. Samples were placed in a thermostat-operated device at 22 ± 2°C for 5 days and the number of germinated seeds, % of germination against the control, length of the hypocotyl, root and seedling were measured. Index of plant development (GI) was calculated for assessment of the allelopathic effect of weeds on the early seedling growth and the initial development. Most pronounced inhibition on the seed germination and GI (especially of the radix) was found for *Matricaria perforata* and *Amaranthus retroflexus* where LC_{50}=0.2-0.4% w/v and LC_{100}<0.8% w/v. Allelopathic potential of *Cirsium arvense, Setaria viridis* and *Sorghum halepense* could be defined as weak as LC_{50}=0.5-0.8% w/v and the lowest concentrations stimulated both germination and hypocotyl development.

Keywords: *allelopathy, weed management, Lactuca sativa, germination, initial development*

Introduction

Weeds constantly accompany the crop plants and can lower crop productivity by 34% (Oerke, 2006) or cause significant damages which often exceed the total losses from the diseases and pests (Kubiszewski and Cleveland, 2012). Importance of weed control in forage production should not be overlooked, especially when the high investment cost associated with high production is considered. Weeds reduce forage yield by competing for water, sunlight, and nutrients. In addition to yield losses, weeds can also lower forage quality, increase the incidence of disease and insect problems, cause premature stand loss, and create harvesting problems. Some weeds are unpalatable to livestock or, in some cases, may be poisonous.

Currently, most reliable weed control methods include herbicide application, mechanical weeding and hand weeding. Due to the evolution of herbicide resistance in weeds and their negative impacts on environmental, human and animal health, many authors revealed that diversity in weed management tools ensures sustainable weed control and reduces chances of herbicide resistance development (Jabran *et al*., 2015). In today's "organic farming", the integrated weed management systems are increasingly being applied, including allelopathic interactions between some plant species as an alternative method of weed control.

Along with its importance in natural ecosystems, allelopathy also has vast implications in agricultural systems. Various allelopathic interactions including weed-weed, weed-crop, and crop-crop have been observed. Because of the increased interest in various agricultural systems where plant interactions are critical, knowledge of allelopathy is a necessity. Allelopathic compounds are metabolites released from plants that might be beneficial or detrimental to the growth of receptor plants. These compounds are involved in the environmental complex of managed or natural ecosystems. Allelopathic compounds have been shown to play important roles in the determination of plant diversity, dominance, succession, and climax of natural vegetation and in the plant productivity of agroecosystems (Chou, 1999).

Aim of this study was to evaluate the allelopathic effect of 10 invasive weeds in forage crops (*Abutilon theophrasti* Medik., *Amaranthus blitoides* S. Wats, *Amaranthus retroflexus* L., *Aristolochia clematitis* L., *Cirsium arvense* Scop. (L.), *Chenopodium album* L., *Matricaria perforata* Merat., *Setaria viridis* (L.) P. Beauv., *Sonchus arvensis* L. and *Sorghum halepense* (L.) Pers.) on the germination and the initial development of *Lactuca sativa* L. cultivar Great Lakes.

Material and methods

Collection and preparation of plant material

Aboveground biomass from ten invasive weed species (Table 1) in forage crops was collected in a natural environment of weed infestation in Institute of Forage Crops, Pleven at BBCH 51-55 (Hess *et al*., 1997). No separated aboveground biomass of available weed species was chopped together to the length of 0.5-3.0 cm, drying to a constant dry weight at 50 ± 5°C and was grind in grinder Retsch SM – 1 at a sieve size of 1.0 mm.

According to Macias *et al*. (2000) and Yasmin *et al*. (2011) the most commonly used test species in allelopathic bioassays is lettuce (*Lactuca sativa* L.). This species is considered to be an ideal screening agent due to a fast germination rate and a high sensory.

Table 1. Taxonomy of the experimental weed species and life cycle

№	Species name	Family	Class	Life cycle
1	*Abutilon theophrasti* Medik.	Malvaceae	Dicotyledonous	Annual
2	*Amaranthus blitoides* S. Wats	Amaranthaceae	Dicotyledonous	Annual
3	*Amaranthus retroflexus* L.	Amaranthaceae	Dicotyledonous	Annual
4	*Aristolochia clematitis* L.	Aristolochiaceae	Dicotyledonous	Annual
5	*Cirsium arvense* Scop. (L.)	Asteraceae	Dicotyledonous	Perennial
6	*Chenopodium album* L.	Chenopodiaceae	Dicotyledonous	Annual
7	*Matricaria perforata* Merat.	Asteraceae	Dicotyledonous	Annual
8	*Setaria viridis* (L.) P. Beauv.	Poaceae	Monocotyledonous	Annual
9	*Sonchus arvensis* L.	Asteraceae	Dicotyledonous	Perennial
10	*Sorghum halepense* (L.) Pers.	Poaceae	Monocotyledonous	Perennial

Experimental design

Ex-situ experiment was carried out as follows: 20 ml (0.75%) agar were pipetted into Petri dishes and the dried weed biomass was added at concentrations 0.05, 0.1, 0.2, 0.4, 0.8% w/v. Samples were stored at 18 ± 2°C for 72 h, then 10 seeds of test plant were placed into agar according to the adapted method of Fujii *et al*. (2003) and Takemura *et al*. (2013). Distilled water was used as a control. Each treatment consisted of five replicates including the control treatment. Samples were placed in a thermostat-operated device at 22 ± 2°C for 5 days and the number of germinated seeds, % of seed germination against the control, length of the hypocotyl, root and seedling were measured.

Allelopathic effect assessment

Index of plant development (GI) was calculated for assessment of the allelopathic effect of weeds on the early growth and the initial development of the root, hypocotyl and seedling. It was determined by the equation of Gariglio *et al*. (2002):

$$GI = \left[\left(\frac{G}{G_0}\right) \times \left(\frac{L}{L_0}\right)\right] \times 100$$

where G and G_0 –seed germination (%) in each treatment and in the control, respectively; L – average length (mm) of the root, hypocotyl and seedling in experimental treatment, respectively, transformed into percentage as against the control treatment; L_0 – average length (mm) of the radix, hypocotyl and seedlings in the control treatment considered as 100%.

Percentage of seed germination was calculated after preliminary arcsin-transformation following the formula Y=arcsin√(x%/100), forwarded by Hinkelman and Kempthorne (1994), and to induce half-maximal inhibition of growth (LC_{50}) and P=0.05 confidence intervals were calculated according to Hamilton *et al*. (1977).

All collected data were analyzed using the software Statgraphics Plus for Windows Ver. 2.1 and Statistica Ver. 10.

Results and discussion

Alellopathic effect of the tested ten invasive weeds in forage crops on *L. sativa* cultivar Great Lakes varied according to the plant species and the concentration applied (Table 2).

Percentage of seed germination decreased in all experimental treatments with the increment of the weed concentration (from the 0.05 to 0.8 % w/v), the differences being statistically significant at P=0.05. Stimulatory effect on the germination process (103.6 % against the control) were found for *A. blitoides* and *A. clematitis* at 0.05 % w/v concentration; for *C. arvense*, *S. viridis* and *S. halepense* at two lowest weed concentrations (0.05 and 0.1 % w/v); and also for *S. arvensis* at 0.05, 0.1, 0.2 and 0.4 % w/v weed biomass in the media.

Most weak pronounced was the inhibitory effect of *S. viridis* and *A. theophrasti* where the LC_{50} >0.8 % w/v was found. Strongest inhibition exhibited *M. perforata* with LC_{50}=0.1-0.2 % w/v and LC_{100}=0.4-0.8 % w/v, followed by *A. retroflexus* (LC_{50}=0.2-0.4 % w/v and LC_{100}=0.4-0.8 % w/v), *A. clematitis, C. arvense* and *Ch. album* (LC_{50} and LC_{100} were in the range 0.4-0.8 % w/v).

Negative effect on the seed germination could be explained by the presence of the glycol alkaloids, tannins and other active substances in the weed biomass which exerted strong toxicity on the test plant. At higher concentrations they had a lethal effect on the seeds of *L. sativa* whereas at lower concentrations they inhibited the germination process at a different extent (Agarwal *et al*., 2002). Differences in the inhibitory effect could be explained both by the biological characteristics of the studied weed species and the diffusion of the soluble allelochemicals from the dried weed biomass into the agar media (Sangeetha and Bascar, 2015).

Data for the length of the root, hypocotyl and seedling (mm) had a great importance for objective assessment of the differences at the initial developmental stages of the test plant depending on the weed species and the weed concentration (Table 2). Depressive effect of the ten studied weed species on the growth of seedlings in all experimental treatments as compared to the control treatment was found. Length decrement was most pronounced at higher concentration and the differences were statistically significant at P=0.05. Stimulatory effect was observed for the hypocotyl growth in the experimental treatments with 0.05 and 0.1 % w/v of *C. arvense*, *S. viridis* and *S. halepense*.

Table 2. Allelopathic effect of ten studied weed species on the seed germination, growth and initial development of *Lactuca sativa* L. cultivar Great Lakes

Allelopathic effect of weeds (concentrations of weed biomass in % w/v: 0.05, 0.1, 0.2, 0.4 and 0.8) on *Lactuca sativa* properties: lengths (mm) of root (**A**), hypocotyl (**B**) and seedling (**C**); seed germination (C%) against the control (**D**); index (%) of plant development (GI) of the radix (**E**), hypocotyl (**F**) and seedling (**G**)

Inhibiton of the root and hypocotyl growth was strongest at the 0.4 % w/v of *Ch. album* reaching up to 93% and 84%, respectively. Inhibitory effect of the ten weed species on the root length was obvious than on the hypocotyl length. Similar results were obtained by Al Hamdi *et al*. (2001), Inderjit and Streibig (2001), and Belz and Hurle (2004) who reported that the root had the highest sensitivity to allelochemicals and its length is more affected than shoot growth. Root length may be a key parameter to verify allelopathic strength. Higher inhibition of roots compared with shoots may be due to their more intimate contact with the allelochemicals in the agar media.

Index of plant development (GI) showed that although the relatively high LC_{50} value (0.4-0.8 w/v) *A. clematitis* exerted very strong allelopathic effect on the early growth and the initial development of the root, hypocotyl and seedling of test plant (61-79% inhibition) even at low concentration (0.05% w/v). Similar results were found also for *A. retroflexus* where the inhibition was between 43 and 63%. Our data confirmed the findings of Ali *et al*. (2013), Takemura *et al*. (2013), Baličević *et al*. (2015) that the effect of the allelochemicals is manifested already during the seed germination but it is more pronounced during the growth and accumulation biomass of seedlings of the test-plants.

Conclusion

Most pronounced inhibition on the seed germination and the initial plant development (especially of the radix) was found for *Matricaria perforata* Merat. and *Amaranthus retroflexus* L. where LC_{50}=0.2-0.4% w/v and LC_{100}<0.8% w/v. Allelopathic potential of *Cirsium arvense* Scop. (L.), *Setaria viridis* (L.) P. Beauv. and *Sorghum halepense* (L.) Pers. could be defined as weak as LC_{50}=0.5-0.8% w/v and the lowest concentrations stimulated both germination and hypocotyl development.

Abstract

The trial was carried out during 2013-2015, comprising twelve cotton cultivars - Chirpan-539, Helius, Trakia, Viki, Filipopolis, IPK-Veno, Boyana, Avangard, Natalia, Darmi, Dorina and Nelina (*Gossypium hirsutum* L.). Influence of herbicides Bazagran 480 SL (bentazone), Pulsar 40 (imazamox) and Express 50 SX (tribenuron-methyl) was studied. These herbicides were used during the budding stage of cotton. The herbicide Bazagran 480 SL has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Trakia and the lowest on the cultivar Natalia. The herbicide Pulsar 40 has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Dorina and the lowest on the cultivars IPK-Veno and Natalia. The herbicide Express 50 SX has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Boyana and the lowest on the cultivar Helius. From the aspect of cotton growing technology, technologically the most valuable are cultivars Viki, Filipopolis, IPK-Veno, Boyana, Avangard, Natalia, Darmi, Dorina and Nelina by foliar treatment with herbicide Bazagran 480 SL. Technologically the most valuable are cultivars Chirpan-539, Helius, Viki, IPK-Veno, Boyana and Natalia by foliar treatment with herbicide Pulsar 40. Technologically the most valuable are cultivars Helius and Trakia by foliar treatment with herbicide Express 50 SX. These variants combine high lengths of the primary root and high stability of this index during the different years.

Key words: *Cotton, Herbicides, Foliar treatment, Cultivars, Length of primary root*

Introduction

Cotton is a crop that is characterized by long growing season and weak competitive capacity to weeds. Therefore, it is highly sensitive to weeding still in the earliest stages of its development (Ashok et al., 2006).

Problem in contemporary farming is secondary weed infestation of crop (Boz, 2000; Bukun, 2004). The competition of weeds leads to a decrease in the cotton plants height, the number and length of the fruit twigs, the number of boxes per plant and the yield (Salimi et al., 2006). In the application of the herbicide during the growing season of the cotton often a manifestation of phytotoxicity, this affects the growth and development, yield, quality of the fiber and the crop properties of the seed of crop (Barakova and Delchev, 2016). When applying herbicides to combat annual weeds during cotton growing, a phytotoxic effect on cotton and a reduction in September yield (Stoychev et al., 2010). Cotton plants show symptoms of damage in the application of the herbicide Staple (pyrithiobac-sodium) for the control of annual broadleaf weeds during cotton vegetation (Vargas and Wright, 1994) The fight against secondary weed infestation is extremely difficult and must look for new approaches and herbicides technology for growing cotton, which are efficacy and selective to crop (Gao et al., 2005).

The aim of this research is to investigate the effect of foliar antibroadleaved herbicides on the length of the primary root of the seeds from different cotton cultivars (*Gossypium hirsutum* L.).

Materials and methods

The trial was carried out during 2013-2015, comprising twelve cotton cultivars - Chirpan-539, Helius, Trakia, Viki, Filipopolis, IPK-Veno, Boyana, Avangard, Natalia, Darmi, Dorina and Nelina (*Gossypium hirsutum* L.). Influence of herbicides Bazagran 480 SL (bentazone) – 1.5 l/ha, Pulsar 40 (imazamox) – 1.2 l/ha and Express 50 SX (tribenuron-methyl) 50 g/ha was studied. These herbicides were used during the budding stage of cotton. It was investigated herbicides Bazagran 480 SL (bentazone), Pulsar 40 (imazamox) and Express 50 SX (tribenuron-methyl). They are treated during budding stage of cotton. The experiment was conducted under the block method, in 4 repetitions; the size of the crop plot was 20 m^2. The foliar herbicides were treated after the herbicidal combination Dual gold 960 EC (S-metholahlor) – 1.2 l/ha + Goal 2 E (oxifluorfen) – 1.2 l/ha, which is applied after sowing before emergence for controlling of primary weed infestation in cotton. Spraying is done with a knapsack sprayer with a working solution 300 l/ha. It was investigated the length of the primary root of cotton seeds. The seeds were taken from the 12 cotton cultivars treated during the vegetation with the respective herbicides. It was accounted is the length of the primary root on 7^{th} day. The math processing of the data was done according to the method of analyses of variance (Shanin 1977; Barov, 1982; Lidanski 1988). The stability of herbicides and cultivars for length of the primary root with relation to years was estimated using the stability variances σ_i^2 and S_i^2 of Shukla (1972), the ecovalence W_i of Wricke (1962) and the stability criterion YS_i of Kang (1993).

Results and discussion

The herbicide Bazagran 480 SL applied during cotton vegetation, mean for the investigated period, has the highest phytotoxicity on the length of the primary root of the seeds from cultivar Trakia (Table 1). At this herbicides is measured at the lower value of the indicator compared to the other cultivars – 5.5 cm. The lowest is the action of Bazagran on cultivar Natalia – 8.4 cm. This is due to the smaller phytotoxicity of the herbicide on the root length of this cultivar. Cultivar Trakia is characterized as the most sensitive to the herbicide Bazagran 480 SL and variety Natalia - the most resistant to this herbicide.

The herbicide Pulsar 40 has the highest phytotoxicity on the length of the primary root of the seed from cultivar Dorina – 3.5 cm. Of the tested cultivars it is defined as the most sensitive to this herbicide. Cultivars IPK-Veno and Natalia have the biggest length of the primary root compared to the other cultivars, respectively – 6.7 cm and 6.6 cm. Pulsar influence the less on this indicator on these cultivars.

The herbicide Express 50 SX has the highest phytotoxicity on the length of the primary root of the seed from cultivar Boyana – 3.5 cm. Cultivar Helius has the biggest length of the primary root – 7.4 cm. Express influence the less on this indicator on this cultivar. Cultivar Boyana is the most sensitive to this herbicide in terms of the length of the primary root.

Analysis of variance for length of the primary root of cotton seeds (Table 2) shows that the herbicides have influence on the primary root – 9.1 % on the variants. The reason for this is the phytotoxic action of some of the herbicides. The strength of influence of years is 6.7 % and the strength of influence cultivars is 7.8 %. The influence of years, of cultivars and of herbicides is very well proven at $p \leq 0.01$. There is an interaction between herbicides and meteorological conditions of years (AxB) – 4.8 %, between cultivars and meteorological conditions of years (AxC) – 11.3 %, and between cultivars and herbicides (BxC) – 22.7 %. They are very well proven at $p \le 0.1$. There is interaction between three experiment factors (AxBxC) – 35.9 %. It also is very well proven at $p \le 0.1$.

Based on proven herbicide x year interaction and cultivar x year interaction, it was evaluated stability parameters for each variant for length of the primary root of cotton seeds with relation to years (Table 3). It was calculated the stability variances σ_i^2 and S_i^2 of Shukla, the ecovalence W_i of Wricke and the stability criterion YS_i of Kang.

Stability variances (σ_i^2 and S_i^2) of Shukla, which recorded respectively linear and nonlinear interactions, unidirectional evaluate the stability of the variants. These variants which showed lower values are considered to be more stable because they interact less with the environmental conditions. Negative values of the indicators σ_i^2 and S_i^2 are considered 0. At high values of either of the two parameters - σ_i^2 and S_i^2, the variant are regarded as unstable. At the ecovalence W_i of Wricke, the higher are the values of the index, the more unstable is the variant.

On this basis, using the first three parameters of stability, it is found that by foliar treatment with herbicide Bazagran 480 SL stable are cultivars Avangard and Natalia. By treatment with herbicide Pulsar 40 stable is cultivar Viki, and by treatment with herbicide Express 50 SL stable are cultivars Chirpan-539, Filipopolis, Darmi and Nelina. Other variants have high instability - values of stability variance σ_i^2 and S_i^2 of Shukla and ecovalence W_i of Wricke are the highest and mathematically proven. The reason for this high instability is greater variation in lengths of the primary roots during years of experience as weather conditions affect those most. At part of them there is instability from linear and nonlinear type - proven values σ_i^2 and S_i^2. At another part of them, instability is a linear type - proven values σ_i^2, the values of S_i^2 are not proven.

To evaluate the complete efficacy of each herbicide should be considered as its effect on length of the primary root of cotton seeds and its stability - the reaction of cotton to this variant during the years. Valuable information about the value of technologic value of the variant give the stability criterion YS_i of Kang for simultaneous assessment of length of the primary root and stability, based on the reliability of the differences in yield and variance of interaction with the environment. The value of this criterion is experienced that using nonparametric methods and warranted statistical differences we get a summary assessment aligning variants in descending order according to their economic value.

Generalized stability criterion YS_i of Kang, taking into accounts both the stability and value of length of the primary root gives a negative assessment of cultivars Avangard, Dorina and Nelina, treated by Pulsar 40, and Viki, IPK-Veno, Boyana, Avangard, Natalia and Dorina treated by Express 50 SX. They are characterized as the most unstable and with low values.

Table 3. Stability parameters for the variants for length of the primary root with relation to years.

	Nelina	5.3	-0.01	0.02	0.08	5

None of these cultivars receive negative evaluation by foliar treatment with herbicide Bazagran 480 SL. According to this criterion, the most valuable technologically appears cultivars Viki, Filipopolis, IPK-Veno, Boyana, Avangard, Natalia, Darmi, Dorina and Nelina by foliar treatment with herbicide Bazagran. The most valuable technologically appears cultivars Chirpan-539, Helius, Viki, IPK-Veno, Boyana and Natalia by foliar treatment with herbicide Pulsar. Cultivars Helius and Trakia have the highest evaluation by foliar treatment with herbicide Express. They combine relatively high lengths of the primary root of cotton seeds with high stability during the different years of the investigation.

Conclusions

The herbicide Bazagran 480 SL has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Trakia and the lowest on the cultivar Natalia.
The herbicide Pulsar 40 has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Dorina and the lowest on the cultivars IPK-Veno and Natalia.
The herbicide Express 50 SX has the highest phytotoxicity on the length of the primary root of seeds of the cotton cultivar Boyana and the lowest on the cultivar Helius.
From the aspect of cotton growing technology, technologically the most valuable are cultivars Viki, Filipopolis, IPK-Veno, Boyana, Avangard, Natalia, Darmi, Dorina and Nelina by foliar treatment with herbicide Bazagran 480 SL. Technologically the most valuable are cultivars Chirpan-539, Helius, Viki, IPK-Veno, Boyana and Natalia by foliar treatment with herbicide Pulsar 40. Technologically the most valuable are cultivars Helius and Trakia by foliar treatment with herbicide Express 50 SX. These variants combine high lengths of the primary root and high stability of this index during the different years.

Abstract

The trial was carried out during 2013-2015, comprising two cotton cultivars – Helius and Darmi (*Gossypium hirsutum* L.). Herbicides Goal 2 E (oxifluorfen), Linuron45 SC (linuron), Wing P (pendimethalin + dimethenamid), Merlin 750 WG (izoxaflutole), Bazagran 480 SL (bentazone) were studied. These herbicides were used alone or in combinations with the growth regulator Amalgerol premium or the foliar fertilizer Lactofol O during the budding stage of cotton. The foliar treatment with tank mixtures Wing P + Amalgerol and Wing P + Lactofol lead to the highest seed germination in case of the cultivar Helius. The foliar treatment comprising the herbicide Bazagran or the tank mixture Bazagran+ Lactofol leads to the highest seed germination in case of the cultivar Darmi. The highest phytotoxicity on seed germination of the cultivar Helius was recorded after using the herbicide Merlin and the tank mixture Goal+ Amalgerol. The highest phytotoxicity on seed germination of the cultivar Darmi was recorded after using the herbicide Linuron and its tank mixtures with Amalgerol and Lactofol. From the aspect of cotton growing technology, technologically the most valuable are combinations of all herbicides with Lactofol, which are followed by Linuron + Amalgerol, Wing + Amalgerol, Merlin + Amalgerol and sole use of herbicide Bazagran on cultivar Helius. Technologically the most valuable are herbicides Goal and Bazagran and tank mixtures Goal + Amalgerol, Merlin + Amalgerol, Bazagran + Amalgerol, Wing + Lactofol and Bazagran + Lactofol on cultivar Darmi. These variants combine high lengths of the seed germination and high stability of this index during the different years. The sole use of the herbicides Linuron and Merlin has low assessment and should be avoided.

Key words: *Cotton, Herbicides, Foliar fertilizer, Growth regulator, Seed germination*

Introduction

Cotton is one of the most valuable crops for Bulgaria. At cotton growing weed control is critical to the yield and quality of production. Problem in contemporary farming is secondary weed infestation of crop. Critical periods of weed infestation in cotton are from 1-2 weeks of cotton germination to the 11^{th}-12^{th} week of the cotton development (Bukun, 2004), from the appearance of first fruit-bearing twig until the end of flowering (Salimi et al. 2006) and the second true leaf stage to budding stage (Stoychev, 2013). There is often phytotoxicity by the application of herbicides during the cotton growing season (Ashok et al., 2006). Phytotoxicity slows growth and development of cotton plants, reduces structural elements of yield and decreases cotton yield, degrades fiber quality (Barakova and Delchev, 2016; Barakova, 2017). The fight against secondary weed infestation is extremely difficult and must look for new approaches and herbicides which exhibit excellent selectivity in technology for cotton growing.

The aim of this research is to investigate the influence of foliar herbicides and tank mixtures with growth regulator and foliar fertilizer on cotton seed germination on two cotton cultivars - Helius and Darmi (*Gossypium hirsutum* L.).

Materials and methods

The trial was carried out during 2013-2015, on leached vertisol soil type, with two cotton cultivars – Helius and Darmi (*Gossypium hirsutum* L.). The experiment was conducted under the block method, in 4 repetitions; the size of the crop plot was 20 m^2.

Herbicides Goal 2 E (oxifluorfen) - 800 ml/ha, Linuron45 SC (linuron) - 2 l/ha, Wing P (pendimethalin + dimethenamid) - 4 l/ha, Merlin 750 WG (izoxaflutole) - 50 g/ha, Bazagran 480 SL (bentazone) - 1.5 l/ha were studied. These herbicides were used alone or in combinations with the growth regulator Amalgerol premium - 8 l/ha or the foliar fertilizer Lactofol O - 5 l/ha during the budding stage of cotton. The foliar herbicides were treated after the herbicidal combination Dual gold 960 EC (S-metholahlor) – 1.2 l/ha + Goal 2 E (oxifluorfen) – 1.2 l/ha, which is applied after sowing before emergence for controlling of primary weed infestation in cotton. Spraying is done with a knapsack sprayer with a working solution 300 l/ha. Weeds in the economic control are removed by hoeing - 3 times during cotton vegetation.

It was investigated the seed germination of cotton. The seeds were taken from the 2 cotton cultivars treated during the vegetation with the respective herbicides and tank mixtures. It was accounted is the length of the primary root on 7^{th} day.

The math processing of the data was done according to the method of analyses of variance (Shanin 1977; Barov, 1982; Lidanski 1988). The stability of herbicides and cultivars for seed germination with relation to years was estimated using the stability variances σ_i^2 and S_i^2 of Shukla (1972), the ecovalence W_i of Wricke (1962) and the stability criterion YS_i of Kang (1993).

Results and discussion

All herbicides reduced laboratory seed germination on cultivar Helius. This is due to their phytotoxic action these herbicides have on cotton plants. Laboratory germination is decreased by the Goal + Lactofol O, Merlin + Lactofol O and Bazagran + Lactofol O (Table 1). They are accounted values lower than that of the economic control – 92.5 %. The highest phytotoxic effect on the laboratory germination has herbicide Merlin 750 WG - 84.0 %, and herbicidal herbicide combinations Goal + Amalgerol, Merlin + Amalgerol, Bazagran + Amalgerol, mixture Goal + Amalgerol - 82.5 %. The other herbicide combinations do not affect the values of the index. The biggest laboratory seed germination is obtained by use of Wing P + Amalgerol - 98.2 % and Wing P + Lactofol O - 97.8 %. The reason for this is that the growth regulator Amalgerol and foliar fertilizer Laktofol reduce phytotoxic effects of the herbicide Wing P in cultivar Helius.

All herbicides reduced the laboratory seed germination of cultivar Darmi too, due to their phytotoxicity on this cultivar. Laboratory germination is decreased by all herbicides and herbicide combinations compared with that of economic control – 96.5 %. In cultivar Darmi growth regulator Amalgerol and foliar fertilizer Laktofol not reduce phytotoxic effects of either of the herbicides. The highest phytotoxic effect on the laboratory germination has herbicide Linuron 45 SC – 79.2 % and herbicidal mixture Linuron + Amalgerol – 78.3 % and Linoron + Lactofol O – 82.7 %. The biggest laboratory seed germination is obtained by use of Bazagran 480 SL – 96.0 % and Bazagran + Lactofol O – 95.0 %. Bazagran has the weakest phytotoxicity on seed germination. All herbicides applied alone have a phytotoxic effect on laboratory germination of the seeds of the two cotton cultivars. All herbicide combinations with foliar fertilizer Lactofol O have bigger seed germination combinations compared with that of sole used herbicides. Lactofol O reduces the phytotoxic effect of the herbicides on this index. Growth regulator Amalgerol reduces phytotoxicity on laboratory seed germination only of herbicides Linuron 45 SC, Wing P and Merlin 750 WG on cultivar Helius.

Table 1. Laboratory seed germination, % (2013-2015).

Cultivars	Variants	2013	2014	2015	Mean

Foliar fertilizer Lactofol O reduces phytotoxicity on the laboratory seed germination only of herbicides Merlin 750 WG and Linuron 45 SC on cultivar Darmi. Analysis of variance for laboratory germination of cotton seeds (Table 2) shows that the herbicides and their combinations have big influence on the seed germination – 25.1 % on the variants. The reason for this is the phytotoxic action of some of the herbicides. The strength of influence of years is 3.3 % and the strength of influence cultivars is 0.7 %. The influence of years, of cultivars and of herbicides is very well proven at $p \leq 0.01$. There is an interaction between cultivars and meteorological conditions of years (AxB) – 1.4 %, between herbicides and meteorological conditions of years (AxC) – 31.3 %, and between cultivars and herbicides (BxC) – 24.1 %. They are very well proven at $p \leq 0.1$. There is interaction between three experiment factors (AxBxC) – 12.9 %. It also is very well proven at $p \leq 0.1$.

Based on proven herbicide x year interaction and cultivar x year interaction, it was evaluated stability parameters for each variant for length of the laboratory germination of cotton seeds with relation to years (Table 3). It was calculated the stability variances σ_i^2 and S_i^2 of Shukla, the ecovalence W_i of Wricke and the stability criterion YS_i of Kang. Stability variances (σ_i^2 and S_i^2) of Shukla, which recorded respectively linear and nonlinear interactions, unidirectional evaluate the stability of the variants. These variants which showed lower values are considered to be more stable because they interact less with the environmental conditions. Negative values of the indicators σ_i^2 and S_i^2 are considered 0. At high values of either of the two parameters - σ_i^2 and S_i^2, the variant are regarded as unstable. At the ecovalence W_i of Wricke, the higher are the values of the index, the more unstable is the variant. On this basis, using the first three parameters of stability, it is found that at cultivar Helius stable are herbicide combinations Wing P + Amalgerol, Wing P + Lactofol O and Goal + Lactofol O. At cultivar Darmi stable are Goal + Amalgerol and Wing P + Lactofol O. Other variants have high instability - values of stability variance σ_i^2 and S_i^2 of Shukla and ecovalence W_i of Wricke are the highest and mathematically proven. The reason for this high instability is greater variation in seed germination during years of experience as weather conditions affect those most. At part of them there is instability from linear and nonlinear type - proven values σ_i^2 and S_i^2. At another part of them, instability is a linear type - proven values σ_i^2, the values of S_i^2 are not proven. To evaluate the complete efficacy of each herbicide should be considered as its effect on laboratory germination of cotton seeds and its stability - the reaction of cotton to this variant during the years. Valuable information about the value of technologic value of the variant give the stability criterion YS_i of Kang for simultaneous assessment of length of the primary root and stability, based on the reliability of the differences in yield and variance of interaction with the environment. The value of this criterion is experienced that using nonparametric methods and warranted statistical differences we get a summary assessment aligning variants in descending order according to their economic value.

Table 3. Stability parameters for the variants for laboratory seed germination with relation to years.

Generalized stability criterion YS_i of Kang, taking into accounts the stability and value of seed germination gives a negative assessment of herbicide Merlin 750 WG and herbicide combination Goal 2 E + Amalgerol on cultivar Helius. Negative assessment on cultivar Darmi has herbicide Linuron 45 SC and its combinations with Amalgerol and Lactofol O, and also herbicide combination Goal 2 E + Amalgerol. They are characterized as the most unstable and with low values. According to this criterion, technologically the most valuable are herbicide combinations Goal 2 E + Lactofol O, Linuron 45 SC + Lactofol O, Wing P + Lactofol O, Merlin 750 WG + Lactofol O, Bazgran 480 SL + Lactofol O, Linuron 45 SC + Amalgerol, Wing P + Amalgerol and Merlin 750 WG + Amalgerol, also sole use of herbicide Bazgran 480 SL on cultivar Helius. Technologically the most valuable are herbicides Goal 2 E and Bazgran 480 SL and herbicide combinations Goal 2 E + Amalgerol, Merlin 750 WG + Amalgerol, Bazgran 480 SL + Amalgerol, Wing P + Lactofol O and Bazgran 480 SL +

Lactofol O on cultivar Darmi. They combine relatively high values of the laboratory germination of cotton seeds and high stability during the years of the investigation. The sole use of the herbicides Linuron 45 SC and Merlin 750 WG receive low assessment and should be avoided. This is due to the high phytotoxicity of these two herbicides.

Conclusions

The foliar treatment with tank mixtures Wing P + Amalgerol and Wing P + Lactofol lead to the highest seed germination in case of the cultivar Helius. The foliar treatment comprising the herbicide Bazagran or the tank mixture Bazagran+ Lactofol leads to the highest seed germination in case of the cultivar Darmi.

The highest phytotoxicity on seed germination of the cultivar Helius was recorded after using the herbicide Merlin and the tank mixture Goal+ Amalgerol. The highest phytotoxicity on seed germination of the cultivar Darmi was recorded after using the herbicide Linuron and its tank mixtures with Amalgerol and Lactofol.

From the aspect of cotton growing technology, technologically the most valuable are combinations of all herbicides with Lactofol, which are followed by Linuron + Amalgerol, Wing + Amalgerol, Merlin + Amalgerol and sole use of herbicide Bazagran on cultivar Helius. Technologically the most valuable are herbicides Goal and Bazagran and tank mixtures Goal + Amalgerol, Merlin + Amalgerol, Bazagran + Amalgerol, Wing + Lactofol and Bazagran + Lactofol on cultivar Darmi. These variants combine high lengths of the seed germination and high stability of this index during the different years.

The sole use of the herbicides Linuron and Merlin has low assessment and should be avoided.

Abstract

Pea is a valuable leguminous crop essential for the balanced nutrition of men and animals. The aim of study was to establish the relationship between yield and yield characteristics of grain legumes spring pea (*Pisum sativum* L.) and wintering pea (*Pisum arvense* L.) and impact of climate factors of Central South Bulgaria on peas yield. The survey was conducted during 2004–2013 in the experimental base of the Plant Growing Department at Trakia University, Stara Zagora. The experiment was conducted by the block method in 4 repetitions. The plants were grown according to the conventional technology. Results obtained for the grain yield and structure components were statistically processed by ANOVA and regression equations among the yield and climatic parameters were developed. It was established that in the environment conditions of Bulgaria *P. sativum* were high productive, compared to *P. arvense*. Good correlations were found between the morphological characteristics. Interpopulation variation (94.48 – 99.90%) of the grain yield and yield characteristics was significantly higher compared to the intrapopulation. The values of the yield and yield structure characteristics depend in a great extent of climatic parameters. Regression equations were developed on this base, which allows preliminary assessment of peas grain productivity with approximate accuracy for practical purposes. Studies to determine the effect of pea variety and year showed that climate conditions over the years as factor had the highest impact on the yield (68.72%). The type of pea as factor had a higher effect on the morphological parameters and yield structure elements (42.54 – 96.28%).

Keywords: *Equations, Peas, Climatic conditions, Yield, Morphological characteristics*

Introduction

Variability of yields and their dependence on climatic factors are one of the most important problems in crop production. This entails the search for new alternative solutions related to crop tolerance to abiotic stressors (Cutforth et al., 2007; Stagnari et al., 2017). From abiotic factors in Bulgaria the bigger role have temperature and humidity, which further defines the expression and effect of biotic factors. Their interaction and complex influence on grain, fix negative effect on leguminous yields, which is the reason for the reduction of their areas (Kirilov, 2016; McMurray et al., 2011). One of the most widespread cereal crops, both in the European Union and in Bulgaria, is peas (Kirilov, 2016). One of his major advantages is that under the terms of a typical continental climate with frequent droughts, without irrigation gives high yields of protein with low cost. (Tekeli and Ates, 2003; Zhelyazkova et al., 2007, 2012). Pea yields are influenced to a significant extent by the environmental conditions and the genotype (Acikgoz et al, 2009; Bueckert et al., 2015; Dore et al., 1998), as their variability by year is an extremely large with a coefficient of variation of 30% (Kuzmova, 2001).

The magnitude of yield on spring pea is influenced most by the change of the main meteorological elements, especially of the precipitation in the spring (Dore et al., 1998;

Kouzmova, 2003). In a good security with moderate rainfall and temperature it blooms longer, the plants are higher and more pods. When rainfall is less and the temperatures of the air – higher height, mass, number of legumes and grains of a plant are lower (Bueckert et al., 2015; McMurray et al., 2011). Excessive moisture during flowering and ripening period can become a reason for obtaining low yields due to lodging of plants, rotting the bottom of the stems, the development of diseases and low insemination (Angelova and Kouzmova, 2001; Kouzmova, 2003; McMurray et al., 2011). Uncertain yields of spring pea varieties are a serious reason to look for a way out in the growing of varieties for the wintering grain (and Kouzmova Angelova, 2001; Cutforth et al., 2007; Kouzmova, 2001; Zhelyazkova et al., 2007). Risk factor in growing wintering peas is the temperature during the winter period as a stronger correlation of indicators of yield with temperature compared to the conditions of humidity can be searched in the autumn-winter water supply, and not solely from the fallen precipitation (Koeva et al.,1990).

The purpose of this study is to establish productive capabilities of grain legumes spring peas (*Pisum sativum* L.) and wintering peas (*Pisum arvense* L.) under the environmental conditions of South-Central Bulgaria, the influence of climatic conditions on productivity and structural elements by examining the relationships between them for a longer period of time.

Materials and methods

The survey was conducted during the period 2004–2013 on the experimental base of the "Plant Growing" Department at Trakia University, Stara Zagora. A field experiment was conducted to establish the growth and productivity of annual grain legumes spring pea (*Pisum sativum* L.) cultivar Bogatir and wintering pea (*Pisum arvense* L.) cultivar Mir. The experiment was conducted by the block method in 4 repetitions, after a wheat as preceding crop.

The legumes were grown according to the conventional technology adopted in the country and the region, without irrigation. For meteorological evaluation of the test period, the degree of certainty of water and air temperature was calculated by the formula $P=i/(n+1)*100$, where: P- certainty; i – serial number of individual members in the row (sorted in descending order for the precipitation patterns and amounts in ascending order for the annual average and growing temperatures); n-total number of items in the line. Representative order with 40 members (1974 – 2013) was used. For very moist and cool are considered years with 0-25%, for moderate wet and cool with an average 25 - 50%, the security for medium-dry and warm with average security 50 - 75% dry and warm – 75 to 100% (Delibaltov et al., 1962). During the experiment the yield of grain in standard humidity (13%) were established and the following morphological parameters were studied: plant height at harvesting, number of pods and grain per plant, grain mass per plant and 1000 grain mass. The data obtained was processed statistically and used to establish the correlation and regression equation by means of StatSoft STATISTICA for Windows (2013).

The soil in the area was typical *Gleic Chromic Luvisols*, moderately supplied with hummus, with a slight acidic reaction, poorly supplied with nitrogen and phosphorus and very well supplied with potassium. These soil conditions are favorable for the development and growth of the grain legumes.

Results and discussion

In the climatic respect the years during which the study was conducted, are characterized by uneven distribution of precipitation. The most humid is a 2005 (P = 2.5%), when the annual amount of precipitation is with 50.7% over the average for the period 1936 - 2002 (Table 1).

Very moist are 2004, 2007, 2009 and 2012. The most dry is 2011 with the annual amount of rainfall with 31.6 percent below average for a long-term period and security 85.0%. In terms of the amount of spring peas growing rains (March - June) average for the test period is 192.6 mm, which is 8.7% below normal.

Table 1.Climate conditions, average for the year and vegetation periods.

Year	Rains, mm				Temperature, ^{0}C			
	I-XII	P, %	X-VI	III-VI	I-XII	P, %	X-VI	III-VI
2004	602.9	20.0	404.7	207.1	12.3	40.0	9.2	13.9
2005	824.3	2.5	445.2	196.8	11.8	12.5	9.2	13.9
2006	506.8	55	435.0	220.9	12.3	45.0	8.3	14.4
2007	730.5	5.0	373.4	241.3	13.2	80.0	10.4	15.5
2008	534.4	37.5	545.8	247.1	12.8	70.0	9.0	15.1
2009	588.2	25.0	322.2	145.3	13.0	75.0	9.8	14.7
2010	725.4	7.5	535.6	218.1	13.2	82.5	9.8	14.4
2011	374.2	85.0	298.4	89.3	12.2	37.5	9.5	14.1
2012	617.0	17.5	482.9	174.5	13.6	90.0	8.8	15.6
2013	534.1	40.0	516.0	185.1	13.7	92.5	10.8	16.1
2004-2013	603.8	29.5	435.9	192.6	12.8	62.5	9.5	14.8
1936-2002	547.0		462.1	210.9	12.4		9.3	14.2

*P - degree of certainty according to the monthly sum of the precipitation and the average monthly air temperature,%

The greatest amount of rainfall during growing period was registered in 2008 – 247.1 mm (17.2% above normal), and the smallest in 2011 – 89.3 mm (57.7% below normal). For wintering peas greatest amount rainfall during growing period (October – June) was registered in 2008 – 545.8 mm (28.4% above normal), and the smallest as it was for spring peas in 2011 – 298.4 mm, (29.8% below normal). In terms of average annual air temperatures-six of the experimental years are warm – 2007, 2008, 2009, 2010, 2012, and 2013. 2005 – is a cool with security and 12.5%, average cool are 2004, 2006, and 2011 years (P = 37.5% to 45%). The highest temperatures during reproductive phases of peas (May - June) are taken into account in 2013. Average air temperature during the growing season of spring peas (March - June) in seven of the experimental years was with values above normal as they are highest in 2013 with about 2.0 ^{0}C above normal. Winter conditions in most of the experimental years are normal and there is no reported damage by low temperatures on crops of wintering peas. In the months of January and February of 2012 have reported record low temperatures, respectively 1.3 and 3.5 ^{0}C below normal, but formed though a thin snow cover and high winter resistance of pea variety “Mir” have led to minimal frost damages and formation of crop with optimal density. Analysis of the integral effect of the two main meteorological factors rainfall and air temperature indicates that within the growing season the peas in the ten years of study there are exceptions by month, with the result that different conditions have been created for the development of plants and their productivity.

The most valuable product in peas is grain. On average for the period of the research productivity of peas grown in the region of South-Central Bulgaria is 2196.9 kg.ha^{-1} with variation of 1092.5 to 3303.3 kg.ha^{-1} (Table 2). Spring pea is distinguished by an average of 9.5% higher productivity. The most favorable in terms of productivity of the peas are the 2004, 2008 and 2010.

Table 2. Yield potential and morphological structure parameters of pea by years, average for the period 2004 – 2013, n=80.

Year	Yield of grain, kg.ha^{-1}	Stem height, cm	Pods per plant, number	Grains per plant, number	Grain mass per plant, g	1000 grain mass, g

Different letters denote statistically significant differences among variants at $P < 0.05$

*** - Statistically significant differences of average values among peas varieties at $P < 0.001$.

The lowest yields of spring peas were reported in 2007, when the distribution of rainfall is growing extremely uneven-there is highly drought in April lasted until the third decade of May as growing 26.6% of rainfall fell at the end of March, and 52.3% in the period 20 - 30 May. On the other hand, at the time of flowering and ripening phases (May and June) average monthly air temperatures are record high – with 1.6 - 2.4 ^{0}C above normal, which has affected negatively on productivity. Low productivity in both types of peas is recorded in 2011, 2012 and 2013 makes good impression that the uneven distribution of precipitation during the growing season of 2012, accompanied by monthly average air temperatures during maturation (June) with 2.8 ^{0}C above the multi-annual average for the same period, affect the development of spring peas. In wintering pea yield this year is almost equal with spring pea. As the winter culture, it has outpaced the development of spring peas, which incurred drought in June 2012, have not responded so negatively to the massiveness of the grain as in spring peas. The height of the stem in peas is highly changing indication as to research period has seen a difference in height almost doubled – from 43.08 up 122.25 cm in spring peas and 113.0 to 151.1 cm in wintering. Arid 2007, 2011 and 2013 have created prerequisites for the formation of the stems with the lowest height compared to other years and in both types of peas. Pea crop grown in agri-environmental conditions of Central South Bulgaria formed an average of 6.8 pods per one plant with 30.3 grains. The highest number of pods and grains from the plant in both types of peas is recorded in 2008. The smaller number of legumes and grains from the plant in the spring peas is recorded in 2007 characterized with sensitive dry periods and temperatures above optimal, not seen in wintering peas, which uses more autumn-winter water supplies. In wintering peas the number of pods is lowest in 2006, characterized by a sharp cold observed in January, coupled with the lack of snow cover and drought extended the period of reproductive phases. Similarly, the impact of weather conditions on the mass of the grains of the plant so that once again the highest in both species, and average for the test period were recorded in 2008. Spring peas formed a grain with a mass of 5.27 g per plant, which is higher with 26.65% compared to wintering peas. Data on the weight of 1000 grains indicate that the most massive grain of spring peas is received in 2004, 2005 and 2010, and the smaller in 2012 and 2013. The mass of 1000 grain in wintering peas is with 46.95% lower than that in the spring peas. As winter culture the highest in 2013-as, he has outpaced the development of spring peas, which is probably the reason the dry and hot period in May and June 2013 not to affect the masiveness of the grain. Analysing the relationship between productivity, plant height and yield structural elements in peas it was established that grain yield is in a good positive correlation with the specific mass of grains per plant (r = -0.812) (Table 3). The height of the stem is in a good positive correlation to

Table 3. Correlation among the pea parameters, n=80

Parameters	Yield of grain, $kg.ha^{-1}$	Stem height, cm	Pods per plant, number	Grains per plant, number	Grain mass per plant, g	1000 grain mass, g
Yield of grain, $kg.ha^{-1}$	1.000					
Stem height, cm	0.228	1.000				
Pods per plant, number	0.144	0.742*	1.000			
Grains per plant, number	0.079	0.700*	0.929*	1.000		
Grain mass per plant, g	0.620*	-0.364	-0.090	-0.043	1.000	
1000 grain mass, g	0.312	-0.812*	-0.732	-0.726	0.674*	1.000

* Statistical significance at $P < 0.05$

the number of pods and grains per plant (r = 0.700 - 0.742) and very good negative relation with the mass of 1000 grains (r = -0.812). Number of pods per plant is in a very good correlation with the number of grains (r = 0.929), and the mass of the grains is in a good correlation with the weight of 1000 grains (r = 0.674).

The statistical analysis for the variation of grain productivity and the structural elements that determined it show that the interpopulation variation is significantly higher (94.48 – 99.90%), while the variation within populations was minimal (0.10 – 5.52%) Interpopulation variation was highest for the mass of the grains from plants and less on the weight of 1000 grains.

Climate conditions during the years as factor had a higher impact on the peas yield (68.72%), $P < 0.0001$ (Table 4).

The power of influence of climate conditions over the years on the indicators of the stem height, number of pods and grain from the plant, mass of grains per plant and weight of 1000 grains is significantly lower. On the height parameters and structural elements the type of peas (42.54-96.28%) as a factor has the greater influence. As in grain yield such as in parameters number of pods and grain per plant and mass of the grains per plant is observed lower interaction among type of culture with climate conditions (13.8-25.18%).

Table 4. Influence of factors on the grain yield and yield structure characteristics, %

Source of variation	Yield of grain, $kg.ha^{-1}$	Stem height, cm	Pods per plant, number	Grains per plant, number	Grain mass per plant, g	1000 grain mass, g
Pea Variety	4.76	72.51	60.03	53.46	42.54	96.28
Year	68.72	21.95	20.75	24.53	38.14	1.46
Pea Variety*Year	25.18	4.15	16.87	18.70	13.80	2.16
Error	1.33	1.39	2.36	3.31	5.52	0.10

Correlation analysis shows that with the most positive impact on productivity of spring peas in a region of Central South Bulgaria are precipitation in June (r = 0.819) and negatively impact the temperatures during the period May-June r = (-0.668) – (-0.715). With the strongest influence on the number of pods, the mass of the grains of the plant and the mass of 1000 seeds in spring peas are precipitation in June (r = -0.633 - 0.657) and temperatures in the second half of the growing season, May-June, r = (0.654) – (0.838).
The yield of grains in wintering peas is positively correlated with precipitation during the period March-June (r = 0.682). On the number of pods and grains and the mass of the grains from plant greatest affect had rainfall in April (r = 0.456 - 0.663) and temperatures in March (r = 0.715 - 0.749). With the strongest influence on the weight of 1000 grains in wintering peas are the temperatures during the growing season (October - June) - r = 0.841.
The good relationships between productivity and structural elements of productivity and on the other hand between the morphological indices of grain yield and climatic factors, allow to develop regression dependences for evaluation of mentioned parameters by climatic factors. The yields of grain and the structural elements of yield in spring peas are determined with high accuracy depending on the amount of rainfall in June (R = 0.632 – 0.819) and temperatures in May (R = 0.653 – 0.715) (Table 5). Grain yields in wintering peas are determined with high accuracy depending on rainfall during the period March-June (R = 0.682). The number of legumes and the mass of the grains from a plant in wintering peas are determined with high accuracy depending on the temperatures in March (R = 0.715 - 0.944).
Developed regression equations are with a good degree of confidence (P < 0.05) and allow to carry out for a preliminary assessment of the productivity of the peas with sufficient accuracy for practical purposes.

Conclusion

In non-irrigated conditions in the area of South-Central Bulgaria productivity of peas is an average of 2197.0 $kg.ha^{-1}$ for spring peas with 9.54 percent higher than wintering peas. There are good correlations between the yield and structural elements in peas. The yield of grain is in good relation with the mass of the grains per plant, the number of pods is in a very good correlation with the number of grains of the plant, and the mass of the grains with the weight of 1000 grains.

Interpopulation variation of productivity and morphological parameters is significantly higher (94.48 – 99.90%) compared to the variation within the population (0.10 – 5.52%). Climatic conditions during the year have the most powerful influence (68.72%) on the yield of grain. The type of peas as a factor has the greater influence (42.54 - 96.28%) on height parameters and structural elements. The most powerful influence on productivity, the number of pods, the mass of the grains of the plant and the mass of 1000 seeds in spring peas exerts rainfall in June and temperatures during the period May-June. In wintering peas strong influence on productivity had precipitation during the period March-June. On the number of pods and grains and the mass of the grains from a plant in wintering peas mainly affect rainfall in April and temperatures in March. Developed on this base regression dependences allow to carry out a preliminary assessment of the productivity with satisfactory accuracy for practical purposes.

Abstract

Knowledge on variability and association of grain quality parameters is important for building an appropriate plant breeding strategy for improving these basic traits for durum wheat. The study was carried out to determine the variation and correlation of the following traits: protein content (PC), wet gluten (WG), yellow pigment and SDS sedimentation value of 24 durum wheat genotypes - varieties and breeding lines of different origin: Bulgaria (FCI – Chirpan, DAI - G. Toshevo), Europe, CYMIT - Mexico and ICARDA - Syria. All genotypes were grown under field conditions in competitive variety trial in three replications during three harvest years (2014 – 2016) in the experimental field of Field Crops Institute – Chirpan, Bulgaria. All parameters were evaluated on whole grains on standard methods. For statistical processing of the data variation analysis, analysis of variance (ANOVA) and correlation analysis were used. The variance component due to genotype explained most of the total variation for the traits: yellow pigment - 66.1 % and SDS sedimentation value - 92.9 %, while the variation of the PC is determined mostly by the environment (51.2 %) and the variation of WG – by the interaction between genotype and environment (45.24 %). Three Bulgarian breeding lines – M- 376 - 16, 26 %; M-6433 – 16,19 % and M-287 – 15,65 % are distinguished with the highest PC - average of three years. With regard to WG three breeding lines exceed foreign varieties DF-009114002 and Auradur, which have the highest values for this trait among all studied varieties. The foreign variety TD -97 is characterized by the highest YP - 9,83 %. All studied foreign varieties are characterized by stronger gluten and greatly exceed Bulgarian breeding materials with regards to the trait SDS. The greatest variation in the sample of the studied genotypes was found for traits YP and SDS. No statistically significant positive correlation was observed between protein and gluten content and gluten strength.

Key words: *plant breeding, durum wheat, grain quality traits, variation, correlation*

Introduction

Protein content (PC) and gluten strength are the most important characteristics in assessing the culinary quality of pasta products. The link between the quantity and quality of protein with the culinary potential of durum wheat is complex and is influenced by other factors as well. Generally, durum wheat dough high in protein and with stronger gluten are tough and non-sticky and are ideal for processing into pasta with excellent culinary quality (Dexter and Matsuo, 1980; Matsuo et al., 1982; Autran et al., 1986; D'Egidio et al., 1990; Feillet and Dexter 1996; Dexter and Marchylo, 2000; Petrova and Cheleev, 2005; Sissons et al., 2005; Dexter, 2008). Protein content in durum wheat ranges from 10 to 21% depending on variety, climate, agro-technology and environmental conditions (Zwingelberg, 1996). Protein and gluten content is an important, but not a sufficient condition for the production of high quality products. This depends mainly on the quality of proteins, respectively gluten strength. Gluten

quality can be successfully determined by its colloidal properties in lactic acid solution. The sedimentation test is well suited for early screening of high gluten and good pasta quality lines of durum wheat since it is more influenced by the genotype than by the environmental conditions.
Concentration of yellow pigments in the grain is an important trait of durum wheat quality and is due to carotenoids. They contribute to the yellow color of semolina and macaroni. The yellow pigment is a highly inherited trait due to an additive genetic effect (controlled by more than one gene), making it very suitable for selection in early generations (Johnston et al., 1983, Joppa and Williams, 1988).
To improve durum wheat quality the efforts of plant breeders should be directed to the creation of cultivars with high protein content, strong gluten and a high content of yellow pigments. One of the most significant problems in this regard is the small differences in the variation of genes controlling these traits in modern durum wheat cultivars (Blanco et al., 1994). This calls for a large number of genotypes of different ecological and geographical origin to be included in the plant breeding programs. Knowledge on variability and association of grain quality parameters is important for building of appropriate breeding strategy for improvement of these basic for durum wheat traits.
The objective of the present study is to be identified the variation of traits related to the quantity, quality and colour of the protein/gluten in the grain and to establish correlations between them in a sample of 24 durum wheat genotypes - cultivars and breeding lines of different ecological and geographical origin.

Material and Methods

The study includes 24 durum wheat genotypes - cultivars and breeding lines of different origin: Bulgaria (FCI - Chirpan, DAI - G. Toshevo), Europe, CYMIT - Mexico and ICARDA - Syria. All genotypes were grown under field conditions in competitive variety trial in three replications during three harvest years (2014 – 2016) in the experimental field of Field Crops Institute – Chirpan, Bulgaria. The following parameters have been analyzed: protein content (PC %), wet gluten content (WG %), yellow pigments (YP) in the grain and SDS-sedimentation value. For comparison the standard varieties Predel and Saturn-1 were used. Protein content in the grain has been determined by the Keldahl method (N x 5,7) according to BDS EN ISO 20483: 2006 and of wet gluten according to BDS EN ISO 21415-2: 2008. The gluten strength assessment has been done by sedimentation volume of whole ground grain with protein detergent sodium dodecyl sulfate (SDS) (ICC 151: 1990). The content of the yellow pigments has been determined spectrophotometrically according to BDS EN ISO 11052: 2006. The principle of the method is extraction of pigments with water-saturated n-butanol and reading the optical density of the clear filtrate at a wavelength of 440 nm. The amount of yellow pigments is calculated as ppm DM versus a standard curve with pure β-carotene.
For statistical processing of the data software package Statistica 6.0. has been used (StatSoft, Inc. 2002). Variation analysis, analysis of variance (ANOVA) and correlation analysis have benn applied.

Results and Discussion

According to the analysis of variance (Table 1), the genotype, the years of growing and the interaction between them have a reliable influence on the variation of the studied traits. Percentages of total sums of squares accounted for genotype, year (environment), and G×E interaction were used to indicate the variation attributed to each component. The variation of protein content in grain is mostly due to the environmental conditions (51.20%), while the variation in the wet gluten content in grain (45.24%) to the genotype-environment interaction. A number of authors have found that protein and wet gluten content in durum wheat grain is largely influenced by environmental conditions (especially years) and report significant involvement of the genotype-environment interaction in the overall variation of these traits (Mariani et al. 1995, Ames et al., 1999, Dechev, 2004). The variation of the parameters yellow pigment content in grain (66.10%) and the SDS-sedimentation value (92.90%) is accounted for to the greatest extent by the genotype. Braaten et al. (1962) and Rharrabti et al. (2003) also reported significant influence of genotype and slight influence of the environment in variation of the SDS-volume and yellow pigment content parameters.

Table1. Analyses of variance on some studied traits in durum wheat genotypes

Traits	Source of variation, % from the total variation								
	Genotype			Year			Interaction

Table 2 and Table 3 present the results of the three years of study and the average values for these years of the following traits: protein, wet gluten, yellow pigments content in the grain, and SDS sedimentation volume.

Protein content and gluten strength are the most important characteristics in assessing the culinary quality of pasta products. In the first year of study, protein content in the grain in the studied genotype samples ranged from 13.71 to 17.65%. Only in four lines protein content in the grain is lower than 13.7-14.6%. In the other lines and cultivars it is around and above 15%. In the second year protein content compared to the 2014 harvest is lower and ranges from 12.60 to 14.99%. During harvest 2016 high protein content and, respectively, wet gluten yield in grain are reported, ranging from 13.99 to 17.43% for the protein and from 26.6 to 36.4% for wet gluten. Protein and wet gluten content averaged for the three years of study ranged from 13.96-16.26% protein and 19.2-32.5% wet gluten, respectively. On average, for the three years of study, the highest values for the traits protein and wet gluten content in the grain were found for the lines M-376 (16.26% protein and 31.63% wet gluten) and D-6433 (16.19% protein and 32.5% wet gluten).

Through SDS-volume protein quality is characterized and, above all, gluten strength. In all three harvest years, the data show that strong gluten in the SDS-volume traits is shown by five breeding lines - D-8367, D-8362, D-8370, TD-97, DF-009114002, the four foreign cultivars Betadur, Selyemdur, Auradur and Superdur, the Bulgarian cultivar Severina and the standards Predel and Saturn 1. The SDS-sedimentation volume of these samples averaged for the three years of study ranges from 45-74.33 cm^3. One of the reasons for the very low quality of gluten in some samples from the 2014 harvest is the severe damage to the grain by sunn pest (Eurygaster integriceps) (3 -10%) in addition to the fact that they belong to weak gluten durum wheat with low SDS volumes. All studied lines and cultivars in harvest 2015 have much stronger gluten compared to gluten from harvest 2014. Sunn pest damage has an adverse effect on the gluten quality of all lines and cultivars, but the degree of impact depends on wheat genotype (Petrova, 2002). Strong gluten lines and cultivars have more internal reserves to meet the enzyme attacks in sunn pest damage and to manifest still good culinary potential with damage of over 5%, as is in line D-8367, cultivar Auradur standard variety Saturn 1. This is of great importance for durum wheat in Bulgaria, where sunn pest damage is often an accompanying factor during its cultivation.

Concentration of yellow pigments in the grain is an important sign of durum wheat quality and is due to carotenoids. During the 2014 harvest, the yellow pigment content in the studied sample of genotypes ranged from 6.85-11.74 ppm. All foreign cultivars have high concentration of yellow pigments (8-10 ppm) and give products of the desired colour (6.5-8.3 ppm). In the 2015 harvest, in all genotypes significantly lower levels of yellow pigments were reported compared to 2014 and 2016 harvests, ranging from 5.01-9.45 ppm. The harvest year 2015 is characterized by more rainfall during the vegetation period - 158.2% compared to the norm, incl. during the grain filling phases. According to Graham and Rosser (2000), stress as moisture deficit during the various stages of grain filling or high temperatures influences the concentration and composition of pigments and contributes to the occurrence of genotype-environment interactions. According to the same authors, concentration of pigments correlates slightly positively with average temperatures and slightly negatively with rainfall during grain filling, the latter dependence being confirmed by our results as well. During harvest 2016, the yellow pigment content in the studied sample of genotypes ranged from 5.94-10.93 ppm. On average for the three years of the study the highest content of yellow pigments in the grain have the lines: M-431 (10.71 ppm), M-615 (9.21 ppm), TD-97 (9.83 ppm), the foreign varieties Superdur (9.09 ppm), Selyemdur (9.01 ppm) and the standard variety Predel (9.25 ppm).

The greatest variation in the overall variation of traits in the sample of studied genotypes determined on the basis of variation coefficients, was found for the traits SDS sedimentation volume (CV-44.20%) and yellow pigment content (CV-14.69%, and the least for the protein content of grain (CV-4,43%). The largest variation in individual years was found for the trait wet grain content in grain during the 2014 harvest (CV-22.04%), probably due to the high levels of sunn pest damage in the respective year.

The presence of large variation in the sample of the studied cultivars and breeding lines for the traits SDS-sediment volume and yellow pigment content, as well as the predominant effect of the genotype in this variation are a prerequisite for including genotypes with the highest values on these parameters in hybridization programs for their breeding improvement.

A correlation analysis has been performed to detect relationships between the studied traits based on the results of the three years of the trial (Table 4). A significant proven positive correlation between protein content and wet gluten content in grain has been found (R = 0.52) and this relationship has been reported by a number of other authors (Ames et al., 2003). There are weak and unproven positive interrelationships between gluten strength (SDS-sedimentation volume) and wet gluten quantity in grain and between the yellow pigments and the SDS-sedimentation volume. We also found unproven and weak negative interactions of protein content with gluten strength and yellow pigment content. There is contradictory information in literature relating to the studied relationships. A number of authors report the presence of a positive correlation between protein content and SDS volume (Fowler and De La Roche, 1975; Autran and Galterio, 1989; Galterio et al., 1993; Novaro et al., 1997; Porceddu et al. 1998), and others - for moderate negative correlation (Autran et al., 1986 and Boggini et al., 1997). According to a third group of authors, protein content and gluten quality are independent and unrelated traits (Grzybowski and Donnelly , 1979, Quick and Donnelly, 1980). No proven correlations between yellow pigment content and protein content in grain have been found so far (Ruiz et al., 2005) and our results confirm the same. The contradictory information regarding relationships among the studied traits related to grain quality can probably be explained by the different methods used to measure gluten strength, various genotypes and growing conditions.

Table 4. Correlations (r) between grain quality traits in durum wheat

Traits	Wet gluten content of grain	Content of yellow pigments of grain	SDS-sedimentation value
Protein content of grain	0.52*	-0.31	-0.10
Wet gluten content of grain		0.06	0.29
Content of yellow pigments of grain			0.10

*Significant at 0.05 level of probability

Conclusions

A statistically reliable influence of genotype, environmental conditions (years) and the interaction among them has been found in the expression of the traits: protein, wet gluten, yellow pigments content in grain and SDS-sedimentation volume. The variation of protein content in grain (51.20%) is due mostly to the environmental conditions, while variation in wet gluten content in grain (45.24%) to the genotype/environment interaction. The variation of the traits yellow pigment content in grain (66.10%) and SDS-sedimentation volume (92.90%) is due to the greatest extent to the genotype.

All genotypes are characterized by a good level of protein quantity and a good potential for its accumulation.

The largest variation in the sample of studied genotypes determined on the basis of the coefficients of variation - CV was found for the traits SDS sedimentation volume and yellow pigment content and the least - for protein content. The presence of large variation in the sample of the studied cultivars and breeding lines on these traits important for durum wheat quality, as well as the predominant influence of the genotype in this variation are a prerequisite for including genotypes with the highest values on these traits in hybridization programs for breeding improvement of Bulgarian durum wheat.

A statistically proven positive correlation between the content of grain protein and gluten and lack of proven correlations between the quantity and quality of protein and yellow pigments have been established.

Abstract

Silver nanoparticles (AgNPs) are one of the most widely used engineered nanoparticles (ENPs) that are expected to enter natural ecosystems. This study reports on the effect of soaking three cultivars (Bronco, Nebraska and Valantino) of the common bean (*Phaseolus vulgaris* L.) for 12h in aerated solution of gum Arabic-coated silver nanoparticles (GA-AgNPs ≈16.7nm), polyvinyl pyrolidine- coated silver nanoparticles (PVP-AgNPs ≈23 nm), and silver nitrate ($AgNO_3$), each at 0.0, 10, 20, 40, 60, 80 and 100 ppm, on germination and seedling growth. The control and the treated seeds were germinated at 25°C ±0.5 under dark controlled conditions for 7 days. AgNPs and $AgNO_3$ significantly improved germination percentage, germination rate and seedling growth criteria of the three tested cultivars, as compared with their corresponding controls. The three cultivars responded in more or less similar trends to the different concentrations of the treatment solutions. With the three cultivars under study, the magnitude of improvement was always greater for GA-AgNPs than for PVP-AgNPs and $AgNO_3$. Moreover, both AgNPs and $AgNO_3$ up to100 ppm significantly increased the activities of polyphenol oxidase, peroxidase and catalase than those of the control. Meanwhile, the enzyme activities progressively increased with the increase of each of the AgNPs under investigation, as well as $AgNO_3$. The results indicated successful use of AgNPs and $AgNO_3$ up to 60 and 40 ppm, respectively, for enhancing the germination potential and subsequent seedling growth of the bean cultivars under study.

Key words: *Bean; Phaseolus vulgaris; Silver Nanoparticles; Silver nitrate; Antioxidant enzymes*

Introduction

Common bean (*Phaseolus vulgaris* L.), family *Fabaceae*, is an economically important vegetable crop produced throughout the world for its edible fruit. Beans are important food to people of all income categories as a source of dietary protein, complex carbohydrates, fibbers and other important dietary necessities (Kutoš *et al*., 2003). Dry beans contain high levels of phenols, starch, vitamins, fibre and fructo-oligosaccharides (Cristiane *et al*., 2013).
Silver is an important plant-growth stimulator, including silver salt (Ag NO_3), silver silicate and silicate with a water soluble polymer (Sharon *et al*., 2010). Silver nanoparticles (AgNPS) are atomic or molecular aggregates, with at least one dimension between 1 and 100 nm (Roco 2003), that can drastically modify their physico-chemical properties, compared to the bulk material (Nel *et al*., 2006). Silver nanoparticles are synthesized by chemical reduction using polyvinyl pyrrolidone as a dispersant (Zhang *et al*., 1996), by gamma rays irradiation at room

temperature and ambient pressure (El-Batal *et al*., 2013& 2014), and via green synthesis using gum acacia (gum Arabic) as stabilizer for capping silver nanoparticles. The interaction of plant cell with the engineered nanoparticles leads to the modification of plant gene expression and associated biological pathways, which eventually affect plant growth and development (Khiew *et al*., 2011; Feizi1 *et al*., 2013). The impact of AgNPs on higher plants appears to depend on the species, age of plant, the size and concentration of the particles and the experimental conditions (Khiew *et al*., 2011). Silver nanoparticles increased root elongation of *Eruca sativa* seedlings at 10 mg Ag/L of either PVP-AgNPs or $AgNO_3$ (Vannini *et al*., 2013) and enhanced seedlings growth of *Brassica juncea* at 25 and 50 ppm silver nanoparticle (Sharma *et al*., 2012a). However, the mechanisms that mediate the effects of AgNPs in plants remain unknown. Therefore, it is important to increase our knowledge about these mechanisms before implementing large-scale agricultural utilization of AgNPs.
Thus, the present study intended to investigate the effect of soaking three cultivars (Bronco, Nebrska and Valantino) of common bean (*Phaseolus vulgaris* L.) in different concentrations of gum Arabic- coated silver nanoparticles (GA-AgNPs), poly-vinyl pyrrolidine- coated silver nanoparticles (PVP-AgNPs) and silver nitrate $AgNO_3$ on the percent and rate of seed germination, seedlings growth criteria, as well as to evaluate their possible effect on the activities of some antioxidant enzymes in Bronco and Nebraska seedlings.

Materials and Methods

Synthesis of silver nanoparticles

Gum Arabic (GA) coated silver nanoparticles (GA-AgNPs≈16.7nm) and poly vinylpyroldine (PVP) coated silver nanoparticles (PVP-AgNPs≈23 nm) were synthesized using gamma-radiolytic reduction method at 15 kGy dose and 1mM AgNO3. Silver nanoparticles (GA-AgNPs and PVP-AgNPs) were characterized by UV-vis spectroscopy, dynamic light scattering (DLS), transmission electron microscopy (TEM), fourier transform infrared (FT-IR) spectroscopy and X-ray diffraction (XRD) according to Abd El Hafz (2016) and El-Batal *et al*. (2016).

Plant Materials and Treatments

A homogenous lot of **s**eeds of three cultivars (Bronco, Nebrska and Valantino) of common bean (*Phaseolus vulgaris* L.) were provided by the Horticulture Research Institute, Agriculture Research Center, Giza, Egypt. The seed indexes, i.e. weight of 100 seeds of the used cultivars are 14.44, 46.47 and 24.02 for Bronco, Nebraska and Valantino, respectively.
The seeds of the three bean cultivars were surface sterilized and then washed thoroughly with bi-distilled water. Afterwards, seeds of each variety were equally divided into two batches and each batch was subdivided into groups (100 seeds each) to be soaked in the different working solutions. Soaking of seeds was carried out by arranging a constant number of seeds of each batch in a zigzag pattern on Whatman No.3 filter paper of constant area (20 X 60 cm). Afterwards, the rolls were placed for 12 h in an upright position in plastic boxes, each containing a constant amount of the treatment solutions (GA-AgNPs, PVP-AgNPs and $AgNo_3$) at concentrations of 20, 40, 60, 80 and 100 ppm, in addition to distilled water as a control. Soaking was carried out in a controlled cabinet (germinator) at 25°C ±0.5 under dark conditions. Afterwards, the seeds of the control and each treatment (4 replicates, 25 seeds each) were washed thoroughly with distilled water, and then allowed to germinate (as the method described previously but the plastic boxes were containing constant amounts of distilled water) for 7 days. The different germination and growth criteria were recorded for the three tested cultivars. The germination experiment was carried out in 2014 at Vegetable Crop Seed Production and Technology Department, Horticulture Research Institute, Agriculture Research Center, Egypt.

Growth Measurement

The germination percentage (%) and the germination rate (days to complete germination) were calculated. At least 10 randomly choice 7-day-old seedlings were taken from each treatment and the control for measurements of different growth criteria (seedling and root length (cm), fresh and dry weights (g) per seedling). The collected samples were either dried in an oven at 105°C until constant dry weight was obtained or representative fresh samples were taken for determination of fresh weights and assaying enzymatic activities.

Enzyme Activities

Catalase, peroxidase and polyphenol oxidase activities were assayed in 7-day-old seedlings of Bronco and Nebrsca cultivars presoaked for 12 h in GA-AgNPs, PVP- $AgNO_3$ or $AgNo_3$ solutions, each at 0.0, 20, 60 and 100 ppm following the method of Kar & Mishra (1976) with some modification as described by Iturbe-Ormaetxe *et al*. (1998). Peroxidase and polyphenol oxidase activities were expressed as the change in optical density/g fresh weigh/hour at 430 nm. Catalase activity was expressed as μM H_2O_2 destroyed/g fresh weight/hour.

Statistical analysis

Statistical Analysis of the data was carried out using one-way analysis of variance (ANOVA) using least significant difference (LSD at 5% level) according to Snedecor & Cochran (1990) followed by Duncan's Multiple Comparison Test (Duncan 1955).

Results and Discussion

In this study, the germination percentage and the rate of germination of the control (H_2O) and the differently treated three bean cultivars (Bronco, Nebrska and Valantino) under study are shown in Table 1. The germination percentage and rate were generally significantly enhanced, as compared to corresponding controls, in response to soaking for 12 hours in different concentrations of gum Arabic-coated silver nanoparticles (GA-AgNPs), poly-vinyl pyrrolidine-coated silver nanoparticles (PVP-AgNPs) and $AgNo_3$. Moreover, the percentage of abnormal germination was also reduced, in response to the different applied treatments (Table 1). With the three cultivars under study, best results were obtained in response to soaking seeds in solutions at 60 ppm of either GA-AgNPs or PVP-AgNPs, or 40 ppm $AgNO_3$. However, the germination percentage and rate of the three bean varieties were positively affected by increasing GA-AgNPs or AgNPs up to 60 ppm and $AgNo_3$ concentrations up to 40 ppm, and then these values were progressively decreased at higher concentrations (still higher than control). These conclusions were in alliance with those obtained with *Brassica juncea*, in response to treatment with 100 ppm silver nanoparticles (Sharma *et al*., 2012a) and 25 ppm gold nanoparticles (Arora *et al*., 2012). The enhanced percentage of germination might be attributed to an increased permeability of the seed testa, thus facilitating the admission of water and di-oxygen into the cells, which would then accelerate germination and concomitant metabolic processes (Zheng *et al*., 2005). In this connection, nanoparticle solutions showed different effects on seed germination of different plants (Rico *et al*., 2011).

Table 2 shows the main growth criteria of 7-day-old seedlings resulting from pre-sowing seed soaking for 12 hours in different concentrations of each of the two experimented silver nanoparticle solutions (GA-AgNPs and AgNPs) and $AgNO_3$. In case of the control, the seedling and the root lengths as well as the fresh and dry weights per seedling were highest in Nebraska

Table 1: Percentage of normal and abnormal germination and rate of germination of three bean varieties (Bronco, Nebraska and Valentino) as affected by presoaking of seeds for 12h in gum Arabic- coated silver nanoparticles (GA-AgNPs), poly-vinyl pyrrolidine- coated silver nanoparticles (PVP-AgNPs) and $AgNo_3$, followed by 7 days germination at 25ºC±0.5. The rate of germination represents time (days) required for maximum germination. Eachvalue represents the mean of 4 replicates (each of 50 seeds) for germination potential. Different letters indicate significant differences between treatments (Duncan test, $P \leq 0.05$). The means in each column followed by similar letters are not significantly different.

cultivar followed by those in Valentino. In case of the different three applied treatments, the above mentioned growth criteria of seedlings were mostly significantly increased, relative to corresponding controls, from 20 to 80 ppm concentrations. In this respect, best performance was induced by 60 ppm of either GA-AgNPs or AgNPs and 40 ppm $AgNO_3$. Regarding the stimulatory effects of the experimented AgNPs, GA-AgNPs was more efficient than AgNPs at comparable concentrations. GA- AgNPs at 60 ppm induced highest significant increase in the seedling fresh and dry weights. Our results could be reinforced by those of other workers where rise in the concentration of AgNPs from 20 to 60 ppm increased shoot and root lengths of common bean (*Phaseolus vulgaris* L.) and corn (*Zea mays* L.) crops (Salama 2012), as well as root elongation of *Eruca sativa* seedlings, in response to PVP-AgNPs or $AgNO_3$ (Vannini *et al*., 2013). Promotion of plant growth by AgNPs was also recorded in *Brassica juncea* (Sharma *et al*., 2012a) as well as *Panicum virgatum* and *Phytolacca americana* (Yin *et al*., 2012). The enhanced seedling growth rates might be attributed to a nanoparticle- elevation effect of some enzyme activities, stimulation of antioxidant activity, and increased abilities for absorbing and utilizing water, as has been concluded by Lu *et al*. (2002) in soybeans. Such increases might be also assumed to be mediated by NPs-modulation of endogenous phytohormones that are known to balance cell proliferation (Shu *et al*., 2015; Li *et al*., 2016).

In the present study, the activity levels of the antioxidant enzymes peroxidase (POD), catalase (CAT) and polyphenol (PPO) oxidase were assayed in 7-day-old seedlings of cultivars Bronco and Nebraska. In this respect, H_2O_2 as a strong oxidant that produces highly active OH^- via the Haber–Weiss reaction (Kehrer 2000), can be decomposed into H_2O and O_2 by peroxidase (POD) and catalase (CAT), thereby preventing potential ROS damage to plants (Rakhra *et al*., 2015). Farther, Phenol compounds leads to more powerful radical scavenging activity (Siddique *et al*., 2010; Spiridon *et al*., 2011), therefore functional analysis of polyphenol oxidases is of peculiar significance. The results of the present work showed that presowing soaking treatments of seeds for 12 h in GA-AgNPs, PVP-AgNPs and $AgNo_3$ solutions induced progressively increased activities of POD, CAT, and PPO, in the 7-day-old seedlings of Bronco and Nebraska cultivars, with increasing the concentrations of each solution from 20 up to 100 ppm (Figure 1). The activities of the above mentioned enzymes in seedlings of the two cultivars were obviously higher than those of corresponding controls, particularly with 60 and 100 ppm treatments. In both the studied cultivars, the enhancement effect was maximum for the three enzymes (POD, CAT, and PPO) at 100 ppm $AgNO_3$ treatment, followed by PVP-AgNPs and finally GA-AgNPs, each also at 100 ppm. The results of the present work, indicating enhancement of antioxidant enzymes in response to AgNPs and $AgNO_3$ treatments, were consistent with those of Krishnaraj *et al*. (2012) in leaf samples of *Bacopa monnieri* plants subjected to AgNPs treatment, Sharma *et al*. (2012a) in *Brassica juncea* seedlings using AgNPs, and Wang *et al*. (2015) in radish root using AgNPs and $AgNO_3$.

According to Krasensky & Jonak (2012), the metabolic network of plants must be reconfigured under different conditions in order to allow both the maintenance of metabolic homeostasis and the production of compounds that ameliorate any stress. To this extent we might conclude that the network of antioxidant/ oxidant levels might be taken as markers to speculate the most suitable treatments for the bean cultivars under investigation. Thus, on these bases, the efficacy of the production of compounds that ameliorate any stress.

To this extent we might conclude that the network of antioxidant/ oxidant levels might be taken as markers to speculate the most suitable treatments for the bean cultivars under investigation. Thus, on these bases, the efficacy of the applied treatments can be arranged in the following order: GA- AgNPs> PVP-AgNPs> $AgNo_3$, with exclusion of 100ppm of each.

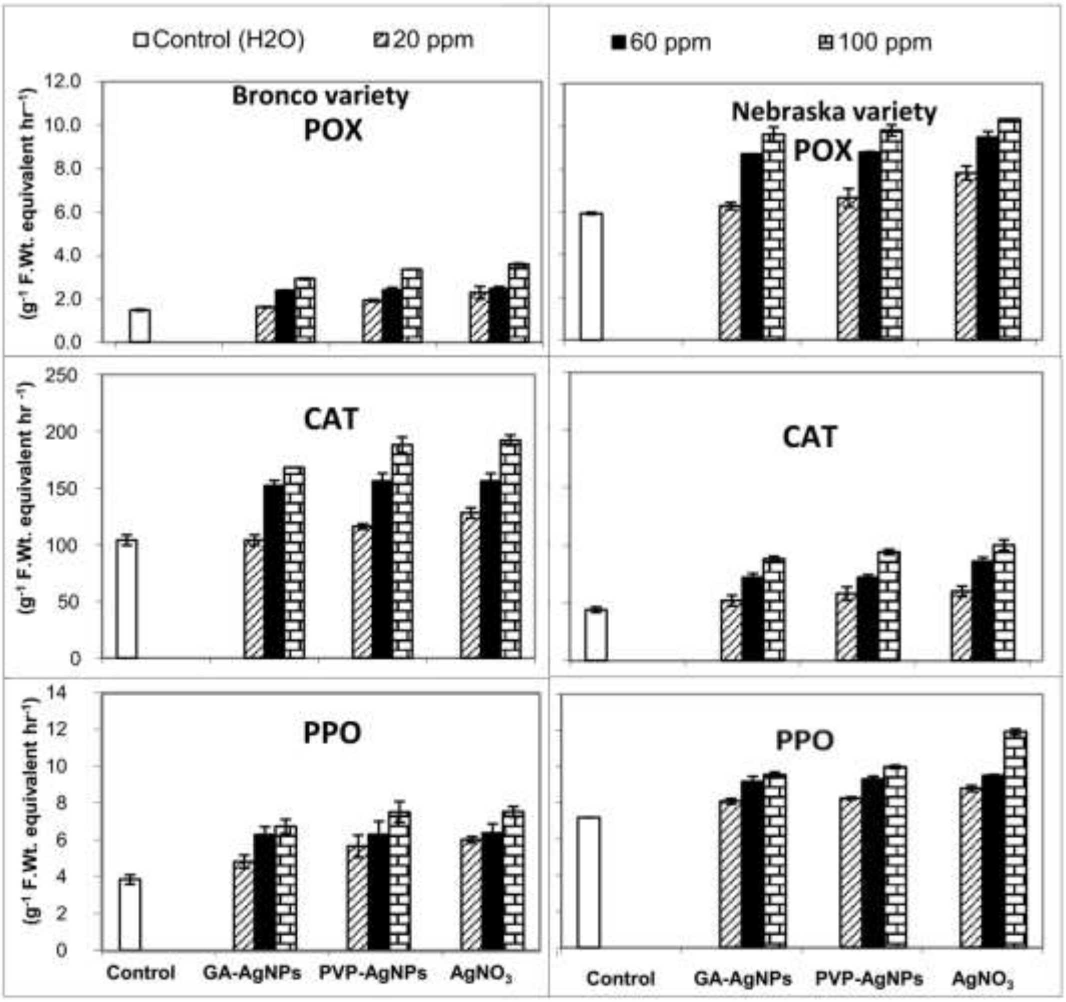

Figure 1: Changes in the activities of peroxidase (POX), catalase (CAT) and polyphenol oxidase (PPO) (/g fresh weight/ hour) of 7-day-old seedlings of Bronco and Nebraska varieties as affected by seed presoaking for 12h in silver nanoparticles (GA-AgNPs, PVP-AgNPs) or silver nitrate ($AgNO_3$) each at 0, 20, 60 and 100 ppm and grown in dark at 25ºC±0.5. Vertical bars represent ± SE.

In this respect, it should be mentioned that the differential enhanced POD, CAT and PPO activities as antioxidants are assumed to represent a defense of the studied common bean cultivars against reactive oxygen species (ROS) alleviation resulting from AgNPs and $AgNO_3$ treatments. The inconsistent trends in our results for CAT in Bronco cultivar might therefore be due to: a. different adaptation strategies in Bronco and Nebraska to cope with the applied treatments, and b.efficient scavenging of ROS requires the action of other antioxidant enzymes and nonenzymatic antioxidants that have not been assayed herein. In this connection, Sharma *et al*. (2012b) reviewed that whether ROS would serve as signaling molecules or could cause oxidative damage to the tissues depends on the delicate equilibrium between ROS production, and their scavenging.

Conclusion

The present study demonstrates that seed soaking three common bean cultivars (Bronco, Nebraska and Valentino) in solutions of AgNPs (GA-AgNPs, PVP-AgNPs) and $AgNO_3$ solutions at different concentrations (20-100 ppm) significantly improved germination percentage, germination rate and seedling growth criteria, as compared to corresponding controls. Generally, GA-AgNPs was the most effective treatment in enhancing germination potentials and seedling growth parameters followed by PVP-AgNPs and finally $AgNO_3$ treatment, compared to controls. A reverse situation was recorded with the antioxidant enzymes POD, CAT, and PPO, where their activities were highest in treatment with AgO_3 followed by PVP-AgNPs and finally GA-AgNPs.

Abstract

Two field experiments were carried out during 2014/2015 and 2015/2016 seasons at Agricultural and Experimental Research Station at Giza, Faculty of Agriculture, Cairo University, Egypt to study the influence of three nitrogen levels (75, 100 and 125 kg N/fad.), one faddan = 4200m^2, three seeding rates (200, 300 and 400 grains/m^2) on growth of three wheat cultivars (Sakha-94, Gemmiza-9 and Giza-168). Flag leaf area in both seasons, absolute growth rate (AGR), leaf area index (LAI) at 80 and 100 days in the second season, net assimilation rate (NAR) increased significantly with increasing N levels up to 125 kg N/fad. Nitrogen use efficiency (NUE) significantly decreased with increasing N levels. Seeding rates significantly affected LAI and AGR at 80 in the first season as well as AGR at 80 and 100 days in both seasons. The highest values for the previous traits were produced with seeding 300 or 400 grains/m^2. Seeding rates did not affect NAR and NUE. All studied traits except AGR at 80 days in the second season, NAR at 80 days in the first one and NUE in both seasons were significantly affected by cultivars. All interactions had significant effect on some studied traits either in one season or in both seasons. Some interactions had significant effect on NAR. Moreover, none of the tested interactions affected NUE significantly. The overall findings indicated that seeding Gemmiza-9 or Giza-168 with 300 or 400 grains/m^2 and application of 125 kg N/fad. could be more beneficial in the study area.
Key words: *Wheat, N levels, seeding rates, cultivars.*

Introduction

Wheat (*Triticum aestivum* L.) is cultivated worldwide primarily/mainly as a food commodity. It is one of the type dominate crop in the world as well as in Egypt. During recent years, many approaches have been made towards improvement yield potentials of wheat crop. Men depend on wheat crop for food and feed animals (Hussain *et al.*, 2012 ; Gheith *et al.*, 2013). Nitrogen fertilization is the most important factors in front of wheat agronomist for achieving large grain yield targets. Crop growth parameters depend on environment condition. Achieving higher growth of wheat is well governed by planting on suitable density and applying of optimal nitrogen levels and favorable climatic condition. The growth attributes are directly influenced by different nitrogen levels (Iftikhar *et al.*, 2012; Achakzai, 2012; Gheith *et al.*, 2013) as well as by cultivars (Javaid Iqbal *et al.*, 2012; Gheith *et al.*, 2013). It is a well-established fact that plant structure is determined by growth parameters such as dry matter accumulation, flag leaf area, leaf area index, crop growth rate, relative growth rate, net assimilation rate, relative water content, relative chlorophyll content, plant height and number of tillers/m^2. These concepts not only involve the final crop yield and its components, but a probe into physiological events that have occurred early in the growth stages causing variation in yield potential (El-Seidy *et al.*, 2015). The present study was designed to investigate the effect of nitrogen fertilizer levels, seeding rates on growth of three wheat cultivars.

Materials and methods

Wheat cultivars (Sakha-94, Gemmiza-9 and Giza-168) were studied under three seeding rates (200, 300 and 400 grains/m^2) and three nitrogen levels, i.e. 75, 100 and 125 kg/fad. (one faddan = 4200 m^2). Experiments were conducted at Agricultural and Experimental Research Station at Giza, Faculty of Agriculture, Cairo University, Egypt during two successive winter seasons 2014/2015 and 2015/2016. The experimental soil was clay loam in texture with 1.6 and 1.9% organic matter, 46.5 and 49.8 ppm available N, 13.7 and 15.3 ppm available P , 336.0 and 367 ppm available K, 2.3 and 2.4 mmhos/cm 25 ^{0} CEC and 7.6 and 7.7 PH in both seasons, respectively.

The preceding crop was corn in the two seasons. Grains of each cultivar were sown in 10 rows (2.0 m long and 20 cm apart) on the third week of November in both seasons. These experiments were laid out in a randomized complete block design having split-split-plot arrangement with four replications. All recommended culture practices were applied according to Ministry of Agriculture recommendations.

Number of days to 50% heading, flag leaf area at 100 days from sowing, Absolute growth rate (AGR) according to Radford (1967),Net assimilation rate (NAR) according to Rodford (1967), leaf area index (LAI) according to Watson (1952) were estimated. Nitrogen use efficiency (NUE) is defined as the extra grain yield harvest for each increase in applied nitrogen according to Good *et al.* (2004) and Rasmaussen *et al.* (2015). All the data collected during the both seasons were subjected to statistical analysis using Excel data sheet by using statistical software package MSTAT-C (Michigan State University, 1990). Least significant differences test (LSD) at 5% probability was used to test the significances among mean values of each treatment (Steel and Torrie, 1977).

Results and discussion

Number of Days to 50% Heading

Results presented in Tables (1 and 2) show that significant effect for nitrogen levels in the first season. It is evident from these results that heading was delayed from 88.50 to 90.38 days in the first season and from 88.86 to 89.58 days in the second one by increasing N levels from 75 to 125 kg N/fad. The increment in heading period may be due to nitrogen addition that favored vegetative growth which in turn delayed time of heading. These results are in harmony with those obtained by Hamam and Khaled (2009) and Gheith *et al.* (2013). No significant effect for seeding rates on heading was recorded. Moreover, significant variations among the cultivars in number of days to heading were noticed. Gemmiza-9 recorded the heigest values, while Giza-168 gave the lowest values in both seasons. These variations in cultivars partially reflect their different genetic background. These results are in agreement with those obtained by Gheith *et al.* (2013). Number of days to 50% heading was significantly affected by all studied interactions in both seasons. The earliest treatment was seeding Giza-168 with 200 or 400 grains/m^2 and fertilizing with 75 or 100 kg N/fad.

Flag Leaf Area

Flag leaf area was significantly affected by nitrogen levels in both seasons and by cultivars in the first season. On the contrary, this effect was not significant with seeding rates in both seasons (Tables 1 and 2). The highest flag leaf area was observed with application of 100 kg N/fad., while the lowest values were produced at 75 kg N/fad. in both seasons. These results are in harmony with those of Ali (2012) and Gheith *et al.* (2013) who revealed those highly significant differences between N levels on this trait. Flag leaf area decreased with increasing seeding rates without any significant in both seasons. Moreover, Gemmiza-9 ranked 1st, Sakha-94 ranked 2nd and Giza-168 came 3rd in the first season. All interactions had significant effect on flag leaf area in both seasons, except N levels × seeding rates and N levels × seeding rates × cultivars in the first season. Seeding Giza-168 with 300 grains/m^2 and application of 100 kg N/fad. had the largest flag leaf area.

Leaf Area Index (LAI)

Differences in LAI throughout the different growth stages due to nitrogen levels were significant at 80 and 100 days age in the second season only (Tables 1 and 2). Increasing N levels up to 125 kg N/fad. increased LAI at 60, 80 and 100 days. The increase in LAI occurred may be differences due to the increase in leaf expansion. These results are in agreement with those obtained by Ali (2012) and Alam (2013). LAI was not statistically affected by seeding rates at all samples in both seasons, except at 80 days in the first season, where the highest value (9.78) was observed at 400 grains/m^2. The superior cultivar was Gemmiza-9 which produced the highest LAI, while the lowest values recorded by Giza-168 at all stages in both seasons. These results might be attributed to the prevailed differences in the makeup of cultivars. All interactions had significant effect except N levels × seeding rates and N levels × cultivars in first season at 60 days. At 80 days, this trait significantly affected by all interactions except seeding rates × cultivars in the second season. At 100 days, N level × seeding rates and seeding rates × cultivars and all studied interactions significantly affected this trait in both seasons. Generally, the largest value was obtained with seeding Gemmiza-9 or Giza-168 with 300 or 400 grains and application of 125 kg N/fad.

Absolute Growth Rate (AGR)

The absolute growth rate Table (1 and 2) showed that AGR become slower at 80 days and declined again at 100 days. These observations are in harmony with those of Asif *et al*. (2010) and Gul *et al.* (2015). AGR was significantly lower with application of 75 kg N/fad. in both seasons. AGR with 125 kg N/fad. had superiority over that of 75 kg N/fad. AGR of wheat has a significant relation with nitrogen fertilization because most of plants were healthy and vigorous which may help the plants to absorb water and light more efficiency have resulted higher AGR (Gul *et al.*, 2013). These results are in harmony with those obtained by Asif *et al.* (2010), Alam (2013) and Gul *et al.* (2013). AGR significantly affected by changing in seeding rates at 80 and 100 days in both seasons, except at 80 days in the first one. The highest values were recorded with seeding 400 grains/m^2. Moreover, the tested cultivars had a significant effect on AGR at both stages in both seasons, except at 80 days in the second season. Gemmiza-9 and Giza168 ranked first at both stages and seasons, respectively. All studied interactions had significant effect on AGR at both stages in both seasons (Tables 1 and 2). Generally, the best combination was seeding Gemmiza-9 or Giza-168 with 300 or 400 grains/m^2 and application of 125 kg N/fad.

Net Assimilation Rate (NAR)

NAR increased significantly with increasing N levels up to 125 kg N/fad. at both times in the second season (Tables 1 and 2). Seeding rates significantly affect NAR at both times and seasons. Moreover, cultivars affected NAR significantly at 80 days in the first season and at 80 and 100 days in second one. At 80 days, Gemmiza-9 ranked first, Giza-168 ranked second and Sakha-94 ranked third in the first season. Whereas, at 80 and 100 days Giza-168 ranked first, Sakha-94 ranked second and Gemmiza-9 ranked third in the second season. The differences in NAR between cultivars might be attributed to the differences in their genetic makeup. All studied interactions except seeding rates × cultivars and N level × seeding rates × cultivars did not significantly affect NAR at 80 days in both seasons. Whereas, all interactions except nitrogen × cultivars and seeding rates × cultivars had significant effect on this trait at 100 days in second season.

Nitrogen Use Efficiency (NUE)

Nitrogen use efficiency was significantly affected by changing in nitrogen level in both seasons. Nitrogen use efficiency was gradually decreased with increasing nitrogen levels up to 125 kg N/fad. The highest NUE values (38.64 and 32.76) were produced at 75 kg N/fad., while the lowest values (23.97 and 22.05) were obtained at 125 kg N/fad. It is evident that when N levels were increased from 75 to 125 kg N/fad. NUE was decreased by 38% and 33% in both seasons, respectively. These results are in harmony with those obtained by Violeta *et al.* (2015) and Limin *et al.* (2016) who concluded that the NUE of wheat decreased with increasing N fertilization levels. Moreover, Limin *et al.* (2016) indicated that when N levels increased from 90 to 180 kg N/ha. NUE was decreased by an average of 19%. Also, Rahman *et al.* (2011) and Kumari (2011) found the same results. Moreover, non of the tested interactions affected NUE significantly in both seasons.

Conclusions

The results of this study showed that flag leaf area, absolute growth rate, leaf area index, net assimilation rate were increased significantly with increasing N levels up to 125gk N/fad. On the contrary, NUE significantly decreased with increasing N levels. The highest values for the above traits were produced with seeding either 300 or 400 grains/m2 All studied traits (except AGR and NAR in one season) significantly affected by cultivars in both season. The over all finding indicated that seeding Gemmiza-9 with either 300 or 400 grains/m2 and application of 125 kg N/fad. could be more beneficial in the study area

Abstract

Field experiments were carried out at El-Gemmeiza Agricultural Research Station. Gharbiua Governorate, Egypt during the two successive winter seasons of 2012/13 and 2013/14. In order to study the effect of dodder weed control treatments (control, hand combing, spraying with sinal, spraying with select super, spraying with a mixture of (sinal and select super) and benzoic acid) on yield, yield component as well as quality for three flax varieties (Sakha 1, Giza 10 and Souzana). Souzana variety gave the tallest plants and recorded the highest values of technical stem length, fiber fineness, fiber length, total fiber percentage and fiber yield per faddan. Moreover it gave the thinnest stem diameter and the lowest values of straw yield per plant and per faddan, in both seasons. Sakha 1 was superior and gave the highest values of stem diameter, straw yield per plant and per faddan, while it recorded the lowest values of plant height, technical stem length, fiber fineness, fiber length; total fiber percentage and fiber yield per faddan, whereas Giza 10 came in the intermediate for all studied traits. On the other side, the select supper recorded the highest values of plant height, technical stem length, straw yields per plant and per faddan, fiber length, total fiber percentage and fiber yield per faddan. Furthermore, the application of the mixture of (sinal and select super) recorded the highest values of main stem diameter, number of apical branches per plant, number of capsules per plant, number of seeds per capsule, fertility percentage, oil percentage and seed index. Moreover, the highest values of seed yield per faddan, oil yield per faddan and the finest fiber were recorded by the hand combing treatment.

Introduction

Flax can be a food resource as well as a fiber crop due to the fiber extracted from the stem of the plant. Flax fiber types are grown in cooler regions of the world, such as many countries in Europe, also in Egypt and China, whereas linseed (oil types of flax) is grown in Canada, Argentina and India. In Egypt, flax is grown during the winter season for both, its seeds and fiber (higher economic benefits). The cultivated area decreased in the last three decades due to the great competition with the other winter crops. Therefore, it is necessary to increase flax productivity per unit area to compensate this shortage. Moreover, it is a poor competitor with weeds and its spreading is considered one of the most effective factors that decreases flax productivity. Dodder (*Cuscuta epilinum* L.*)* is the most dangerous weed that harming flax plants in the field. It has no normal roots and leaves, its stems twine around flax plants, attaching to them by gaustoria. Stems are yellow-green, thread-like, slightly branched, 1.5 mm in diameter. Flowers are sessile, yellowish-white, aggregated by 5-15 into dense glomes. Maximum productivity of seeds is 4000 seeds. It is a fast growing plant; one individual plant can infest up to 120 flax plants, and the speed of infesting new plants is faster if the flax is still in succulent stage. Infestations of flax plants with dodder highly decrease fiber and seed

yields, therefore, the specific objectives of this research were:
1- Comparing among three flax varieties to evaluate their performance.
2-Study the influence of dodder weeds control on yield, yield component as well as quality for these three flax varieties and determine the most effective dodder control treatment.

Material and methods

The present investigation was carried out at El-Gemmeiza Agriculture Research Station, Gharbiua Governorate, Egypt during the two successive winter seasons of 2012/13 and 2013/14. The effect of dodder weed (*Cuscuta epilinum* L.) control on yield, yield component as well as quality for three flax varieties was the main objective of this study. The preceding crop was sorghum (*Sorghum vulgare*) in the first season, while it was sunflower (*Helianthus annus*) in the second one. The two experiments were sown on 1st of November 2012 and 4th of November 2013. Field experiment was carried out each season using a split-plot design with four replications. Flax varieties were plotted in the main plots and weed control treatments were arranged in the sub-plots, where each sub-plot size was 6 m^2 (2x3 m). The main plots included three flax varieties (Sakha 1 a local dual purpose type, Giza 10 a local fiber type and Souzana an imported fiber type). In this study six treatments were used as follows:
Control (weeds were not controlled).
Hand control (removing the dodder plants by hand) at 30, 60 and 90 days from sowing.
Spraying with sinal %10 (2.6 chloro 5.7 dim thoxy .3 methyl 1.2 .4 triad 2010 (1.5) apymidine 2 sulfonanilide 100 cm^3/20 L.w after 30 days from sowing.
Spraying with select super 12.540 (chethodium 2.5%) after 30 days from sowing at the rate of 100 cm^3/20 L.w.
Spraying with a mixture of (sinal % 10 and select super) after 30 days from sowing with 100cm^3/20 L.w.
Benzoic acid was sprayed after 30 days from sowing at the rate of 500 (p.p.m) as an organic acid.
A sample of ten plants was taken at random from each plot to estimate some of growth characters. The characters which were estimated were: straw yield characters (plant height, technical stem length, stem diameter, straw yields per plant and per faddan), seed yield characters (number of apical branches, number of capsules per plant, number of seeds per capsules, fertility percentage, seed yield per faddan, oil percentage, oil yield per faddan and seed index) and fiber yield and its technological characters (fiber length, fiber percentage, fiber yield per faddan and fiber fineness which was determined using Radwan and Momtaz's method (1966) according to the following equation where: **N.m = (N x L)/ W**)
The analysis of variance was used for the two experiments (using MSTAT-C) according to Snedecor and Cochran (1982). The least significant difference (L. S. D) test at 0.05 and 0.01 levels of significance was used to indicate mean comparison. The data was statistically analyzed for each season and the homogeneity of experimental error, in both seasons, was tested. Then the combined analysis of data was performed for the characters over two seasons (Le Clerg *et al.*, 1962) to present the first and second order interactions.

Results and Discussion

A- Straw yield and its related characters:

In both seasons, the analysis of variance for plant height, technical stem length, main stem diameter, straw yield per plant and straw yield per faddan showed highly significant differences among the three tested flax varieties: Giza 10, Sakha 1 as local varieties as well as Souzana variety as an imported variety.

The results in Table (1) cleared that, Souzana and Giza 10 varieties gave the tallest plants and recorded the highest values of technical stem length in the first season without any significant difference between them. However, Giza 10 ranked the second with highly significant difference after Souzana variety in the second one. On the other hand, Sakha 1 variety recorded the lowest values of these traits in both seasons. The present results are mainly due to the differences in the genetical constitution of these genotypes.

These results are in a good agreement with those obtained by ***El-Deep (2002), Abou-Zaied and Mousa (2007), Assar (2008), El-Refaey et al. (2010)*** **and** ***El-Refaey et al. (2015),*** where they indicated that, fiber types were superior in total height and technical stem length compared with dual-purpose and oil types.

In both seasons, Sakha 1 (dual-purpose type) gave the thicker stem diameter, followed by Giza 10 with highly significant differences between them. On the other hand, the thinnest measurement was obtained from Souzana in both seasons. The present results are mainly due to the genetic differences and potentiality between the fiber and dual-purpose genotypes of flax. These results are in a good agreement with those obtained by ***Assar (2008), El-Refaey et al. (2010) and El-Refaey et al. (2015)*** where they revealed that dual and oil types surpassed fiber types in main stem diameter. Also, ***El-Refaey et al. (2009)*** indicated that ideal fiber types are characterized by the thin stem diameter.

Sakha 1 gave the highest values of straw yield per plant and per faddan, followed by Giza 10 which came in the intermediate. While, Souzana gave the lowest values of straw yield per plant and per faddan in both seasons. These results are mainly due to differences in the genetic make up of the three tested varieties. It is worthy to mention that, Sakha 1 genotype surpassed other genotypes in main stem diameter, number of apical branches and consequently surpassed other genotypes in straw yield per plant and per faddan. These results are in the same line with those obtained by ***Zahana (2004), Abdel-Dayem (2007), El-Refaey et al. (2010) and El-Refaey et al. (2015),*** where they concluded that dual-purpose types were significantly superior the other genotypes regarding to straw yield per plant and per faddan.

Results in Table (2) indicated that, in both seasons the select supper as a herbicide treatment gave the best results in all straw yield and its related characters except main stem diameter. In both seasons, the select supper recorded the highest values of plant height, technical stem length, straw yield per plant and straw yield per faddan, followed by the mixture (sinal and select super) then the hand combing treatment, benzoic acid, sinal and the control treatment which gave the lowest values, (in a descending order). However, the only noticeable change in the data trend was in main stem diameter, where the select supper treatment ranked the second after the mixture of (sinal and select super) in both seasons. However, the select super and mixture (sinal and select super) treatments had no significant differences with respect to straw yields per plant and per faddan. It is obvious that, all tested herbicides positively affected straw yield and its related characters when compared to the control objects. These results are in a good agreement with those obtained by ***(Mankowski et al, 2015)*** where they found a positive effect of herbicides on the length of the straw and explained it by its negative influence on the weed growth, as weeds competing with flax plants for water and nutrition elements can reduce plant height, technical length, stem diameter and consequently straw yield per plant. Also, ***Heller (2007)*** indicated that, the greater number of weeds reduced number of flax plants per unit area, which may lead to reduction in straw yield per faddan. In addition, ***Soliman and Hamza (2010),*** reported that, the reduction in straw yield values under hand combing and control treatments reflected the negative impacts of the dodder on flax growth, which may be occurred as a result of the competition among flax plants and dodder weed. Also, the results showed that using the tested herbicides was necessary to eliminate this weed and to avoid its negative impacts on flax plants. Worthy to note that, among the studied herbicides, select supper was the best and recorded the highest values of plant height, technical stem length, straw yield per plant and straw yield per faddan, and this superiority of the select supper may be due to that, it is a member of the cyclohexanedione group of herbicides and has the inhibition of acetyl coA carboxilase mode of action. Also, the variation among the studied herbicides on straw yield and its related characters may be due to the special phytotoxic action of each herbicide on flax, which expressed by deformations and plant necroses, the increased rate of maturation and reduced yield ***(Mankowski et al, 2015)***. Also, may be a result of dodder weeds resistance which may initiate by the using of the same herbicide repeatedly.

The interaction between seasons and flax varieties had highly significant effect on stem diameter and straw yield per plant (Figure 1). However, Sakha 1 variety in the second season recorded the highest values of stem diameter and straw yield per plant. Also, the interaction between flax varieties and weed control treatments had highly significant effect on plant height, technical stem length, main stem diameter and straw yield per faddan (Figure 2). The select supper significantly recorded the highest plant height and technical stem length under Souzana variety. On the other hand, the mixture of (sinal and select super) significantly recorded the highest main stem diameter and straw yield per faddan under Sakha 1 variety.

Table (1): Means of straw yield and its related characters as affected by flax varieties in both seasons:

Varieties	Plant height (cm)	Technical stem length (cm)	Stem diameter (mm)	Straw yield (gm) per plant	Straw yield (ton) per faddan
Season 2012/13

Figure (2): Effect of interaction between flax varieties and weed control treatments on straw yield and its related characters:

B- Seed yield and its related characters:

Data in Table (5) presented that, Sakha 1 recorded the significantly highest values for all seed yield related traits, followed by Giza 10 variety. However, the lowest values were noticed by Souzana variety in both seasons. The highest means of seed yield and its related characters for Sakha 1 as a dual purpose type are attributed to the genetic constitution of the variety. The trend of data was so clear and similar to expectations as it is known that, the dual purpose type is superior in seed yield and its related characters compared with fiber types. Also, local fiber type tended to be higher in seed yield and its related characters compared with imported fiber types due to its adaptation to the climatic factors in Egypt. These results are in harmony with those mentioned by **Abdel-Dayem (2007),** ***Abou-Zaied and Mousa (2007), Assar (2008), El-Seidy et al. (2010) and El-Seidy et al. (2015)*** where they pointed out that, oil types produce the maximum values of seed yield and its related characters, while the lowest values were recorded by fiber types. However, the dual types come in the intermediate**.** Also, ***El-Shimy and Moawed (2000) and Omar (2002)*** noticed that, local dual-purpose types surpassed imported and local fiber types in seed yield and its related characters.

Data in Table (6) revealed that, in both seasons, the application of the mixture of (sinal and select super) recorded the significantly highest values in all seed yield and its related characters, except seed and oil yields per faddan where the best weed control treatment was hand combing in these respects. Application of the select supper herbicide ranked the second after the mixture of (sinal and select super) with highly significant differences for number of apical branches per plant, number of seeds per capsule, fertility percentage and oil percentage traits. However, the differences between the two weed control treatments didn't reach to the level of significance for number of capsules per plant and seed index traits. Utilization of benzoic acid as a herbicide ranked in the third grade after the mixture of (sinal and select super) and the select super with highly significant differences with application of sinal herbicide which ranked the fourth grade and hand combing treatment which ranked the fifth grade for number of apical branches per plant, number of capsules per plant and oil percentage traits. On the other hand, the control treatment gave the lowest values in both seasons. This might be attributed to the fact that flax plants in control plots were exposed to severe competition with flax dodder. These results are in a good agreement with those obtained by ***Ghalwash and Soliman, (2008) and Soliman and Hamza (2010),*** where they revealed that, application of herbicides significantly increase number of capsules per plant, number of seeds per capsule, fertility percentage, oil percentage and seed index. Also, they reported that, herbicides application was necessary to eliminate dodder and to avoid its negative impacts on flax plants. Noticeable changes in the data trend were observed in seed and oil yields per faddan traits, where the hand combing treatment ranked the first, followed by the mixture of (sinal and select super), then the select supper, sinal, benzoic acid and control treatment, in a descending order, in both seasons.

It is obvious that, all tested herbicides negatively affected seed yield per faddan and consequently decreased oil yield per faddan compared to the hand combing treatment. These results may be due to the bad effect of the herbicides on pollen vitality. These results are in harmony with those obtained by ***Guo et al., (2009),*** where they found that all herbicides significantly decreased pollen germination and pollen tube growth in *S. canadensis* at relatively low doses. Also, ***Schmitz et al., (2013),*** reported that herbicides caused a sub lethal effect by reducing flower intensity by 85% on the common buttercup. In addition, ***Boutin et al. (2014),*** reported that, delays in flowering and reduced seed production occurred widely in plants sprayed at the seedling stage or at later reproductive periods.

The interaction between seasons and flax varieties had highly significant effect on number of seeds per capsule and fertility percentage traits (Figure 3). However, Sakha 1 variety in the second season recorded the significantly highest values of number of seeds per capsule and fertility percentage, compared to the other interactions. Moreover, the interaction between flax varieties and weed control treatments had highly significant effect on number of apical branches per plant, number of seeds per capsule, fertility percentage, seed yield per faddan, oil percentage, oil yield per faddan and seed index (Figure 4). The mixture of (sinal and select super) recorded the significantly highest values of number of apical branches per plant, number of seeds per capsule, fertility percentage, oil percentage and seed index under Sakha 1 variety. On the other hand, the hand combing treatment recorded the significantly highest seed and oil yields per faddan under Sakha 1 variety.

Table (5): Means of seed yield and its related characters as affected by flax varieties in both seasons:

Varieties	Number of apical branches	Number of capsules per plant	Number of seeds per capsule	Fertility percentage (%)	Seed yield per faddan (kg)	Oil Percentage (%)	Oil yield per faddan (kg)	Seed index (gm)

Figure (3): Effect of interaction between seasons and flax varieties on seed yield and its related characters.

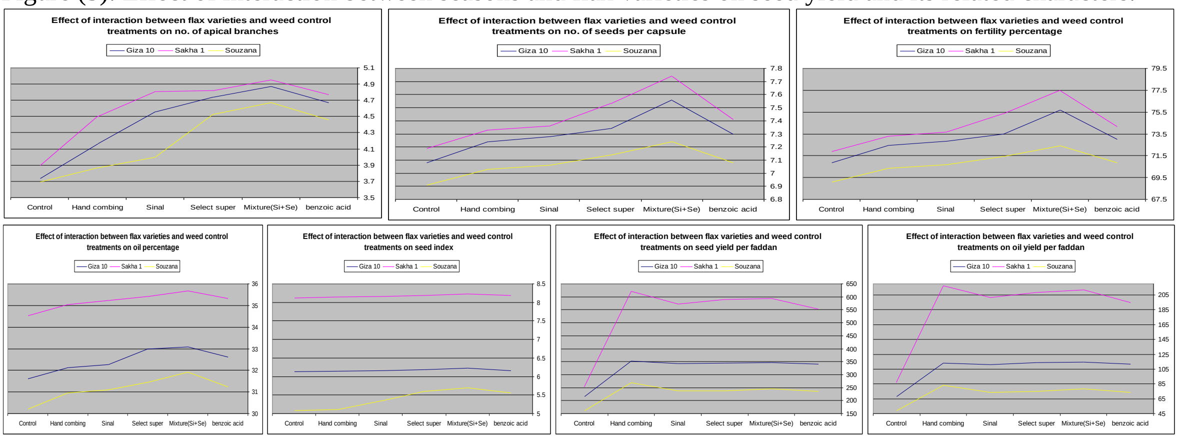

Figure (4): Effect of interaction between flax varieties and weed control treatments on seed yield and its related characters

C- Fiber yield and its technological characters:

Data in Table (9) cleared that, Souzana variety ranked the first and recorded the significantly highest values for all fiber yield and its technological characters, followed by Giza 10 which ranked the second with highly significant difference than Souzana variety for these characters. On the other hand, Sakha 1 variety recorded the lowest values of these traits in both seasons. The trend of these results may be due to the genetical differences among fiber and dual-purpose types, such differences could be attributed to genetic constituents of varieties, whereas, Souzana and Giza 10 are behaved as fiber types and Sakha 1 is a dual-purpose type. Also, worthy to mention that fiber types gave the highest values of fiber percentage which were proportionally with the loss in straw yield per faddan after retting. The loss in straw yield per faddan after retting for dual-purpose type (Sakha 1 variety) was higher than the other fiber types.These results are completely agreed with those obtained by ***El-Refaey et al. (2010)***, where they showed that imported fiber types recorded the highest fiber fineness, fiber length, total fiber percentage and fiber yield per faddan, followed by the local fiber types then the dual-purpose types, while the lowest values were recorded by oil types. Also, ***Kineber***

(2004), ***Zahana (2004) and El-Refaey et al. (2015)***, noted that fiber types-generally-exceeded dual and oil types in fiber fineness, fiber length, fiber percentage and fiber yield per faddan due to its genetic potential.

Results in Table (10) indicated that, in both seasons the select supper as a herbicide treatment gave the best results in all fiber yield and its technological characters, except fiber fineness character. Select supper recorded the highest values of fiber length, total fiber percentage and fiber yield per faddan, followed by the mixture of (sinal and select super) then the hand combing treatment, benzoic acid, sinal and the control treatment which gave the lowest values (in a descending order). However, the only noticeable variation in the data trend was in fiber fineness, where the control and hand combing treatments recorded the finest fiber with no significant difference between them, followed by the mixture of (sinal and select super), then select super and sinal. On the other hand, the most coarseness fiber was recorded by benzoic acid in both seasons. It is obvious that, the select supper and the mixture of (sinal and select super) herbicides positively affected fiber length, total fiber percentage and fiber yield per faddan when compared to the hand combing treatment, in both seasons. However, hand combing treatment was highly significant surpassed sinal and benzoic acid for these traits, with no significant difference with benzoic acid only in fiber yield per faddan, in both seasons. From these results, it could be concluded that, the trend of fiber length was similar to that of technical stem length. Moreover, the reduction in straw yield per faddan with application of sinal or benzoic acid comparing with application of select supper or the mixture of (sinal and select super) caused the same trend in fiber yield per faddan character.

These results are in a good agreement with those obtained by ***(Mankowski et al, 2015)*** where they found a positive effect of some herbicides (application of chlorsulfuron and linuron) on fiber length and fiber yield but in the same time other herbicides may have an equal negative effect comparing with control plots on these traits. ***(Karimmojeni et al., 2013),*** showed that, in despite of high herbicidal effectiveness of bentazon, it reduced both the amount and quality of the fiber yield when compared to chlorsulfuron. Also, ***(Rennebaum et al., 2002),*** reported that, active substance of herbicides used in flax cultivation had a significant impact on both the thinness of the fiber (tex) and its divisibility (Nm) whereas, thicker and less divisible fiber was obtained after bentazon than from the control plots.

The interaction between seasons and weed control treatments had highly significant effect on fiber length Figure (5). However, the select supper herbicide in the second season recorded the longest fiber length. Furthermore, the interaction between flax varieties and weed control treatments had highly significant effect on fiber fineness, fiber length, total fiber percentage and fiber yield per faddan (Figure 6). The select supper herbicide recorded the highest values of fiber length, total fiber percentage and fiber yield per faddan under Souzana variety. On the other hand, the control treatment as well as hand combing recorded the finest fiber under Souzana variety, where there is no significant difference between the two interactions.

Table (9): Means of fiber yield and its technological characters as affected by flax varieties in both seasons:

Varieties	Fiber fineness (N.m)	Fiber length (cm)	Fiber percentage	Fiber yield per faddan (kg)

Figure (5) : Effect of interaction between seasons and weed control treatments on fiber length

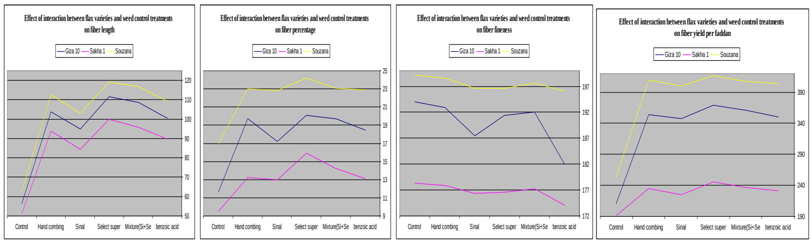

Figure (6): Effect of interaction between flax varieties and weed control treatments on fiber yield and its related characters

Conclusions and recommendation

Souzana variety performance surpassed other varieties in respect to fiber yield traits, whereas Sakha 1 was superior in seed yield traits. The select supper as a herbicide treatment recorded the highest values of straw and fiber yield traits, while the mixture of (sinal and select super) gave the highest values of seed yield traits

This study suggests that under heavy infestation of dodder weed in flax fields, it is recommended to use the select supper that will increase the straw and fiber yields and its related characters in case of cultivation fiber types. On the other hand, it is recommended to apply the mixture of (sinal and select super) in case of cultivation dual purpose types.

Abstract

The present study was carried out at Itay EL-Baroud Agriculture Research Station farm, EL-Behaira governorate, Egypt during the two agriculture seasons of 2012/13 and 2013/ 14. Three faba bean varieties Nubaria 1, Giza 716 and Sakha 1 were used in the present study to examine seed yield, its components and chemical composition under four commercial growth substances with control. In the first season of 2012/13, the three faba bean cultivars were sown and evaluated in experiment designed in a split plot design with three replications. The result indicates that, the cultivar Nubaria 1 expressed the best desirable mean values for number of branches/plant, 100- seed weight, seed yield /plant, seed yield. in both seasons and number of pods/plant, number of seeds/plant in 2012/13, carotain content, chlorophyll B and protein percentage in both seasons. The growth substance Crop plus showed the most desirable effect on plant height, number of pods/plant, number of seeds/pod, number of seeds/plant, 100- seed weight, seed yield/plant and seed yield in both seasons, carotain content, chlorophyll A, chlorophyll B, protein percentage and carbohydrate percentage in both seasons.

Keyword:

Introduction

Faba bean is an annual legume known botanically as *vicia faba* l. The crop is known by many names, most of which refer to a particular subgroup rather than the whole species. The world harvested area of faba bean, dry was 2.15 million hectares and the total production was 4.14 million tons in 2014 while, the harvested area in Egypt was 37677 hectares and the production quantity was 134175 tons in 2014 (FAO STAT 2014). Faba bean is used as human food in developing countries and as animal feed, horses, poultry and pigeons in industrialized countries. It can be used as a vegetable, either green or dried, fresh or canned. Spraying plant growth substances such as GA and IAA had significantly affected plant height (cm), number of branches/plant, number of pods/plant, number of seeds/pod, number of seeds/plant, 100–seed weight (g) seed weight of plant, and seed yield (ton/ha) (Kandil *et al.* (2011).
The aims of this study were to estimate the effect of some growth substances on yield and yield quality of three faba bean cultivars to determine the best cultivar and the best growth substance that may use under Delta condition to improve seed yield and its quality of faba bean.

Materials and Methods

The present study was carried out at Itay EL-Baroud Agriculture Research Station farm, EL-Behaira governorate, Egypt during two agriculture seasons of 2012/13 and 2013/14.Three faba bean varieties Nubaria 1, Giza 716 and Sakha 1 were used in the present study to examine seed yield, and chemical components under four commercial growth substances with control i.e., Dotra Firt, Dotra Micro Plus, Dotra Frost, Crop Plus and control. During the two seasons.The commercial name, chemical component of the four growth substances are presented in Table 1.

Table 1: The commercial name, chemical component of the four growth substances

no	Commercial name	Chemical components	Added rate/ ha.
1	**Dotra Firt**	19% N + 19% P +19%K + 4.14% S	6 (kg/ha.)
2	**Dotra Micro Plus**	2% Zn + 4% Fe +2% Mn.	2.4 (later/ha.)
3	**Dotra Frost**	3% B +1% Mo	600 (ml later/ha.)
4	**Crop Plus**	1.2% Cytokinin + 0.8 % Oxcine + 3% Zn +1.7 % Fe + 1.4 % Mn + 1.3% Cu +4.5% S + 9% Citric acid	600 (ml later/ha.)
5	**Control**	Without any add.	Without any added

In the first season 2012/ 13, the three faba bean cultivars were sown in 15/11/ 2012 and evaluated in experiment designed in a split plot design with three replications. The plot size was 5 ridges. Each ridge was 4 meters long and 0.6meters apart. Seeds were sown on two side of the ridge at 15 cm hill spacing with one seed per hill. Meanwhile the growth substances were sprayed three times after 50, 65 and 85 days from sowing. The following readings and measurements were recorded as on individual plants basis at harvest. Data were recorded as average of 10 individual random plants chosen from each experimental plot. In the second season2013/ 14 the experiment was repeated with the same procedure.

Studied characters were: -

Data were recorded as follows: -

A-Seed yield and yield components traits: At harvest, 10 plants from each plot were chosen randomly and the data recorded as follows:

Plant height (cm), number of branches/ plant, number of pods/plant, number of seeds/pod, number of seeds/plant, 100-Seed weight (g), seed yield /plant (g) and seed yield (ardab/ha.)

B-Chemical traits: Carotain content (mg/g), chlorophyll A: (mg/g), chlorophyll B (mg/g) fresh weight, protein percentage and total carbohydrates%

The data were analyzed by using Two-way ANOVA followed by LSD test through Mstat-C. The treatments means were compared using least significant difference (LSD) tested at significant levels of 5% and 1% respectively as described by Gomez and Gomez (1984).

Results and discussions

1-Effects of cultivars, growth substances and their interactions on yield and yield components.

Cultivar effects: It could be detected from the presented results in Table 2 that, Nubaria 1 cv. had highly significant difference in mean values for number of pods/ plant in 2012/13with no significant difference than Giza 716, 100-seed weight (g), seed yield/plant (g) and seed yield(ardab)/ha. in both seasons. While, Giza 716 cv. exceeded the three cultivars used in number of branches/plant in both seasons with no significant difference than the cultivar Nubaria 1, number of pods /plant and number of seeds/ pods in 2013/14 season. Finally, Sakha 1 cv. expressed the highest significant mean values for plant height in both seasons. With respect to number of seeds /pod in both seasons and number of seeds /plant in 2012/13 season, the results revealed insignificant differences among the three cultivars. The differences between cultivars may due the widely genetic makeup among them and this result was in agreement with those reported by Talaat, and Abdallah (2008), Kandil *et al*. (2011) and Khalil *et al.* (2015).

Growth substances effects: From the present results listed in Table 2. It could be clear that, the differences between all growth substances and the control treatment were highly significant for all yield and yield components traits in both seasons. However, Crop plus treatment significantly exceeded all others treatments for all yield and yield components traits, except number of seeds/pod where the superiority of this trait was recorded by Dotra micro plus and Dotra frost treatments, with no significant difference between the two treatments. Although, the superiority of Crop plus treatment for yield and yield components traits , this exceeded did not differ significantly from Dotra micro plus for plant height and number of branches/plant in both seasons and Dotra firt for 100-seed weight in the first season .This exceeded of Crop plus treatment in yield and yield components compared with all others treatments, this could be due to the highest ability of this growth substance to increase the total numbers of flowers/ plant, reduced shedding percentage and promoted pod setting. The superiority of Crop plus might be due to its chemical composition, where the growth substance contains three growth regulators, cytokinen, Oxcine and Citric acid in its composition and these substances absent in other growth substances (Table 1). Moreover, these components had high ability to increase holding flowers and pods. The application of growth substances such as Crop plus and Dotra micro plus alone or in mixtures resulted in significant increases in yield and its components. Such increases might be due to the fact that ions of Zn, Fe and Mn are co-factors of several enzymes, but rarely if ever with a high degree of specificity (Mourad *et al.* (2004). The previous results were in agreement with those reported by El-Hawary *et al.* (1991), Hegazy *et al.* (1992), Hegazy *et al* (1993), Shehata and Bondok (1996), Mahmoud *et al.* (2006), El-Gizawy and Mehasen (2009), Hanafy *et.al.* (2010), Davood (2013) and Ali and Sadiq (2014).

The interactions: It could be clear through the results shown in Table 3 that, highly significant effect of the interaction between cultivars and growth substances on plant height, number of pods/plant, number of seeds/plant, seed yield/plant and seed yield/ha in both seasons. The highest values of the interactions for plant height were presented in the combinations of Crop plus with the three cultivars and these interactions exceeded all other interactions. However, the interactions between Dotra Micro Plus treatment and the cultivars Giza 716 and Sakha 1 did not significantly differ than the three interactions mentioned before with respect to plant height in both seasons. On the other side, the significant of the interactions were absent for number of branches/plant, number of seeds/pods and 100-seed weight, indicating that the three cultivars had not a different response to the different growth substances for these traits. For no. of pods/plant, the interactions between Crop Plus treatment and the three cultivars had highly significant difference than the other interactions in both seasons. For no. of seeds /plant, the interactions, Crop Plus x Nubaria 1,Crop Plus x Giza 716 and Crop Plus x Sakha 1 exceeded the other interactions in this respect in both seasons. However, the interactions; Dotra Frost x Nubaria1 and Dotra Frost x Sakha 1 in the first season and the interactions ; Dotra Frost x Giza 716 and Dotra Micro Plus x Giza 716 in the second season did not significantly differ than the other interactions pointed out with respect to no. of seeds /plant .For seed yield (g) / plant , the results in Table 5 indicated that, the interaction between Crop Plus treatment with Nubria 1 cv.was significantly exceeded the other interactions in both seasons with respect to seed yield/ plant and seed yield (ardab)/ha, the results pointed out that ,the interaction between Crop Plus treatment and Nubaria 1 cv. had a superiority over the other interactions in the first season , while the interaction between Crop Plus and each of Nubaria 1 and Giza 716 were significantly exceeded the other interactions in the second season. This result in harmon with those reported by Magdi (2011) where he found significant differences between cultivar and spray treatment interaction for plant height, number of branches/plant total green yield, weight of 10 pods, pod length and weight of 100 green seeds and Khalil *et al.* (2015) found that, the interaction between calcium nutrition and varieties had a significant effect on weight of seeds/plant, seed index and harvest index, in both seasons.

2- Effects of cultivars, growth substances and their interactions on chemical composition traits.

Cultivars effects: It could be clear from the results shown in Table 4 that, Giza 716 cv. had highly significant mean values for carotain in the second season and chlorophyll A in the first one and carbohydrate % in both seasons. With respect to carotain in 2012/13season, chlorophyll A, and B and protein content in 2013/14 season, the results revealed insignificant differences among the three cultivars. Nubaria 1 cv. seemed to be surpassed the other cultivars for carotain content in 2013/14 season and chlorophyll B and protein content in 2012/13 season. Meanwhile, Sakha 1 cv. expressed highly significant mean values for chlorophyll A in 2012/13 season. From the comparison between the three cultivars in chemical composition, it could be clear that, the cultivar Giza 716 followed by Nubaria 1 were the best among all tested genotypes. The differences between the three tested cultivars may due to the widely diversity in genetic constitution of these cultivars and the ability of each cultivars to uptake and accumulation the micro- nutrients from the soil. Also, it may be due to the difference in leaf area and the total canopy and the ability of canopy to absorption these micro- elements. The cultivars differences in chemical composition were reported before by Magdi (2011) which indicated that, significant differences were observed among the cultivars with respect to chemical compositions.

Growth substances effect: It could be clear that the differences between all growth substances and the control treatment were highly significant for all chemical composition traits in both seasons. However, Crop plus treatment significantly exceeded all others treatments for chemical composition traits as shown as in Table 4. The control treatment seemed to be the worst among all treatments in all chemical composition traits. Generally, the growth substances play a major role in increase chemical compositions of faba bean cultivars. This result was in agreement with those reported by Mahmoud *et al.* (2006) which indicated that, boron foliar fertilization in a concentration of 25 – 50 ppm as spray solution in combination with 96 ton nitrogen/ha as soil treatment has significantly increased seed protein and carbohydrate. Ibrahim *et al.* (2007) found that, all the used bio regulators caused significant increase in the protein and total carbohydrate percentage of the produced seeds resulted from the treated plants. El-Gizawy and Mehasen (2009) reported that, adding 72 ton/P_2O_5 mixed with PDB markedly increased protein%, N%, P%, N and P uptake, Hanafy *et.al.* (2010) indicated that, addition of humic acid as well as foliar application with novavol, putrescine and vegi max significantly increased plant pigments, i.e. chlorophyll a, total chlorophyll and carotenoids concentrations either in leaves or pods. Similar results were found by Abou EL-Yazied and Mady (2012), Amin *et al.* (2014) and Reda *et al.* (2014).

The interaction effects: The highest significant values of the interactions were presented in the combinations of Crop plus with Nubaria l cutivar for carotain in both seasons and the interaction between Crop Plus and the three cultivars i.e. crop Plus x Nubaria 1 , Crop Plus x Giza 716 and Crop Plus x Sakha 1 for chlorophyll A in both seasons, as shown as in Table 5.With respect to chlorophyll B,the interaction between Crop Plus and Nubaria 1 in both seasons and Crop Plus with Sakha 1 in the second season were significantly surpassed the other interactions. The interactions between Crop Plus and each of the three cultivars in both seasons and between Dotra Micro Plus and each of the three cultivars in the first season gave the significantly highest values for protein content. For carbohydrate percentage, the interaction between Crop Plus and each of the three cultivars in both seasons had a superiority in this respect. This indicated that, the three cultivars had a different response to the different growth substances and the confirms the overlapping effect of the cultivars with the resulting effect on the growth substances in these traits, and this overlap value will vary depending on the cultivar and the degree of its response to the growth substance.

Table 2. Effect of cultivars, growth substances treatments, yield and yield components and their interactions in both seasons.

Abstract

Soil organic matter (SOM) has long been considered a key factor in sustaining the physical, chemical and biological properties of soil. A network of 40 pairs of organic and conventional farms across four regions of Germany was established focusing on research on climate impacts and sustainability indicators in agricultural production. In one part of the joint project "Climate Effects and Sustainability of Agricultural Systems – Analyses in a Network of Pilot Farms" soil chemical, biological and physical properties were investigated. We aimed to study the influence of climate (precipitation, temperature and altitude) on SOM (C_{org} and N_t) in four regions (East, South, West and North) of Germany. To analyse different effects on soil properties soil samples were taken between 2009 and 2011 on 80 farms (10 pairs of neighbouring farms in four regions). The measurements are based on 207 plots located on cropland and 56 plots located on grassland. The data was analysed with cluster analyses. The analysis created and compared four groups with similar climate data and four groups of plots with similar C_{org} and N_t. In cropland 46.9% of the plots with similar climate data had similar SOM in depth 0-30 cm. In grassland this was the case for 48.2% of the plots in depth 0-10 cm and only 37.5% in depth 10-30 cm. The results suggested a higher effect of climate variables on SOM in cropland than in grassland. The differences might be caused by different site conditions. For further research other site conditions (soil texture, ground water etc.) will be included.

Keywords: *Carbon, Nitrogen, Precipitation, Grassland, Cropland*

Introduction

To achieve sustainable land use, it is important to understand the influences of agriculture on biotic, abiotic and structural parameters of soils. To answer these questions, a network of 40 pairs of organic and conventional farms across four regions of Germany (East, South, West, and North) was established with focus on research on climate impacts and sustainability indicators in agricultural production. The 10 farm pairs in each region are composed of 10 organic and 10 conventional managed farms. The chosen farm pairs (organic and conventional) were selected close together. In consequence the farm pairs in each region have similar soil and climatic conditions. The farms can be classified as cash-crop, dairy and mixed farms. In a part of the joint project "Climate Effects and Sustainability of Agricultural Systems – Analyses in a Network of Pilot Farms" soil chemical, biological and physical indicators are investigated. This article is focusing only on soil organic carbon (SOC).

SOC plays a key role in the global carbon cycle. Lately carbon sequestration in surface soils, especially in relation to agricultural land-use, has often been discussed as a possible mitigation strategy for global climate change (Davidson et al. 2000; Martin et al. 2011).

The SOC content depends on many factors, e.g. climatic conditions and land-use. The relationship between climatic variables and the amount of organic carbon in the soil is well known. According to Chaplot et al. (2010), variability in SOC was correlated with average annual precipitation and was affected by land use. E.g. more SOC was localized under shifting cultivation than under continuous cultivation. Despite land-use, Arrouays et al. (2001) identified contrasting climatic conditions and elevation as the main factors for the soil carbon distribution in France as well. To climate conditions include temperature and its indirect effect - soil moisture (Conant et al. 2011). Temperature is an important factor controlling SOM turnover (Haddix et al. 2011). According to Martin et al. (2011), the effect of temperature was important, but less than the effect of precipitation. As suggested by Jenny (1941) and Post et al. (1982), cool conditions and wet soils can impede decomposition, and SOC is highest under cool and moist conditions and lowest under hot and dry conditions. Climate conditions also affect yield and thus the input of carbon to the soil.

Here is a remarkable lack of information about the status quo of organic carbon in agricultural soils. We therefore aimed to study the effects of organic as well as conventional farming on soil organic matter in four regions (East, South, West and North) of Germany. The aims of the present study were to (i) report the soil organic carbon (C_{org}) and (ii) total nitrogen (N_t) content. For the evaluation of the SOC an inventory of the SOC content was carried out. Further, the content of SOC was investigated in relation to climate conditions (annual sum of precipitation, seasonal mean of temperature and altitude). We studied these factors controlling the levels of organic matter in soils in order to identify sustainable strategies for land management and to properly assess SOC in relation to potential greenhouse gas (GHG) emissions.

Material and Methods

In total at 80 farms across four regions of Germany (East, South, West, and North) soil samples were taken. 207 soil samples were collected from arable land and 56 from grassland. The elevation of the monitoring plots in the South region (Tertiary Hills and Allgäu) ranges from 444 to 776m, in the West region (Lower Rhine Bay and Mittelgebirge) from 21 to 421m, in East region (Loess dry sites in Central Germany and diluvial sites Altmark and Spreewald) from 28 to 316m and in the North region (North and East Baltic-Sea coastal region) from -4 to 52m. The study areas include maritime climate in the north, dry-continental conditions in the east of Germany, high-precipitation areas in pre-alpine region in the South and mild humid climate in the west with typical soil conditions for the areas.

In arable land/cropland, the soil was sampled in fields with winter cereals. At each experimental site all data were collected in four sampling plots, each 10 m × 10 m in size. Each monitoring plot is a square of about 100m2 and the positions of the corners have been exactly measured and their coordinates determined with a global positioning system (GPS). For each monitoring plot there is a database with detailed information comprising crops, intermediate crops, amount and kind of mineral and organic fertilizers applied and tillage (management practice data). This SOM investigation was only one part of a larger sampling including various chemical, physical and biological soil properties.

Samples were collected on cropland from the soil layer 0-30 cm and in layers 0-10cm and 10-30cm for grassland. To measure bulk density in the middle of each study site 5 undisturbed soil cores were collected. For the bulk density the steel cores (54 mm internal diameter and 40 mm height, with wall thickness approximately 1.5 mm) were used for sampling grassland at 0-10 cm and 10-30 cm depth, taking five replications of each undisturbed soil per plot. For arable land, the two depths were not differentiated and together 10 cores were taken up. In the laboratory the soil samples were weighted and later dried in the oven at 105°C for 24 h.

Soil samples for analysis were air dried and passed through a 2 mm sieve. Basic components of SOM (C_{org} and N_t-content) were simultaneously determined by the dry combustion method

(Dumas method) in a vario Max CNS elemental analyzer (ELEMENTAR, Germany). Soil samples composed of carbonates were treated in a muffle furnace. After oven drying of the sediment to constant weight (or dry matter) and cooling to room temperature, organic matter was combusted to ash and carbon dioxide at temperatures 550°C. The organic carbon (C_{org}) was calculated as $C_{org} = C_t - C_{carbonate}$.

The SOC and N_t variability was evaluated using cluster analysis in the STATISTICA 8.0 program (Statsoft, Tulsa). This analysis was based on the content C_{org} and N_t and on climate conditions (annual sum of precipitation, seasonal mean of temperature and altitude) for different sites.

Results and Discussion

Over two years (2009-2011), 263 plots (207x cropland with winter cereals, 56x grassland) of 80 organically and conventionally managed farms were sampled and soil samples were analysed. The plots were located in four regions in Germany (East, South, West, and North). For first evaluation, the plots were characterized by climate conditions (annual sum of precipitation, seasonal mean of temperature and altitude).

In the first step, the cluster analysis created four groups of plots with similar climate conditions. The regions were hereby redefined. Some plots in regions had similar climate conditions with plots in other regions, e.g. because of its location in mountain areas. The climate characteristics of 4 groups in crop land as well as in grassland are shown in Tables 1 and 2.

Table 1. Four groups of sites with winter cereals defined through/with their similar climate conditions (annual sum of precipitation, seasonal mean of temperature and altitude).

		Precipitation (mm) annual sum	Temperature (°C) seasonal mean	Altitude (m)
Group 1	Min	675	8.4	-4
n = 76	Mean	739	9.2	55
	Max	820	10.8	235
Group 2	Min	510	8.2	12
n = 71	Mean	568	8.7	78
	Max	641	9.6	220
Group 3	Min	450	8.8	91
n = 11	Mean	451	9.0	168
	Max	452	9.1	297
Group 4	Min	785	7.3	341
n = 48	Mean	934	7.6	509
	Max	1109	8.0	665

In cropland, the first group was described by 675-820 mm of annual precipitation sum with 8.4-10.8°C and hight at -4-235 m a.s.l. The second group was defined by 510-641 mm, 8.2-9.6 °C and 12-220 m a.s.l., the third by 450-452 mm, 8.8-9.1°C and 91-297 m a.s.l. and the fourth by 785-1109 mm, 7.3-8.0°C and 341-665 m a.s.l.

In grassland, the first group was described by 785-1109 mm of annual precipitation sum with 7.3-8.3°C and altitude at 329-632 m a.s.l. The second group was defined by 1228-1507 mm, 6.9-7.2 °C and 650-776 m a.s.l., the third by 686-820 mm, 8.4-10.8°C and -3-209 m a.s.l. and the fourth by 451-641 mm, 8.4-9.6°C and 20-305 m a.s.l.

Table 2. Four groups of grassland sites defined through/with their similar climate conditions (annual sum of precipitation, seasonal mean of temperature and altitude).

		Precipitation (mm) annual sum	Temperature (°C) seasonal mean	Altitude (m)
Group 1	Min	785	7.3	329
n = 11	Mean	982	7.8	490
	Max	1109	8.3	632
Group 2	Min	1228	6.9	650
n = 12	Mean	1367	7.0	747
	Max	1507	7.2	776
Group 3	Min	686	8.4	-3
n = 19	Mean	750	9.2	58
	Max	820	10.8	209
Group 4	Min	451	8.4	20
n = 14	Mean	550	8.8	92
	Max	641	9.6	305

In the second step, the cluster analysis created four groups of plots in cropland with similar C_{org}, N_t and C:N ratio. Details are shown in Table 3.

Table 3. Four groups of sites with winter cereals with their similar C_{org}, N_t and C:N ration in the soil depth 0-30 cm.

		C_{org} (%)	N_t (%)	C:N ratio
Group 1	Min	0.65	0.04	14.4
n = 29	Mean	1.75	0.11	16.3
	Max	2.41	0.15	19.3
Group 2	Min	0.50	0.04	11.4
n = 87	Mean	1.26	0.10	12.4
	Max	2.41	0.21	14.3
Group 3	Min	2.52	0.21	10.4
n = 16	Mean	3.73	0.32	11.7
	Max	5.59	0.54	13.5
Group 4	Min	0.53	0.05	8.1
n = 77	Mean	1.40	0.14	10.4
	Max	2.37	0.23	11.4

The members of four groups with similar climate conditions were compared with members of the four groups with similar values C_{org}, N_t,and C:N ratio. In cropland 46.9% of the plots with similar climate conditions had similar SOM in depth 0-30 cm. C_{org} of plots with winter cereals ranged from 0.5 to 5.59%, N_t ranged from 0.04 to 0.54% with C:N ratio between 8.1 to 19.3.
The cluster analysis created four groups of plots with similar C_{org}, N_t and C:N ratio in grassland as well. The groups for the depth 0-10 cm are defined in Table 4 and for the depth 10-30 cm in Table 5.
The groups were separately compared for depths 0-10 cm and 10-30 cm. In the upper layer, 48.2% of the plots had similar climate and SOM conditions. Only 37.5% of the plots had similar climate and SOM conditions in depth 10-30 cm. In grassland in depth 0-10 cm, C_{org} ranged from 2.28 to 18.25%, N_t from 0.13 to 1.61% with C:N ratio from 7.6 to 18.1. In the depth 10-30 cm, C_{org} ranged from 0.92 to 21.62%, Nt from 0.07 to 1.85% with C:N ratio from 8.1 to 19.2.

Table 4. Four groups of grassland with their similar N_t, C_{org} content and C:N ration in the upper 10 cm in the soil.

		C_{org} (%)	N_t (%)	C:N ratio
Group 1	Min	3.32	0.36	7.6
n = 13	Mean	5.25	0.52	10.0
	Max	10.13	0.98	10.9
Group 2	Min	11.49	0.76	9.6
n = 5	Mean	13.71	1.22	11.7
	Max	18.25	1.61	15.6
Group 3	Min	2.28	0.13	9.7
n = 26	Mean	3.16	0.28	11.5
	Max	4.93	0.37	18.1
Group 4	Min	5.15	0.52	9.8
n = 12	Mean	7.95	0.72	11.1
	Max	10.65	1.04	12.6

Table 5. Four groups of grassland with their similar Nt, Corg content and C:N ration in the depth 10-30 cm in the soil.

		C_{org} (%)	N_t (%)	C:N ratio
Group 1	Min	1.10	0.09	11.0
n = 5	Mean	1.42	0.12	11.6
	Max	1.98	0.17	12.9
Group 2	Min	0.92	0.09	8.1
n = 12	Mean	2.34	0.23	10.0
	Max	5.07	0.50	11.0
Group 3	Min	1.01	0.07	12.9
n = 26	Mean	2.86	0.19	15.2
	Max	4.55	0.35	19.2
Group 4	Min	6.01	0.48	10.1
n = 13	Mean	8.93	0.77	11.8
	Max	21.62	1.85	16.8

We concluded, that the climate conditions are one of the main influences on SOC. However, Wiesmeier et al. (2013) suggested climate effects (mean annual temperature and precipitation) had minor importance in cropland soils because these are attenuated by management.

Generally lower C_{org} and N_t content in the soil were found for cropland soils. Grassland soils stored more amount of SOC in both soil layers as suggested by many authors (e.g. Arrouays et al. 2006; Leifeld et al. 2005). In accordance with results of Leifeld et al. (2005) organic carbon increased in grassland with altitude.

Further, Leifeld et al. (2005) evaluated the clay content and its influence on the variability in SOC concentrations in the fine earth of arable soils. However, he effect was not significantly related to SOC in grassland soils at higher altitudes. Probably, the differences in SOC can be explained on sites with different land-use by several other influences. Different land-use is associated with different bulk density (BD). In the next step, SOC stocks will be converted to the soil volume.

Further research is needed and other soil parameters should be taken into account as well as the farm characteristics (farm type. crop rotation. fertilizers. tillage. etc.). The study of the main factors affecting the spatial SOC distribution may improve the selection of suitable land use and management designed to enhance the C sequestration and predict the potential impacts of changes in climate and land use on GHGs emission from soils.

Conclusions

We studied the influence of climate, soil and organic as well as conventional farming on SOM in four regions of Germany Climate conditions affected SOC pools the most, followed by agricultural land-use and soil characteristics. Nevertheless, more factors need to be taken into account to properly evaluate GHG emissions and enhance carbon sequestration.

Abstract

Root distribution plays an important role in estimating soil organic carbon in agroecosystems. The evaluation of root distribution is difficult due to laborious measurements and root variability. Soil texture affects root penetration and thus alters the morphology and distribution of roots. The soil profile wall method is suitable for evaluating the effects of soil and other variables on root length density (RLD). RLD of winter cereals (wheat and rye) and their preceding crop sugar beet was observed using the profile wall method up to 2 m depth at three sites in Lower Saxony (Germany). The sites differed in soil texture comprising sandy (sand 84%, silt 14%, clay 4%), silty (1%, 80%, 19%) and clayey (2%, 56%, 42%) sites. Generally, the winter cereals had higher RLD than sugar beet and simultaneously the differences in RLD were higher between the sites. The results indicated a high variability of RLD in the topsoil (sugar beet: 0.394 - 0.973 cm cm^{-3}, winter cereals: 2.172 - 5.553 cm cm^{-3}). For both, sugar beet and winter cereals, importance of soil texture increased in the subsoil (soil layers 60-90 cm and 90-120 cm). In the depth 60-90 cm, the highest RLD of all species was found at the silty site. In the depth 90-120 cm the highest RLD was recorded for sugar beet at the clayey site. In this soil layer the highest RLD of sugar beet was recorded at the silty site. RLD of sugar beet and winter cereals was correlated at all sites ($p < 0.05$). The correlation coefficient at the sandy site was r=0.85 (df=25), followed by the silty site with r=0.83 (df=25) and clayey site with r=0.69 (df=25). This might indicate that sandy soil texture influences the species similarly.

Keywords: *Beta vulgaris, Profile wall method, Root length density, Winter wheat.*

Introduction

Root distribution of crops plays an important role in maintaining water and nutrient supply to plant tissues. It also contributes to the maintenance of soil organic matter (Jenkinson & Coleman, 2008). Additionally, roots are important because of their close relationship to the yield of aboveground organs (Lamb et al., 2000).

The evaluation of root distribution is difficult due to the variability in root distributions and soil properties. The root length density (RLD) can be used to assess root distribution. RLD is an important parameter for characterizing root system features and spatial distribution at different soil depths. RLD, expressed as cm root length per cm^3 of soil volume, reflects the relative distribution of root length in the soil profile. One way of assessing the RLD is the profile wall method. It is used to evaluate changes in soil structure induced by agricultural management considering compaction and the presence of cracks (Neves et al., 2003). Additionally, it describes the relationship between soil characteristics and root variability. Knowledge about root distribution over the soil profile and with time can be used in the design of crop rotations with improved N use efficiency (Kristensen & Thorup-Kristensen,

2004). Hence, more studies about root distribution with depth are needed. Further, Thorup-Kristensen et al. (2009) suggested that observations below 1 m are important in order to understand N dynamics in wheat cultivation.
Soil texture also affects root penetration and thus alters the distribution of roots. Anderson (1988) recorded more deep roots in fine- and coarse-textured soils than in medium-textured soils.
Although the RLD of different crops under different soil conditions has frequently been studied, there is a lack of studies under field conditions on real farms. The present study was therefore conducted to investigate the spatial distribution of RLD of sugar beet and the winter cereals (wheat and rye) that followed sugar beet in the crop rotation.
The main aim of this paper was to answer the following research questions: (i) How does the RLD of sugar beet and winter cereals differ according to depth? (ii) Is there some relationship between RLD of the preceding crop sugar beet and the RLD of winter cereals?

Material and Methods

The RLD measurements were taken from three sites on a conventionally-managed farm in Lower Saxony. The sites differed in soil texture comprising sandy (sand 84%, silt 14%, clay 4%), silty (1%, 80%, 19%) and clayey (2%, 56%, 42%) sites. Sugar beet was investigated in 1987 and winter cereals in the following year using the profile wall method (Böhm, 1979) in all cases. Winter wheat was investigated at the silty and clayey sites, winter rye at the sandy site. The experimental areas were located at an altitude ranging from 100 to 145 m. a.s.l. The average annual precipitation and temperature ranged from 610 mm and 8.3°C at 100 m a.s.l. to 680 mm and 8.6°C at 145 m a.s.l. The distance between rows was 45 cm for sugar beet at all sites and 12.5 cm for the winter cereals. The yield of all crops was recorded. The sugar beet was sampled four times during the season (from BBCH 33 to BBCH 59) and cereals twice in BBCH 32 and BBCH59. For the evaluations, the mean of the sampling dates was used.
RLD and root distribution over the soil profile were assessed using the profile wall method. A rectangular pit was dug at each site at right angles to the plant rows down to 2 m soil depth. The counting depth at all sites was 2 m. On each sampling date two counts were carried out, and before each count a fresh profile layer was prepared by removing a 0.2 m soil layer. Each sampling transect was 0.9 m (measured perpendicular to the rows).
Steel nails (with heads 3 mm wide) were pushed into the profile wall at intervals of 10 cm and afterwards the soil layer was smoothed by washing away about 3 mm of soil with a sprayer. The correct thickness of the removed layer was indicated by the nail markers. After smoothing the roots were visible and root lengths were counted using a square grid with square size of 5 x 5 cm. The root diameter was not measured. For the estimation of root length a screwdriver with a tip edge 5 mm in width was used to define one countable root unit. Thus, every part of an exposed main or lateral root was counted. RLD (cm cm^{-3}) was calculated for each grid cell by dividing root length (root unit count x 0.5 cm) by the volume of the sprayed-off soil layer (5 x 5 x 0.3 cm).

Results and Discussion

Generally, the winter cereals had higher RLD than sugar beet. Winter wheat and winter rye had higher RLD than sugar beet. The different RLD distributions of winter wheat and sugar beet at the three sites with different soils are shown in Figure 1.

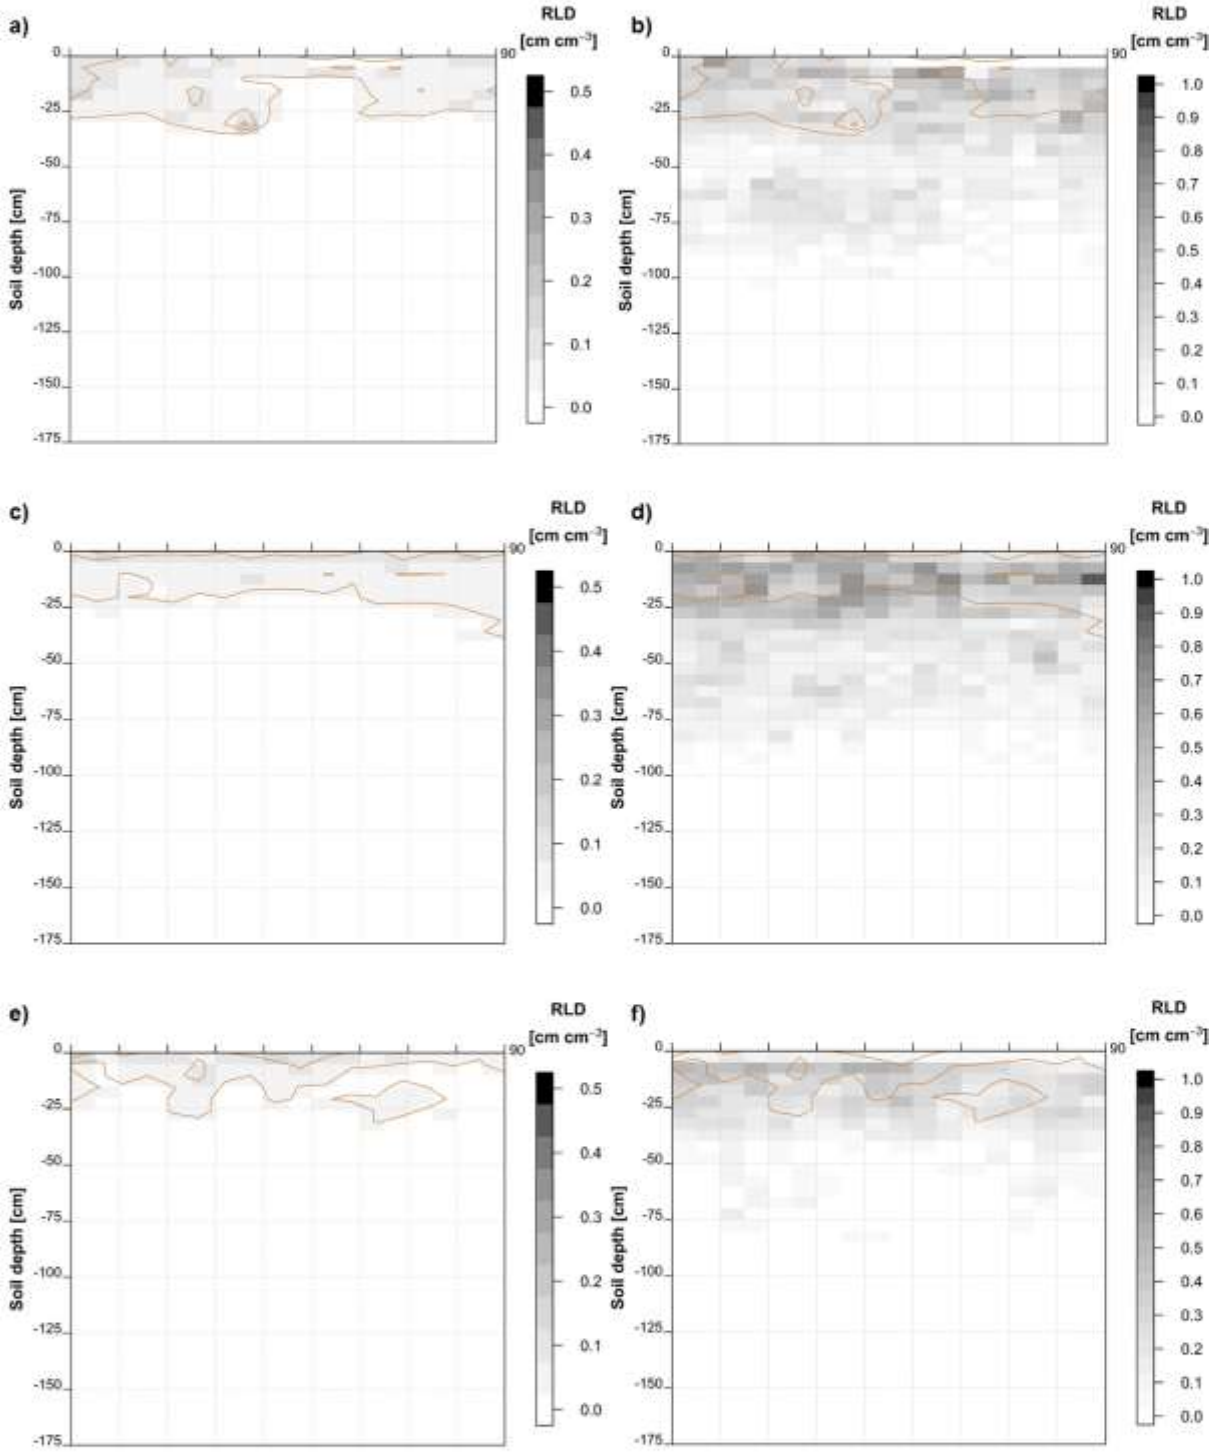

Figure 1. Profile walls at sandy site (a) sugar beet and (b) winter rye; at silty site (c) sugar beet and (d) winter wheat and at clayey site (e) sugar beet and (f) winter wheat

Sugar beet (BBCH 59) roots were recorded from 0 to a depth of 165 cm at the clayey site, from 0 to a depth of 115 cm at the silty site and from 0 to a depth of 85 cm at the sandy site. One year later, winter wheat (BBCH 59) roots were recorded from 0 to a depth of 90 cm at the clayey site, from 0 to a depth of 125 cm at the silty site. Winter rye (BBCH 59) roots were recorded from 0 to a depth of 135 cm at the sandy site.

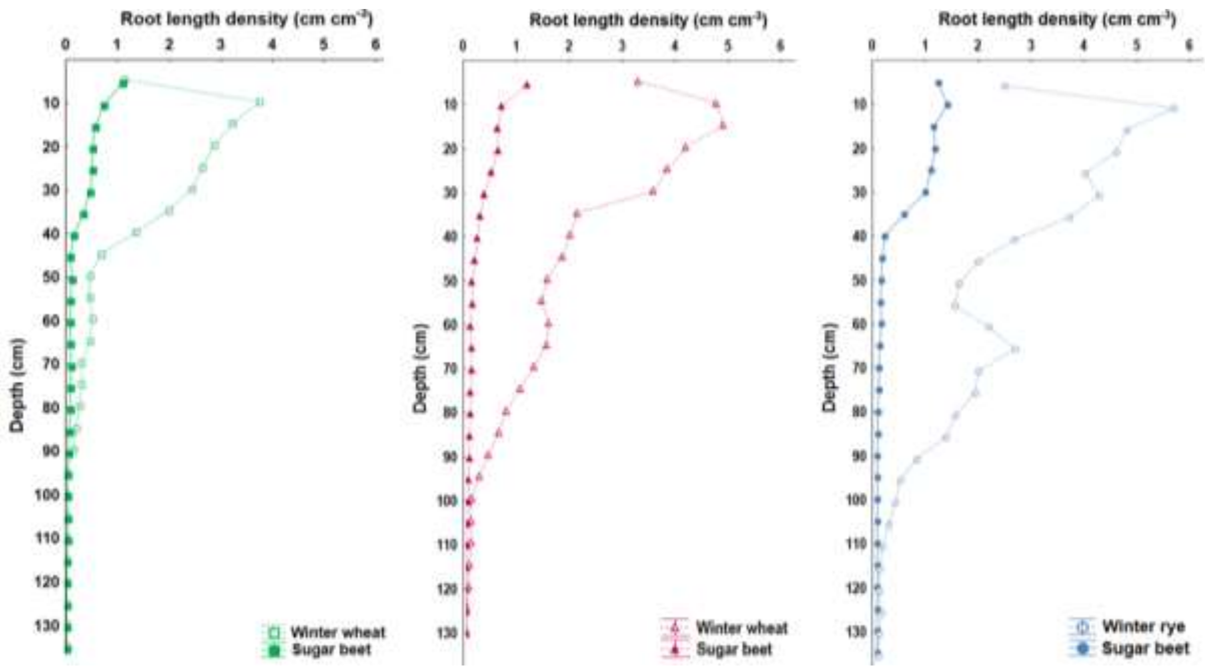

Figure 2. The RLD distribution of winter wheat and sugar beet at (a) clayey, (b) silty and the RLD distribution of winter rye and sugar beet at (c) sandy site

The RLD in the topsoil was significantly higher than in the subsoil. The results indicated a high variability of RLD in the topsoil. RLD of sugar beet ranged between 0.394 - 0.973 cm cm^{-3} and RLD of winter cereals between 2.172 - 5.553 cm cm^{-3}. For both, winter cereals and sugar beet, the importance of soil texture increased in the subsoil (soil layers 60-90 cm and 90-120 cm), where RLD was affected through bulk density and water availability. In the depth 60-90 cm, the highest RLD of all species was found at the silty site. In the depth 90-120 cm the highest RLD was recorded for sugar beet at the clayey site. In this soil layer the highest RLD of sugar beet was recorded at the silty site. In Figure 2, RLD of sugar beet and winter cereals was correlated at all sites ($p < 0.05$). The correlation coefficient at the sandy site was $r=0.85$ (df=25), followed by the silty site with $r=0.83$ (df=25) and clayey site with $r=0.69$ (df=25). This might indicate that sandy soil texture influences both crops similarly.
Thus, the taproots of a dicot (sugar beet) and fibrous monocot roots (cereals) had different root distributions, sugar beet having lower RLD. This fact is in accordance with results of Mengel et al. (2001). He reported that monocots had much longer roots than dicots. Hamblin & Tennant (1987) even reported that the root lengths of cereals were consistently 5-10 times larger than those of legumes.
For the assessment of the RLD the profile wall method was chosen, which has advantages and limitations (Vepraskas & Hoyt, 1988; Basilio de Azevedo *et al.*, 2011). One of the limitations is that the profile method was not applicable in the deep subsoil on clayey soil. Kücke et al. (1995) used the method only down to 0.45 m soil depth because the clay swelled so much that the marking nails disappeared when the trench wall was sprayed with water. For that reason the winter wheat at the clayey site was investigated only up to 0.9 m. Nevertheless, this qualitative method provides a unique set of relative comparisons that cannot be obtained using other methodologies.

Conclusions

Winter cereals had higher RLD than sugar beet. The root distribution of winter cereals was correlated with root distribution of sugar beet mostly at the sandy site. The deepest roots were recorded for sugar beet (BBCH 59) with roots down to a depth of 165 cm at the clayey site.

Abstract

The 1BL.1RS wheat-rye chromosome translocation offers to the host cultivar, among others, high yield potential and drought resistance. In order to study how the above traits are affected by this translocation, three Hellenic spring wheat varieties with translocation (cvs. Acheron, Elissavet and Orfeas) and six without the translocation (cvs. Apollonia, Acheloos, Vergina, Doirani, Nestos and Strymonas) were used. The Russian cultivar Kavkaz/Cgn was used as control. The complete randomized block design was applied with four replications and the experiment was established in the main farm of the Western Macedonia University of Applied Sciences in Florina. The following physiological traits were measured: total chlorophyll content, chlorophyll fluorescence, CO_2 assimilation rate, stomatal conductance, intercellular CO_2 concentration and transpiration rate. No significant differences were recorded except for total chlorophyll content. Cultivar Achellos, which does not carry the translocation and is characterized by high yield potential, differed significantly from all the other cultivars in total chlorophyll content. Regarding the other traits, cultivar Doirani performed better in stomatal conductance, cultivar Nestos in intercellular CO_2 concentration and cultivar Acheloos in transpiration rate, but the differences were not significant. In order to find out the effect of the physiological traits on yield potential the above results were compared to the yield performance of the corresponding cultivars. This comparison led to the conclusion that the 1BL.1RS chromosome translocation does not give an advantage regarding the physiological traits studied. Further research is required to confirm the results of the present study.

Keywords: *yield potential, drought resistance, chlorophyll, assimilation rate.*

Introduction

One of the main problems in releasing new cultivars is that this new germplasm has to be grown on marginal environments due to the irrational waste of territorial resources noticed in previous years. Furthermore, the drought in spring is the crucial obstacle of agricultural production in the southern regions of Europe (Yau and Saxena, 1997) complicating the problem. Thus, one of the most decisive factors in all breeding programs is the identification and integration of genes into cultivated varieties that confer resistance or tolerance to drought (Blum, 1988). This led breeders and especially those working on wheat, to look for new gene pools to face the problem (Fehr, 1987). According to various reports bread wheat *(Triticum aestivum* L em Thell) cultivars carrying the 1BL.1RS wheat-rye chromosome translocation are characterized among other traits by high yield potential (Kim *et al*., 2004; Xynias *et al.*, 2007) and resistance to drought (Hoffmann, 2008). The 1BL.RS translocation is originated from cv. Kavkaz/Cgn, and according to Weng *et al*. (2007) possesses resistance genes to different biotic and abiotic stress conditions. The unique traits of the translocation are attributed to genes located on the short arm of the first chromosome of rye (Schlegel and Meinel, 1994; Xynias *et al*., 2007). Common physiological traits used to recognize increased stress tolerance are gas exchange parameters such as assimilation rate (A), stomatal conductance (g_s), transpiration rate (E) and intercellular CO_2 concentration (c_i), chlorophyll content and chlorophyll fluorescence (Hura *et al.*, 2007; Živčák *et al.,* 2008). Physiological traits have showed a good correlation with tolerance to stresses and yield parameters with a high heritability and repeatability (Fotovat *et al.*, 2007; Sayar *et al.*, 2008).

The aim of the present study was to investigate the effect of the 1BL.1RS wheat-rye chromosomal translocation on six physiological traits and elucidate how they affect yield and drought resistance.

Materials and Methods

a. Plant material

For the purpose of the study, nine Hellenic bread wheat cultivars (eg. Acheron, Elissavet, Orfeas, Apolonia, Acheloos, Vergina, Doirani, Nestos and Strymonas) that were developed at the Cereal Institute of Thessaloniki (Anonymous 1985) and the Russian cultivar Kavkaz/Cgn, one of the donors of the 1BL.1RS wheat-rye chromosome translocation (Xynias *et al.,* 2006; Weng, 2007) were used. Three of the Hellenic cultivars were found to carry the 1BL.1RS wheat-rye chromosome translocation (cvs. Acheron, Elissavet and Orfeas) whereas the other six cultivars, were lacking the specific translocation (Xynias *et al*., 2006; Peros *et al.,* 2015).

b. Method

The examined cultivars and the control were sown in early November 2015 in a field at the University of Applied Sciences of W. Macedonia Farm in Florina Greece (40°46′ N, 21°22′E, 707 m asl), in a sandy loam soil with pH 6.3, organic matter content14.0 g kg^{-1}, N-NO_3 100 mg kg^{-1}, P (Olsen) 50.3 mg kg^{-1} and K 308 mg kg^{-1} and water holding capacity 21.8% (0 to 30 cm depth). Seedbed preparation included mouldboard plough, disc harrow and cultivator. Nitrogen and P_20_5 at 80 and 40 kg ha^{-1}, respectively, were incorporated into the soil as diammonium phosphate (20-10-0) before sowing. The crop was kept free of weeds by hand hoeing when necessary. The Randomized Complete Blocks (RCB) experimental design was applied, with four replications (Steel and Torrie, 1960). The plots were consisted of five rows (plot area $3m^2$) of which the three inner were threshed (harvest area $1.8m^2$).

The mechanically harvested grain was weighed and a sample of grain was dried in an oven at 105° C for 24 h to determine grain moisture content. Grain yield was referred to 12% grain moisture. Chlorophyll content readings were taken with a hand-held dual-wavelength meter (SPAD 502, Chlorophyll meter, Minolta Camera Co., Ltd., Japan). For each plot six fully expanded flag leaves per plot were used when the plants were at physiological maturity with six measurements per leaf, a total of 36 readings per plot. A portable photosynthesis system (LI-6400 XT, Li-Cor, Lincoln, Nebraska, USA) equipped with a 2X6 (12 cm^2) open top narrow leaf chamber was used for determinations of CO_2 assimilation rate (A), transpiration rate (E), stomatal conductance to water vapour (g_s), and intercellular CO_2 concentration (C_i) during grain filling period. Leaf gas exchange was measured on the fully expanded flag leaf during the grain-filling period on six plants from each plot from 09:00-12:00 in the morning to avoid high vapor-pressure deficit and photoinhibition at midday. The quantum photosynthetic yield of photosystem (PS) II or Y was measured with the portable OS5p Chlorophyll Fluorometer (Opti-Sciences Inc. Hudson, NH, USA).

The means were compared according to the L.S.D. method. The data obtained were analyzed statistically with Mstat-C (Freed and Eisensmith, 1986).

Results and Discussion

Significant differences were recorded between the examined cultivars in yield (significant differences at p = 1%, Table 1). Regarding the physiological traits studied, only in total chlorophyll content the differences were significant. In all other physiological traits no differences were observed between the examined cultivars regardless of the presence of the translocation (Table 1).

Table 2. Ranking of the bread wheat cultivars according to yield and total chlorophyll content.

Cultivar	Yield	Total chlorophyll content
Acheron	880.4 a	41.10 c
Apolonia	868.1 a	44.13 c
Doirani	688.7 b	49.22 ab
Elissavet	657.1 bc	45.30 bc
Vergina	652.2 bc	45.60 bc
Acheloos	580.7 bc	51.53 a
Strymonas	546.8 c	41.67 c
Kavkaz/Cgn	344.7 d	41.28 c
Nestos	277.8 d	44.97 bc
Orfeas	209.6 d	41.64 c
LSD	135.2	4.77

Source: Author s' elaboration based on the obtained results.

Yield ranged from 880.4 g per harvest plot in cultivar Acheron to 209.6 g per harvest plot area in cultivar Orfeas (Table 2). Both of these last cultivars carry the 1BL.1RS wheat rye chromosome translocation. The insufficient yield performance of cvs. Orfeas Nestos and Kavkaz/Cgn can be attributed to the inappropriate soil characteristics of the field where those cultivars were grown (relatively high water holding capacity in conjunction with very low temperatures). Cultivar Apolonia, which does not carry the translocation, was ranked second performing equally well with cultivar Acheron. The above results suggest that there must be no any effect of the wheat rye chromosome translocation. Sufficient yield can be produced by elite cultivars despite the effect of the translocation. This questionable effect of the translocation was also reported in other studies. Lazaridou *et al.* (2017) suggested that any positive effect of the translocation on the host cultivar is determined by the genetic background of the host cultivar itself.

Except for the total chlorophyll content, no differences were recorded in all other traits. Cultivar Acheloos, which does not carry the translocation, was ranked first in total chlorophyll content. This was expected since this cultivar has large leaves and is considerably robust. As for the other traits, cv. Doirani performed better in stomatal conductance, cv. Nestos in intercellular CO_2 concentration, and cv. Acheloos in transpiration rate, but the differences were not significant.

Conclusions

A first estimate of these results leads to the conclusion that the 1BL.1RS wheat rye chromosomal translocation does not give any advantage over the physiological traits studied. The correlation of the aforementioned traits with yield, further complicate the conclusion, probably suggesting that any positive effect of the translocation could be influenced by the genetic background of the host cultivar. However, further research is required to verify this last statement.

Abstract

Seed germination is the most critical stage in life cycle of cereal plants while temperature is the main factor affecting plant growth and development. In this study, was investigated the effect of different temperatures and the use of two new ingredients for seed dipping of winter cereals (*Triticum durum, Triricum aestivum, Avena sativa, Hordeum vulgare,* and *Secale cereale*). Seed germination rate was measured at different temperatures in the range 2-22^{o}C in a growth chamber with constant parameters (light, water). In each species there were three treatments (blanc, ingredient A, ingredient B) which were repeated four times for each temperature value, where 200 seeds were placed in different separate containers. The measurements were taken at a-day intervals for the increased temperatures and at a three-day interval for the low temperatures. A seed was deemed to have germinated when at least 1 mm of radicle was visible.Temperature seems to be the most limited factor on germination process while the increase of 5 degrees is enough to give better germination results and in association with the dippedseeds with the tested ingredients shown that winter cereals had different germination rates which may help farmers to have a substantial germination risk. It was found that ingredients A and B did not play a significant role in germination except the case of Triticum durum where helped it to present better germination rate than the blanc treatment. The temperature of 12-22^{o}C represents the optimum seed germination in a period of 8-10 days for *Triricum aestivum, Avena sativa, Hordeum vulgare,* and *Secale cereale* regardless of the different treatments.

Keywords: *germination rate, winter cereals, temperature, ingredients.*

Introduction

Cereals are grasses widely cultivated for its seed. A cereal grain is a worldwide staple food (Shewry, 2009; Mauseth, 2014). The more widely grown winter cereal is wheat and it is grown on more land area than any other food crop (FAOSTAT, 2014), and the world trade in wheat is greater than for all other crops combined (Curtis et al., 2002).

One of the most crucial factors that affect plant growth and specifically the rate of plant growth and development is the temperature. The most critical stages in the plant life cycle is seed germination and seedling establishment (Walck et al., 2011; Baskin and Baskin, 2014).

There is a defined range of maximum and minimum temperatures form the boundaries of observable growth for each species. Furthermore, Hatfield et al. (2008, 2011, 2015) found an index of cardinal temperature values for different annual crops of different species.

Successful crop establishment, which is crucial for reliable plant production, depends on seed quality, environmental factors and genotypes. A review of the literature confirmed that the differences in the responses of cereal seeds and seedlings to different temperatures were associated with their geographic origin.

Since germination speed is very important for about earliness in the plant growing it can differ according to species, soil structures, sowing methods and especially temperature and soil moisture ratios. Knowledge of seed germination response to environmental factors is required not only for understanding and predicting the ecological adaptation of the species but also for formulating effective strategies for restoration.

The effect of temperature can be modeled by thermal time and predict seed germination progress well but also to provide “a measure of physiological time” and yield coefficients (Bradford 2002).

The purpose of this study was to quantify the germination temperatures of five winter cereals (*Triticum durum, Triticumaestivum, Hordeum vulgare, Avena sativa, Secalecereale*) in a range of temperatures and the use of two ingredients as vegetation accelerators.

Material & Methods

This research was carried out in the laboratory of Agronomy and Applied Crop physiology in the University of Thessaly The study was performed in a growth chamber adjusted to 5 different temperatures (22, 17, 12, 7, 5°C) for five winter cereals (*Triticum durum, Triricum aestivum, Avena sativa, Hordeum vulgare,* and *Secale cereale*). In each species there were three treatments (blank, Vitanica RZ, Nutriseed) which were repeated four times for each temperature value, where 200 seeds were placed in different separate containers. The used ingredients are commercial preparations containing phytocomones, amino acids, vitamins, algal extract of *Ecklonia maxima* and of course nitrogen, potassium, while the pH is about 3.5. The measurements were taken at a-day intervals for the increased temperatures and at a three-day interval for the low temperatures. A seed was deemed to have germinated when at least 1 mm of radicle was visible. The number of germinants was measured at frequent and regular intervals by the rate of germination. The maximum germination percentage for each temperature treatment was calculated as the average of the four replicates. The rate of germination was taken as the reciprocal of the time at which 50% of this maximum germinant number was reached.

Results and Discussion

As shown in Figure 1, the germination of five winter cereals (*Triticum durum, Triticumaestivum, Hordeum vulgare, Avena sativa, Secalecereale)* at 22^{o}C varied at different levels. The wheat presented top germination as from the 2nd day showed rapid germination of seeds (about 90% for Vitanica Rz and, 95% for Nutriseed vs 20% for Blanc), and on day 8 reached the final percentage. All the other winter cereal seeds hierarchical followed: *Secale cereale* > *Hordeum vulgare* > *Triticum durum* > *Avena sativa* for the two vegetation accelerators. For the blank treatment followed: *Secale cereale, Triticum aestivum* > *Hordeum vulgare* > *Avena sativa* > *Triticum durum.*

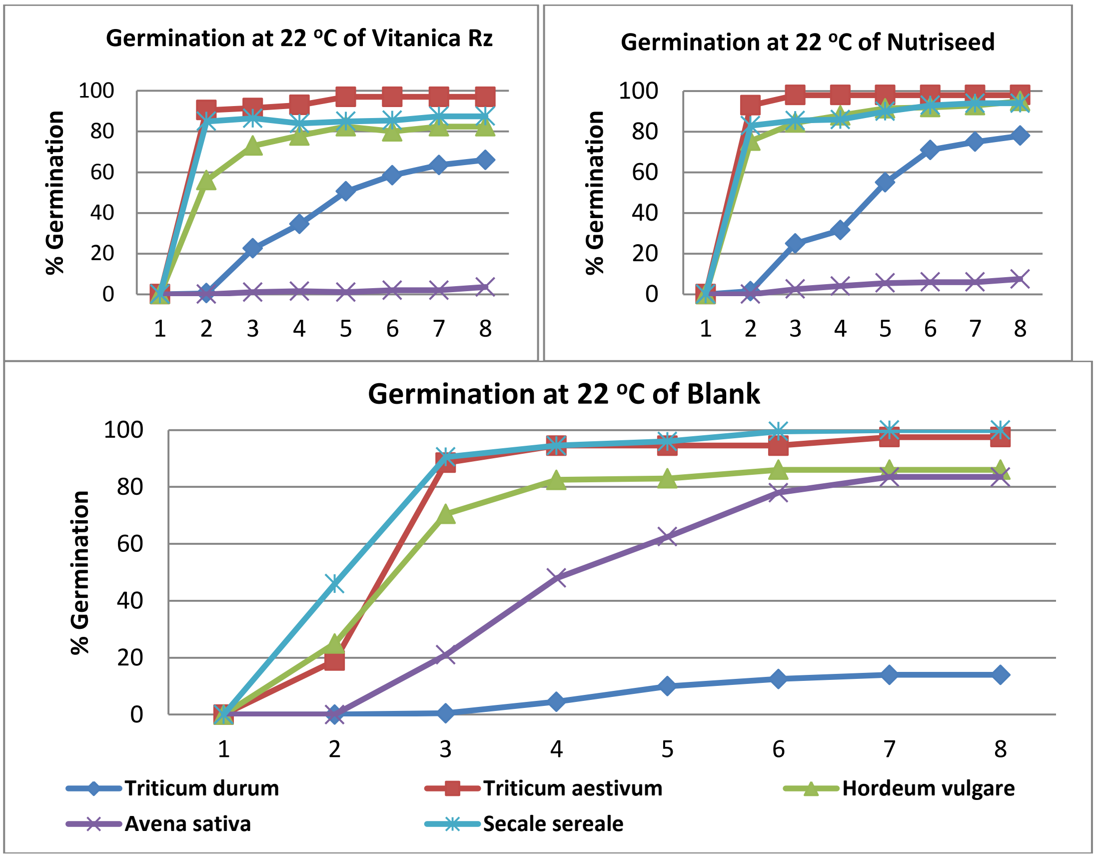

Figure 1. Seed germination percentage of five winter cereals (*Triticum durum*, *Triricumaestivum*, *Avena sativa*, *Hordeum vulgare*, and*Secalecereale*) at 22^{o}C under three different treatments.

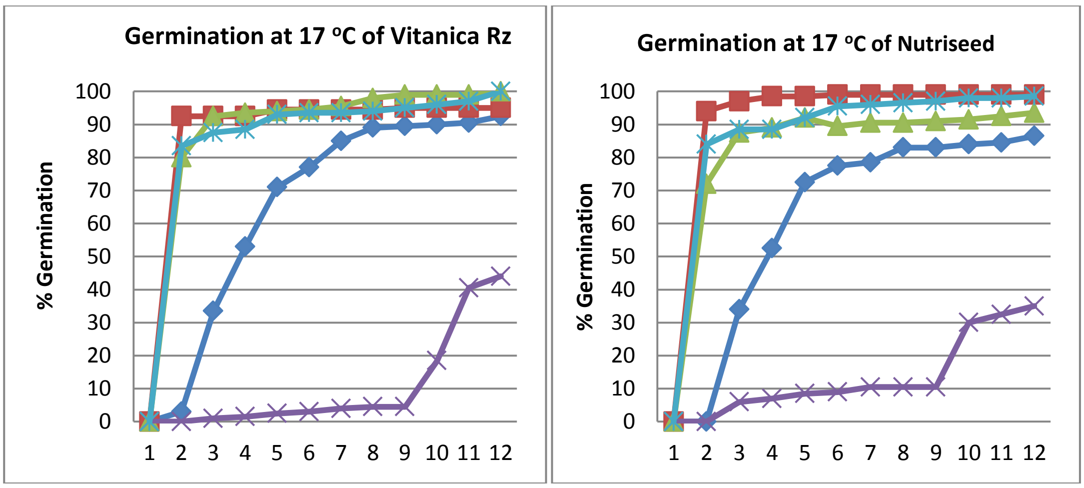
Decreasing the temperature by 5 degrees of Celcium (up to 17^{o}C), the germination of the below five winter cereals (Figure 2) varied at different levels. Secale cereale presented top germination as from the 2nd day increased the germination percentage up to 82-90%, for all treatments while Avena sativa showed better germination as far as the blanc treatment is concerned (on the 12th day reached the final percentage 90%).



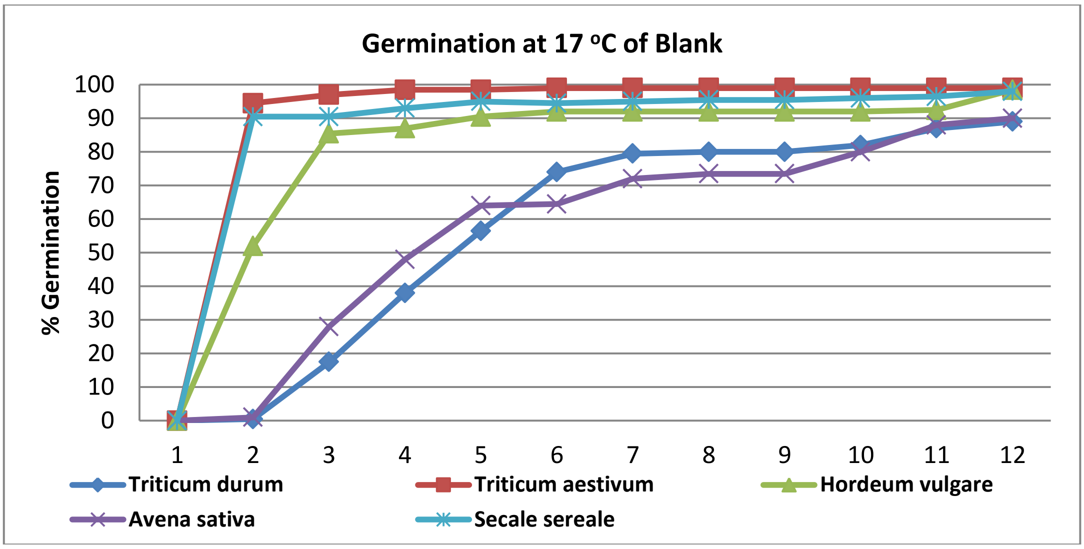


Figure 2. Seed germination percentage of five winter cereals (*Triticum durum*, *Triricumaestivum*, *Avena sativa*, *Hordeum vulgare*, and*Secalecereale*) at 17^{o}C under three different treatments.

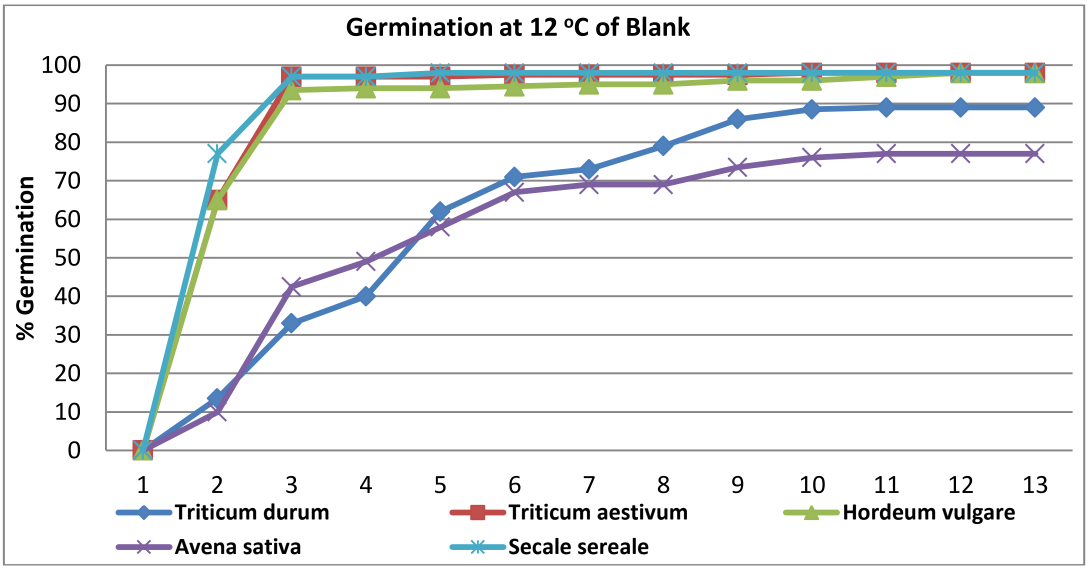
As shown in Figure 3, the placement of seeds at a temperature of 12 ^{o}C showed similar results for all the treatments. The only difference is the *Avena sativa* which doubled the germination rate at the blanc treatment vs germination accelarators treatments. Vitanica Rz excelled against Nutriseed in the case of Avena sativa and Triticum durum up to 10th day. Triticum durum germination at the 9th day was about 90 % while in case of Nutriseed reached the top of 98%.



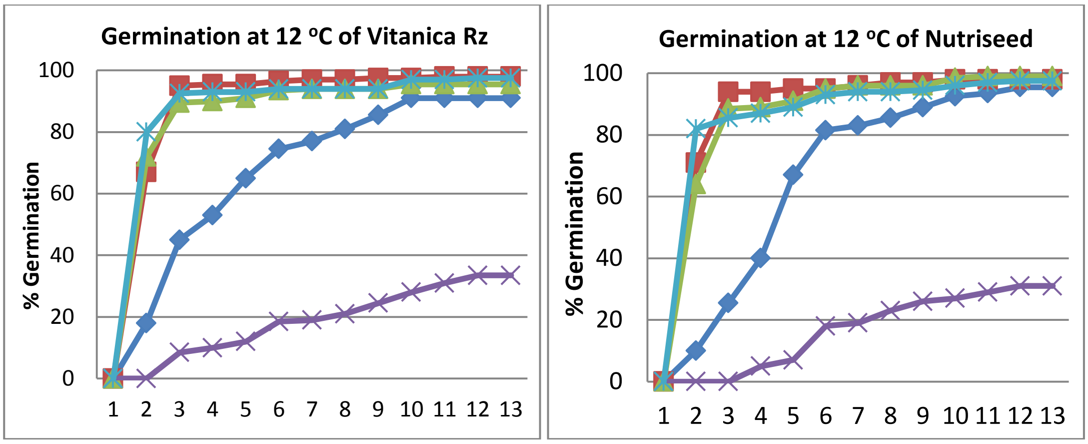


Figure 3. Seed germination percentage of five winter cereals (*Triticum durum*, *Triricum aestivum*, *Avena sativa*, *Hordeum vulgare*, and *Secale cereale*) at 12^{o}C under three different treatments.

Furthermore, decreasing the temperature more, 7^{o}C as shown in Figure 4 the germination rate slowed down for all the species and all the treatments. Specifically, all winter cereal seeds reached the maximum germination (60-100% of germination) on the 10th day. In this case, the hierarchy that was noticedis: *Secale cereale*, *Triticum aestivum* > *Hordeum vulgare* > *Triticum durum* >*Avena sativa* . *Avena sativa* showed better performance in the Nutriseed treatment.

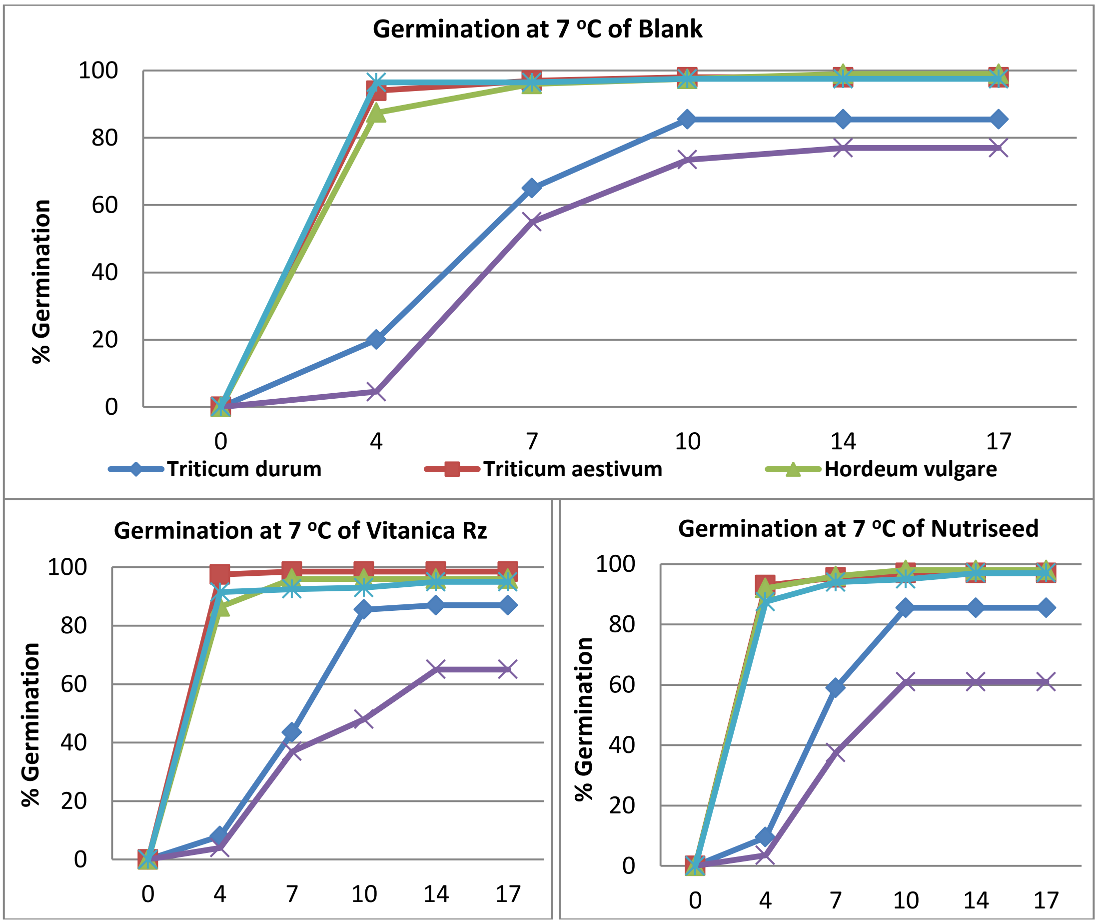

Figure 4. Seed germination percentage of five winter cereals (*Triticum durum*, *Triricum aestivum*, *Avena sativa*, *Hordeum vulgare*, and *Secale cereale*) at 7^{o}C under three different treatments.

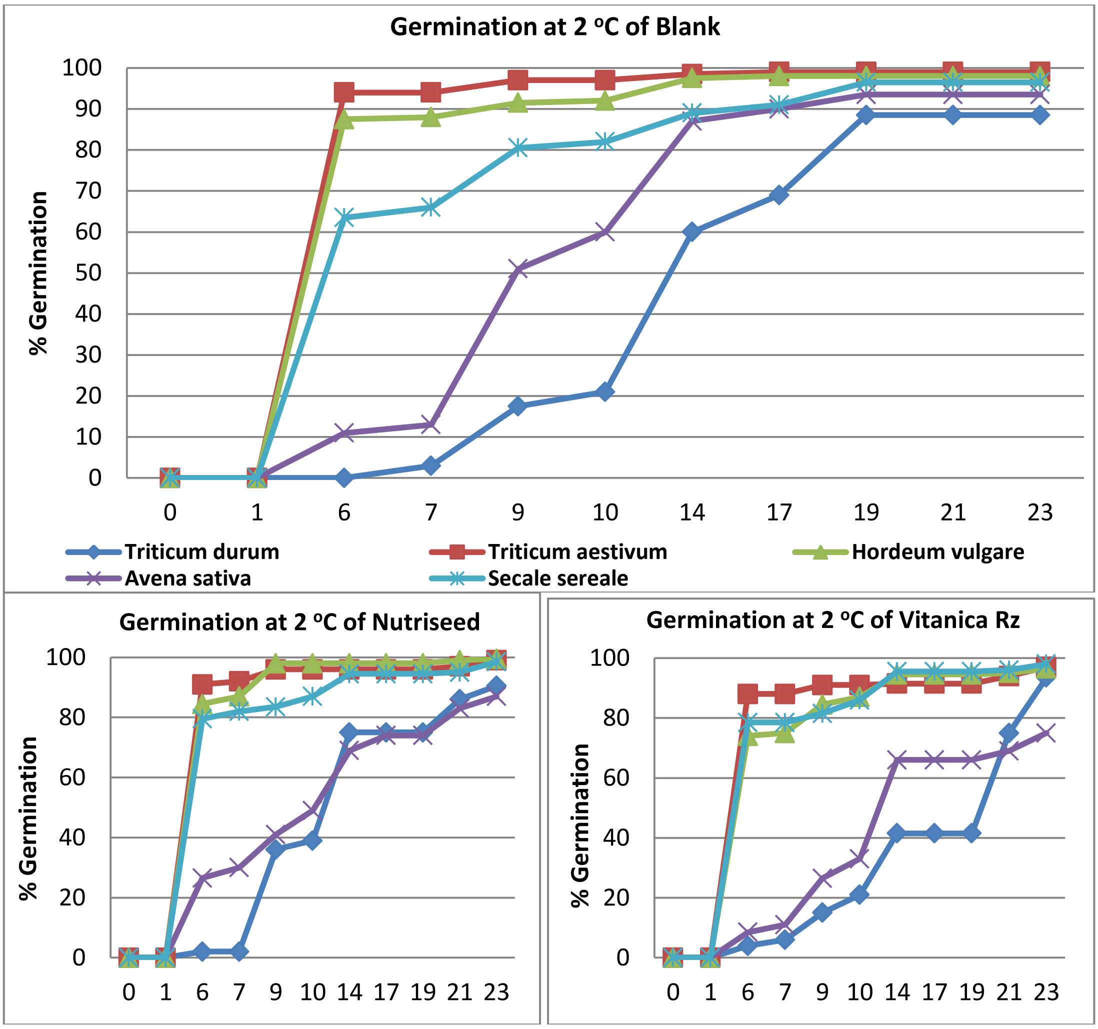

Figure 5. Seed germination percentage of five winter cereals (*Triticum durum*, *Triricum aestivum*, *Avena sativa*, *Hordeum vulgare*, and *Secale cereale*) at 2^{o}C under three different treatments.

Finally, decreasing the temperature 5 ^{o}C further (2 ^{o}C) the germination time increased to 23 days. In this temperature, Nutriseed treatment showed better presentation than the two other treatments. *Triricumaestivum*, *Hordeum vulgare*, *Secale cereale* reached the 100% of germination (9 to 14 day) while *Avena sativa* and *Triticum durum* reached the 90% (23 day).
In each temperature was noticed that *Triricum aestivum* reached the maximum germination while *Avena sativa* the minimum. Moreover, only in the case of 17^{o}C *Avena sativa* was able to reach the final germination percentage of 95%.

Conclusions

Triricum aestivum is the most vigorous seed at tested temperatures (2, 7 12, 17, 22^{o}C) of the five winter cereals. On the other hand, *Avena sativa* was found to have less seed germination percentage, and only at temperature of 17^{o}C reached 90% germination (blank treatment).
In the case of *Avena sativa* an important postpone germination appeared in the vegetative accelerator treatments in relation to the blank treatment, at the temperatures 7 up to 22 ^{o}C.
Additionally, in the case of 2, 7, 12, 17, 22^{o}C the germination period was 14, 14, 10, 10, 8 days for all the winter cereals, respectively. According to the above results, it is concluded that the temperatures of 12-22^{o}C represent the optimum seed germination, in a period of 8-10

days for *Triricum aestivum, Avena sativa, Hordeum vulgare,* and *Secale cereal,* regardless of the different treatments.

As a general conclusion, Vitanica RZ and Nutriseed may satisfactory helped *Triticum durum* to present better germination rate at 22^{o}C.

In the case of the other seeds, vegetative accelerators did not show significant superiority.

Finaly, all the five winter cereals could be proposed as cultivation in Greece.

Abstract

Wheat and barley are the most common cereals which are the most widely grown of all crops, and they consists those cereals with the highest economical interest. Plant breeders produced many varieties to increase the grain yield, to reduce the plant's sensitivity and the final quality. Moreover, many chemical substances are sold stating that they can increase the final yield and the seed quality and more specifically the protein content. For the purposes of this study the effect of different fertilization scenarios was investigated on the growth and final yield of wheat and barley, grown on a fertile clay loamy soil at Velestino (Thessaly plain; central Greece) in 2016-17. It was demonstrated that both crops at the *treatment 1* (with microgranular easy start 11-48-0, 20 kg ha^{-1}) obtained quicker germination and reached numerically superiority on biomass during the early growing stages. This quicker germination of the above cereals may be helpful for farmers who live in rather cool micro-environments, and their sowing in the fall may be postponed for some weeks without substantial germination risk. In both cases *Triticum durum* and *Hordeum vulgare* there were found significant differences for the harvested grain yield for the fertilized practices with the *treatment 1* produced higher yields.

Keywords: *Wheat, barley, yield, biomass, Greece.*

Introduction

Levelling-off or reduced rates of improvement in cereal crop yields are common features of agriculture worldwide (Bell et al., 1995; Calderini and Slafer, 1998; Slafer and Peltonen-Sainio, 2001).

There are two major contributors to changes in yield trends: genetic improvements and changes to crop management practices. Developments in both depend on growing conditions. Challenges arising from the environment are emphasized at the edge of the agricultural production area.

The Mediterranean agricultural region comprises the lands surrounding the Mediterranean Sea: the southern strip of Europe, northern lands of Africa and west Asia. This region is characterized by relatively cold and wet winters, dry and hot spring-summers (Aschmann, 1973) while the soils have typically low fertility (Ryan et al., 2009). Rainfall seasonality restricts agriculture to winter-spring crops and the amount and variation of rainfall drives relatively low and highly variable yield.

Drought and heat stress, particularly during flowering and grain filling, are the main climatic characteristics of the Mediterranean region (Loss and Siddique, 1994; Acevedo et al., 1999). The term "terminal stress" has been used to characterize these environments, hence the emphasis on agronomic practices and crop traits to balance water use, before and after anthesis to reduce the likelihood of extreme water deficit during grain filling (Fischer, 1979; Mitchell et al., 1996; van Herwaarden et al., 1998b; Leport et al., 1999; Sadras, 2002; Palta et al., 2004).

From a physiological point of view, the strong correlation between cereal yield and grain number and the modest contribution of grain size to yield variation in European Mediterranean environments, highlights the importance of growing conditions between stem elongation and few days after flowering, when grain number is determined. Management and environmental conditions that favor growth during this period have a direct impact on grain number and yield.

Fertilization and liming are critical management practices for wheat production. A properly managed fertility program, including recommended fertilization and liming practices, can improve yield and quality more than any other single management practice. Such a program includes soil testing, knowledge of crop nutrient requirements and removal, timely application of nutrients, and record-keeping.

Nitrogen rates and timing of application are key management factors for making good wheat yields. Nitrogen is also the most expensive fertilizer nutrient and variable input cost for wheat. Therefore, nitrogen rates should be based on soil potential, cultivar, realistic yield goal, previous crop and residual N.

Seasonal rainfall is therefore the main source of water as well as a key driver of yield (Keatinge et al., 1986; Garabet et al., 1998). Water stress has thus been considered the dominant yield-limiting factor in these environments (Loss and Siddique 1994; Bennet et al., 1998; Acevedo et al., 1999). Water availability, however, only accounts for part of the variation in yield in these environments, typically about one-third (French and Schultz, 1984a,b; Sadras and Angus, 2006).

This study was conducted in the main agricultural plain (Thessaly) to evaluate the effect of different fertilization practices in the performance of the main winter cereal crops (*Triticum durum* and *Hordeum vulgare*) cultivated in Greece.

Materials and methods

For the purposes of the study, field experiments were established in East Thessaly (Velestino, Volos). The selected crops were Triticum durum and Hordeum vulgare, in order to assess the effect of different fertilization scenarios in their performance, which are the most prevalent winter cereals in Greece.

Soil characteristics. Velestino soil is characterized as Calcixerollic Xerochrept according to USDA classification (1975). It is a clay loam (sand 19-21%; clay 39-41%, silt 38-42%) calcareous (pH = 8.1-8.3) rich in organic matter (2.3-2.7% in soil profile of 40cm).

Field management and experimental design. The selected varieties were “Meridiano” in case of Triticum durum and “Grace” in case of Hordeum vulgare. Sowing was occurred using a modern seeding machine applying 200 kg ha-1 seeds at the first ten days period of November 2016. There was performed pre- and post-emergence herbicide application, to control weeds. Basic fertilization applied one-two days before sowing using a dispenser and then the fertilizer was incorporates using a rotary cultivator.

Triticum durum. The experimental design of Triticum durum was a completely randomized design with four fertilization treatments and four replications (blocks). Specifically, *Treatment 1:* basic fertilization (200 kg ha-1 of Novatec 22-8-10, with nitrification inhibitor and 20 kg ha-1of microgranular easy start B.S. 11-48-0), nitrogen fertilization (200 kg ha-1 of Novatec 40-0-0, with nitrification inhibitor), foliar fertilization (Basfoliar 36-0-0: 3 l ha-1 and Basfoliar Triple Flo: 0.75 l ha-1 with micronutrients Zn, Cu, Mn).

Treatment 2: seed coat with Nutriseed (0.3 l ha-1) basic fertilization (200 kg ha-1 of Novatec 22-8-10 with nitrification inhibitor), nitrogen fertilization (200 kg ha-1 of Novatec 40-0-0 with nitrification inhibitor), and foliar fertilization (Basfoliar 36-0-0: 3 l ha-1 and Basfoliar Triple Flo: 1.5 l ha-1 with micronutrients Zn, Cu, Mn).
Treatment 3: Common cultivation practice used in Greece with basic fertilization (250 kg ha-1 of 20-10-10), and surface fertilization (300 kg ha-1 of 34.5-0-0).
Treatment 4: Zero fertilization (Control).
Hordeum vulgare. The experimental design of Hordeum vulgare was a completely randomized design with four fertilization treatments and four replications (blocks). Specifically,
Treatment 1: basic fertilization (150 kg ha-1 of Novatec 22-8-10 with nitrification inhibitor and 20 kg ha-1of microgranular easy start B.S. 11-48-0), nitrogen fertilization (150 kg ha-1 of Novatec 40-0-0), foliar fertilization (Basfoliar 36-0-0: 5 l ha-1 and Basfoliar Triple Flo: 0.75 l ha-1).
Treatment 2: seed coat with Vitanica RZ (0.24l ha-1) basic fertilization (150 kg ha-1 of Novatec 22-8-10 with nitrification inhibitor), nitrogen fertilization (150 kg ha-1of Novatec 40-0-0 with nitrification inhibitor), foliar fertilization (Basfoliar 36-0-0: 3 l ha-1 and Basfoliar Triple Flo: 0.755 l ha-1 with micronutrients Zn, Cu, Mn).
Treatment 3: Common cultivation practice used in Greece with basic (200 kg ha-1 of 20-10-10), and surface fertilization (250 kg ha-1 of 34.5-0-0).
Treatment 4: Zero fertilization (Control).
Measurements. Fresh and dry biomass was monitored by means of samplings (3 samplings per experiment through crop life cycle till the final harvest; analytically according to Zadocks scale: 1st sampling at tillering 21-29, 2nd sampling at anthesis-flowering 61-69 and 3rd sampling at ripening stage 91-99). To avoid any border effect, 1 m2 in the inner plot was harvested in each sampling above the ground. The samples were weighed fresh and then a sub-sample was taken for further laboratory measurements. The plants of each sub-sample were oven-dried at 65 ˚C until constant weight (3-4 days) and weighed again to determine the final dry weights.
The statistical package GenStat (7th Edition) was used for the analysis of variance (ANOVA) within sample timings for all measured and derived data. The LSD0.05 was used as the test criterion for assessing differences between means (Steel and Torrie, 1982).
Meteorological data. Meteorological data were recorded in Velestino from the established meteorological station of University of Thessaly.

Results and Discussion

Meteorological data. In Figure 1 is illustrated the average temperature and precipitation during crop growth. Decreased air temperatures for the season were prevailed during sowing but also through the whole crop life cycle. Precipitation was almost the same but the real problem occurred in few days. Almost zero precipitation and low air temperature in early November resulted a postponed germination but hopefully without problems in terms of the final population plants and the successful establishment of crops. Both in late April and early May unsatisfactory rainfall occurred, so it was expected a decreased final yield which did not allow better exploitation of fertilization.

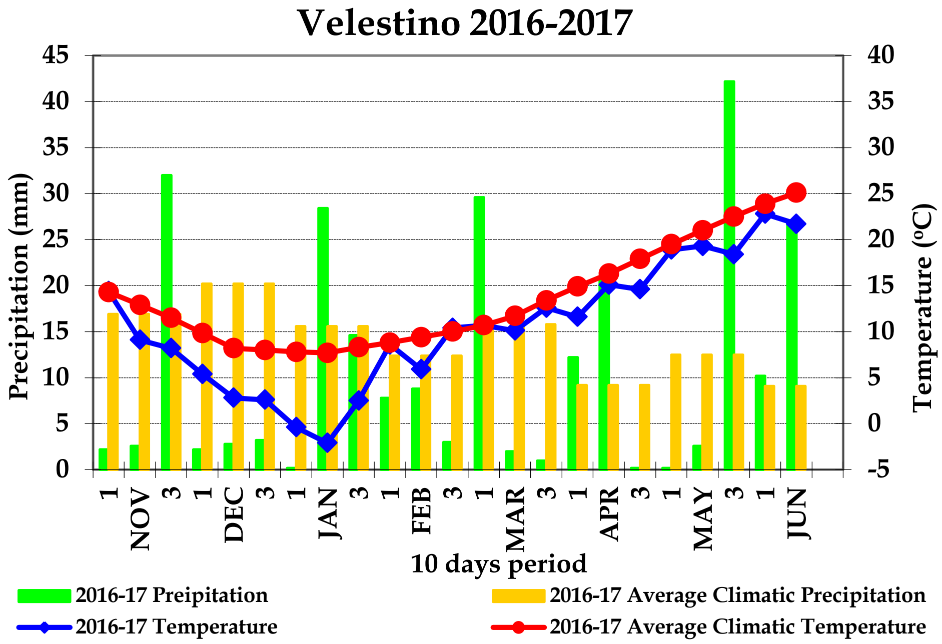

Figure 1. Average air temperature and precipitation (●, ■) for ten days period at Velestino in 2016-2017, and the average climatic conditions of the region during the last 50 years (●, ■).

Yield and growth characteristics

Triticum durum**.** The results have shown none statistical significant differences between the tested fertilization practices except of grain yield (Table 1) which is the product of economic value.

There were not noticed statistically significant differences for the fresh and the dry weight of durum wheat during the first samplings on 17-3-2017 (Zadocks scale: tillering 21-29) and 7-5-2017 (Zadocks scale: anthesis-flowering 61-69), but in all cases demonstrated numerically superiority of the 1st and 2nd fertilization scenarios.

Only during the final growing stage was clearly shown on field that plants of the fertilized treatments had bigger grains (data not shown). This observation was confirmed at the final harvest (Table 1) were the fertilized treatments had statistically significant differences in comparison with the control treatment while the treatment 1 produced higher yields.

Table 1. Fresh, dry biomass and grain yield of *Triticum durum* under fertilization practices and fertilizer combinations.

Factor \ Characteristic		Fresh Biomass 17-3-2017 (kg ha^{-1})	Dry Biomass 17-3-2017 (kg ha^{-1})	Fresh Biomass 7-5-2017 (kg ha^{-1})	Dry Biomass 7-5-2017 (kg ha^{-1})	Grain Yield (kg ha^{-1})

ns: non-significant

Hordeum vulgare. The same results were also noticed in case of barley. Specifically, it was observed that there were not statistical significant differences between the tested fertilization practices except the grain yield at the final harvest (Table 2).

There were not noticed statistically significant differences for the fresh and the dry weight of barley during the first samplings on 17-3-2017 and 7-5-2017. Also in all cases demonstrated numerically superiority of the 1st and 2nd fertilization scenarios.

During the final growing stage (Zadocks scale: ripening stage 91-99) was clearly shown on field that plants of the fertilized treatments had bigger grains (data not shown). This observation was confirmed at the final harvest (Table 2) were the fertilized treatments had statistically significant differences in comparison with the control treatment while the treatment 1 produced higher yields.

Table 2. Fresh, dry biomass and grain yield of *Hordeum vulgare* under fertilization practices and fertilizer combinations.

CV (%)	38.8	26.6	14.2	10.9	10.7

ns: non-significant

Conclusions

In both crops, *Triticum durum* and *Hordeum vulgare,* there were found significant differences for the harvested grain yield for the fertilized practices with the *treatment-1* be the quantifiable one. Due to the fact that the above results were found through the first year of experimentation, safer conclusions expected to arise after the repetition of the experiments in the same place for a second and a third year. In case that the results of the third year will confirm the previous results then fertilization practice of the treatment-1 should be proposed in future fertilization schemes.

Abstract

In the present study, the effect of nutrient solution composition on plant growth and quality of *Cichorium spinosum* L. was examined. Five fertilizer treatments were applied through irrigation water differing in the nitrate: ammonium nitrogen ratio of total nitrogen, namely (1) 100:0, (2) 75:25, (3) 50:50, (4) 25:75, 5) 0:100 NO_3:NH_4, while an extra treatment (6) with total nitrogen only in urea form was applied. All the treatments received the same amount of fertilizer units (20-20-20 mg L^{-1} of N, P and K, respectively). Plants were grown in 2 L pots containing peat (Klassman-Deilmann KTS2) and harvested three times during the growing period, and when they reached marketable size. At each harvest day, plant development was assessed (number, fresh and dry weight of leaves, and rosette diameter). The results suggest that nitrogen form has a significant effect on plant growth and yield of *C. spinosum* plants. In particular, fresh weight and number of leaves, and rosette diameter were significantly increased when ratio of nitrate: ammonium nitrogen was 75:25 or 0:100, especially in the 1st harvest, while in the 3rd harvest treatment 100:0 showed the best results. However, this did not affect total fresh weight and number of leaves which were higher for treatments 100:0 and 75:25, respectively. Therefore, higher ammonium nitrogen rates seem to be beneficial for plant development only during the early stages, while at later growth stages nitrate nitrogen has better results. In any case, ureic nitrogen is not suggested since it has severe effects on plant development, probably due to toxicity issues.

Keywords: *Ammonium nitrogen, Cichorium spinosum L., nitrate nitrogen, stamnagathi, urea*

Introduction

Cichorium spinosum L. is a wild edible chicory, which is self-grown in Crete and other regions of island and mainland of Greece. Rich in vitamins, minerals, fatty acids and antioxidants, with a distinct bitter flavor, it is also very popular abroad. Given the fact that it grows nearby coastal areas which suffer from high salinity, it is a well-adapted species under adverse conditions with considerably low cultivation needs (Chatzoulakis and Klapaki, 2006). As a fresh product, it has important nutritional value and achieves very high prices in the retail market. Therefore, it would be beneficial to study its cultivation for commercial purposes (Meliou at al., 2003; Zeghichi et al., 2003; Simopoulos, 2004).
Modern agricultural practices have rendered the application of fertilizers necessary for higher yields and better quality of final products. Nitrogen has a fundamental role in biosynthesis of acids, proteins, enzymes and chlorophyll of plants, rendering it an essential macronutrient (Barker et al., 1974). However, despite the positive effect of nitrogen fertilizers on yield and

quality, they can be toxic if supplied in irrational rates, especially in leafy vegetables which tend to accumulate nitrates with severe effects on human health (Hord et al., 2009). Moreover, apart from the overall nitrogen application rate, nitrogen form may affect the quality of the final product, especially phytonutrients content such as organic and fatty acids (Fontana et al., 2006; Szalai et al., 2010).

Although during the last few years farmers in many Mediterranean countries have started to commercially cultivate the species, scarce literature is available the nutrient requirements and the effect of fertilizers rates on yield. Therefore, the aim of the present study was to evaluate the effect of various ammonium and nitrate nitrogen rates on growth and development of *Cichorium spinosum* plants.

Materials and Methods

Plants were grown from seeds as previously described by Anesti et al. (2017). *Cichorium spinosum* L. seedlings were obtained from Vianame S.A. (Crete, Greece) at the stage of 3-4 leaves. Seeds were put in seed trays containing peat on 27/09/2016. Transplantation was carried out on 14/02/2016 and young seedlings were put in 2 L pots containing peat (Klassman-Deilmann KTS2). After transplantation, six fertilizer treatments were applied, namely (1) 100:0, (2) 75:25, (3) 50:50, (4) 25:75, 5) 0:100 NO_3:NH_4, while an extra treatment (6) with total nitrogen only in urea form was applied. One seedling was put in each pot, while each treatment consisted of 20 pots. Nutrient solution composition of each treatment is presented in Table 1. The various solutions were prepared by using appropriate amounts of the following fertilizers: a) ammonium nitrate (34.5% total nitrogen, with a ratio of 1:1 for NO_3-N: NH_4-N), b) potassium nitrate (13.5% of nitrate nitrogen and 46% of K_2O, c) magnesium nitrate (11% of nitrate nitrogen and 15% of MgO), d) monopotassium phosphate (52% of P_2O_5 and 34% of K_2O), e) ammonium sulphate (21% of ammonium nitrogen and 24% of 24 of SO_3), f) mono-ammonium phosphate (12% of ammonium nitrogen and 61% of P_2O_5), and g) urea (46% of ureic nitrogen).

Table 1. Nutrient solution composition for each treatment (mg L^{-1}).

	Treatments (NO_3^-:NH_4^+)					
Fertilizer type	100:0	75:25	50:50	25:75	0:100	Urea
Total nitrogen	200	200	200	200	200	200

Mg	178.3	136.3	0	0	0	0
S	0	0	0	136.4	252.8	24.0

Harvests was carried out on 22/03, 06/04 and 25/04/2016 for the 1st, 2nd and 3rd harvest, respectively. On each day of harvest, rosette diameter, number of leaves, fresh and dry weight were measured. For dry weight evaluation, samples of fresh leaves were oven dried at 72 °C to a constant weight (approximately for 48 hours). Water content was estimated as % percentage by subtracting dry weight from the initial fresh weight.

Experimental design was laid out according to Completely Randomised Design (n=20). Statistical analysis was conducted with the aid of JMP v 4.0.2 (SAS Institute Inc.) and Statgraphics 5.1.plus (Statistical Graphics Corporation). Data were evaluated by analysis of variance (ANOVA), whereas the means of values were compared by Tukey's HSD Test with $\alpha = 0.05$.

Results and Discussion

According to the results of Table 2, the ammonium fertilizer affects the growth and the quality of *Cichorium spinosum*. More specific, in the 1st harvest fresh weight was higher in treatment 0:100, followed by treatment 75:25, whereas the treatment with ureic nitrogen had negative effect on yield. In contrast, Szalai et al. (2010) have reported a negative effect of high ammonium nitrate concentration in nutrient solution on fresh weight of purslane plants, which could be due to the shorter growth cycle of purslane comparing to *C. spinosum* plants that does not allow nitrification of ammonium nitrate to take place. Moreover, according to Marschner (1995) and Britto and Kronzucker (2002), the negative effects of ammonium nitrogen have been associated with changes of pH of growth medium and the toxicity of free NH_4^+. Considering that in our study no negative effects of ammonium nitrogen were observed in the early growth stages (1st harvest), it could indicate a cumulative effect of NH_4^+ on growth media which is being established only at late growth stages and after the application of significant amounts of nutrient solution. In a previous study of Anesti et al. (2016), it has been suggested that high ammonium nitrogen rates (up to approximately 50% of total nitrogen) have a beneficial effect only when multiple harvest are applied which could also indicate the negative effect of accumulation of NH_4^+ in tissues of plants where no successive harvests are applied.

In the following harvests and especially for the 3rd harvest and for total fresh weight (Tables 3 to 5), the highest content of nitrates (100:0) in nutrient solution resulted in higher fresh weight. Ge (2002) and Wang et al. (2005) have also reported that high nitrate: ammonium nitrogen ratios resulted in higher plant yield of spinach, while Ulrich et al. (2017) have also suggested the beneficial effect of nitrates on fresh weight of lettuce plants. In the study of Ulrić et al (2017), it is also reported that high nitrate nitrogen rates increased leaf length and number of leaves, which also observed in the present study. This could be attributed to the fact that nitrogen in nitrate form is more easily available to plants than ammonium nitrogen and urea, as well as to the cumulative toxicity effects of ammonium nitrogen. This is more apparent after the first and second harvest where the temperature increase induces biosynthesis, therefore resulting in a significantly higher total fresh weight. Similar trends with fresh weight were observed for the number of leaves and rosette diameter in the 1st and 3rd harvest, with nutrient solution containing 100% of nitrate nitrogen having the better results, except for total number of leaves which was higher for treatment 75:25 (Table 2 and 4). However, this did not affect total fresh weight yield which was higher for treatment 100:0, as already mentioned. Dry weight did not show specific trends between the various treatments and harvests (Tables 2 to 5). In contrast, Wang et al. (2009) have reported an increase of dry weight in spinach leaves when ammonium nitrogen content increased.

In addition, the treatment where nitrogen applied in the form of ureic nitrogen had detrimental effects on plant development, probably due to toxicity effects which affected negatively all the measured parameters, except for dry weight of leaves.

Table 5**.** The effect of nitrate: ammonium nitrogen rates on total fresh weight and number of leaves of *Cichorium spinosum*.

Treatment (NO_3^-:NH_4^+)	Total fresh weight (g)	Total number of leaves
100:0	45.8 a	40.5 b
75:25	42.2 b	43.0 a
50:50	36.7 c	38.0
25:75	41.1 b	34.6 c
0:100	41.8 b	40.1 b
Urea	33.7 d	29.9 d

* Means in columns followed by different letters without parenthesis, and means in columns followed by different letters in parenthesis are significantly different at $p<0.05$ by Tukey's HSD test.

Conclusions

The application of high nitrate rates (75:25 and 100:0 NO_3^-:NH_4^+) to *Cichorium spinosum* plants resulted in a significant increase of total fresh weight, mostly through the formation of more leaves. In addition, ammonium nitrogen (0:100) was beneficial only at the first harvest when plant requirements for nitrogen are lower comparing to the later stages when higher temperatures increase biosynthetic rates and therefore nitrogen uptake. Finally, ureic nitrogen had negative effect on fresh weight and total number of leaves, probably due to toxicity effects, therefore it cannot be proposed as a sole nitrogen source in nutrient solutions.

Abstract

Durum and bread wheat are two of the most important crops for global economy. However, their productivity is limited by drought, which is nowadays the main abiotic stressing factor. In order to study the effect of drought stress eight durum wheat (Anna, Sifnos, Mavragani, Elpida, Mexicali, Papadakis, Thraki, and Athos) and seven bread wheat cultivars (Acheron, Orfeas, Apollonia, Acheloos, Doirani, Nestos and Strymonas) were evaluated at three levels of drought treatment in completely randomized design with four replications. Mature embryos of the aforementioned genotypes, were cultured in modified MS solid medium with two different concentrations of polyethylene glycol (5 and 10% PEG 8000), whereas a same medium but without PEG was used as control. The response of the genotypes was measured as embryo germination and callus production. Cultivar Acheron, which carries the 1BL.1RS wheat rye translocation, was the only one not affected by the presence of PEG. The drought treatment reduced the proportion of embryo germination in all other cultivars. This reduction was smaller in bread wheat Acheloos and Apollonia and in durum wheat in cultivars Thraki and Anna, whereas in two durum wheat cultivars (Papadakis and Mexicali) no germination was recorded in the presence of PEG. Regarding the second trait studied, the callus production was not affected by the presence of PEG. Surviving of the germinated plants cultured on the same medium with the presence of PEG decreased with increasing the osmotic stress. It was concluded that there are considerable differences in drought resistance between the genotypes studied.

Keywords: *wheat, drought resistance, embryo germination, callus production, translocation*

Introduction

Drought is a worldwide problem and a major proportion of agriculture land is affected with varying degrees of drought. Water deficit combined with extreme temperatures lead to drought which is the main abiotic stressing factor that limits the growth and productivity of the crops in the Mediterranean area. Furthermore durum and bread wheat, two of the most important crops for global economy are affected by drought, as regard to their productivity and quality (Singh and Chaudhary, 2006). In order to meet the needs of modern agriculture and in an attempt to face the prevailing drought conditions in the southern part of Europe, the creation and use of high-yielding varieties that are resistant to biotic and abiotic stresses and adapted to extreme environments is considered necessary (Acevedo and Fereres, 1994). Water stress acts by decreasing the percentage and rate of germination and seedling growth. Germination of seeds in the most critical phases of plant life is greatly influenced by draught and salinity (Misra and Dwivedi, 2004). Thus, the evaluation of the existing genetic material characterized by resistance to draught is the only approach that could decisively contribute to

the problem. Applying osmotic stress during the regeneration phase was found to be the most efficient for drought tolerance (Hsissou and Bouharmont, 1994). Polyethylene glycol (PEG) a draught induced chemical is frequently used to screen out draught tolerant varieties at early stage of seedlings under laboratory conditions. Previous studies revealed that PEG can be used to modify the osmotic potential of nutrient solution culture and thus induce plant water deficit in a relatively controlled manner (Zhu *et al.*, 1997). Polyethylene glycol of high molecular weights have been used to simulate drought stress in plants as non penetrating osmotic agents lowering the water potential in a way similar to soil drying. Application of polyethylene glycol or mannitol as osmotic stressing agent is an efficient and simple enough method to be used for rapid evaluation of drought tolerance in a large number of genotypes (Hassanein, 2010). Soliman and Hendawy (2013) reported that PEG 8000 can be used as water stress creating agent under *in vitro* conditions for durum wheat genotypes.
This study was undertaken to evaluate in vitro the drought resistance of sixteen Greek bread and durum wheat cultivars under drought stress conditions using polyethylene glycol 8000.

Materials and methods

For the purpose of the study seeds of eight durum wheat (Anna, Sifnos, Mavragani, Elpida, Mexicali, Papadakis, Thraki, and Athos) and seven bread wheat cultivars (Acheron, Orfeas, Apollonia, Acheloos, Doirani, Nestos and Strymonas) developed at the Cereal Institute of Thessaloniki (Cereal Institute 1985) were used. The effect of drought stress was measured *in vitro* at different osmotic potential levels. Mature embryos of the aforementioned genotypes, were cultured onto a MS solid medium supplemented with thiamine 0.5mg/l, glutamine 150mg/l, 2.4D 1.5mg/l, NAA 0.5mg/l and two different concentrations of polyethylene glycol (5 and 10% PEG 8000), whereas mature embryos were incubated on the same medium without PEG to serve as control. Before the incubation in the medium the seeds of all cultivars were placed in petri dishes on wet filter paper for five hours. (Kondic and Sesek, 1998). Then the seeds were surface sterilized with 90% ethanol for 1 minute and then with 70% solution of commercial bleach and consequently washed with distilled water for three times. After four weeks the number of germinated embryos was measured, and the proportion of germinated embryos in three different concentrations of PEG was compared. The germinated plants were cultured in the same medium supplemented with 5% and 10% PEG respectively. Survival and the callus production were measured. The response of the genotypes and the resistance to drought was measured as embryo germination and callus production. Statistical analysis was performed using chi-square two-way table format and proportion comparisons were performed by the z means test.

Results and Discussion

The presence of PEG affected the embryo germination in all bread and durum wheat cultivars studied except the bread wheat cultivar Acheron (tab. 1, fig. 1). The proportion of germination ranged from 2.5 % in cultivar Apollonia to 32.5 in cultivar Anna in the control treatment, whereas it ranged from 0 (cultivars Papadakis and Mexicali) to 20 (cultivar Acheron) and from 0 (cultivars Papadakis and Mexicali) to 23.4 (cultivar Acheron) in 5% and 10% concentration of PEG, respectively. Thus the drought treatment reduced the proportion of embryo germination in all cultivars except the bread wheat cultivar Acheron. This reduction was smaller in bread wheat cultivars Acheloos and Apollonia and in durum wheat in cultivars Thraki and Anna, whereas in three bread wheat cultivars (Doirani, Orfeas and Strymonas) and one durum wheat cultivar Athos no germination was recorded in the higher concentration of PEG (10%) and in two durum wheat cultivars (Papadakis and Mexicali) no germination was recorded in the presence of PEG (5% or 10% concentration) (tab. 1, fig. 1, fig. 2). This reduction is statistically significant, except in the durum wheat cultivar Thraki. In this cultivar even though the proportion of germination is very low seems to be not affected by the presence of PEG. Additionally the bread wheat cultivar Acheloos and the durum wheat cultivars Anna and Elpida exhibited a quite high proportion of germination in the presence of PEG, so they showed tolerance under the drought stress conditions.

The presence of PEG was lethal to the isolated embryos of durum wheat cultivars Papadakis and Mexicali and the highest concentration of PEG (10%) was lethal to the isolated embryos of cultivars Doirani, Orfeas, Strymonas, and Athos. The surviving ability of the wheat varieties was used earlier as a screening technique in order to characterize them as tolerant to draught or not (Khakwani *et al.,* 2011).

Table 1. The embryo germination (% of incubated seeds) of seven bread wheat and eight durum wheat cultivars in control and with 5% PEG and 10% PEG

Cultivar	Control	5% PEG	10% PEG
Acheron	22.2	20.0	23.4
Apollonia	2.5	1.1	1.5
Doirani	7.5	4.7	0.0
Nestos	15.3	1.7	2.7
Orfeas	1.5	1.9	0.0
Acheloos	17.2	6.0	8.7
Strymonas	3.8	1.2	0.0
Athos	10.4	3.6	0.0
Thraki	2.8	1.4	2.7
Mavragani	20.0	1.3	2.7
Papadakis	15.6	0.0	0.0
Sifnos	28.0	2.0	3.1
Elpida	57.1	6.0	18.2
Mexikali	3.7	0.0	0.0
Anna	32.5	5.0	22.2

The presence of the 1BL.1RS wheat-rye translocation in many modern bread wheat cultivars offers to the cultivars a number of important agronomic traits, i. e. high yield potential (Kim *et al*., 2004), broad adaptation, resistance to drought and biotic stress conditions and a sustainable wheat production (Lazaridou *et al.,* 2017). The bread wheat cultivar Acheron, which carries this translocation, was the only one not affected by the presence of PEG. (fig. 3a, 3b, fig. 4a, 4b). This may be an evidence that the aforementioned translocation really prevents plants with drought tolerance. Regarding the second trait studied, the callus production was not affected by the presence of PEG. Soliman and Hendawy (2013) studied the response to immature embryo culture, and the *in vitro* drought tolerance of six durum wheat genotypes. Their results showed that increasing PEG concentration in the medium callus growth parameters are gradually decreasing revealing a negative correlation between callus fresh weight and increase of the concentrations of PEG. However, this was in disagreement with the results of the present study.

Conclusions

There are considerable differences in drought resistance between the genotypes studied. The presence of PEG, or otherwise the drought stressing conditions reduced the embryo germination in all cultivars studied except in cultivar Acheron which is characterized as resistant to drought. Additionally the cultivars Acheloos (bread wheat), Anna and Elpida (durum wheat) were found to be more resistant to drought conditions compared to the other genotypes, whereas Mexikali, Papadakis, Doirani, Orfeas, Strymonas, and Athos were the most sensitive to drought stress conditions. The bread wheat cultivar Acheron, which carries the 1BL.1RS wheat rye translocation, was the only one not affected by the presence of PEG. The presence of the translocation in this cultivar seems to help its resistance to drought, but further research is needed to confirm it.

Abstract

Poor population in India amounts to more than 300 million people, with almost 30 percent of rural population living in poverty. An estimated 43 per cent of children under the age of five years are malnourished (WFP, 2012). Pulses, being rich and cheap source of protein can supplement the diet for poor and malnourished people. Pulse crops can be grown in almost all types of climate and comes to harvest by 3-6 months of duration, with a minimum amount of water requirement. Keeping these things in view this study has been designed to study the production techniques viz., integrated crop management including integrated pest, diseases, weeds and nutrient management in pulses and also the cost of cultivation in the north coastal regions of Southern India in five locations each. The yields under each traetment that is ICM practices Vs farmers practices and also the cost benefit ratios in each crop and each location were studied and their average means were compared for analysis. The results of the study in case of pigeon pea, Mung bean and Urd bean will also give further directions and help to develop the concrete strategies through the implementation of the interventions in a mission mode byactively engaging all stake holders at various levels for the increased and sustainable pulse production under the National food security Mission Programme being implemented by Government of India to keep India as a zero hunger country in forthcoming years with safe and secured nutrition.

Keywords: *India, Food security, Pulses, ICM practices,Zero hunger.*

Introduction

India's poor population amounts to more than 300 million people, with almost 30 percent of India's rural population living in poverty. Even though, the poverty has been on the decline in recent years, (rural poverty declined by 8 percentage points from 41.8% to 33.8% and urban poverty by 4.8 percentage points from 25.7% to 20.9%) (World Bank, 2012), the country is suffering from malnutrition and hungry population. An estimated 43 per cent of children under the age of five years are malnourished (WFP, 2012). Pulses, being rich and cheap source of protein can supplement the diet with more protein for poor and malnourished people. Pulses provide high quality protein complementing the cereal proteins for predominantly substantial vegetarian population of the country. Pulses also provide essential amino acids in adequate amounts and the food value will be increased manifold in terms of both economically and nutritionally. Pulses are also rich source of micro nutrients including Iron, which is of particular relevance in developing countries where every second pregnant woman and about 40%of preschool children are estimated to be anemic.

Pulses are mostly cultivated under rain fed conditions and do not require intensive irrigation facility and this is the reason why pulses are grown in areas left after satisfying the demand for cereal and cash crops. In addition to that pulses also improve soil fertility and physical structure, fit in mixed/inter-cropping system, crop rotations and dry farming and provide green pods for vegetable and nutritious fodder for cattle as well. Pulse crops can be grown in almost all types of climate and comes to harvest by 3-6 months of duration, with a minimum amount of water requirement. Various agronomic researches have shown that improved cultivation practices, such as seed replacement with improved varieties, raised bed planting method, use of bio fertilizers, foliar application of fertilizers at critical stages in rain fed areas, application of secondary and micro-nutrients and adoption of appropriate modules for integrated weed and pest management, etc. have great potential in gearing–up pulses productivity.

Per capita availability of pulses in India

As a result of stagnant pulse production and continuous increase in population, the per capita availability of pulses has decreased considerably. The per capita per day availability of pulses in 1951 was 60 g that dwindled down to level of 35.4 g in the year 2010. (Commodity Profile for Pulses, 2017).

Table 1: Per capita availability of pulses in India

Year	Pulses availability (gms/capita/day)	Pulses availability (Kgs/capita/year)
1951	60.7	22.1
1961	69.0	25.2
1971	51.2	18.7
1981	37.5	13.7
1991	41.6	15.2
2001	30.0	10.9
2011	43.0	15.7
2014	47.2	17.2

Source: *Agricultural Statistics at a Glance, 2014*

So In order to meet the projected demand of 32 million tonnes of pulses by 2030, a growth rate of 4.2% has to be ensured. This will be achieved through the coordinated and concerted efforts followed in crop production and protection through certain strategic and scientific approaches. Production of major pulses is constrained by both biotic and abiotic stresses. For example the major constraints to productivity in pigeonpea are biotic stresses such as pod borer, pod fly, Fusarium wilt, and sterility mosaic disease. Similarly, pod borer, aphids, cutworm, powdery mildew, rust and wilt are the major pests and diseases affecting lentil production in India. The richness of legumes in N and P, makes them attractive for insect pests and diseases (Sinclair and Vadez, 2012). Poor drainage/water logging during the rainy season causes heavy losses to pigeonpea on account of low plant stand and increased incidence of phytophthora blight disease etc. (Gowda *et al*., 2013). The most potential technologies in pulse production include improved crop establishment and management practices, integrated soil fertility and pest management practices, etc. which enhance not only the productivity and profitability but also warrants environmental and social sustainability besides nutritional security. (Vijaya punia, 2015)

Keeping these things in view this case study has been designed with the following objectives in the north coastal region of South India.

Evaluation of the crop performance through yield comparisons in case of the major pulse crops grown in this region *i.e* Pegion pea, Urd bean and Mung bean is studied with the objectives of

Integrated nutrient, pest and disease management in Pegion pea

Integrated weed , pest and disease management in green gram(Mung bean)

Integrated weed , pest and disease management in black gram (Urd bean)

Materials and methods

Case study design of the experiment was taken up as the research and analysis were taken up in a limited area of North coastal region of South India comprising the state of Andhra Pradesh with tropical climate conditions mostly rainfed farming systems, where rice fallow pulses was the predominant cropping system was purposively selected by the researcher as a peculiar case for pulse production. In this region pegion pea is generally grown as sole or intercrop as a first (kharif) crop and the remaining two crops viz, green gram and black gram are grown as second (rabi) crops.The respective treatments in the respective crops is based on the recommendations of the ICM package in each crop and were compared with the conventional farmers' practice. The field data was recorded in each hectare of farmer’s fields of 5 nos each in each crop with treatments, against the farmer treated plots of one hectare each in each crop and the yields were compared and also the benefit cost ratios were worked out based on the prevailing market price of that particular crop.

Results and discussion

Pigeonpea (Arhar) commonly known as red gram or tur is a very old crop of this country It accounts for about 11.8% of the total pulse area and 17% of total pulse production of the country (Agricultural Statistics, 2013). The average yield per ha *i.e* the productivity of the crop is 650 kg/ha against the world average of 762 kg/ha, this regions average productivity is still low that is around 562 kg/ha. This gap is mostly because of the poor management practices of the crop and also because of the regular occurrence of pests and diseases in this region. So an evaluation study has been designed in the farmers’ fields where a scientifically recommended package of practices was suggested in case of nutrient and pest management against *Maruca testulalis* and pod fly (*Melanagromyza obtuse*).

In general farmers use fertilizers with approximation without going for soil testing in case of pulse crops. But in this experiment a structured nutrient management schedule was developed based on the soil analysis in 5 locations and the yields were compared over three consecutive years. 25-30 kg N, 50-75 Kg P_2O_5, 30 kg K_2O and 10-15 kg $ZnSO_4$ in one ha area are applied as Recommended doses of fertilizers. Applied 20 kg S per ha in addition to NP at the time of sowing. For correcting Zn deficiency, foliar spray of 0.5 kg ZnSO4 with 0.25 kg lime or soil application of $ZnSO_4$ @ 25 kg per ha to one crop on Zn deficient soils is helpful to both the crop of pulse based cropping system. Mo deficiency is corrected by applying 1 kg sodium molybdate per ha and for boron deficient soils foliar spray of B @ 1.0 – 1.5 kg B per ha or soil application of 4 kg borax. Spray 1.0 per cent FeSO4 to recoup the crop from Fe deficiency. Application of fertilizer is based on soil testing. The recommended practice is also supplemented with the application of FYM @2.5 T/ha, whereas, the farmers practice is general application of 50 Kgs of urea and 50 kgs of DAP or other complex fertilizers like 28-28-0 around 50 Kgs /ha.

Regarding the pest management in pegionpea the crop is mostly affected by Maruca pod borer and pod fly in this region and causing 30-40% yield loss in various situations. Spraying with Monocrotophos (0.04%) or Chloropyriphos (0.05%) or Fenvalerate (0.004%) or Cypermethrin 0.004%). Imidachloprid 17.8 SL @ 70 g/ha. Use of neem seed kernels (5%) extract with 1 % soap solution was recommended as a practice for the control of Maruca pod borer and spraying of Monocrotophos (0.04%) or Dimethioate (0.03%) or Novaluron (0.01%) (Chitti Babu *et al.,* 2011). Flubendiamide 480 SC 48 g/ha solution was recommended as a practice for the control of fruit fly against the farmers practice of indiscriminate use of pesticides like acephate and monocrotophos in non-recommended doses.

Table 3: Comparative yields in Pigeon Pea

S. No	Year	No of locations	ICM package	FP	Yield increase	CB ratio
1	2014-15	5	518	364	42.3	1:1.50
2	2015-16	5	525	395	32.9	1:1.62
3	2016-17	5	540	372	45.0	1:1.45

The above table No 3 clearly indicates that there was a yield increase of 33 to 45 Percent over the three years with a benefit cost ratio of 1.45 to 1.62 depending on the season, cost of cultivation and the prevailing price situation. However there was an increasing trend in the yields in the treated plots when compared to farmers plots. In the treated plots a prescribed integrated crop management schedule was given including the pest and disease management, where as in the farmers plots no organised plant protection and nutrient management was taken up in all the five locations. So recommended practices of INM and IPM in Pigeon Pea will definitely contribute for significant yield increase and profitable for the farmer.

Urd bean (black gram)

Urd bean is popularly known as Blackgram which differs from other pulses in its peculiarity of attaining a mucilaginous pasty character when soaked in water. The significant character of this crop is its short duration and photo insensitive varieties, those fit well in different cropping situations, especially intensive crop rotations. The pulse legume is used as a green manure after picking the pods and with its characteristics to fix the atmospheric nitrogen. In this region of India, the blackgram is generally suffering from a peculiar weed infestation *Vicia sativa* which is almost similar in its seed and canopy characteristics. Control of this weed will definitely show the significant yield improvement in this region. Similarly sucking pests like aphids and diseases like Yellow Mosaic Virus, powdery mildew are also very common in this region.

Vicia sativa is a common weed in north coastal region of south India with the similar phenotypical characteristics of blackgram. Farmers generally cannot identify the weed in the early stages; hence they cannot go for weed management. To control this it is spraying of Sodium Aciflourfen 16.5%+ Cladinofop-Propargyl 8% EC type is used as a selective post emergence herbicide was taken up along with the other pest and disease control measures. The most common pests those affect the crop are sucking pests and whitefly, which also acts as the vector for spreading of the YMV.

To control the sucking pests Monocrotophos 40 EC @ 0.04% or Confidor 200 SL @ 7.5 ml/10 litre of water, to control whitefly Monocrotophos (0.04%) or Dimethoate (0.03%) are sprayed. In case of YMV incidence growing of the resistant varieties like LBG 752, Destroying the infected plants, Applying Phorate or Disulfoton granule @ 1 Kg a.i./hectare at the time of sowing, Spraying the crop with Metasystox @ 1 ml per litre of water to control vector population were practiced in a whole package form for three consecutive years and the yields were observed.

Table 4: Comparative yields in Urd bean

S. No	Year	No of locations	ICM package	FP	Yield increase	CB ratio
1	2014-15	5	650	453	43.5	1:1.46
2	2015-16	5	597	428	39.4	1:1.62
3	2016-17	5	675	474	42.4	1:1.51

The above table No 4 clearly indicates that there was an yield increase of 39 to 44 Percent over the three years with a benefit cost ratio of 1.46 to 1.62 depending on the season, cost of cultivation and the prevailing price situation. However there was an increasing trend in the yields in the treated plots when compared to farmers plots. In the treated plots a prescribed integrated crop management schedule was given including the pest and disease management, where as in the farmers plots no organized plant protection and weed management was taken up in all the five locations. So recommended practices of Integrated weed management and Integrated pest Management in Urd Bean will definitely contribute for significant yield increase and profitable for the farmer.

Mung bean

Mung bean is popularly known as green gram. Short duration and photo insensitive varieties of mung bean fit well in many intensive cropping systems across the country. Summer greengram is especially help in sustaining the productivity levels of rice-wheat cropping system of Indo-Gangetic belt of northern India without any competition to rice or wheat, with additional yield of 10-15 q/ha.

The average yield.per ha *i.e* the productivity of the crop is around 405 kgs against the national average of 461kgs/ha against the world average of 904kgs/ha. But the yield of this crop is mostly affected by the weeds, pests and diseases. The highest crop yield was obtained when weeds were removed 35 days after sowing. Any further delay in weed removal results in a corresponding decrease in yield. Cuscuta being the predominant weed in this region a comprehensive integrated strategy was adopted to control the other weeds along with cuscuta. A maximum of 2 hand-weedings in the initial stages of crop growth up to 30-35 days, were taken up to take care of the weed problem. Pre-emergence application of Lasso or Tok E-25 @ 2kg ai/ha in 1,000 litres of water ensures complete weed control. Application of Pendimethalin (PI) + Imazethapyr (POE) 1250+100 g a.i./ha at 0-3 (PI) and 20-25 (POE) DAS control weeds. The other pests and diseases are almost common in case of green gram and black gram.

To control the sucking pests Monocrotophos 40 EC @ 0.04% or Confidor 200 SL @ 7.5 ml/10 litre of water, to control whitefly Monocrotophos (0.04%) or Dimethoate (0.03%) are sprayed. In case of YMV incidence growing of the resistant varieties like LBG 752, Destroying the infected plants, Applying Phorate or Disulfoton granule @ 1 Kg a.i./hectare at the time of sowing, spraying the crop with Metasystox @ 1 ml per litre of water to control vector population were practiced in a whole package form for three consecutive years and the yields were observed. To control the powdery mildew spraying the crop with wettable Sulphur @ 3 g/litre of water or Dinocap @ 1 ml/litre water was taken up.

Table 5: Comparative yields in Mung bean

S. No	Year	No of locations	ICM package	FP	Yield increase	CB ratio
1	2014-15	5	684	476	43.6	1:1.46
2	2015-16	5	628	452	38.9	1:1.61
3	2016-17	5	690	498	38.5	1:1.58

The above table No 5 clearly indicates that there was an yield increase of 38.5 to 43.6 Percent over the three years with a benefit cost ratio of 1.46 to 1.61 depending on the season, cost of cultivation and the prevailing price situation. However there was an increasing trend in the yields in the treated plots when compared to farmers plots. In the treated plots a prescribed integrated crop management schedule was given including the pest and disease management, where as in the farmers plots no organised plant protection and weed management was taken up in all the five locations. So recommended practices of Integrated weed management and integrated pest Management in Mung Bean will definitely contribute for significant yield increase and profitable for the farmer.

Summary and conclusions

The North coastal region of South India comprising the state of Andhra Pradesh with tropical climate conditions mostly rain fed farming systems, where rice fallow pulses was the predominant cropping system was purposively selected as a case to study the strategies for pulse production. In this region pegion pea is generally grown as sole or intercrop as a first (kharif) crop and the remaining two crops viz, green gram and black gram are grown as second (rabi) crops in the research area that is the North coastal India is the largest producer, 25% of world's production, and consumer 27% of total pulses of the world. The domestic production is often less than the estimated demand *i.e.* 2324 million tons. So the regular periodic management practices with an integrated approach for weed, pest and disease control along with specific nutrient management principles will definitely contribute for significant yield increase in this region. Efforts through compilation have been made to have an access to most of the FAQs on pulses development, plan effort's impacts, scenario, strategies, post-harvest and processing aspects along-with the production technology. However, scientific and technological development without reaching farmers through proper distribution channels is not fruitful. Hence, the increased availability of quality seeds at the village level through innovative seed production and distribution mechanisms is important. Efforts need to be made to increase farm mechanization through varietal development and innovative custom hiring facilities to reduce peak season labour requirement. (Reddy, 2015)

It is also proposed for increasing production of pulses through area expansion and productivity enhancement; restoring soil fertility and productivity; creating employment opportunities; and enhancing farm level economy to restore confidence of farmers of targeted districts. The basic strategies were implementation of interventions in a mission mode through active engagement of all the stake holders at various levels. These interventions include promotion and extension of improved technologies i.e., Seed, INM (micro-nutrient, soil amendments), IPM and resource conservation technologies (RCTs) and capacity building of farmers. Certain technological options including Short duration pulse cultivation, Pulses as summer crops, shift to pulses from other crops, Inter cropping will also help to increase the pulse production in this area. Interventions proposed were integrated with the district plan and target for each identified district was fixed. Constant monitoring and concurrent evaluation were done for assessing the impact of the interventions for a result oriented approach by the implementing agencies. In this paper, an attempt has been made to discuss improved pulse production practices which can play a vital role in sustainable pulse production in this region. Besides this, area expansion through their introduction in non-traditional area would also add to national pulse production. The improved production practices and strategies with context to pulses crop in Indian perspective discussed in this paper would definitely enlighten the agricultural professionals and policy makers to enhance their capabilities for sustainable pulse production in India in spite of various production vulnerabilities.

Abstract

Agriculture is one of the most contributing sector that support Indonesia’s economic growth, placing in second highest contributor in GDP (Gross Domestic Product) in Indonesia (BPS, 2016). The importance of agriculture in Indonesia triggers the uprising of local wisdom related to agriculture. One of the so called local wisdom is “Pinanggal Dwasa Ayu” which harness the combination of traditional calendar system. This combination will reflects based on actual climate condition, so it can be utilized to determine crop rotation. This local wisdom system is frequently used by local farmers. While it is widely used, this method is not scientifically tested yet. Based on this condition, it is necessary to research and test the accuration of “Pinanggal Dewasa Ayu” method. Goals of this research is to prescribe the accuration and precision of “Pinanggal Dewasa Ayu” method to determine crop rotation in Bali Province. Expectation is made that this method could help local farmers decide the most effective crop rotation which increase the agriculture productivity in Bali. This research is using Cropwat 8.0 software as testing ware. Cropwat 8.0 is a software which process agroclimate data from FAO (Food and Agriculture Organization). As much as 11 testing is conducted, resulting in 100% accuration and 86.8% of crop planting effectivity. The accuration and effectivity result indicates that “Pinanggal Dewasa Ayu” Method relevance is high and can be used as reference in Bali Province.

Keywords: *“Pinanggal Dewasa Ayu”, Crop rotation, Cropwat, Agriculture*

Introduction

Agriculture is one of the main sectors of Indonesian economy Central Bureau of Statistics show that the agricultural sector accounted on average for 14% of revenue in Gross Domestic Product figures, placing agriculture in second position after the industry sector (Central Berau of Statistic, 2017) . This condition supported by Indonesia's geographical location at a latitude of 0^0 and located in the area of Ring Of Fire makes Indonesia fit to be agrarian country.Not only get Benefit from this physical condition, Indonesia also has the social potential in developing agriculture. Indonesia is the country peaked at # 4 as the country with the greatest population density. A large quantity of the population, can be used to build the agricultural sector..

The most planted commodity in Indonesia is rice The majority of Indonesian people consume rice as a staple food. Seeing the importance of the role of rice in Indonesia, the productivity of rice plants must continue to keep savings national rice stock. Bali is one of the provinces which acts as the national granary owned by Indonesia. Although, agricultural land in Bali thinning, but Bali is able to maintain rice production to maintain good cropping system. Arangging crop pattern can be done by looking at environmental factors. The environmental factors eg precipitation or rainfall. Rain factor that may affect plant growth is the amount /

volume of rain, deployment / distribution of the rainfall and rain effectiveness. The amount and distribution of rainfall affects the kinds / types of plants that can be cultivated on an area (Krisnawati, 2011) .In addition, in his book entitled whiteman Manuaaal in Tropical Pasture Science said precipitation is a linear function of evaporation, transpiration, run-off (stream surface), and infiltration (the water that goes into the ground). Infiltration is a linear function of percolation, seepage and soil moisture. Knowing these facts, then peyesuaian planting time is important, particularly in Indonesia, which has the advantage of the tropical climate with abundant rainfall. Adjustment rainfall patterns with the cropping pattern can be done through agro-climatic studies. Agroclimate is Agroclimatology is climate science that studies the relationship between climate elements by processes of plant life. Studied in Agroclimatology is how climate elements that play a role in the life of the plant (Bargumono, 2012). Agroclimate known by theories of climate division that divides Oldenman altitude zones with precipitation character and describe plant species that live in it.

The importance of this agro-climatic analysis, makie agroclimate analysis methods still growing until now. Since ancient era, Bali has introduced a system of agro-climatic analysis. This was stated in the determination of good doctrine called pawukon system. Basically pawukon use combination of moon cycle and sun to see the best time in starting the planting cycle (Gorgol,2013). Using pawukon calculations, farmers in the province of Bali can determine planting cycles prior to the development of agro-climate-related science. Pawukon calculation is still believed by local farmers, and now included in the calendar in the province of Bali (Suwintana,2014). However, this system still has not been tested scientifically accurate. So it needs related research about pawukon system accuracy test in determining the crop pattern in the province of Bali.

On the other hand, with the development of technology, integration of multiple data sources become easier. Now, the Food and Agriculture Organization of the United Nations launched CropWat 8.0 software. CropWat 8.0 for Windows is a computer program for the calculation of crop water requirements and irrigation requirements based on soil, climate and crop data. In addition, the program Allows the development of irrigation schedules for different management conditions and the calculation of scheme water supply for varying crop patterns. CropWat 8.0 can also be used to Evaluate farmers' irrigation practices and to estimate crop performance under both rainfed and Irrigated conditions (fao.org, 2017). This software analyzes the cropping pattern by integrating climate-related data and the determinants of plant characteristics. Several previous studies have made use of this software to determine the cropping pattern of a particular plant. Considering the frequent use of this software in the research, this software can be used for assessing accuration of Pinanggal Ayu System.

Materials and methods

This research study method used literature and comparative studies. Literature study was conducted to determine the working system of *Pinanggal Ayu* calculation, and find the appropriate cropping patterns according to this *Pinanggal Ayu*. Final calculation result, will be compared with the calculation of cropping patterns in CropWat 8.0. The method of *Pinanggal Ayu* obtained from the study from related research journal about *Pinanggal Ayu* appropriate calculation methods. The calculation method will be adjusted to the calendar in 2016. Some journals are collected, so the authors came to the conclusion about and match it with other 2016.. Calendar which has been obtained from *Pinanggal Ayu* method, calculated in the application CropWat 8. 0 to test accuracy. Accuracy test conducted by contingency tables. From the contingency table, you will get a percentage of a match which reflect the accuracy of the method pawukon.

Results and Discussion

Ayu pinanggal calculation or determination of the system either include many activities, such as marriage, home building and other funeral.Crop pattern analysis is one of them. Indeed, the crop pattern is described in detail based on the classification of plants. However, in this study, the pattern of the selected plants limited to rice, peanuts, tobacco consider all four of these commodities which plays a major role in Indonesian agriculture.Calculation of pinanggal ayu consists of a combination from *pawukon* and *wewaran*.*Wewaran* is the plural form of the word Wara meaning Today (weekdays), amounting to one to ten, namely: Eka Wara, Dwi Wara, Tri Wara, Chess Wara, Panca Wara, Sad Wara, Sapta Wara, Asta Wara, Sanga Wara, and Dasa Wara. Said numbers in the wewaran name indicates the number of days with the name of each, but not entirely fixed cycle, such as Eka Wara, Dwi Wara Wara Chess, Asta Wara Wara and Dasa Wara (Darmayasa,2016).Wewaran Sanga has Urip or Neptu and numbers or numbers, which is refer to direction of the wind, as well as the name of his gods (Swarsi, 2003: 87).

The calculation to obtain a good day in the cropping cycle is composed of Saptawara, pancawara contained the formula below.After put all the components in the formula, it will obtain a number. The last digit of calculation result represent the prediction result. Number one represent good time to starting crop pattern

Pinanggal ayu = last digit of (Urip Saptawara + pancawaraBirth) + (Urip Saptawara + pancawara start businesses / events)

Umanis	Urip 5
Paing	Urip 9
Pon	Urip 7
Wage	Urip 4
Kliwon	Urip 8

Table 1. pancawara

Redite	0
Soma	1
Anggara	2
Buda	3
Wrespati	4
Sukra	5
Saniscara	6

Table 2. Saptawara

After entering this equation, the following is obtained either as a date

Rice	4-Jan	12-Jan	18-Jan	27-Jan	2-jun	10-jun	16-jun
Peanut	18-Jan	17-jun	14-Oct				
Tobacco	9-Jan	8-May	6-Aug				

These dates and then inserted into the software CropWat 8.0dan produced the following results:

CropWat \ Pinanggal (Rice)	4-Jan	12-Jan	18-Jan	27-Jan	2-jun	10-jun	16-jun	17-jun
Schedule Eficiency	100%	100%	100%	100%	100%	100%	100%	100%
irrigation Efficiency	88%	92%	92.50%	96.80%	100%	100%	100%	100%
CropWat \ Pinanggal (Peanut)	18-Jan	17-jun	14-Oct					
Schedule Eficiency	100%	100%	100%					
irrigation Efficiency	54.5%	98.1%	64.1%					

CropWat \ Pinanggal (tobacco)	9-Jan	8-May	6-Aug
Schedule Eficiency	100%	100%	100%
irrigation Efficiency	52.4%	94.5%	96.80%

Comparative test results showed that the determination of the cropping pattern good for rice, peanuts, tobacco when viewed from rainfall that include in greatly category according to the type of plants. This is because the comparison test of the schedule efficiency has already reached 100% .While the efficiency of irrigation water for the greatest number obtained from rice plants that achieve of 96% in accuracy. The second sequence is occupied by the tobacco plants that have irrigation efficiency of 81.23% and the latter has an efficiency of 72.23% is peanuts.

If we look at the scientific side of the calculations associated with the ayu pinanggal system can be seen by the results for the month. Sapta wara consists of seven phases, which represent the seven phases of different weather. The essence of the meaning sapta wara, lies in the element of the moon and sun. In Saptawara redite represent climate phase transition from dry season to the rainy season. In this phase, the effect of moon or sun is not too strong.The second one is soma symbolizing dominance phase of the moon, while the sun is not yet showing its rays. anggara symbolizing the sun scorching conditions, while wrespati symbolizes the potential storm and lightning conditions tha always identical with bad decition to start crop pattern.Pancawara symbolize the daily cycle of the sun, or mean time in a day that can be used for planting. The cycle begins from sunrise to sunset.

Conclusion

Comparative test results showed that the determination of the cropping pattern good for rice, peanuts, tobacco when viewed from rainfall that has suffered greatly according to the type of plants. This is because the comparison test of the efficiency of the schedule has already reached 100% .While the efficiency of irrigation water for the greatest number obtained from rice plants that achieve an accuracy of 96%. The second sequence is occupied by the tobacco plants that have a presentation irrigation efficiency of 81.23% and the latter has an efficiency of 72.23% is peanuts.

Abstract

Poor germination and weak plant establishment are lentil (*Lens culinaris* L.) production problems in arid and semi-arid areas. Seed priming may provide a solution to these problems by improving the rate and percentage of seedling emergence, establishment of more optimum plant densities and ultimately improving seed yield. A study was carried out to investigate mycorrhizal inoculation with *Glomus mosseae* and *Glomus intraradices* in combination with seed priming. The five treatments included Hydropriming, treatment with GA3100 ppm, salicylic acid 100 ppm, and GA3 100 ppm + salicylic acid 100 ppm as well as non-primed seeds as a control in a factorial experiment using a randomized complete block design with four replications. The experiment was conducted at GonbadeKavoos University in 2013-2014 winter seasons. Mycorrhizal inoculation increased pod number, harvest index, grain yield and the total biological yield. Also, mycorrhiza reduced the number of days to flowering and pod development, and frequency of empty pods. Priming treatments and combination treatment (seed priming + mycorrhizal inoculation) improved seed yield and components of yield. Hydropriming increased seed yield with and without mycorrhiza inoculation; however, hydroprimed seed increased yield when also inoculated with *Glomus intraradices*.

Keywords: *gibberellic acid, salicylic acid, seed priming, seed yield, seed yield components.*

Introduction

As previously reported (Anon, 2009), lentil (*Lens culinaris* L.) contains 24-28% protein, 30-40% minerals and 22% vitamins and is an important component in the diets of people in semi-arid regions of the world. Yields of lentil average is 1077 kg/ha worldwide and 560 kg/ha in Iran (FAO 2012). In developing countries lentil is a good source of protein and amino acids in the diet of the people. Due to its ability in nitrogen fixation, lentil helps to maintain soil fertility and tends to improve yields of other crops in rotations (Parsa and Bagheri, 2008). However, FAO (2012) reports average lentil yields in Iran are much lower than the world average. The poor yields appear to be related to poor germination, weak seedling emergence, weak seedlings, biotic and abiotic stresses and generally undesirable plant establishment. This situation has forced us to look for ways to overcome early plant establishment problems.

One of methods for increasing germination and seedling quality is through seed priming. Priming is a process in which seeds absorb water and initiate the seed germination process prior to planting (McDonald, 2000). Different priming methods included osmopriming, hydropriming, matric priming, hormonal priming and biopriming. Priming can lead to faster growth of seedlings (Eisvand *et al.*, 2011a), improved germination percentage (Eisvand *et al.*,

2011b), hardier seedlings against unfavorable conditions (Eisvand *et al*., 2011a), and increased yield and quality (Azarnia and Eisvand, 2013).
Germination percentage is important for crop establishment yield. Priming is a simple and effective technique to cope with environmental stresses and improve germination percentage (Bradford, 1986; Taylor and Harman, 1990). Some phyto-hormones such as salicylic acid and gibberellic acid can be used in priming (Zaki and Radwan, 2011). Pretreatment of salicylic acid depending on the desired concentration, species, and environmental conditions during growth plays an important role in regulating various physiological processes such as seed germination, plant development and photosynthesis (Iqbal and Ashraf, 2006). It is also an important signal molecule in plants and fluctuates in response to environmental stresses (Senaratna *et al*., 2000).
Gibberellic acid is involved in many physiological processes such as cell division, increase in cell length (Khoshkhouy *et al*., 1999), germination and seedling growth (Eisvand *et al*., 2011a; Eisvand *et al*., 2011b), earliness, flowering and yield (Kaur *et al*., 2005; Azarnia and Eisvand, 2013). Therefore, this study was designed to investigate the effects of mycorrhiza inoculation and seed priming with plant growth regulators (GA3 and SA) on yield and yield components of lentil.

Material and Methods

Seeds of Kimiya a well-known lentil cultivar grown by farmers in GonbadeKavoos were prepared at GonbadeKavoos Agricultural Research Centre. A field experiment was conducted during 2013 -2014 at the research farm of GonbadeKavoos University, Iran. The experiment was arranged using a factorial design in a randomized complete block with four replications. The first factor was the application of mycorrhiza at three levels (control, inoculation of soil by *Glomus intraradices* and inoculation of soil by *Glomus mosseae*) and the second factor was priming treatments at five levels (hydropriming with distilled water, priming with GA3 100 ppm, priming with SA 100 ppm, priming with GA3 100 ppm + SA 100 ppm and non-primed seed as control). Soil was inoculated by propagol (Mixed fungal spores, external mycelium and root colonization). Both mycorrhizal fungi (*G. intraradices and G. mosseae*) were obtained from Zist Fannavaran Company, Iran.
Priming: seeds were disinfected with sodium hypochlorite (2%) then washed with distilled water and transferred to priming solutions (GA3 100 ppm, SA 100 ppm, GA3 100 ppm+ SA 100 ppm) for 8 h. For aeration during the priming process, an air pump was used. Seeds were then dried at 24 °C. These seeds are called primed seeds. Mychorrizal inoculation 5g mycorrhiza (2×10^3 spore per gram) per gram of seeds was applied at the time of sowing in the soil. Lentil seeds were sown as R×R=25 cm (interval of between rows) and P×P=4 cm (interval between plants on the rows) in plots with 1.25×7 m. Distance between plots was 50 cm. The Field visited daily after seedling emergence and establishment, and characteristics such as days to 50% flowering, days to 50% podding, number of pods, number of grains per pod, the ratio of filled pods to empty pods, empty pod percentage, grain yield and harvest index were recorded. The ratio of filled pods to empty pods was calculated according to the following equation:
ratio of filled pods to empty pods

$$\text{ratio of filled pods to empty pods} = \frac{\text{filled pods}}{\text{empty pods}} \times 100$$

Days to 50% flowering and podding were also calculated based on the days to flowering and podding when half of plants in a plot had one opened flower or had one pod respectively (Anwar, 2003).

Results and Discussion

Grain weight and grain number per pod

All treatments significantly affected 100 grain weight (table 1). Results showed that priming and combined application of priming and mycorrhiza increased 100 grain weight and the highest grain weight was achieved by priming and mycorrhiza inoculation. There was no difference between the single application of gibberellic acid and combined applications of hydropriming and salicylic acid. It should be mentioned that there were no significant differences between other treatments in bio-fertilizers treatments (table 2). Results showed that effects of priming and combined applications of priming and mycorrhiza were significant on grain number per pod (table 1). Mycorrhiza inoculation did not significantly increase grain number per pod while the maximum grain number per pod was achieved with hydropriming and the lowest number of grains per pod was related to the combined application of 100 ppm salicylic acid + 100 ppm gibberellic acid (table 2). Previously it has been reported that priming increases grain number per pod and per plant (Kaur *et al*., 2005; Azarnia and Eisvand, 2013).

Pod number and filled pods to empty pods ratio (FP /EP)

The effect of all of the treatments on pod number was significant (table 1). Mycorrhizal inoculation increased pod number up to 21%. Priming treatment at all mycorrhiza inoculation treatments increased pod number where maximum pod number was observed with hydropriming + *Glomus intraradices* inoculation and minimum pod number was related to 100 ppm gibberellic acid (table 2). Main effects of mycorrhiza inoculation and priming treatments and interaction of them had meaningful effects on the filled pod to empty pod ratio (table 1). Combined effects of priming and mycorrhiza inoculation increased the filled pod to empty pod ratio. The highest ratio was at single mycorrhiza inoculation by *Glomus mosseae* combined with *Glomus intraradices* and 100 ppm salicylic acid (10.3 and 5.43 respectively) and the lowest ratio was related to *Glomus mosseae* and 100 ppm salicylic acid and 100 ppm gibberellic acid + priming by 100 ppm salicylic acid (table 2). Number of pods, number of grains per pod and grain weight is important components in the formation of lentil yield. Numbers of seeds per pod and seed weight is mostly influenced by genetics and are less affected by environmental factors. It seems that the number of pods, is the most important variable in the formation of seed yield of lentil. In the present study, each treatment also increased the number of filled pods and ultimately directly increased grain yield which was obvious with mycorrhizal fungi and priming treatments. On the other hand, it seems that plants have mechanisms that regulate the size of the sink based on the amount of available assimilate, thus in seasons with drought stress and closing of stomata and reduced photosynthesis and subsequently reduction of assimilate, plants respond by dropping of flowers and pods to decreased the sink resulting in reduced yields (Kumudini, 2002). Mohammadi *et al*. (2011) indicated that drought stress reduced lentil pod number; however, applications of bio-fertilizers increased pod number even under drought stress. Azarnia and Eisvand (2013) reported that priming of chickpea grains under rainfed condition increased pod number compared to the control treatment which is in agreement with results of Mohammadi *et al*. (2011) and Azarnia and Eisvand (2013).

Biomass and grain yield

All treatments significantly ($P \leq 0.01$) affected biomass yield (table 1). Priming in combination with mycorrhiza inoculation improved biomass yield and maximum biomass was achieved from the combination of *Glomus intraradices* and 100ppm salicylic acid and there was no difference when compared to the *Glomus mosseae* and hydropriming treatment. Minimum biomass also was achieved from the 100 ppm gibberellic acid treatment without mycorrhizal inoculation (table 2). All treatments significantly ($P \leq 0.01$) affected grain yield (table 1). Increased lentil grain yields were obtained from applications of bio-fertilizers and inoculation

Means within each column with at least a letter in common are not significantly different at α= 0.05.

with Glomus intraradices and Glomus mosseae when compared to the control (30.8 and 22.4% respectively). These results are in agreement with Mohammadi et al. (2011); Badr et al., (2013) and Kurle and Pfleger (2005). The combined effects of priming and mycorrhiza inoculation also improved grain yield and maximum grain yield was obtained from the Glomus intraradices and hydropriming treatment and was not significantly different from the Glomus mosseae and hydropriming treatment. The lowest grain yield was obtained from 100 ppm gibberellic acid combined with priming by 100 ppm salicylic acid and without applications of bio-fertilizers. Without bio-fertilizer application, maximum and minimum grain yields were obtained from the control as well as the 100 ppm gibberellic acid treatment. There were no significant differences between treatments where both Glomus intraradices and Glomus mosseae were inoculated and bio-fertilizers were applied. The highest and lowest of grain yield was related to hydropriming and control treatments, respectively (table 2). Researchers reported that priming increased yield and yield components of chickpea (Kaya et al., 2010; Azarnia and Eisvand, 2013), lentil (Ghassemi-Golezani et al., 2013) and soybean (Ghassemi-Golezani et al., 2011; Arif et al., 2014). Some researchers have reported that mycorrhiza inoculation improved yield of lentil (Mohammadi et al., 2011) pea (Badr et al., 2013) and soybean (Kurle and Pfleger, 2005) that are compatible with our results.

Harvest index

All treatments significantly ($P \leq 0.01$) affected harvest index (table 1). Glomus intraradices increased harvest index 16% when compared to the control and *Glomus mosseae* increased of harvest index by 2 % when compared to the control. Priming treatments and the combined effects of priming and Mycorrhiza inoculation improved the harvest index with the maximum being observed from the combination of Glomus intraradices and hydropriming. The least effect on harvest index was obtained from inoculation with *Glomus mosseae* (table 2). These results are compatible with Azarnia and Eisvand (2013) results.

Conclusion

In many areas of dryland farming, unfavorable conditions can inhibit germination, emergence, plant establishment and density, growth and ultimately grain yield. Priming of seeds prior to planting was shown to reduce risks in a wide range of environmental conditions. In the present study, gibberellin treatments and hydropriming at different levels of biological treatments that caused early flowering can result in a lower percentage of empty pods and higher yields. The overall beneficial effects of priming are rapid seedling emergence enabling escape from drought stress later in the growing season. Mycorrhiza inoculation reduced the days to flowering and increased podding to produce increased individual grain weight, more seeds and ultimately improved lentil yields. The results also showed that priming is a simple and useful method to enhance the yield and quality of lentils. The beneficial effects of priming can help establish better plants, create an ideal and uniform density, and improve and enhance yield of whole grains. Glomus intraradices was the most effective fungus used in this research. Results of this study indicated that mycorrhizas in combination with seed priming were ideal for increasing plant emergence, plant growth and seed yields.

Abstract

Effective and successful regeneration is the critical stage of plant genetic transformation methods. Success in transgenic is paving the way to prepare novel and new desirable genotype especially in cut flowers. In order to investigate regeneration potential of GUS transformed rose plants, direct regeneration from four lines of transgenic plantlet was performed. In our study were used leaf and petiole explants from transgenic rose (*Rosa hybrida* L.), using adventitious organogenesis pathways for plant regeneration. Transgenic lines were obtained by *Agrobacterium tumefaciens*-mediated transformation of embryogenic calli. Explants were cultured on MS medium containing different concentration of (0.5, 1, 1.5 mg/L) TDZ in combination with (0, 0.05, 0.1 mg/L) IBA. Regeneration percentage, time to shoot regeneration, number of adventitious buds per explants and adventitious shoot length were noted. Shoot regeneration was observed after 35 days in most treatments. The result showed that the highest regeneration rate (87%) was obtained by leaf explants in media containing (1.5 mg/L) thidiazuron (TDZ) + (0.05 mg/L) indole-3-butyric acid (IBA) in third line. Combination of TDZ with IBA was more effective for direct regeneration. Increasing Concentration of TDZ from 0.5 to 1.5 mg/l, promotes shoots length. Present results indicate that rose genotype (different transgenic lines) and explants had significant effect on regeneration rate.

Key words: *Rosa hybrid, leaf segments, direct regeneration, TDZ.*

Introduction

In recent years, cut roses are believed to be the most important decorative fresh cut flowers. They has more than 20,000 commercial cultivars, which concertedly are based on just eight wild species (Gudin, 2000). Plant biotechnology, together with conventional breeding methods, could facilitate rose improvement since resistance or tolerance to fungi pathogens, flowers shape and color, vase life and odor (Rout *et al.*, 1999; Nybom *et al.*, 2004). Nevertheless, a reliable and efficient *in vitro* culture method that results in efficient shoot development and regeneration is an essential requirement for improvement of new varieties through genetic transformation or mutagenesis (Fanourakis *et al.*, 2010; Gudin, 2000).
Although several protocols have been described in the literature for rose regeneration, development of an optimal *in vitro* culture system still remains a major challenge since it seems that genotype dependent (Bimal and Kiran, 2014; Ibrahim and Debergh, 2001; Kumar Pati *et al.*, 2004; Ozel and Arslan, 2006; Pati *et al.*, 2006). Different plant growth regulators exhibit significant roles in direct or indirect *in vitro* regeneration process. Thidiazuron (TDZ) and benzyladenine (BA) are the most frequently used cytokinins to induce regeneration, although their efficiency entirely depends on genotype, explant type and media composition (Magyar-Tábori *et al.*, 2010; Kumar Pati *et al.*, 2004; Pati *et al.*, 2006). TDZ roles have been reviewed in the regulation of morphogenetic potential, which is related to the metabolism and

action of purine-based cytokinins and auxins (Murthy *et al.*, 1998; Kou *et al.*, 2016). TDZ has been found to be more effective to stimulate shoot organogenesis and somatic embryogenesis in the most plant spices including roses (Pati *et al.*, 2004; Pourhosseini *et al.*, 2013; Davies, 2013). In the other hand, different type of auxins, such as IBA, NAA, 2,4-dichlorophenoxyacetic acid (2,4-D) and newly 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), have been employed in induction of direct regeneration or somatic embryogenesis in various plant species in combination with cytokinins (Pati *et al.*, 2006; Pourhosseini *et al.*, 2013; Davies, 2013).
Many review were published the regeneration pathways in roses and gave an account on *in vitro* propagation of roses, but no single method or explant type have been proved convenient to all rose varieties. Since, direct shoot regeneration in rose is highly dependent on genotype; therefore, the objective of the present study was to evaluate an *in vitro* plant regeneration system for four GUS transformed lines by studying the influence of TDZ and IBA, as a prerequisite for regeneration of roses after genetic transformation.

Material and Methods

Rosa hybrid L. transgenic lines were obtained by *Agrobacterium tumefaciens*-mediated transformation of embryogenic calli (Yari, 2011). Full strength MS medium supplemented with 2% (w/v) sucrose, 0.7% (w/v) agar and different concentrations and combinations of TDZ and IBA were used for direct regeneration. The leaves and petioles of Gus Transformed explants from four different lines were transferred into glass vial containing 25 ml MS medium supplemented with different concentration of (0.5, 1, 1.5 mg/L) TDZ in combination with (0, 0.05, 0.1 mg/L) IBA (Table 1). After 35 days; regeneration percentage, time to shoot regeneration, number of adventitious buds per explants and adventitious shoot length were noted. All cultures were incubated at 23 ± 2°C in a growth room on a 16/8 hour light/dark and 3,000 lux light intensity provided by cool-white fluorescent light. Noted Values represent the measuring traits per lines in 3 glass vial with 5 explants and three replicates. The statistical analysis was performed using one-way ANOVA and the significance of differences among treatment means were contrasted with Duncan at $P < 0.05$. The program SAS version 9.1 was used.

Results and Discussion

Shoot regeneration began with the swelling of explants (leaves or petioles), after 35 days of culture. The shoots were multiplied by culturing them in the regeneration medium every 3 weeks intervals until shoots were developed. The Table 1 show the effect of lines on the regeneration percentage of shoots induced from leaf/ petioles of transformed roses regarding of the TDZ and IBA concentration. The shoots regeneration differed significantly among the lines evaluated. The higher percentage of shoot formation was obtained using (1.5 mg/L) thidiazuron (TDZ) + (0.05 mg/L) indole-3-butyric acid (IBA) on line 3> line 2> line 1= line 4 by leaves explants. Moreover, the higher average of shoots length was obtained using line 3 > line 2 > line 4 > line 1(Table 2). On the other hand, no significant differences were observed in the number of days to form shoots from explants (data not shown).

Independently of lines, significant differences were observed in the number of regenerated shoots among the treatments evaluated. Increasing Concentration of TDZ from 0.5 to 1.5 mg/l promotes shoots length (Table 2). In this study, TDZ and IBA played an important role in the induction of organogenic regeneration in the transgenic roses evaluated. Further, discussions on direct organogenesis in the genus Rosa demonstrate the preference of TDZ application in inducing shoot morphogenesis on leaf explants(Pati *et al.*, 2006; Rout *et al.*, 2006) . It is well known that cytokinins stimulate plant cell division, adventitious bud formation, lateral buds growth and participate in the cell cycle (Basra, 2000; McGaw and Burch, 2013). It has been demonstrated that Adding TDZ to the medium containing BAP promoted accessory and axillary bud formation in Rosa damascene, due to cytokinin activity; TDZ added to the culture medium in order to improve growth attributed to the affect on the level of endogenous auxins and cytokinins, (Mamaghani *et al.*, 2010; Kou *et al.*, 2016) . TDZ can be used as a substitute for both auxin and CK to promotes adventitious shoot formation indirectly from calli or directly from explants (Kou *et al.*, 2016). TDZ is an artificial plant growth regulator, which is displaying primarily CK-like activity for inducing shoots and somatic embryos, protoplasts, and flower *in vitro (*McGaw and Burch, *2013;* Kou *et al., 2016).*

In this sense, there are few reports about the biochemical or genetic mechanisms underlying how cells acquire regeneration competence following induction by TDZ. TDZ shows CK[1]

[1] Cytokinins

activity in bioassays that is a highly stable compound. Previous researches have suggested that TDZ can modify the metabolism of endogenous CK, or mimic an auxin response. Recently Kou *et al.* (2016) reported that the application of TDZ promoted the accumulation of IAA and a Z-type CK, ZR[2] but reduced the level of an iP-type CK, iPA[3] in *Rosa canina* L.
Our results suggest that TDZ, in combination with IBA, improves the process of direct organogenesis. Some explanations for this are possible. One possibility is that TDZ acts as a precursor for natural cytokinin synthesis or enhances natural cytokinin biosynthesis; another possibility is that TDZ acts as a synergist of cytokinins.
In contrast to our results, (Canli, 2003) reported that the application of TDZ at different concentrations did not produce shoot regeneration from leaf explants of chimera *Rosa multifolra*. Such contrasting results could be due to differences in cultivars, physiological state of explants and the type of explants. Regeneration protocols using different explants of *Rosa hybrid* L. have been reported; which infer regeneration and multiplication through organogenesis or somatic embryogenesis (Pati *et al.*, 2006). Although a few report have been noted on direct regeneration of adventitious buds in Rosa. These reports indicate that shoot regeneration response in the genus Rosa has been obtained from roots, leaves, leaflets and petioles (Bimal and Kiran, 2014; Mamaghani *et al.*, 2010; Pati *et al.*, 2006; Debener and Hibrand-Saint Oyant, 2009; Ginova *et al.*, 2012). Many factors induce forming new bud/ shoots via organogenesis, but it has been demonstrated that regenerative capacity and response to growth conditions is species and genotype dependent as reported in genus *Rosa* (Ozel and Arslan, 2006; Pati *et al.*, 2006; Rout *et al.*, 2006; Bimal and Kiran, 2014).

Conclusions

Our results confirmed earlier observations that the genotype influences the regeneration process via organogenesis in the roses (Yari, 2011).The genotype effects suggest that genetic factors are important in the response to *in vitro* tissue culture. In this sense, due to the increasing genetic variability in modern rose cultivars, the composition of the shoot induction medium is important in the regeneration process through organogenesis. Therefore, understanding the genotype effect and how these can be minimized is critical for successful *in vitro* culture. This *in vitro* protocol reported could be used for direct regeneration to obtain competent target tissue for genetic modification or for proliferation of transgenic plantlets

Abstract

In order to study the effect of plant growth regulators IAA, GA3 and PLANTS density on yield and yield components of two potato varieties was done. This experiment was carried out in Savin tissue culture laboratory and greenhouse in 2014 seasons. The experiment was factorial based on randomized complete bloke design with the replication separately. In this experiment variety in two stages (Jelly, Banba), effect of density in three stages (100, 150, 200) plants per square meter and growth regulators in four levels (IAA, GA3, IAA+GA3 and control). The results showed that hormone therapy increased the plant height. Combination therapy (IAA+GA3) had the greatest height. Banba cultivar of this treatment have shown greater response. Plants treated with combination therapy regulators with a density of 200 plants per square meter had the highest leaf area. There was no significant difference. Characteristic traits were identified for stolon and sub-stolones. The highest number of tuber was related to combination therapy regulators. There was no significant difference between IAA and GA3. The results showed the maximum length for stolen the type Banba 100 plants per square meter. Combination therapy with regulator & minimum length is for jelly (150-200 ps). No significant difference was between hormone consumed. Plants treated with regulators, respectively shows 30-55-35% increase in plant height, leaf area index for length of stolen compared to the control sample in addition, an increase of 44-66-38 per cent of the number of stolen and sub-stolen and number of tuber per plant can be seen. So consumption regulator of with influence on morphological traits and yield components that affect performance running effective economic performance.

Introduction

Potato is the fourth biggest crop of the world after Asia, especially in the developing countries like wheat, rice and maize (Nipa, 2013). Potato originated in the Andes of South America (Hawkes, 1992) where it was cultivated mostly at altitudes between 2000, and 4000 m in a region characterized by short daylength, high light intensity, cool temperatures and relatively high humidity. From there, the potato was introduced to Europe, where the long photoperiod inhibited tuber formation. The most significant change that subsequently allowed higher tuber yields in Europe was selection against the obligatory demand of short photoperiod for tuber initiation and growth. The long days and moderate temperatures of the temperate regions of Europe allowed longer periods of photosynthesis, efficient translocation of assimilates from haulm to tubers and low transpiration rates during the cool nights. By 1800, the potato was widely grown in Europe and became an important staple due to its high yielding capacity and highly nutritious qualities (Salaman, 1949). From Europe, the potato spread to much of the rest of the world during the 18th and 19th centuries over the last few decades (Simmonds, 1971; International potato Center, 1984). Potato is now a worldwide crop grown under many climatic conditions. The highest average yields are obtained in regions with moderate climate, such as northern United States and northwestern Europe, where potato is grown under long days, moderate temperatures and modern cultivation methods. Tuber productivity of good seed tubers in potatoes relies on factors like; day length , temperature , physiological age of seed tubers, plant density, nitrogen, water supplying, and finally growth regulating materials or plant growth regulators (PGR) (Gregory, 1965). Plant growth regulators (PGR) have considerable effects on tuber fertility and it is highly related to hormonal balance (Stuart and Cathey, 1961; Vreugdenhil and Struik, 2006). Auxins are shown many characteristics features suchas polar translocation, root and shoot growth, root induction, delay in abscission and differentiation of xylem elements (Ahmed et al 2011). PGRs are involved in initial hormone binding and activating the genes of meristematic cells by altering the secondary and tertiary messengers of a cellular cascade. Several PGRs can influence the growth and development; a particular response probably results from a changing ratio of hormones rather than from the presence or absence of an individual hormone (Suri et al., 1995). Perhaps, PGRs may indirectly control gene expression through biosynthetic pathway enzymes and messengers by acting during transcription, mRNA processing, mRNA stability, and at translational and post-translational modifications (George et al., 2007). The regulator of the Group of auxin IAA in plants causes high increases stem height and leaf area (Evans, 2003). Xu et al. (1998) indicated that GA is a dominant regulator in tuber formation and promoted stolon elongation and inhibited tuber formation. Timm et al. (1962) treated dormant or sprouted seed potatoes with various concentrations of gibberellic acid and indicated that emergence of plants from treated seed was more rapid than from untreated seed. Wareing and Jennings (1980) proved that the growth of secondary buds in potato stolons, has been intrigued and this phenomenon should predominate final dominancy. Racca and Tizio (1968) found that before tuberization the shoots contained large quantities of gibberellin-like substances which decreased after tuberization and it is suggested that these substances are of importance in the control of tuberization. Also, GA3 leads to smaller tubers resulting in increased bud numbers and stolons by removing of apical dominance. Foliar application of GA3 (5 and 10 ppm) increased the length of stems and stolons, and decreased the tuber fertility, but causes elongation of the stolons (Burton 1989; Chapman, 2006). GA3 is the regulator of Gibberellin groups that can break through the apical dominance in potato tubers, to increase the number of stolons in plants. In this study, density and plant growth regulators indole acetic acid and gibberellic acid were studied on yield and yield components of two cultivars of potato cultivars Jelly and Banba under greenhouse conditions.

Material and methods

The study was conducted in the fall of 2014 at Savin tissue culture center located in Hamedan for triple factorial randomized complete block design with three replications factor. The first factor involves the use of growth regulators in four levels (indole acetic acid, the use of gibberellic acid, the use of combined growth regulator and the lack of them), the second factor density at three levels, including 150, 100 and 200 plants per square meter and the third factor involves two stages (Jelly, Banba). That their initial plantlets were prepared from Isfahan biotechnology Institute And with using MS medium, single node cuttings were propagated in the center of the tissue culture medium plants (Murashige & Skoog, 1962). Each test includes a piece, with a width of 130 cm and a length of 80 cm. substrates of sand was used and for the disinfection of hydrogen peroxide H_2O_2. Nutrition of testing units was carried out in the form of hydroponics that include all of macro and micro elements according to the CIP recommendation and after the cultivation were treated in the same way. The plantlets were in a growth chamber for 30 days with 60 mol m s light intensity and temperature 22± 1 ° C. For ambient light from fluorescent lamps to 16 hours of light and 8 hours of darkness were used. transfer operation was performed after reproduce and prepare the conditions for growing plantlets in the greenhouse,. Then for the desired density, distances between plants and rows planted to a density of just under 100, 150 and 200 plants per square meter were taken into consideration. To do this 10 x 10 cm (distance between plants and rows) for a density of 100 plants per square meter and are 6.6 x 10 cm to 150 plant square meters and a distance of 5 x 10 cm Density 200 plants per square meter was considered. After the transfer operations and cultivate seedlings to adapt to greenhouse conditions for 8 to 10 days of clear plastic stretched over the row, and then was removed from the mentioned period (Haghtalab, 2006). Growth regulators for foliar treatment was performed. Spraying indole acetic acid(IAA) was done at a concentration of 50 ppm for 20 and 30 days after planting and spraying gibberellic acid(GA3) at a concentration of 50 ppm for 60 and 70 days after planting. For plots to use a hand sprayer and spray it on other plots to prevent a protective spray was used at the time. To determine the trend of leaf area index and seedling establishment after the first sampling interval was 14 days. Plant height was measured 60 days after planting. The following regression equation for charting changes during the growth period and calculates the maximum leaf area index (LAI) was used. Greenhouse ambient temperature range of 20 ± 5 ° C during the period of the experiment, light intensity was of ,650 -1,300mol m per second between sodium lamps canopy for just 8 hours of light and 16 hours darkness was applied. Shoots were removed during 100 days and were harvested two weeks later. Desired traits such as number of stolons, stolon length, number of branches and number of tubers per plant was measured. Software SAS was used for data analysis and for comparison of the least significant difference test was used at the 5% level.

Results and Discussion

Based on analysis of variance, plant height were compared by one percentage point by the main effects and interactions and growth regulators. Banba cultivar is higher than the Jelly genetically and both varieties showed significant response to indole acetic acid and combined application of plant growth regulators and showed an increase of 31% compared with control samples. These results correspond with the results of Aksenova (2001). It seems that the probability of no response to GA3 is related to the time of use of both varieties. Bodlaender (1989), used different concentrations of gibberellic acid in different growth stages of potato on the foliage and concluded that the usage of GA3 increased the length of the stem and stolom, and reduced the glandularity. But the usege of the regulator during the growth of stolons, increased the formation of the first growths and tubers with a diameter of 45-28 mm. According to the results of the analysis of variance of plant height were affected by a percent density, so that the plant height increased with increasing density. In this study, the maximum height is related to the density of 200 plants per square meter. It seems the reason is the increasing in intra-specific competition . Also Sarkar et al,(1997) examined the effect of seedling planting density in the micropropagation of two potato cultivars and seedling reported that the highest density were highest during the shoot, there were significant differences between the varieties of potato. Most LAI maximum is related to the jelly and Banba with 200 plants per square meter and in combination IAA and GA3, which increased by 55% compared with control samples and no significant difference between two cultivars in this density. There is a significant difference between the jelly and the Banba at 150 plant per square meter and has more leaf area index (LAI) lowest (LAI) related to the jelly on with a density of 100 plants per square meter in control samples and there was no significant between the control and use of GA3. The result of findings (2000 Boozina,) announced that IAA increased leaf area to be coordinated. The trend of leaf area index showed that plant growth regulators treated with combination therapy earlier than other treatments reached the maximum leaf area index. Comparisons between plants treated with GA3 and control samples show no significant difference in maximum leaf area index between them, but it has been reported that the use of GA3 delay the aging leaves (Evans, 2003). The trend of (LAI) plants treated with IAA also shows speed increased leaf area index was higher in ranged from 40 to 60 days after planting compared to the control (no growth regulator). IAA has been reported to slow the decline leaves (Evans, 2003). The number of stolons treated plants was evaluated. Studies show heads the largest number of stolons in both cultivars were obtained with combination therapy indole acetic acid and GA3 and compared with control samples increased 44 percent and the lowest was observed cv Jelly and in terms of consumption growth regulators. . There was no significant difference between taking two hormone GA3 and IAA individually about the number of stolons but significant differences were observed between consumption and avoiding the use of a percent. The combination of these two regulators growth-boosting effect on the 24 percent increase in the number of stolons per plant compared to the separate use of each of the two regulators IAA and GA3. These results are consistent with the findings of Kumar et al (1979) which had announced combination, IAA, GA3 and cytokinin on growth stolons, tuber formation and yield of potatoes is effective and enhances them and corresponded with the results Dehitall (2004) report the application of auxin increased the number of stolons and leads to an increase in the number of tubers. The largest number of stolons branch of the Banba with concomitant administration of IAA and GA3, but no significant difference in the situation with the Jelly compared to control 66 per cent is the lowest number of stolons branch of the Banba in the control sample. Haghtalab (2006) declared regulators BAP and GA3 increases the number of stolons radiating the stage stolons formation, the findings of this study are consistent. Also Biemelt et al (2000) reported the use of GA3 at the stage of tuber formation the number of branching stolons very impressive and confirms these results. Analysis of variance showed that the number of tubers per plant was affected by the main effects and interaction between cultivar, regulator and density. Banba with combined consumption figure is the highest number of tubers per plant regulators, which is a 38% increase compared to the control sample. The results show significant differences between the figures can be seen in terms of production potential. Between the growth regulators also showed a significant difference in their combination with other treatments. Among the different densities the density of 100 plants per square meter has the largest number of tubers per plant. The results of this study with the results Shaterian & Niamanesh (2003) that reported consumption regulators to increase number of tuber per plant and the number of tubers production per plant gradually decreases with increasing plant density is consistent. Due to the low rate of reproduction at high density. Also Karafyllidis et al , (2006) reported an increase in the density of the resulting tubers and increased yield per unit area, but tuber size and yield per plant is reduced.

Conclusions

According to the results Banba has the height and leaf area index is greater than furtive. Increasing plant density and mixed use growth regulators led to an increase in both the number and height of leaf area index. Simultaneous use of growth regulators to increase the number of stolons of both varieties, but the number of branching stolons with IAA consumption increased only in the Banba cultivar. The total number of tubers for seed production as well as the number of tuber size combined with the use of growth regulators increased significantly for both varieties. Therefore, in general, can be recommended to increase the number of tubers with 150 plant growth regulators, particularly in the Banba used per square meter.

Abstract

In order to estimate the combining ability, genetic variance components and heritability of traits related to rapeseed (*Brassica napus* L.) grain oil yield, an experiment was designed using the line×tester method. Fifteen hybrids derived from crosses of three spring and high yielding testers (SPN34, RGS003, SPN1), with five lines specific to a hot climate (SPN3, SPN9, SPN36, SPN30, DH4) were tested using a randomized complete blocks design with two replications at the Seed and Plant Improvement Institute in Karaj (Iran) during 2014-2015. The traits under study included: grain yield, biological yield, harvest index, 1000-grain weight, the percentage of oil, and oil yield. The difference among hybrids was significant for all traits, which was a reason for the presence of high genetic diversity among hybrids. The value of additive variance was higher than the dominant type for all traits. The additive variance was important in controlling the 1000-grain weight and biological yield, but for the rest of the traits, two components of variance were included with different values. Referring to high broad-sense heritability (89.84%-98.26%) and low differences between phenotypic and genotypic coefficients of variation, it was concluded that the role of genetical variance was more important than the phenotypic one. The values of narrow-sense heritability were different, from 55.77% of oil yield to 88.67% for 1000-grain weight. Among the tester and the lines, SPN1 as a tester and DH4 and SPN30 as lines were most combinatorial for grain yield and oil yield. In addition, DH4×SPN1, SPN36×RGS003 hybrids were distinguished as the best hybrids and, so it was advised to use their parents in the production of hybrid varieties by using the male sterility system.

Keywords: *rapeseed, yield components, heritability, combining ability, variation, yield*.

Introduction

Yield as a complex trait with polygene inheritance is influenced by various quantitative traits. By being aware of the mode of genetics control and heritability of yield components, we are able to choose the best breeding methods to improve yield. Breeders estimate trait controlling genetic components in plant populations using different crossing designs. In order to evaluate combining abilities and also to estimate phenotypic variance components, line×tester method has been used especially in the cultivation of plants like rapeseed (Ashraf and Neilly, 2004). In most cases, the additive effect of genes was more important, but the dominant effect of genes was also intervened in the controlling of traits (Roy and Basu, 2009). Amiri-Oghan (2000), by studying F2 genotypes in rapeseed, showed that the role of the additive and non-additive effect of genes are equal in the genetic control of grain yield. Whereas, for oil yield, the non-additive effect of genes was highly important in the controlling of this trait. The non-additive gene action for grain yield in rapeseed controlling was reported by Thukral and Singh

(1987). In a report by Thakur and Sagwal (1997), traits like yield and its components and the percent of oil were under control of both additive and non-additive genes. Low narrow-sense heritability of grain yield and the percent of grain oil was reported in a study on F1 and F2 populations of rapeseed trials conducted at different locations and years (Brown *et al.*, 1996). In addition, Malik *et al.* (1995) studied the inheritance of grain yield, and they understood that the heritability for grain yield is low. The high estimation of narrow-sense heritability of grain oil in winter rapeseed was reported by Wu *et al.* (2006) as well as Malik *et al.* (1995). Jeromela *et al.* (2007) investigated the general combining ability (GCA) and specific combining ability (SCA) in diallel crosses with five rapeseed. The effect of GCA was statistically significant for all traits, with exception of grain yield.

The aim of this research was to obtain information pertaining to genetic diversity, effect/mode of actions of genes, heritability, and combining ability for grain yield and oil yield in rapeseed.

Materials and Methods

This experiment was performed in Karaj Seed and Plant Cultivation and Registration Institute of Iran. In this research, 15 spring hybrids derived from the crosses between 5 lines adopted for Iran warm climate (SPN3, SPN9, SPN36, SPN30, DH4) and 3 testers (SPN34, RGS003, SPN1) were evaluated through randomized complete block design with two replications. The traits included grain yield, biological yield, harvest index, 1000-grain weight, percent of oil and oil yield were measured by a random sample of 5 competition plants. The percent of the oil was measured by Nuclear Magnetic Resonance Spectrometry (NMR) is used for determining the percent of oil.

For statistical analysis, line×tester method was used (Kempthorne, 1957). In order to calculate genetic variance components, refer to the homogeneity of genotypes and use of F1 generation, inbreeding coefficient equal to one was used. The mode of gene action was determined by the ratio of GCA mean of the square (S^2_{GCA}) to SCA mean of the square (S^2_{SCA}). The mean of dominant degree is obtained from the square root of double dominance variance divide to additive variance.

Results and Discussion

The differences among lines were statistically significant for all traits, as well as among tester with exception of the percent of grain oil and harvest index. This finding indicated that diversity among lines is more than among testers for the percent of grain oil and harvest index. The significant difference among the tester as well as lines for different traits is an indicator for controlling traits by additive effects of genes. In plant breeding, selection for traits under control of additive genetic effects is confidential and consequently, transfer of such traits to next generation is more feasible. The line×tester effects were significant for all traits, with exception of the 1000-grain weight seeds, showing the varied reaction of different lines in combination with different testers. This is a reason for the superiority of non-additive genetic effects in controlling the mentioned traits (tab. 1).

Table 1: Variance analysis of studied traits for 15 spring hybrids derived from the crosses between 5 lines of Iranian rapeseed for line×tester analysis.

S.O.V	df	Mean Squares (MS)

ns, * and **: Non-significant and significant at 0.05 and 0.01 probability.

Genetic variance was separated into additive and dominance variances for all traits (tab. 2). The value of additive variance was higher than the dominant one for studied traits. Broad-sense heritability of traits was relatively high, varied from 89.48% for oil percent to 98.26% for harvest index. In this regard, it can be stated that environmental variance was extremely low and the importance of genetic variance was higher than environmental variance. However, due to conducting the test in one year, some part of the genetic variance probably is due to the variance from the interaction between the genotypes with the environment. The percent of narrow-sense heritability was higher than average for all traits, being between 55.77% for oil yield and 88.76% for the 1000-grain weight (tab. 3). Amiri-Oghan *et al.* (2010) reported high broad-sense heritability for yield-related traits by line×tester analysis, while the value of narrow-sense heritability for most traits was intermediate.

Table 2: Estimation of genetic variance, the average degree of dominance, heritability, and coefficients of variation for 15 spring hybrids derived from the crosses between 5 lines of Iranian rapeseed.

Genetic statistic	1000-grain weight	Oil Percent	Biologic Yield	Harvest index	Grain Yield	Oil Yield
V_A	0.44	1.25	3985.92	132.78	8620.16	15.18
V_D	0.03	0.65	10207.74	87.52	5564.94	10.57
$(2V_D/V_A)^{0.5}$	0.37	1.02	0.71	1.15	1.14	1.18
h^2_B	94.92	89.48	94.93	98.26	94.73	94.58
h^2_N	88.76	58.86	75.49	59.22	57.57	55.77
V_G	0.47	1.89	50062.66	220.29	14185.10	25.75
V_P	0.49	2.12	52791.66	224.20	14973.91	27.23
GCV	18.82	3.23	54.24	28.24	55.74	55.66
PCV	19.32	3.42	55.70	28.49	57.27	57.23
S^2_{GCA}	0.22	0.62	19927.46	66.39	4310.08	7.59
S^2_{SCA}	0.03	0.65	10207.74	87.52	5564.94	10.57
S^2_{GCA}/ S^2_{SCA}	7.21	0.96	1.95	0.76	0.77	0.72

V_A: additive variance, V_D: dominance variance, $(2V_D/V_A)^{0.5}$: average degree of dominance, h^2_B: broad sense heritability, h^2_N: narrow sense heritability, V_G: genotypic variance, V_P: phenotypic variance, GCV: genotypic coefficient of variation, PCV: phenotypic coefficient of variation, S^2_{GCA}/ S^2_{SCA}: The ratio of GCA variance to SCA variance.

The phenotypic coefficient of variation (PCV) was higher than the genotypic coefficient of variation (GCV) for all investigated traits, although the differences between them were relatively low, an indication of slight effects of the environment. The higher value of GCV was pertained to grain yield and oil yield, while the percent of oil had the lowest GCV (Table

2). Esmaeili *et al.* (2015) regarded the higher value of GCV to oil yield and then to grain yield, conforming to the results of this research.

In the estimation of gene action, if the rate of S^2_{GCA}/ S^2_{SCA} is higher than one, it shows the important role of additive genetic variance in controlling of the trait, and if it is lower than one, it reveals non-additive genetic variance. In this experiment, the role of additive genetic variance was more significant than the non-additive genetic variance in order to estimate the 1000-grain weight and biologic yield (tab. 2). The results of this experiment is conformed to the results of Gholami and Moghaddam (2006), Tekelwold and Becker (2005), Qureshi *et al.* (2017) in concerning the 1000-grain weight, Gholami and Moghaddam (2006), Satwinder *et al.* (2000) and Ahmadi and Sameezadeh (2006) on the percent of oil, as well as Ahmadi and Sameezadeh (2006), Satwinder *et al.*, (2000), Singh *et al.*, (2002), Varsha *et al.*, (1999) for grain yield.

The average degree of dominance for traits was varied from 0.37 for the 1000-grain weight to 1.18 for oil yield (tab. 2). The higher and lower average degree of dominance to one, shows over-dominance and relative dominance of genes action, respectively. The average degree of dominance higher than one in traits including oil percent, harvest index, grain yield and oil yield, emphasizing the dominance action of genes controlling these traits. But given that dominance genetic variance is lower than additive genetic variance, the over-dominance action of genes can be false and due to the accumulation of incomplete dominance and/or linkage of genes (Amiri-Oghan, 2000). In a research on rapeseed by Gholami *et al.* (2008) using line×tester analysis, the average degree of dominance for grain yield was estimated more than one, which represents the over-dominance gene action and also the important role of non-additive action of genes in the genetic control of this trait. This finding was consistent with the result of our research.

Table 3: Estimation of general combining ability (GCA) for lines and testers of Rapeseed.

	Rapeseed genotypes	1000-grain weight(g)	Oil Percent (%)	Biologic Yield (g)	Harvest index (%)	Grain Yield (g)	Oil Yield (g.plot^{-1})

	SPN1	-0.96*	-0.78**	252.00**	-3.12**	141.33**	5.73**

ns, * and **: Non-significant and significant at 0.05 and 0.01 probability.

Among the studied genotypes in this research, some of them had the highest positive and significant general combining ability (tab. 3). These are included: line DH4 for harvest index, oil yield, and grain yield, SPN30 for the percent of oil and biologic yield, line SPN36 for the 1000-grain weight, tester SPN34 for the 1000-grain weight and harvest index, tester RGS003 for percent of oil, and tester SPN1 for biologic yield, grain yield and oil yield. These genotypes have the ability to transfer their genetic superiority for yield potential to their progeny. Therefore, these genotypes can be used in breeding programs to produce rapeseed hybrid varieties with high performance. In the breeding process of rapeseed, the target is not only to find the best pure line, but also to find the best hybrid combination with suitable characteristics in genotype and phenotype, since it was observed that the best lines for general combining ability cannot always produce the best hybrid.

In plants such as rapeseed, which the ultimate aim is grain yield, the emphasis is on grain yield-related traits. Refer to values of specific combining ability, the best combinations included SPN36×RGS003 for percent of oil, biologic yield, grain yield and oil yield, as well as DH4×SPN1 for harvest index and grain yield, and DH4×SPN34 for the 1000-grain weight (tab. 4). The experiments on different types of Brassica like rapeseed emphasized that the effect of general combining ability (GCA) in F1 population was significant for the components of yield and the effects of specific combining ability (SCA) were slightly significant, conforming to the results of this research (Chopra and Prakash, 1996).

Table 4: Estimation of specific combining ability (SCA) for crosses of Rapeseed.

ns, * and **: Non-significant and significant at 0.05 and 0.01 probability.

Conclusion

In this study, there was sufficient genetic diversity in traits related to grain and oil yields, so that it can be used to enhance yield and create new varieties. The results showed that the impact of additive variance was more significant than non-additive variance for the 1000-grain weight and biologic yield. Hence, it is suggested to breed these traits with the selection-based methods. The degree of dominance was more than one in traits including percentage of oil, harvest index, grain and oil yields, which represents the over-dominant effects of genes control these traits. Consequently, the dominance gene effects of these traits can be used for hybrid seed production. The tester SPN1 and the lines DH4, and SPN30 were extremely nice genotypes for the combination of grain and oil yield-related traits. Furthermore, DH4×SPN1 and SPN36×RGS003 were as superior hybrids combinations among hybrids for grain and oil yield-related traits. Hence, the parents of these hybrids can be used in the program for hybrid seed production using male sterility system. Broad-sense heritability was very high for investigated traits. The difference between the coefficient of the phenotypic variation and the coefficient of genotypic variation was very low, and it can be concluded that the genetic variance is important than the environmental variance in the control of traits studied in this research. It is necessary to mention that the results of this research cannot be extrapolated to other rapeseed genotypes which are not included in this study because the effect of genotypes is assumed to be fixed. As if, some of the differences in the findings of this study with others is due to plant materials. Thus, employment of genotypes with a wide range of diversity may result to a comprehensive conclusion on partitioning genetic variation. Regardless of the accuracy of results derived this experiment, it is necessary to perform the study in more year and place to estimate the interactive effects of genotype with the environment to estimate the heritability of traits by high reliability.

Abstract

The most of the cultivated crops are often facing with drought stress and application of some nanoparticles and growth regulators alleviate the adverse effects of stress. Present study is performed to evaluate the effects of foliar application of salicylic acid (S-A), glycine betaine (G-B), ascorbic acid (A-A), nano-silica (nano-SiO_2) and nano titanium dioxide (nano-TiO_2) on yield and yield component of sunflower. Chlorophyll content, leaf length, leaf width, days to 50% flowering, day to maturity, plant height, husk percentage, number of seeds per head, head number per plant, percentage of empty achenes, 1000-seed weight, kernel weight, grain length, straw yield, harvest index, grain yield and oil percent were measured. Results showed that the first two principal components were used to create a two-dimensional treatment by trait biplot that accounted percentages of 49% and 19% respectively of sums of squares of the TT interaction. The vertex treatments were A-A, G-B, Nano-TiO_2 and control which Nano-Ti_2 treatment indicated high performance in chlorophyll content, day to maturity, number of seeds per head, head number per plant, kernel weight, grain length, straw yield, harvest index, grain yield and oil percent. Treatments suitable for obtaining of high seed yield were identified in the vector-view function of TT biplot and displayed nano-silica and nano titanium dioxide as the best treatmentS suitable for obtaining of high seed yield. In short, nano-fertilizer could increase crop yields and improve the fertilizer efficiency.

Introduction

Sunflower annual production in Iran is about one million tones which achieved from 700 thousand hectares while the average yield is relatively low and it has been recorded about 1050 kg ha^{-1}. In semiarid areas, where the proportion of less fertile soils is high, it may be difficult to fulfill the nutritional needs of crops and fertilizer application represents a suitable tool to compensate nutrient deficiencies and to replace elements removed in the products harvested. Utilization of exogenous compatible solutes and growth regulators in semi-arid regions can be an effective practice for improving crop performance which is generally applied to mitigate the adverse effect of environmental stress (Senaratna et al., 2003). Compatible solutes are molecules that protects cells from desiccation by maintaining a high intracellular osmolality and among different materials, glycine betaine (GB) has been further investigated and suggested that GB has very imperative role in crops protection under extreme environmental conditions (Farooq et al., 2008).
Salicylic acid (SA) is naturally occurring plant hormone, influences various physiological and biochemical functions in plants because it can play role as a regulatory signal mediating plant response to abiotic stresses such as drought. Ascorbic acid (AA) has been used to as a cofactor for enzymes involved in regulating photosynthesis, hormone biosynthesis, and regenerating other antioxidants; and it is essential to many aspects of plant growth and responses.

Nano-titanium dioxide particles are promising as efficient nutrient source for plants to improve biomass production by enhancing metabolic activities and conversion of light energy (Gao et al., 2008), and also, it increase the activity of the enzymatic antioxidant factors such as superoxide dismutase peroxidase (Hong et al., 2005). According to Raliya et al. (2015), foliar application of nano-titanium dioxide particles on mung bean could significantly improve morphological traits, chlorophyll content and soluble leaf protein and according to Siddiqui et al. (2015), foliar application of nano-silica has gained greater consideration during growth period. Also, foliar spray of nano-silica on plants improve the plant growth and performance by enhancing the accumulation of antioxidant enzymes and increase the efficiency of photosynthetic apparatus (Kalteh et al., 2014). Therefore, the aim of the this investigation was to determine the possible role of glycine betaine, salicylic acid and ascorbic acid growth regulators and nano-silica ($nSiO_2$) and nano-titanium dioxide (TiO_2) particles on morphological traits, yield components, seed yield and oil content of sunflower.

Material and methods

The experiment was performed based on randomised complete block design in four replicates with Azargol sunflower seeds at 28 March. Each experimental plot was consisting of 8 rows, 4.5 m length, and at 60×20 cm inter-plant and inter-row, respectively. Weeds were controlled by hand-hoeing. Treatments were Control: water spray, Nano-Si: foliar application of nano-silica suspension (2 mM), G-B: foliar spray of glycine betaine (100 mM), S-A: foliar spray of salicylic acid (1 mM), A-A: foliar application of ascorbic acid (1 mM), and Nano-Ti: spray of nano-titanium dioxide suspension (2 mM).

Chlorophyll content (CHL) was measured with a hand-held dual wavelength meter (SPAD 502, Chlorophyll meter, Japan) in fully expanded upper leaves at the flowering stage. Leaf length (LL) and leaf width (LW) were measured at the end of flowering stage on ten randomly selected plants. Also, traits days to 50% flowering (DF) and day to maturity (DM) were recorded. The morphological traits plant height (PH), husk percentage (HP), number of seeds per head (NSH), head number per plant (HNP), percentage of empty achenes (PEA), 1000-seed weight (TSW), kernel weight (KW), grain length (GL), straw yield (STY), harvest index (HI), grain yield (GY). Oil percent (OIL) of seed were measured using a Near-infrared seed analyzers analyzer (Zeltex). Treatment by trait (TT) analysis using biplot analysis (Yan and Kang, 2003) was used to determine which treatment was best and for what trait which were generated using the standardized values of the traits means. All analyses reported in this study were conducted by using the GGEbiplot software (Yan, 2001).

Results and discussion

The first two principal components explained 68% of total variation (Fig. 1). In order to distinguish meaningful groups of tester (traits), repeatable patterns among traits have to be demonstrated through treatment by trait interaction biplot analysis. Fig. 1 shows the "which-won-where" view of biplot and the outmost treatments (four in this case) formed a four-side polygon and the biplot was divided into four sectors delimited by the lines perpendicular to each side of the polygon. The measured traits fell into all of the four sectors. For traits within a sector, the nominal "winner" is at the vertex and so, Control and A-A (ascorbic acid) were the wining treatments only for a single trait, percentage of empty achenes (PEA) and plant height (PH), respectively (Fig. 1). However, G-B (glycine betaine) was the winning treatments in the sector containing the husk percentage (HP), days to 50% flowering (DF), leaf length (LL), 1000-seed weight (TSW) and leaf width (LW) traits. Finally, Nano-Ti was the winning treatments in the sector containing the other 10 traits including chlorophyll content (CHL), day to maturity (DM), number of seeds per head (NSH), head number per plant (HNP), kernel weight (KW), grain length (GL), straw yield (STY), harvest index (HI), grain yield (GY) and oil percent (OIL).

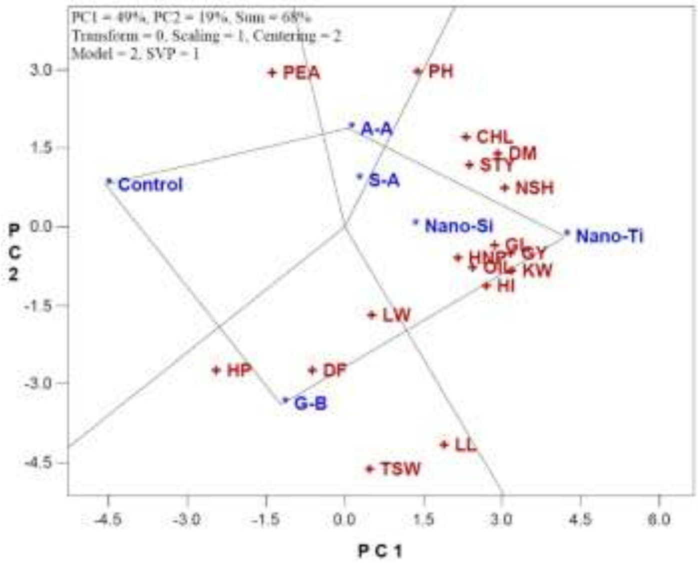

Fig. 1. Polygon-view of treatment by trait (TT) biplot showing which treatment had the highest values for which traits.

The results shown in Fig. 1 suggested that there might be distinct groups of traits (four in this case) in compliance with the large magnitude of treatment by trait interaction and the high value of PC1 and PC2 contributions to the total sum of squares in TT biplot. Summary of the interrelationships among the treatments for different traits provides Fig. 2. The lines connecting the biplot origin with the markers for the traits are called trait vectors and the angle between the vectors of two traits is related to the correlation coefficient between them. The cosine of the angle between the vectors of two traits approximates the correlation coefficient between them (Yan and Rajcan, 2002). Based on the cosine of angles of traits vectors, there were positive correlation among CHL, STY, DM and NSH as well as among GY, GL, KW, HNP, OIL and HI (Fig. 2). Also, there was near zero correlation between LL with PH, between LL with HP, between PEA with PH, and between TSW with CHL, STY, DM and NSH traits (Fig. 2). The presence of wide obtuse angles i.e. strong negative correlations among the traits (between PEA with LL, between PH with DF and between HP with CHL, STY, DM and NSH) is indication of strong cross-over TT interactions (Yan and Tinker, 2006). According to literature, such results have also been reported for positive correlation between seed with 1000-seed weight (Singh et al., 1990) and oil content (Jhagirdhar, 1986).

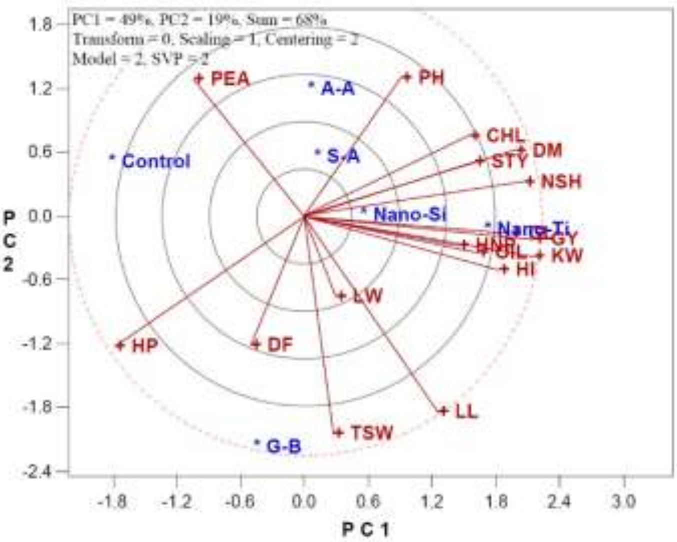

Fig. 2. Vector view of treatment by trait (TT) biplot showing the interrelationship among measured traits under different treatments.

The best treatment for obtaining of high grain yield (GY) and high oil content (OIL) could be find in the special vector-view of TT biplot (Fig. 3) which shows treatments that have close association with a target trait among other traits. According to these biplots of Fig. 3, Nano-Ti following to Nano-Si treatments were the best treatments suitable for obtaining of high performance of grain yield as well as high oil content. Thus, application of this treatment combination is expected to lead to improve the target trait under rainfed growing conditions in semi-arid region. This suggests that using nano-titanium dioxide suspension (2 mM) or nano-silica suspension (2 mM) will not only result in the development of high grain yield but also cause to obtain the other desirable agronomic traits which are associated to grain yield such as oil content. Therefore, it seems that application of Ti and Si nanoparticles had good effect on sunflower yield performance, yield components and morphological traits in comparison to application of glycine betaine (100 mM), salicylic acid (1 mM), ascorbic acid (1 mM) compounds of water spray (Control). Nano-titanium dioxide has been studied as photocatalysts (Ullah and Datta, 2008). In another experiment, Zheng et al. (2005), considered, germination rate and vigor index of spinach old seeds that treated with the nano-titanium dioxide and observed that most traits increased in seeds treated while Lu et al. (2002) reported that evaluations for super oxide dismutase and catalase increased in soybean that had been treated with nano-titanium dioxide. Also, Owolade et al. (2008), reported that nano-titanium dioxide application on some traits of cowpea such as number of seeds per pod, number of pod per plant, 1000 seed weight and grain yield performance were better than of these traits increased compared to the control. Some treatments like as nano-titanium dioxide and nano-silica increased the plant growth characteristics and partly expanded the source size, thus, it revealed that nanoparticles improved the both vegetative and reproductive traits. These findings further support the idea of Jaberzadeh et al. (2013) who reported that application of nano-titanium dioxide increased wheat growth and significantly improved grain yield under drought stress condition. Our finding about increment of oil percentage in yield performance by application of beneficial nanoparticles corroborates these earlier findings. Davar-Zareii et al. (2014) found that foliar application of nanoparticles during reproductive growth stage significantly improved the oil percentage in safflowerTherefore, results of present study suggested that foliar application of nano-titanium dioxide in proper concentrations under semi-arid highland region can be suitable option for improving sunflower production.

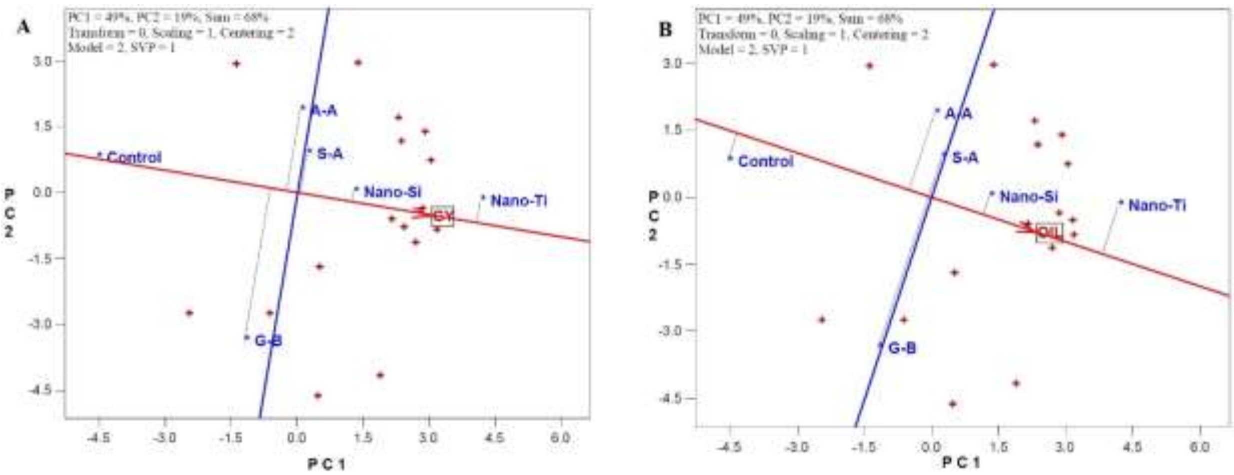

Fig. 3. Vector view of treatment by trait (TT) biplot, showing the relationships of different treatments with grain yield (GY) and oil content (OIL) traits.

Our study results indicate that nano-titanium dioxide and nano-silica play a significant role on increasing of sunflower yield and other traits, so that higher amounts of traits obtained with spraying of nanoparticles in compared with spraying distilled water (Control), A-S, A-A and G-B. The studies on improving photosynthesis suggested that nano-Tio_2 could increase this process and protect chloroplasts (Yang et al., 2006). Nano-Tio_2 particles enhanced seed germination and growth of canola seedlings (Mahmoodzadeh et al., 2013), as well as improving plant growth and yielded components of wheat under drought stress conditions (Jaberzadeh et al., 2013). Application of nano-SiO_2 and nano-TiO_2 particles improved seed germination of soybean by increasing nitrate reductase (Lu et al., 2002) and also by enhancing seeds ability to absorb and utilize water as well as nutrients (Zheng et al., 2005). The lower concentrations of nano-SiO_2 improved seed germination of tomato (Siddiqui and Al-Whaibi 2014), and seedling growth of Changbai larch while nano-SiO_2 enhances the plant growth and development by increasing chlorophyll parameters, such as net photosynthetic rate, transpiration rate and photochemical quench (Siddiqui et al., 2014).

Conclusions

Foliar spray of nano-titanium dioxide following nano-silica nanoparticles considerably enhanced the yield and yield components of sunflower performance in semi-arid region. In contrast application of glycine betaine, salicylic acid and ascorbic acid had not any positive effect on sunflower. The biplot analysis could help to visualize the interrelationships among treatments, traits and interaction between them and so was an efficient statistical tool for interpreting such dataset.

BIPLOT ANALYSIS OF PRE-SOWING TREATMENTS OF DRAGONHEAD (*DRACOCEPHALUM MOLDAVICA* L.) WITH SOME NANO- PARTICLES

Reyhaneh Hamedi ESFAHLAN*, Naser SABAGHNIA

Department of Plant Production and Genetics, Faculty of Agriculture, University of Maragheh, Maragheh, Iran.
*Corresponding author: reyhane.hamedi@yahoo.com

Abstract

In this research, two types of nano-particles including nano-iron and nano-silicon particles have been investigated in seed priming of dragonhead processing. The pre-hydration treatments were nano-silicon dioxide levels consist on (Si1) 0 mM or distilled water, (Si2) 1 mM and (Si3) 2 mM and nano-iron oxide levels consist on (Fe1) 0 Mm or distilled water, (Fe2) 1 mM and (Fe3) 2 mM. Some seed germination characteristics including germination percent, root fresh weight, shoot fresh weight, root length, shoot length, dry weight of the seed residue, root dry weight and shoot dry weight were measured in each experimental unit. The treatment by trait biplot technique was used to data and showed that the first two principal components, explained 80% of variation. Traits germination percent, root fresh weight, shoot fresh weight, root length, shoot length and root dry weight were in the same sector, with Si2-Fe3 treatment (1 mM nano-silicon dioxide and 2 Mm nano-iron oxide) as the best treatment. The best treatment combination suitable for obtaining of high values of germination properties was determined as S2-F3 (1 mM nano-silicon dioxide plus 2 mM nano-iron dioxide) based on ideal entry biplot tool.

Keywords: *nanoparticle, Dracocephalum moldavica L. seed germination*

Introduction

Dragonhead is originated from south Siberia and is native to central Asia and naturalized in eastern and central Europe (Omidbaigi et al., 2010). Its essential oil is used widely in medicine, food, cosmetic and health industries. Dragonhead is used in folk medicine as a painkiller and is distributed in high altitudes in central and northern regions and it has been used as analgesic agent and a part of the remedy against many diseases. In stress condition, early sowing can hasten plant growth and may avoid the facing of critical stages of development with terminal stresses (Janmohammadi et al., 2013).) Pre-sowing seed treatments are applied by various methods for enhancing pre-germination and post-germination activities of seed.

Nanoparticles can easily enter into plant by overcoming the cell wall barrier and have achieved greater consideration because of their highly reactive surface-to-volume ratio property (Lyons et al., 2011). The study of Janmohammadi and Sabaghnia (2015) indicated that controlled imbibition of sunflower achene in nano-silicon solution followed by dehydration could significantly enhance seed germination. These positive effects of nano-silicon in primed seeds may suggest that they would exhibit more acceptable agronomic and physiological performance in sunflower. Using of nano-particles has given a lot of interesting by different investigators especially by those studying seed properties and some useful nano-particles were reported to have a useful effect in plants such as by nano-silicon dioxide and nano-iron oxide. The purpose of present study was to investigate the effect of seed priming with nano-silicon dioxide and nano-iron oxide particle treatments on seed germination of dragonhead to find out the most promising concentration by using biplot method.

Materials and methods

Primary germination rate of seeds was greater than 90%. Seeds were subjected to pre-hydration treatments by soaking in three levels of nano-silicon dioxide as; (Si1) 0 mM nano-silicon dioxide or distilled water, (Si2) 1 mM nano-silicon dioxide concentration and (Si3) 2 mM nano-silicon dioxide concentration and three levels of nano-iron oxide as; (Fe1) 0 Mm nano-iron oxide or distilled water, (Fe2) 1 mM nano-iron oxide concentration and (Fe3) 2 mM nano-iron oxide concentration. One piece of filter paper was put into each 100 mm × 15 mm Petri dish, and 10 mL of each test solution was added to each experimental sample. Forty-five seeds were selected and placed in each Petri dishes and then were covered and sealed with tape, placed in an incubator. Germination percent (GP) was calculated. All measurements were executed as described in Seedling Evaluation Handbook (AOSA, 1991). RFW, root fresh weight (g); SFW, shoot fresh weight (g); RL, root length (cm); SL, shoot length (cm); DWS, dry weight of the seed residue; RDW, root dry weight (g); and SDW, shoot dry weight (g) were recorded. Each treatment combination (Si-Fe: nano-silicon dioxide × nano-iron oxide) was conducted with five replications. The two-way treatment × trait (TT) biplot model is used based on Yan and Rajcan (2002). Visual analysis of TT biplot was performed using figures which were generated via the GGEbiplot software (Yan, 2001), using scores of first two principle components analysis (PC1 and PC2). The statistical properties of biplot interpretation have been described in detail by some researchers (Yan et al., 2007; Sabaghnia et al., 2015).

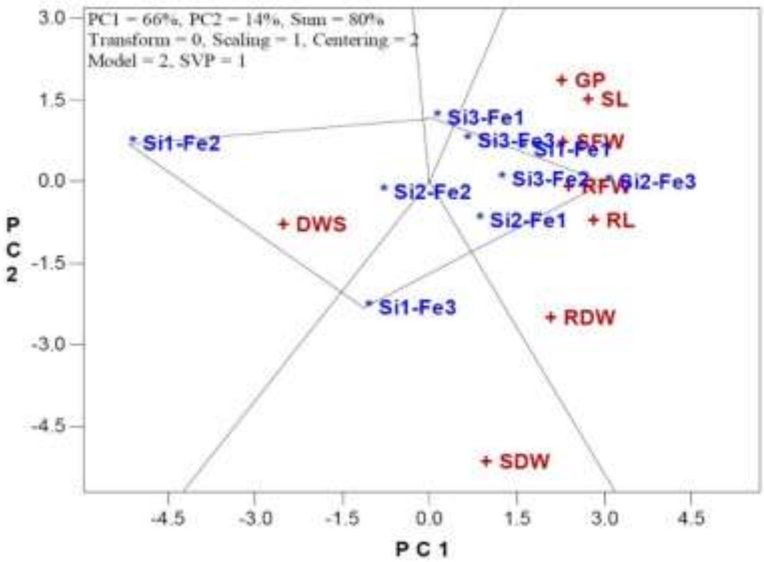

Fig. 1. Polygon-view of TT biplot showing which treatment had the highest values for which traits. Fore abbreviations, refer to the text.

Results and discussion

The first two PCs (PC1 and PC2) based on TT biplot method together explained 80% (66 and 14% for the PC1 and PC2, respectively) of the observed variation for the measured traits of dragonhead under priming treatments (Fig. 1). Biplots could effectively identify TT interaction and which-won-where information (Yan et al., 2000) and using this method, seed priming treatments can be evaluated for their performance in individual traits and across traits. Figure 2 indicates which seed priming treatment won where for dragonhead germination properties. Most of the measured traits including germination percent (GP), root fresh weight (RFW), shoot fresh weight (SFW), root length (RL), shoot length (SL) and root dry weight (RDW) were in the same sector, with Si2-Fe3 treatment (1 mM nano-silicon dioxide and 2 Mm nano-iron oxide) as the best treatment (Fig. 1). Dry weight of the seed residue (DWS) was in the other sector, with Si1-Fe2 treatment (0 mM nano-silicon dioxide and 1 Mm nano-iron oxide) as the best fertilizer treatment while shoot dry weight (SDW) was in the another sector, with Si1-Fe3 treatment (0 mM nano-silicon dioxide and 2 Mm nano-iron oxide) as the best fertilizer treatment (Fig. 1). The other vertex fertilizer treatment Si3-Fe1 treatment (2 mM nano-silicon dioxide and 0 Mm nano-iron oxide) was not the best in any of the measured traits (Fig. 1). Therefore, it seems that for obtaining the best performance in most of the measured traits, application of Si2-Fe3 treatment would be useful for good seed germination of dragonhead, following to Si1-Fe1, Si2-Fe1, Si3-Fe2 and Si3-Fe3 treatments. The present findings seem to be consistent with other researches, which found that the significant beneficial influences of the nano-silicon particles on seed germination properties of lentil and sunflower (Sabaghnia and Janmohammadi, 2014; Janmohammadi and Sabaghnia, 2015).

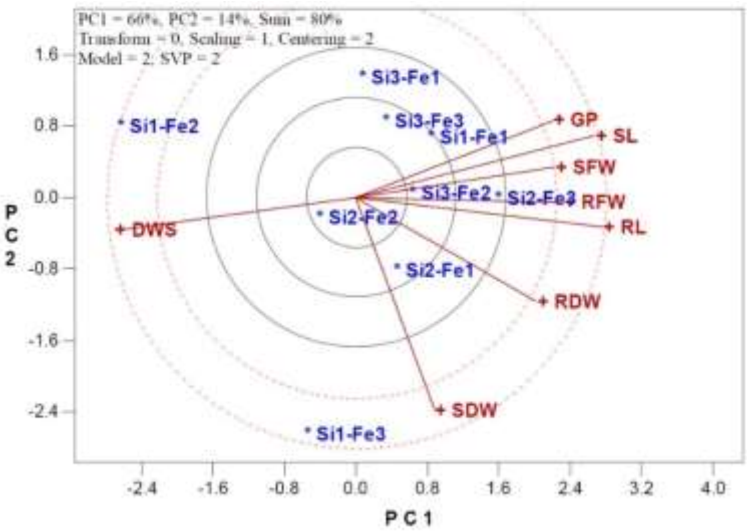

Fig. 2. Vector view of TT biplot showing the interrelationship among measured traits of dragonhead under different priming (Nano-Si and Nano-Fe) treatments. Fore traits' abbreviations, refer to the text.

Figure 3 is showing the interrelationship among the measured traits using the lines connecting each trait marker to the origin of the biplot, the length of each trait vector approximates the standard deviation of each trait and the cosine of the angle between the vectors of any two traits approximates the correlation coefficient between the traits. From Fig. 2, GP, SL, SFW, RFW and RL were highly positively correlated and it shows they all gave similar information about variability among the treatments. These results were in agreement with those reported by Bhagowati and Saikia (2003) and Tuncturk and ÇiftÇi (2005). Also, dry weight of the seed residue (DWS) had approximately negative correlation with GP, SL, SFW, RFW and RL. A near zero correlation between SDW with DWS, and between SDW with GP, SL, SFW, RFW and RL traits as indicated by the near perpendicular vectors (Fig. 2).

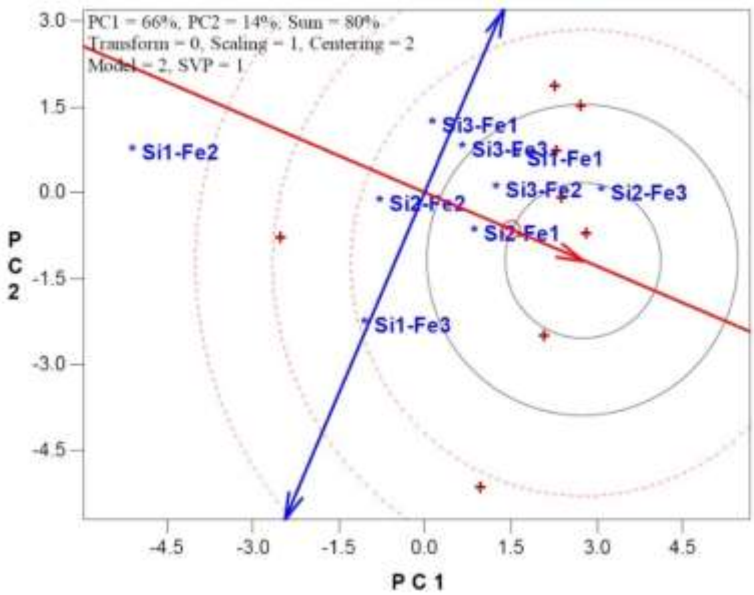

Fig. 3. Ideal entry view of TT biplot, showing the relationships of different priming (Nano-Si and Nano-Fe) treatments with ideal entry (treatment) in dragonhead. Fore traits' abbreviations, refer to the text.

An ideal entry or treatment has been defined as the treatment that combines several good traits in its performance and it should possess the highest mean performance across traits (average tester coordinate) abscissa and shortest entry-vector, thus, it should be close to the ideal entry represented by the innermost concentric circle with an arrow pointing to it (Sabaghnia, 2015). It can be used as a reference check in subsequent trials where the set of traits will be measured. In the biplot of Fig. 3, the single-arrow line that passes through the biplot origin is referred to as average tester coordinate and on this line is ranked the cultivars in terms of their morphological performance. The double-arrow line (average tester coordinate ordinate) divides the average tester coordinate abscissa into two at the middle and the portion of the average tester coordinate towards the right displays the above average cultivars and towards the left shows those treatments below average. Based on this biplot, the treatments that performed above average were Si1-Fe1, Si2-Fe1, Si2-Fe3, Si3-Fe2 and Si3-Fe3; while Si1-Fe2, Si1-Fe3 and Si2-Fe2 performed below average in terms of germination properties (Fig. 3). Si2-Fe3 treatment (1 mM nano-silicon dioxide and 2 Mm nano-iron oxide) is closest to the position of an ideal treatment and it is ranked the highest in term of germination performance because it is desirable in terms of most of the germination properties. This treatment could serve as a priming treatment from the other treatments. However, priming at high concentration of nano-silicon as well as nano-iron particles could improve seed germination percentage.

Seed priming with nano-silicon dioxide broke the seed dormancy for tall wheatgrass, hence it seems that nanoparticles could be an alternative potential for breaking of seed dormancy (Azimi et al., 2014). We believe that high concentration of nano-silicon dioxide (2 mM) could be toxic for dragonhead seed, therefore high concentration adversely affected on seed performance. Also, our results suggested that response of dragonhead germination to pre-hydration at various concentrations of nano-silicon and nano-iron solution were very different which indicates the influences of the nanoparticles on early seedling growth of plants are almost unpredictable. Exogenous application of bulk silicon at high concentration considerably improved germination characteristics of borage seeds (Torabi et al., 2012), our findings emphasized that the best result could be obtained at low concentration of nano-silicon.

Conclusions

In conclusion, obtained results revealed that the application of nanoparticles enhanced seed germination potential in dragonhead. The most important traits were germination percentage, energy of germination, promptness index and germination rate which are reflect the rate and power of seed germination and seedling growth in dragonhead.

Acknowledgement

We wish to thank kindly Professor Dr. W. Yan (Eastern Cereal Oilseed Research Center of Agriculture and Agri-Food Canada) for making available a time-limited version of GGEbiplot software as “Test Biplotxlsx.”

Abstract

A contribution to the solution of environmental problems, like accumulation of greenhouse gases in the atmosphere inducing global warming, as well as soil pollution and reduced fertility, could come from the past and be enclosed in a known material: charcoal or "biochar". Biochar is a rich-carbon charcoal obtained by pyrolysis of different biomasses, which is used since ancient times as soil amendment. It can be used for long-term storage of carbon in the soil thus reducing the amount of CO_2 released in the atmosphere, but also to improve the chemical and physical characteristics of the soil. In fact, biochar reduces leaching of nutrients and water, increases the pH of the soil, favours nitrogen-fixation and retains heavy metals and toxic substances. Despite a renewed interest in this sustainable practice, there is still a lack of knowledge about biochar effects and mechanisms of action on plants. In the literature for instance, there is conflicting evidence about biochar effects on plant's ability to respond to stress. In this study, molecular data are presented concerning the administration of biochar to tomato cultivations. The starting material used for the production of our biochar was a mixture of beech, chestnut and acacia wood. We choose tomato cultivations, variety San Marzano, because of their great economic relevance and their large diffusion in the Mediterranean area, especially in South Italy. As the result of the administration to the tomato cultivations of small amounts of biochar we observed a positive effect on plant growth. The effect of biochar administration was analyzed regarding gene and protein expression profiles. The data obtained allowed to ascertain that different enzymes of carbon metabolism and photosynthesis were up-regulated by biochar, whereas some stress responsive and defense genes were down-regulated. Hence, in conclusion, proteomic and RT-PCR analysis of tomato plants, confirmed at the molecular level the growth-promoting effect of biochar and showed a significative detrimental effect on the expression of genes involved in the response to environmental and biotic stress.

Keywords: *proteome, tomato, biochar, climate change.*

Introduction

The exponential development of the industrial sector since the mid-twentieth century, the massive use of fossil fuels, anthropogenic effects such as deforestation, breeding and intensive agriculture, have greatly influenced the environment. The amount of greenhouse gas emissions, resulting from human activities, has increased 41% since 1990 (Samimi *et al*., 2012). Climate change affects all levels of biodiversity, from the single organism to the full bioma. The alterations of these parameters are both able to reduce genetic diversity by strong selective pressure, leading to the migration of entire populations (Botkin *et al.,* 2007). However,our knowledge about the effects of global warming on biodiversity is still insufficient and requires the use and integration of multiple approaches to plan a conservation strategy for species and ecosystems (Dawson *et al*., 2011). In agriculture, stress can be

defined as "any environmental pressure that can reduce the potential productivity of a crop" (Lichtenthaler, 1998). Environmental stresses are the main limiting factors for agricultural productivity and therefore have a huge impact on the economy. Temperature, light intensity, availability of water and nutritional values deviating from the optimum levels may cause a strong culture wound leading, in extreme cases, to a total crop loss (Vernieri *et al*., 2006). Carbon, naturally seized by the plants and transformed into organic molecules, can be converted through the pyrolysis in molecules that can be stored in the soil for millennia, so reducing CO_2 in the atmosphere and mitigating climate change. Biochar is a fine grain carbon, obtained from pyrolysis of various types of vegetable biomass, like corn, rice, figs or wheat waste. When added to the soil, this can improve its characteristics and simultaneously reduce carbon emissions. Most studies on effects of biochar on plants focused on high economic relevance in cultivations. These have shown several beneficial effects of biochar especially in terms of plant yield and productivity. Plant effects are a consequence of the beneficial effects that biochar has on soils and which obviously affect resident flora and fauna. In a recent work (Viger *et al*., 2014), biochar was shown to have a regulatory effect on genes involved in growth such as auxin, brassinosteroids, espansine, sucrose and nutrient carriers. At the same time, a down-regulation of genes involved in secondary metabolism and in biosynthetic pathways of jasmonic acid and salicylic acid that play key roles in plant defense against pathogenic agents (Abe *et al*., 2008) was observed. These latter data are in contrast to previous studies showing a positive effect of biochar in inducing systemic acquired resistance (SAR) and induced systemic resistance (ISR) (Elad *et al*., 2011; Harel *et al*., 2012).
In this work we analyzed by a proteomic and RT-PCR approach the molecular effect of biochar administration to tomato cultivations of tomato, of the South Italy, high value San Marzano.

Materials and methods

Tomato plants were grown in a greenhouse, under controlled conditions in two kind of soils; a control using normal soil and soil with 65g/kg of a biochar, made of corn waste with a pyrolysis temperature of 550 °C, and 81.1% of carbon and 1.19% of nitrogen. Fully-ripen tomato fruits and leaves were collected and placed in liquid nitrogen, lyophilized and finely-powdered in liquid nitrogen. Proteins were extracted using the method of phenolic extraction (Rocco *et al*., 2006). Protein pellets were washed with ice-cold methanol and ice-cold acetone, dried and dissolved in IEF buffer. Protein concentration was quantified using the BioRad protein assay. IPG strips (17 cm, pH 4–7, BioRad) were rehydrated and proteins were focused using a Protean IEF Cell (BioRad) at 127˚C, applying 250 V (90 min), 500 V (90 min), 1000 V (180 min) and 8000 V for a total of 52 KVh. After focusing, proteins were reduced by incubating the IPG strips with 1% w/v DTT for 15 min and alkylated with 2.5% w/v iodoacetamide. Electrophoresis in the second dimension was carried out using a Protean apparatus (BioRad) and 12% polyacrylamide gels with 120 V applied for 12 h. Each sample was run in triplicate. 2-DE gels were stained with colloidal Coomassie G-250 and scanned using a GS-800 calibrated densitometer (BioRad). Image analysis was performed using the PDQuest software. Spot detection and matching between gels were performed automatically, followed by manual verification. After normalization of the spot densities against the whole-gel densities, the percentage volume of each spot was averaged for six gels for fruits sample (three replicates for control and three for biochar fruits) and six gels for leaves sample (three replicates for control and three for biochar leaves). Student's t-test analysis ($p<0.05$) was performed to determine significant protein proportional changes associated with the presence of biochar in soil. Spots from 2-DE were excised from gels and digested with trypsin (Rocco *et al*., 2006). Samples were desalted using mZipTipC18 tips (Millipore) before MALDI-TOF-MS analysis (Rocco *et al*., 2006).

For molecular analysis of fruit and leaf samples, RNA was extracted using the "Spectrum Plant Total RNA Kit", Sigma. The extracted RNA was readily retroscripted to cDNA which, having a double filament structure, is more stable. cDNA synthesis was performed using the "EasyScript Plus cDNA Synthesis Supermix". After bibliographic research we prepared primers for AOS and PR1 genes using the PRIMER BLAST (NCBI) program. PCR reaction was performed using DNA Polymerase Master Mix Taq (for the protocol: si.vwr.com) and a temperature gradient for the AOS gene was fixed at 57 to 61 ° C, and for the PR1 gene from 47 at 50 ° C. The thermocycler program was adapted to the amplification length and annealing temperatures of the primers. PCR products were loaded (12µl template + 5µ Quick-Load® PCR Marker | NEB) on an agarose gel (2%), A 100 bp DNA Ladder was used as a marker. After the staining the gel was acquired using ChemiDoc.

Results and discussion

The molecular effects of biochar on tomato plants were first evaluated through the analysis of protein expression profiles in tomato berries and leaves by a comparative proteomic approach, based on 2D gel electrophoresis and mass-spectrometry. Representative 2D gels of berries and leaves from control and biochar-treated samples are shown in Figures 1 and 2, respectively average proteomic maps for fruits grown in control soil and biochar-treated showed 607 spots and 626, respectively; similarity between samples was 68% (control/biochar). As far as tomato leaves, the average proteomic maps showed 320 spots in control sample and 293 spots in leaves grown in biochar-treated soil; similarity between samples was 61% (control/biochar).The statistical analysis ($p \leq 0.05$) revealed 35 (berries) and 21 protein spots (leaves) as differentially expressed between control and biochar. 13 (barriers sample) and 9 (leaves sample) of these proteins have currently been identified and functional classification according to literature data allowed to group them into two main functional classes: energy and carbon metabolism and stress and defense (Table 1).

Down-regulated proteins

Both in berry and leaf tissues most of polypeptides which were down-regulated by biochar amendment belonged to the functional class of stress and defense. In fact, four proteins in tomato berries, namely: Ascorbic peroxidase, (APX); Gluthathione-S-Trasferase jclass; 17.6 kDa class 1 Small heat shock protein; Chaperonin 21 and two in leaves, namely: 17.6 kDa class 1 Small heat shock protein, and Disulfide isomerase-like 1-1 were identified. Shsp1 and chaperonin 21 are molecular chaperones whose up-regulation by different abiotic stress is well-documented. In particular Shsps (Haslback, 2002) are the most prevalent heat shock proteins in plants, they are divided into six multigene families and are expressed in different cell compartments in response to a wide spectrum of environmental stresses, including oxidative stress (Wang *et al*., 2004; Sunet *et al*., 2002). Shsp1 in our study was identified as a strongly down-regulated protein both in tomato berries and leaves. Two proteins involved in protection from oxidative damage were found down-regulated in tomato berries after biochar treatment: APX and Gluthathione–S-trasferase. APX is the main enzyme responsible for H_2O_2 removal in the plant cell through the ascorbate-glutathione cycle, while Gluthathione-S-trasferase is involved in the reduction of organic hydroperoxides to limit oxidative damage (Caverzan *et al*., 2012). In tomato leaves, Protein disulfide isomerase levels were down-regulated after biochar treatment. This protein, catalyzing reduction of -S-S- bridges of proteins is involved in both protein folding and control of cell redox homeostasis (Gruber *et al*., 2006) Among other identified proteins not belonging to the stress and defense class, a PP2C resulted down-regulated. Information concerning PP2C functions in plants is very scarce but it has been shown in Arabidopsis that the PP2C ABI 1 is involved in the signaling pathway of the stress responding hormone abscisic acid (Rocco *et al*. 2006). On the overall, our data indicates that biochar treatment induces a marked reduction of the expression levels of proteins related to stress response and particularly to protein folding and protection from oxidative damage.

Up-regulated proteins

Both in berry and leaf tissues most of polypeptides which were up-regulated by biochar amendment classified in the energy production and carbon metabolism class. In fact, five different polypeptides were identified in tomato berries, namely: Malate dehydrogenase Oxygen-evolving enhancer protein 1; Ribulose bisphosphate carboxylase/oxygenase activase; Ribulose bisphosphate carboxylase/oxygenase large chain; Ribulose bisphosphate carboxylase/oxygenase small chain 2A and five in leaves, namely: Ribulose bisphosphate carboxylase/oxygenase large chain; Ribulose bisphosphate carboxylase/oxygenase activase; Oxygen-evolving enhancer protein 2; Oxygen-evolving enhancer protein 2-1; ATP synthase CF1 alpha subunit. On the overall these data, which show a marked increase in both tissues of main components of the carbon reduction cycle, appear to be well correlated with the plant growth-promoting effect of biochar treatment already reported (Roberts *et al*., 2015). Interestingly, up-regulation of Malate dehydrogenase occurred only in berries, a fact that could be linked to accelerated ripening of biochar-treated berries. In fact, malate dehydrogenase determines malate oxidation during ripening (Rocco *et al*. 2006).

To further analyse possible differences in the capability to respond to stresses of biochar-treated tomato plants as compared to control ones. The trancriptional levels of two genes involved in two different biotic stress response pathways were evaluated in tomato leaves: the …*nome*….(.AOS) gene, the key gene in the jasmonic acid biosynthetic pathway and the Pathogenesis Related protein 1 (PR1) gene, whose transcription is induced by salicylic acid. RT-PCR results (Fig. 3) showed that the AOS and PR1 genes were expressed only in control samples. These data are in good accordance with what observerd by Viger *et al*.(2014) . In fact, they demonstrated that biochar induces a clear down-regulation of different genes involved in defense against pathogens, and inactivation of both SAR and ISR pathways.

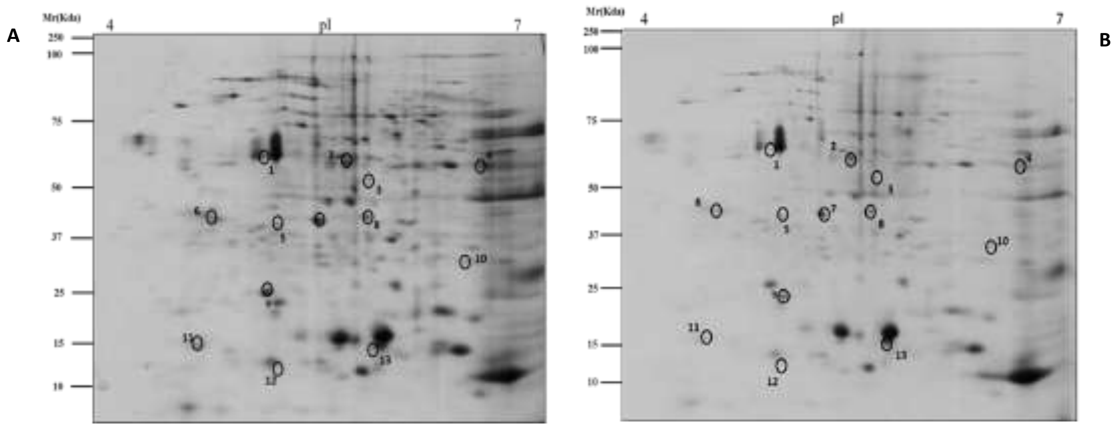

Figure1. Tomato (*L. esculentum*) 2-DE proteomic maps of fruits grown on control soil (A) and on biochar added soil (B). Protein extracts were analysed in first dimension (pH 4–7 linear IPG, 17 cm); second dimension was performed on a vertical slab gel (12% T). Protein detection was achieved using colloidal CBB G-250 staining.

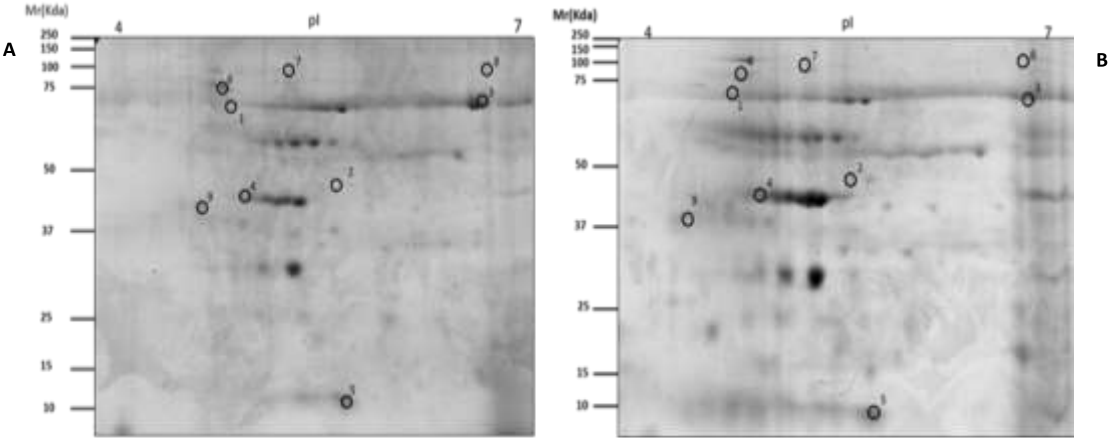

Figure 2. Tomato leaves (*L. esculentum*) 2-DE proteomic maps, sample grown on control soil (A) and on biochar added soil (B). Protein extracts were analysed in first dimension (pH 4–7 linear IPG, 17 cm); second dimension was performed on a vertical slab gel (12% T). Protein detection was achieved using colloidal CBB G-250 staining.

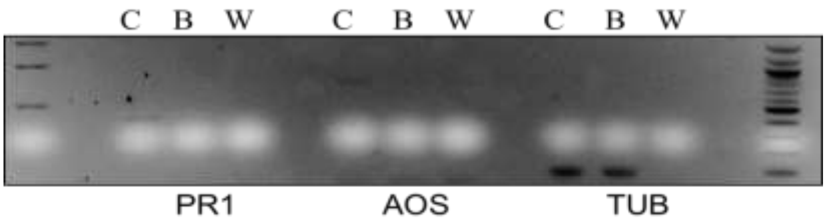

Figure 3. RT-PCR on leaves samples grown on control soil and biochar soil in which primers for PR1, AOS and housekeeping TUB (coding for α-tubulin protein) were used. C = control, B = biochar, W = white

Table1. Spots identified by peptide mass MALDI-TOF fingerprint (PMF), mLC-ESI-IT-MS-MS (MS/MS) or gel matching (GM) analysis from 2-DE gels are reported. Spot number, protein name, accession/EST number, method of identification, number of peptides identified, and fold change for biochar versus control sample are listed. Proteins were considered as differentially expressed when a relative fold change > 2.0 or < 0.5 was measured.

Conclusion

Sustainable development is not one of the possible choices, but it is the only model that can be implemented over the next twenty years to fight climate change (Directive 2009/28 / EC). Only green energy policies and environmental protection can do an appreciable climate mitigation and reverse the negative effects of global warming. In this perspective, soil amendment with biochar can be a valuable practice to reduce the amount of CO_2 in atmosphere while at the same time improving soil quality and productivity. Despite renewed interest in the use of this sustainable resource, scientific information about its effects on plant growth and physiology are still very scarce. Our work was aimed to shed light at molecular level on the effect of biochar treatments on tomato plants of the high-quality variety San Marzano, from South Italy. Results obtained by proteomic and RT-PCR approaches allowed to ascertain that biochar is able to induce in tomato berries and leaves a significant increase of enzymes deputed to carbon metabolism, an effect that is fairly correlated with the well-documented growth-promoting effect of biochar. At the same time, a marked decrease in the expression of genes involved in the response to abiotic and biotic stress was observed. This latter finding, suggesting that also basal levels of expression of defense genes are costly in plants (Corrado *et al* 2011) thus limiting plant growth, is intriguing and prompts further work to shed light on the molecular relationship between plant growth and environmental fitness.

Abstract

The experiment was conducted in order to determine the influence of the microbiological fertilizer Slavol on the number of microorganisms in the soil where cauliflower was grown in open field.
It was used the variety Barselona F1 which was grown in Skopje region during three years (2011, 2012, 2013). The treatments were as follows: Ø control - without use of microbiological fertilizer, V-1 - foliar treatment every 7 days with 0.1% solution of Slavol and V-2 - drip irrigation treatment every 2 days with 0,1% solution of Slavol. The total number of bacteria and the number of examined physiological groups of microorganisms in the rhizosphere (nitrogen fixing bacteria 10^{-4}, cellulolytic microorganisms 10^{-4}, yeasts 10^{-4}, nitrifying microorganisms 10^{-4} and molds 10^{-3}) were counted.
According to the results during three years examination highest average number of total bacteria was determined in the variant V-1 and V-2 in comparison to control and the soil before planting. The number of nitrogen fixing bacteria was from 4863519 in V-1 to 4923807 in V-2. The number of cellulolytic microorganisms was from 3288588 in V-1 to 3312114 in V-2. The number of yeasts was lower than control (3813208) and was from 3681506 in V-1 to 2585089 in V-2. The number of nitrifying microorganisms was very high in V-1 (7502534) and V-2 (7323212) in comparison to control (1331717) and fallow land. The number of molds was higher in V-1 (422192) and V-2 (352608) in comparison to control (340149) but lower in comparison to fallow land (474851).

Keywords: *cauliflower, microbiological fertilizer, groups of microorganisms, rhizosphere*

Introduction

The activity of microorganisms in agro-ecological systems is influenced by the physical-chemical properties of soil, climatic conditions, agro-technical measures, plant species, pesticide and heavy metals content (Milosevic et al., 1997; Jarak et al., 2003).
In the production of some vegetable crops which produce relatively high yields, intensive soil cultivation, different agro-technical measures, large amounts of mineral fertilizers and pesticides are used which contributes to disturbance of balance between microorganisms and soil, soil degradation and overall disruption of the course of natural processes.
In our study, cauliflower (*Brassica oleraca var. botrytis*) was used which belongs to *Brassicaceae* L. family. It is characterized by high nutritional value and medicinal properties due to its chemical composition. Cauliflower is rich in many vitamins, minerals, proteins, carbohydrates and fats. The cauliflower is characterized by a pleasant and refreshing taste and it can be consumed freshly prepared in a different way or processed. Thus it is appreciated in households and industry throughout the year.
For high and qualitative yields in the cauliflower, it is necessary to fertilize with a combination of organic and mineral fertilizers Simonov and Aladzajkov (1985).

In order to improve the microbiological activity in the rhizosphere, today by improving the isolation method and obtaining pure cultures of microorganisms there are microbiological fertilizers – bio-fertilizers that treat crops with different methods of application (with a sprinkler or drip system). In order to improve growing conditions and obtain greater and better yields of cauliflower, microbiological fertilizer Slavol (combination of 6 bacteria, natural vitamins, enzymes and bio stimulators) was used. The objective of the research was to count the number of microorganisms in the soil treated with the microbiological fertilizer Slavol in cauliflower.

Materials and methods

The experiment was conducted in the vicinity of Skopsko, the Jurumleri settlement with GPS coordinates 41 ° 58'20.84" north and 21 ° 33'24.44" east of 276m altitude, on the soil type alluvium, during 2011, 2012 and 2013.

The subject of the trial was cauliflower (*Brassica oleracea L. var. botrytis*), hybrid Barcelona F_1, which was grown by seedlings in cold beds, and planted in the open field.

During 2011 and 2012, the sowing was carried out on May 20, and the planting was on July 16, while in 2013 the sowing was on May 25, and the planting was on July 17.

The trial was designed according to randomized complete block design according to the Fisher Method in three treatments, with four repetitions.

The treatments were based on the time and method of treatment with the microbiological fertilizer, Slavol, which is a combination of 6 bacteria belonging to the group of free nitrogen fixing bacteria *Azotobacter chrococcum* (108 cfu / ml) *Azotobacter vinelandii* (108 cfu / ml), *Derxia sp.* (109 cfu / mL), and phosphorous decomposing bacteria *Bacillus licheniformis* (109 cfu / mL), *Bacillus suptilis* (109 cfu / mL), *Bacillus megaterium* (109 cfu / mL). It also contains natural vitamins, enzymes and bio-stimulators.

The treatments were according following order:

1. Ø control - without the use of microbiological fertilizer;
2. Variant 1 (V-1) – tretating the seedlings by immersion in a solution of 5 L water and 50 mL Slavol for 5 minutes and treating during vegetation through leaves with portable sprayer every 7 days with a solution of 2 mL Slavol dissolved in 2 L water and
3. Variant 2 (V-2) - treating the seedlings by immersion in a solution of 5 L water and 50 mL Slavol for 5 minutes and treating during vegetation through drip system (spaghetti type) with a solution of 150 mL Slavol dissolved in 150 L water with irrigation rate per emitter of 2 L per hour, every two days.

Also, at the end of the vegetation before harvest, three samples from the rhizosphere of the soil with cauliflower were taken for microbiological analyzes (∅, V-1, V-2).

The following groups of microorganisms were examined before the beginning and the end of the vegetation: total number of bacteria in soil (Sarić, 1992), nitrogen fixing bacteria (Jarak, 2004), nitrifying microorganisms (Jarak, 2004), cellulolytic microorganisms (Sarić, 1992), yeasts (Govedarica et al.,1997) and molds (Govedarica et al.,1997).

Table 1 shows the composition of the growth medium for the examined groups of microorganisms.

Table 1. Examined groups of microorganisms, growth medium and incubation period

	Growth medium	Composition of growth medium	Incubation period
Total number of bacteria	Agar plus nutrients	agar 15 grL^{-1}, peptone 15 grL^{-1}, beef extract 3 grL^{-1}, NaCl 5 grL^{-1}, K_2HPO_4 0,3 grL^{-1}	5 days on 28 °C
Groups of microorganisms			
Nitrogen fixing bacteria	esbi agar	sucrose 20 grL^{-1}, K_2HPO_4 0,2 grL^{-1}, $MgSO_4$ x $7H_2O$ 0,2 grL^{-1}, K_2SO_4 0,1 grL^{-1}, $CaCO_3$ 5 grL^{-1}, agar 15 grL^{-1}	7 days on 28 °C
Nitrifying bacteria	Mineral medium	$(NH4)_2SO_4$ 2 grL^{-1}, K_2HPO_4 1grL^{-1}, $MgSO_4$ 0,5 grL^{-1}, Fe SO_4 0,4 grL^{-1}, NaCl 0,4 grL^{-1}, $CaCO_3$ 1grL^{-1}, Mg CO_3 1grL^{-1}, agar 15grL^{-1}, distilled water 1 L	5-7 days on 22 ^{0}C
Cellulolytic bacteria	Waxman –Garey	$(NH_4)_2$ HPO_4 2.5 grL^{-1}, $MgSO_4$ 0,5 grL^{-1}, $FeSO_4$ 0,01 grL^{-1}, KCl 0.5 grL^{-1}, $CaCl_2$ 0.02 grL^{-1}, $MnSO_4$ 0.001 grL^{-1}, agar 15 grL^{-1}, Na-carboxy methyl cellulose2grL^{-1}	7-14 days on 28 °C
Yeasts	Czapek-Dox Agar	$NaNO_3$ 2 g/L, KH_2PO_4 1grL^{-1}, $MgSO_4$ 0,5 grL^{-1}, KCl 0,5 grL^{-1}, $FeSO_4$ 0,01 grL^{-1}, sucrose 30 grL^{-1}, agar 20 grL^{-1}	7 days on 25 °C
Molds	Czapek-Dox Agar	$NaNO_3$ 2 grL^{-1}, KH_2PO_4 1 grL^{-1}, $MgSO_4$ 0,5grL^{-1}, KCl 0,5 grL^{-1}, $FeSO_4$ 0,01 grL^{-1}, sucrose 30 grL^{-1}, agar 20 grL^{-1}	7 days on 25 °C

After the incubation, the number of microorganisms brought up in the petri plates was determined. The total number of bacteria for all physiological groups of microorganisms on gram absolutely dry soil is calculated empirically according to the formula (Sarić, 1992; Govedarica et al., 1997):

$\mathbf{x} = \dfrac{\mathbf{a} \times \mathbf{b} \times \mathbf{c}}{\mathbf{d}}$	a= average number of grown colonies;
	b= amount of inoculum;
	c= dilution;
	d= mass of one g absolutely dry soil.

The obtained results were the subject of further analysis through the arithmetic mean, the ratio for calculating and representing the number of bacteria by variants compared to the number in fallow land and control.

Results and discussion

Table 2 shows the number of all examined groups of microorganisms in order to be perceived the influence of the applied microbiological fertilizers.

***** IFL = index of fallow land; IC = Index of the control								

The total number of soil bacteria is considered the main indicator of its liveliness. The total number of microorganisms is the total number of bacteria that grow on soil agar (Govedarica et al., 1999). Depending on the type of soil, the total number of bacteria ranges from several hundred thousand to hundreds million in gram-soil (Govedarica and Jarak, 1995). In the three years of examination, the total number of bacteria has increased significantly in all variants at the end of vegetation in relation to fallow land. Regarding the index control, it can be concluded that bacteria have only slightly increased in V-2 by 0.8% in terms of control, while the number of bacteria in V-1 decreased by 9.9% in comparison to control.Trials on the total number of bacteria in different species showed that in sugar beet (Govedarica et al., 1999), potato (Najdenovska et al., 2004), soybean and corn (Jarak et al., 2004), the largest number of bacteria was at the end of vegetation. For the life and activity of the free aerobic nitrogen fixing bacteria, as well as for the nitrogen fixation of great importance are some of environmental factors and influences. Thus, if the aeration of the soil is greater, the faster the development of nitrogen fixing bacteria is, and the nitrogen elevation is also higher. Soil moisture also plays a significant role, and it has been established that nitrogen fixation occurs in soils with a moisture of 3 to 25% and more. The reaction of soil and soil temperature also influence the process of nitrogen fixation, where nitrogen fixation occurs in acid soils poorly or not at all, while in soils with neutral to weak alkaline reaction, or pH from 7 to 8, nitrogen fixation takes place more intensively. The temperature range in which nitrogen fixation takes place is from 7 to 35 ° C (Micev et al., 1988). Nitrogen fixing bacteria are an important component of rhizosphere microorganisms (Malik et al., 2005), for which Mrkovač et al. (2006) indicate that they are entering into community with non-leguminous crops, which is important for sustainable agricultural production. Nitrogen fixation is of great importance in the process of maintaining the nitrogen balance in the soil, and in general the fertility of the soil. In our study, the soil has neutral to

moderate alkaline reaction. It is structural with a good ratio of capillary and non-capillary pores, which is a convenient environment for the development of nitrogen fixing bacteria. On average for the three years of examination, nitrogen fixing bacteria have increased in all variants during vegetation in relation to fallow land. The highest increase was obtained in V-2 (167.1%), then in V-1 (163.8%), while in the control the increase was 138.4%. Regarding the index to control between variants at the end of vegetation, a greater presence of nitrogen fixing bacteria was found for 10, 6% in V-1 and 12% in V-2. From the foregoing we can conclude that the variants treated with microbiological fertilizer have a higher presence of nitrogen fixing bacteria in comparison to untreated variant - control. From previous investigations regarding the presence of nitrogen fixing bacteria, Govedarica (1986) found that in the corn the nitrogen fixing bacteria were most present in the rhizosphere at the end of the vegetation. Najdenovska et al. (2004) also found the greatest presence of azotobacter in the application of pure culture *Azotobacter chroococcum* at the end of vegetation in all three years studied in potato varieties latona and lizeta. Aerobic cellulose bacteria represent a separate physiological group that has adapted to using cellulose as a source of carbon and energy. In the three years of the study, the number of cellulolytic bacteria increased in all variants in relation to fallow land. The highest increase was recorded in V-2 (97.0%). Regarding the control index at the end of the vegetation, it was found that in V-1 the number of cellulolytic bacteria increased by 32.6%, while in V-2 it increased by 33.6% (Table 2). Yeasts in soil are present in smaller numbers and are important because they decompose monosaccharaides under anaerobic conditions. Yeasts are more common in soils with acid pH and high humidity such as peat soils. Table 2 gives data on the average number of yeasts per year in relation to the index of fallow land before vegetation and at the end of vegetation in control, V-1 and V-2. In the three years of the study, the number of yeasts increased in all variants in comparison to fallow land. The highest increase was obtained in the control variant (320.6%). The average number of yeasts for three years of testing in terms of control at the end of vegetation has been reduced in variants treated with microbiological fertilizer. The presence of nitrifying bacteria in the soil depends on the presence of free oxygen and the reaction of the soil. In soils with a pH below 5 the number of nitrifying bacteria is low. Nitrifying bacteria are widely represented in nature. They are found in soils with sufficient humidity and aeration, favorable pH and nutritional conditions. The optimum temperature for their activity is 30-35°C. According to the data presented in Table 2, in the three years of the study nitrifying bacteria have increased only in the first and second variants in vegetation depending on the prevalence before vegetation. Regarding the index at the end of vegetation, between control and variants, a significant increase in the number of nitrifying bacteria was observed in the variants treated with microbiological fertilizers in comparison to control.
The molds are multinuclear, filamentous, bonded, aerobic fungi, built of hyphae. The optimal conditions for the development of the mold are a temperature of about 30°C, moisture, pH 6 and free access to oxygen (Sarić, 1991). In the three years of examination in relation to the soil that is not sown (fallow land), the mold decreased in control, V-1 and V-2. Regarding the index control at the end of vegetation, between control and variants, it was determined that V-1 and V-2 had a higher number of mold compared to control (24,1% and 3,6% respectively).

Conclusion

In our study the highest values of total number of bacteria and nitrogen fixing bacteria were found in the V-2 treatment, the presence of the yeast is the highest in control, while under fallow land conditions were found the highest presence of molds. The average number of cellulolytic bacteria is highest in V-2, and the insignificant difference in relation to V-2 is also obtained in V-1. The average number of nitrifying bacteria is greatest in variants treated with microbiological fertilizer V-1 and V-2.

Abstract

This paper is about the research made to determine the number of different groups of microorganisms in soil, rhizosphere and root area of wheat and barley in two different agricultural regions (Bitola and Skopje in the Republic of Macedonia). Surveys were carried out over two year period, under laboratory and field conditions. The microorganisms in the soil have direct influence on the soil's fertility the availability on the ascimilatives for wheat and barley. The main objective of these studies was to determine the dynamics (number) of rhizosphere microflora in different stages of vegetation in wheat and barley. Soil samples were taken during the vegetation phases: four petals, blooming stage and physiological maturity stage of wheat and barley. This research confirms that the dynamics of the rhizosphere microflora increases when compared to the dynamics of the vegetation period, reaching their peak during the period of intense development and flowering of both cultures. Compared to the rhizosphere zone, the number of test organisms in the root zone is greater in both cultures. In the third phase of the wheat and the barley, compared to the second stage, the rhizosphere microflora is greater. The number of molds, in both regions, decreases during the vegetation in the rhizosphere, and increases in the soil more widely. The number of investigated groups of microorganisms is the largest in the rhizosphere and in the soil more widely in the maturation phase This increase in numbers of microorganisms, is probably influenced by the root exudates of the cultures and applied agro-techniques. Exudates make selection and improve the profiling of bacteria that a affect their needs the most.

Keywords: *Microorganisms, Soil, Rhizosphere, Wheat, Barley.*

Introduction

The growth, development and yield of the wheat (Triticum aestivum, L) and barley (Hordeum vulgare, L), beside other factors, depend on the presence of assimilatives during the vegetation.
The microorganisms in the soil have direct influence on the soil's fertility the availability on the ascimilatives for wheat and barley (Najdenovska et al., 2004).
In the soil live different types of microorganisms that constitute large part of the genetics of the soil's biodiversity. The number of the microorganisms in the soil, the mass and the activity depend on the biotic and the abiotic factors suchs as: the type on the microorganisms, the type on the soil, the depth and the type on the plant vegetation (Najdenovska, 2001; Govedarica and Jarak.,1995). In the soil with a well formed profile, the microorganisms sustain the structure, the level of organic material and the fertility. The dynamics of the microorganisms in the soil is the biggest in the rhizosphere, but smaller in the soil a part from the root (Najdenovska, 2013; Usman et al., 2016). The most active relations between plants and the microorganisms in the soil are established in the rhizosphere (Kennedy, 2005).
The purpose of this research was to establish the impact of the vegetation stages of wheat and barley grown in Skopje and Bitola region (Macedonia) on the dynamics of the rhizosphere microflora.

Materials and Methods

This paper examined the dynamics of microorganisms in the soil wider and the rhizosphere of wheat from the Altana variety and barley of the variety rex grown in the Bitola and Skopje region (Macedonia). Microorganisms are isolated from depths of 0 cm to 30 cm on agricultural land under wheat crop (Triticum aestivum, L) and barley (Hordeum vulgare, L) in the Bitola and Skopje region. The research in this paper covered agrochemical and microbiological analysis of the land. The agrochemical analysis of soil included the pH value; Content of easily available nitrogen, phosphorus and potassium; Content of carbonates (Bogdanovic et al., 1996).
Soil samples from the (rhizosphere and the soil wider) for microbiological examinations were taken three times during the vegetation of the crops: firstly in the phase of 4 petals (autumn); secondly (May); third time at the stage of physiological maturity of wheat and barley (end of June); In this paper we examined: total number of bacteria, ammonifiers, actinomycetes, fungi and molds according to the dilution method and seeding of selective nutrients, while the examination of the physiological groups of microorganisms (nitrogen bacteria, nitrificiators and aerobic cellulolithic microorganisms) was done according to the method of fertile grains Soil (Govedarica and Jarak, 1997).

Results and discussion

According to the obtained results from the agrochemical analysis of the soil, it was found that the pH value of the soil solution in the two examined regions is neutral (6.80 in the Bitola region and 6.85 in the Skopje). The tested soil in both regions is well secured with nitrogen (8,20 mg / 100gr soil in the Bitola region) and 7,35 mg / 100gr soil in Skopje. Also, it is intermediately secured with phosphorus (9.50 mg / 100gr soil) in the Bitola and 13,55 mg / 100gr soil in the Skopje region. Soil in the Skopje region is well secured with potassium (25.70 mg / 100gr soil), in contrast to the soil in the Bitola region that is intermediately secured (15.70 mg / 100gr soil). In the Skopje region, the soil has a very low presence of $CaCO_3$, (0.002%) and in the Bitola the presence of $CaCO_3$ in the soil has not been established. The results of the study of the number of microorganisms in the soil under wheat are presented in Table 1. According to Morgan et al ., (2005) and Solano et al . (2006), the number of bacteria is 2-20 times higher in the rhizosphere compared to wider soil, primarily because plants excrete 20 to 50% of photosynthetic products. In our studies (Table 1), it was found that in the wheat in the Skopje region, the number of all investigated groups of microorganisms is twice as large in the rhizosphere than in the soil more widely in the three phenological phases of the culture. The results of the examination of the dynamics of microorganisms in the land under wheat and barley in the Skopje and Bitola region are presented in Table 1. In the Bitola region the total number of bacteria, ammonifiers, actinomycetes and yeasts, as well as nitrifiers, azotobacter and aerobic cellulolytic microorganisms is greatest in the flowering stage in the rhizosphere, and the smallest (56,79) in the phase of four petals in the soil wider (Bever et al., 2012). The highest representation of the mold is in the stage of blooming of wheat in the soil wider (56, 56), and the lowest in the phase of physiological maturation in the rhizosphere (24). The greatest dynamics of the total number of bacteria, ammonifiers, actinomycetes and yeasts is in the barley rhizosphere of the blooming phase (5590, 2650, 228, 97), the smallest in the soil in the phase of 4 petals (2100 , 1100, 123.35). The highest prevalence of azotobacteria and nitrification was observed in the blooming stage in the rhizosphere (84, 63), and the smallest in the soil in the pheno-phase of four petals (49, 37). The number of investigated groups of microorganisms is the largest in the rhizosphere and in the soil more widely in the maturation phase (Table 4). Exudates make selection and improve the profiling of bacteria that affect their needs the most. (Saharan i Nehra, 2011).

	Phenophase: A = 4 livestock, B = flowering,C = physiological germination								

Conclusion

Based on the results obtained in these investigations, it can be concluded that the dynamics of microorganisms, except for the wheat and barley rhizosphere rips, increase in the two regions during the vegetation of the culture in relation to microorganisms in the soil more widely, which is conditioned by the increase of the concentration of exudates on and around the root system and their composition. The number of molds, in both regions, decreases during the vegetation in the rhizosphere, and increases in the soil more widely.

The number of investigated groups of microorganisms is the largest in the rhizosphere and in the soil more widely in the maturation phase (Table 4). Exudates make selection and improve the profiling of bacteria that a affect their needs the most. (Saharan i Nehra, 2011).

Abstract

Tobacco has widespread areal of distribution and great adaptation towards outdoor conditions. During the production, the time of acceptance of seedlings, and the number of accepted plants per unit area are different and primarily depend on: biological potential of the varieties, technical measures and agro-environmental factors at the time of transplanting, but mostly from the quality of seedlings. The experiment was conducted in random block system, in four replications on two varieties of oriental tobacco (*prilep NS 72, yaka JV 125/3*) in three variants: variant 1-control; variant 2 Float Tray -N (TERRA STAR/22:11:22+2Mg) and variant 3 Float Tray -P (CHELAN/ 11:49:12+2Mg). The results show a statistically significant difference between numbers of accepted plants in the studied years. The results show that a high level of acceptance of tobacco after transplantation is greatly conditioned the result of seedling production technology. Therefore it is necessary, putting into practice appropriate, modern and profitable technologies for the production of tobacco seedlings, for successful and productive tobacco production.
Keywords: oriental tobacco, tobacco seedlings, quality, acceptance.

Introduction

The production of tobacco (*Nicotiana tabacum* L.) in Macedonia has a very long tradition. Tobacco is one of the most economically important agricultural crops in the country. To produce high-quality tobacco, growers must begin with healthy seedlings. The ideal seedling is disease free, resistant enough to survive transplanting shock, and available for transplanting on time. In general, earlier transplanted seedlings give better yield than late-transplanted tobacco (Smith et al., 2003). During the vegetation, a large number of factors have an impact on the tobacco that allow or interfere on the tobacco plant to express its biological and production potentials. Except the biological potential of the varieties, the largest influences have taken scientific farming methods and agro ecological conditions during the growing season. Each type of tobacco, variety of each individual area requires separate intervention, depending on the intensity of biotic agents, soil and climatic conditions, as well as cultural, traditional practices. Tobacco as an industrial crop can be grown on different soil type; therefore amounts and quality received are highly dependent on the type of soil and its physical and chemical properties. The influence of soil conditions is correlated with a complex of other environmental factors. Thus, the same soil type but with different climatic conditions, we get the raw tobacco material with different yield and quality. The production of oriental tobacco in Macedonia is located almost in all regions, mostly soils with weaker productivity. Usually, for growing oriental tobacco loamy-sandy soil with weaker productivity are preferred (Georgievski, 1990), where rarely other agricultural plant cultivation would be cost-effective. On the other hand, for successful tobacco production good quality seedlings are needed, to obtain uniformity according to morphological and biological characteristics of tobacco at field. Traditionally, seedlings in Macedonia are produced at the open field, in *cold beds*, covered with polyethylene. The most critical period in the development of tobacco occurs immediately after transplanting in the field. The plants are torn away from the previous, favorably living environment and immediately underwent to a radically different and many times unfavorable external conditions, resulting in stress in young plants. This change is significant in terms of seedlings produced by classical mode of production, where there is an extremely large imbalance between the root system and the new conditions that often result in extended periods of stress, poor reception and slow plant growth (post transplanted shock). This shock is caused by the loss of most of the root system in the process of uprooting the seedlings from the beds (Hoyert,1979). Climatic conditions also cause the severity while transplanting (from cold and wet spring, into a rapid shift to hot and dry summer). Applied practice and scientific research in the production of tobacco seedlings indicate that on the Balkans; the production technology is quite conservative and it is very demanding to implement a new one. According to Chaluhov (1987), in spite of great importance of changing the traditional production technology, there is a lack of interest by the majority of tobacco growers to introduce new technologies for the production of oriental tobacco seedlings. The seed quality is also an important factor in production of tobacco seedlings. Karajankov (1982) concluded that seed which is large has a higher energy of germination and final germination, which is a guarantee of getting healthy and quality plants per unit area (m^2), with well-developed root system, which remains in production in the field and provides precondition for higher yield and quality of tobacco. The production of healthy seedlings, with certain length and thickness of the stalk, is the first step in the process of excellence tobacco production. The last decade has resulted in increased awareness of tobacco producers about the importance of quality tobacco seeds. Although the seeds with a declaration of minimum 90% germination, seedling producers fail to get 90% germination during nursery stage according to Clarke et al. (2001). It is believed that there is no method that guarantees the safe production of seedlings, although today there are many computer programs for the establishment and management of parameters and analysis of the results of the process. For this reason, education and human responsibility at work are decisive factors. Improving tobacco production requires good agricultural practice which among other things involves implementation of new production technologies. The goal of the research was to contribute to the improvement of the process of tobacco seedling production in Macedonia, and whether and how the container mode - FTS production reflects first of the quality of the tobacco seedling, but continues to transplanted tobacco on the field in terms of biological and morphological properties of tobacco plants, compared to the traditional way of producing tobacco seedling.The introduction of new varieties of tobacco in the structure of production of tobacco in the country, with higher yield and quality is of great importance as well, considered Kabranova and Arsov (2009).

Material and Methods

The experiment was placed in the region of Veles in Macedonia in the period of three years experiment (2007/2008/2009). It was conducted in random block system, in four replications on two varieties of oriental tobacco *Prilep NS 72* and *Yaka JV 125/3*, in three variants: Variant 1-Control (traditional production - means the formation of the so-called *cold improved beds* with length 10 m and width 1 m. The surface of the beds was treated with the herbicide Devrinol WP-50 (am. Napropamid). The first half dose was applied before sowing the seeds in an amount of 2 L / ha (2 ml / 10 m^2). The sowing of the tobacco was carried out with natural tobacco seeds (as a organ of reproduction), intended for the production of tobacco seedling, manually, in the amount of 0.5 g / m^2. For easier sowing and good distribution, the seeds were mixed with sand. After, the seeds were covered with a thin layer (0.5 cm) of well-sown and burnt manure, as a cover. Then the surface of the seedbeds was narrowing in order to establish a better capillary between soil and the seed. The application of the second half of herbicide Devrinol WP-50, 2 g / 10 m^2, was immediately after. Follow watering (60 L / 10 m^2) and placing metal bows along the beds, at a distance of 0.7 m. The beds are covered with a transparent polyethylene. Thus formed a tunnel that opened on both sides for easier thermoregulation and ventilation. During nursery stage the seedlings were regularly watered. A week before transplanting, we stopped the watering, and the beds were completely open (to prepare the seedlings for the new conditions at the open field). Floating tray technology was applied on Variant 2 -Float Tray (TERRA STAR 22:11:22+2Mg with microelements: Fe-0,0335 %, Cu-0,017 %, Mg-0,1 %, B-0,01 %, Mn-0,017 %, Mo in traces, Zn-0,01 %, Co in traces, +EDTA and Auxin) and Variant 3 -Float Tray (CHELAN 11:49:12+2Mg with microelements: Fe-0,0335 %, Cu-0,017 %, Mg-0,1 %, B-0,01 %, Mn-0,017 %, Mo in traces, Zn-0,01 %, Co in traces). The total quantity of fertilizer was added in water beds (0,001 % solution). The required quantity of certificated tobacco seed (granulated tobacco seed for FT variants) was sown in polystyrene trays (589 alveolus per tray) filled with peat 50% and perlite 50%); polyethylene for covering water beds; agril (as a protector towards condensation) and adequate protection against diseases, insects' damage. Conductivity of water into the pool was followed regularly for keeping the concentration of fertilizer. Thermoregulation above the pool was conducted with uncovering of the tunnel. For traditional technology of seedlings production (control) additional fertilizers were needed (1% solution is applied to seedlings), followed with application of fungicides and insecticides in order to get vigorous seedlings. All agro-technical measures for proper development of plants were made for both technologies of seedlings production, in order to obtain maximum healthy, usable seedlings per unit area. Common agro-technical measures for successful production experiment were conducted (Pearce & Palmer, 2005). Transplantation of tobacco was done manually. Transplanting time was in close connection with the meteorological conditions during the test period. After transplantation of tobacco seedlings, the number of accepted plants (%), and the crisis period (from transplanting to acceptance) were analyzed. The results were processed by SPSS for Windows, procedure Sum of squares, Model III.

Results and Discussion

The period after transplanting is considered crucial for the overall production at the end of vegetation. Therefore, after transplanting, the plants should have enough available moisture well to embrace and develop the first strip of leaves. Thus, precipitation in this period should be in amount of 60 mm. In case of insufficient moisture and high temperature, however, the growth and development of plant are reduced and the plant suffers from drought. The temperature regime for oriental tobacco, together with precipitation in the initial stages of growth and development of tobacco should give a stimulating effect. As optimal, preferred temperatures throughout the vegetation period are from 22 to 25 ºC. In the period from 2007th to 2009th, the climate conditions had the great importance for the development of tobacco. Distribution of rainfall was not appropriate for the plant during the growing season, while the air temperature values were relatively high. There is statistically significant difference ($p \leq 0.01$) between percentage of accepted plants between 2007th compared to 2008th and 2007th compared to 2009th ($p \leq 0.05$), shown below, in Table 1. The plants requirements at the field differ from those of tobacco seedlings Therefore, plants experiencing a biological stress as result of the drastically negative changes in the environment and manifested by the reduced growth and development of plants with altered biological functions. Depending on the intensity changes of permanent damage caused by low or high temperature, drought, etc. may occur. If this stress is lower, the plants will begin with normal growth and development faster (Vukadinović,1999). Production of tobacco continues with the transplantation of tobacco seedlings in the field, depending on the seedlings and weather conditions at the time of the year. The level of acceptance of tobacco seedlings depends on agro-environmental conditions at the time of transplanting, agrotechnical measures, but mostly from the quality of seedlings. Plants are often competitive in terms of external factors: light, CO_2, H_2O, oxygen, minerals, substrate (in the area where the roots develop). Competition does not always bring negative consequences, because according Vukadinović (1999), it affects the formation of the size of the habitus of plants. During the pulling-out seedlings, part of the root system is damaged, great part is reduced, and most of the roots parts are disconnected from the soil particles. In the early days after the transplant plants implement certain degree of physiological deadlock and are unable to satisfy their need for water. Therefore, wilted leaves are leading to reduction of surface assimilation of plants. In this part of the stage, the processes of degradation exceed synthesis processes. It should be pointed out the special role of stem which actually is the main reservoir of food that supports the life of the plant. Plants that have a thicker stem, are easier to accept than those who have a thin stem that often, if not die giving underdeveloped plants with weak productive opportunities. In this phase, the elevated parts of the plant almost do not grow. After successful acceptance of plants in the field, a strong root system is developing and the plant is ready for further rapid increase (Uzunovski, 1989). The seedlings derived from the classical mode of production (variant 1 - control), have a critical period after transplantation in the average range of 7 to 10 days in both examined varieties (*Prilep NS 72* and *Yaka JV 125/3*). In that period, many of the plants suffer due to poorly developed root that after transplantation, it adapts to the new, often less favorable conditions for growth and development. Therefore it is necessary to add, replace with new plants between. Table 1 shows the variations in % of acceptance after transplanting.

Table 1. Acceptance of tobacco seedlings after transplanting (%)

Year	Variant						Year, average
	Variant 1 - control		variant 2-FT, N		variant 3-FT, P		
	prilep NS 72	*yaka JV 125/3*	*prilep NS 72*	*yaka JV 125/3*	*prilep NS 72*	*yaka JV 125/3*	
2007	68.5	72.5	94.8	90.8	90.0	88.0	84.1
2008	79.3	80.5	95.0	93.8	89.8	89.3	87.9
2009	77.9	75.8	94.2	91.9	91.5	89.7	86.8
Variety, average	75.2	76.3	94.7	92.1	90.4	89.0	
Technologya verage	75.7		93.4		89.7		

Acceptance of tobacco seedlings (Table 1) is different during the three-years trials and presented as an average of all tested varieties is: 84.1% for the 2007^{th}, 87.9% for 2008^{th} and 86.8% for 2009^{th}. The three-year results show the highest average of accepted plants in variant 2-FT –N (93,4%), while 89.7% in the variant 3-FT- P. The lowest acceptance shows variant 1-control (75.7%). In the same technology of production (FT). variant 2-FT –N showed greater acceptance of tobacco seedlings which is certainly the result of the tested fertilizers. Choice of the appropriate combination of macro-and micronutrients is an additional factor that contributes to the normal development of seedlings. The seedling, because of good care and support with the necessary ingredients (nutrition, water, air, etc.) and not existence of mutual competition, were equal, with balanced growth and development of plants (strong roots, well-developed stem and number of leaves) giving the higher acceptance of plants in the field. Increased percentage of acceptance of the FT seedling was as a result of the short period of time needed for their acceptance after transplantation. Accepted plants in the field, did not respond to altering conditions, means that tobacco seedlings are completely healthy and strong enough to resist the shock of transplantation. Acceptance in the field depends on tobacco seedlings quality, expressed above all with a well developed root system and morphological uniformity in terms of its dimensions (Pearce ve Palmer, 2005). As for the differences due to the variety, the results showed that percentage of accepted plants variant 2-FT, N was 94.7% in the variety prilep NS 72, or 92.1% of the variety yaka JV 125/3. The average of accepted plants in variant 3-FT, P was 90.4% in the variety prilep NS 72, or 89.0% of the variety yaka JV 125/3. The results show greater acceptance and minimal crisis period indicate that seedling of this quality have no need of additional transplantation in rows, so the plants continue their rapid development equally. These plants are morphologically identical during growth and development in terms of height, number of leaves, the size of the leaves that are almost identical (Turshic, 2000). Statistical analysis of the values of factors: interaction between year and technology tested with F-test shows statistically significant difference at the level P = 0.01 (Table 2).

Table 2. Interaction between year and technology

Dependent variant	Year		Difference of mean values between years	Standard error	Significance
% accepted plants	2007	2008	-3,8333**	0,99121	0,004
	2007	2009	-2,7400*	0,99121	0,022
	2009	2008	-1,0933	0,99121	0,299
Dependent variant	Technology		Difference of mean values between variants	Standard error	Significance
% accepted plants	1	2	-22,6600***	0,99121	0,000
	1	3	-18,9633***	0,99121	0,000
	3	2	-3,6967**	0,99121	0,005

*** The difference between the mean values is significant at level of 0.001
** The difference between the mean values is significant at level of 0.01
* The difference between the mean values is significant at level of 0.05

Data presented in Table 2, showed statistically significant difference between percentage of accepted pants in 2007th compared to 2008th and 2007th compared to 2009th. Also, in terms of production technology can be seen that there is a statistically significant difference between the percentage of accepted plants in variant 1-control and variant 2-FT -N, the variant 1-control and variant 3-FT -P as well as variant 3-FT, P and variant 2-FT –N.

Conclusion

Accepting tobacco in the field depends on its quality, expressed above all with a well developed root system and morphological uniformity in terms of its dimensions; As primary limiting factor for successful transplanting, and thus better accepting, the quality of seedlings should be emphasized, or the way how tobacco seedlings are produced. Selecting the right technology for tobacco seedling production along with the selection of varieties, are key factors for getting high yield and quality of tobacco raw material, with respect to the impact of agro-environmental conditions and agro-technical measures implemented during the vegetation of tobacco; Agro ecological conditions have strong influence on its biological, morphological and technological characteristics. We believe that the future will do its own and that the data obtained from many experimental years will push tobacco producers to accept the technology of FTS (floating containers for the production of transplants), and in that way to contribute to the quality tobacco production.

MORPHOLOGICAL CHARACTERISCS OF FRUITS OF SOME BIFEROUS FIG (FICUS CARICA L.) VARIETIES GROWN IN MONTENEGRO

Miroslav ČIZMOVIĆ*, Tatjana PEROVIĆ

Biotechnical Faculty Podgorica, Montenegro
Center for subtropical cultures Bar, Montenegro
*Corresponding author: miroslaw@t-com.me

Abstract

The results of a two-year study (2015-2016) on main morphological characteristics of eight biferous varieties of fig are presented in this paper. The research was carried out on three „white“ skin varieties ('Sultanija Bijela', 'Petrovača Bijela' and 'Skadranka'), and five „black“ skin varieties ('Crna Sušilica', 'Crna Rapka', ' Petrovača Crna ', 'Crna Sultanija' and 'Krutska Crna'). The highest weight of fruit (111.27 g) was registered in first crop of variety 'Sultanija bijela', statistically significantly higher compared with other varieties, except 'Crna Petrovača'. First crop of 'Crna Sušilica' variety had the lowest mass of fruits (21.87 g), lower than second crop of this variety, what is rarity, and also registered in 'Crna Rapka' variety. 'Crna Petrovača' (85.32 g) and 'Sultanija Bijela' (80.21 g) had the highest weight of flesh, statistically significantly higher than other varieties. 'Sultnija Bijela' has the elongated-pyriform shape of fruit (width/length ratio 0.53), while the variety 'Crna Sušilica' has flat-pyriform shape (1.14). There was a highly significant correlation between weight of fruits and weight of flesh (r=0.9813**), and weight of fruits in relation to width of fruit (r=0.8341**). Morphological characterization can be a useful tool in distinguishing varieties and the first step in their evaluation.

Keywords: *morphological characteristic, fig, Ficus carica* L.

Introduction

Fig is the deciduous subtropical fruit species from the *Moraceae* family. It has 2n = 26 chromosomes and belongs to genus *Ficus* that includes about 800 species. The species name is related to the Caria area in Turkey, where they used to produce excellent dry figs belonging to Smyrna type (Condit, 1947). It is considered to be the first domestificated fruit species (Kislev et al., 2006), 11,000 years ago, which has been growing since ancient times in the Mediterranean region. Although, the area of former Persia is considered as a gene-center of figs, favorable agro-ecological conditions have an abled the spreading of wild and edible figs, and improved the richness of their diversity. Turkey is the largest world producer with 274.535 tons, followed by Egypt (171.062 t), Algeria 110.058 t, Morocco (102.694 t), etc. (FAO, 2016).
There is no reliable data when the fig tree was introduced into production in Montenegro. The earliest written record of the growing of fig in the Adriatic area is the Diocletian's Edict from 301. According to foreign literature sources (Zohary and Spiegel-Roy, 1975) figs were being cultivated in the Mediterranean region since the end of the Bronze Age. In our country, figs are traditionally grown on the edges of the fields or in the gardens, without the use of any cultural practices. Areas in which this species could be grown are in the coastal region up to 600 m altitudes, and in its hinterland up to the high mountains in the north. According to official agricultural census, Montenegro has 215.910 fig trees, of which 201.740 are bearing trees, with an average yield of 18 kg / tree (MONSTAT, 2011). The unifera and bifera types of varieties are represented, with black and yellow skin color. All of our fig varieties belong to common type, and produce parthenocarpic fruits (Stover at al., 2007).

The new plantation orchards were established in the last decade, and one of them nearby the Podgorica city produce organic fig. Most of the fruits are sold as a fresh fruit, the smaller part is dried, and only a small amount is processed into sweet, marmalade or other products.

Figs are easily propagated , which allows the spreading of this species. This features created two types of problem. The first is linked to spreading of viral diseases caused by cuttings propagation (Perović et al., 2016), which lead to a poorer quality of fruit and lower yields. Another type of problem is a large number of homonims and synonyms throughout the whole fig tree growing area (Bellini et al., 2007), which creates a problem in nursery production and agronomic evaluation of varieties. According to the report of previous researchers in Montenegro, 72 genotypes of figs were registered, of which Redžić (1968) described 58. By urbanization and restitution to previous owners, this material is permanently lost. A similar problem has been described in Slovenia (Podgornik et al., 2010) and other countries (Giraldo et al., 2010). The main objective of this study is to examine and evaluate the agronomic value of some biferous fig varieties according to the current descriptor. Also, this creates the basis for solving the problems of synonyms and homonyms, which is of great importance for nursery production.

Materials and methods

The research included 8 different autochtonous biferous fig varieties during two consecutive years (2015-2016). Three "white" varieties of figs were examined: 'Sultanija Bijela' (SB), 'Petrovača Bijela' (BP) and 'Skadranka' (SC). The skin color of these varieties is green with a yellowish strips in full maturity. Varieties 'Crna Sušilica' (CC), 'Crna Rapka' (CR), 'Petrovača Crna' (CP), 'Crna Sultanija' (CS) and 'Krutska Crna' (KC) were analyzed from "black skin varieties" groups. Number 1 joined to the abbreviation of each variety indicates the first crop, which is most often referred to as "breba" in the literature (Bellini et al., 2007), and the number two is the mark for the main crop (second crop).

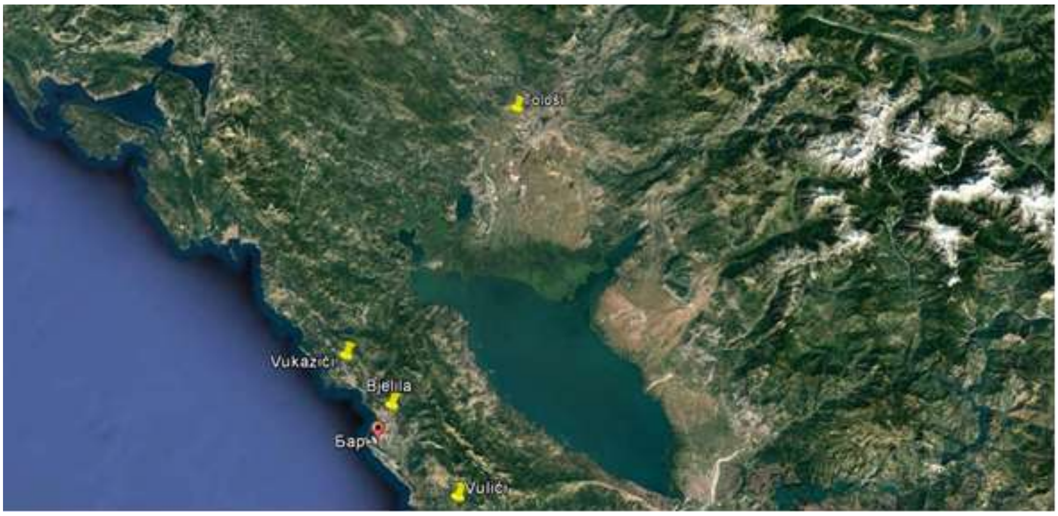

Figure 1. Sites where figs are found

All examined trees were in full bearing maturity, 14-18 years old. Varieties 'Crna Rapka' and 'Crna Petrovača' were found in the village of Vulići, Gornji Mrkojevići (252 m altitude), and the varieties 'Black Sušilica', 'Black Sultanija' and 'Krutska Crn'" were located in Bjelila, Bar (29 m altitude) . Varieties 'Petrovača Bijela' and 'Skadranka' are located in the village Vukazići, Sutomore (102 m altitude), while 'Sultanija Bijela' was found in Tološi, Podgorica (37 m altitude)(Figure 1). The following parameters were tested for morphological analysis: Fruit weight (FM), pulp weight (PW), skin weight (SW, data not shown), fruit length (FL), maximum width (FW1), smallest width (FW2, DW), fruit shape (IN), stalk (penduncle) length (ST), ostiole size (OS), percentage of pulp in relation to total fruit weight (PP) and percentage of skin (PS, data not shown). The data was tested by analysis of variance as a two factorial trials (tested parameters and years), and the significance of differences between means was tested by the LSD test for the levels of significance 0.05 and 0.01). The correlation dependency is calculated according to Pearson's correlation matrix for all parameters. Coefficient of determination was calculated as a square of correlation (Hadživuković, 1991).Variation of morphological charactersitics was calculated by Principal Component Analysis (PCA) with eigenvectors 2. Coefficints of discrimination were determined for values greater than 0.71 or smaller than -0.71 (Skinner et al., 1999). All studied parameters are evaluated by the descriptive list (Bellini et al., 2007), except FW1, FW2 and DW. These parameters should show differences in fruit shape at the horizontal axis (level) which can be useful data for distinguishing varieties.

Results and discussion

The results of the examination of the most important morphological characteristics of the biferous fig varieties are given in Table 1. The first crop of the biferous varieties of figs is formed from the inflorescence of the previous year (Stover et al., 2007) and is considered to have the greatest economic impact (Redžić, 1968). The variety 'Sultanija Bijela' has the largest fruit weight in both crops, but the percentage of skin comparing to the weight of the fruit is statistically significantly higher than in other varieties (46.3% for skin). The most popular variety is 'Crna Sultanija', which has balanced fruit of both generations and excellent fruit quality. Although the quality and taste are factors that are more difficult to determine (Crisosto et al., 2010), the market favors this attribute in the varieties 'Crna Petrovača' and 'Bijela Petrovača'. CP has a large breba crop, with the thinnest skin (skin percentage in relation to the pulp is 15.27%), and this is economically the most important crop in this variety. The only imperfection of this variety is the significant cracking in ostiole region, especially in the rainy spring.

Similar descriptions of these varieties are given by researchers from Slovenia (Bandelj-Mavsar et al., 2008), which shows that these varieties are spread all over the Adriatic coast. The breba usually have the highest fruit mass comparing to main crop, although the variety 'Black Sušilica' has the larger fruits mass in the main crop, which mature when there are no other figs. That could be its advantage. All varieties, except CC, have a short stalk (peduncle) of the fruit, which greatly complicates harvesting. Fruits harvested without a stalk are prone to deterioration (Salunkhe and Desai, 1984). The tested varieties have different shapes of fruit, from completely elongated-pyriform shaped (SB1, index of shape 0.53), asimetrical (KC1) to flat-pyriform (CC2, 1.45).

The highest fruit widths have varieties CP1 and KC1, but the difference between the largest and the lowest widths in these varieties is greatest (Table 1, columns FW1 and FW2). Due to the marked difference between these two values, it can be concluded that these varieties at the cross-section are asymmetric and have an ellipsoidal form. This feature is the specificity of these varieties, and can be crucial in their recognition. The studied characteristics of morphological traits have shown certain statistically significant correlation dependencies. The results of all correlations are given in Table 2.

p< 0.05 * statistically significant

p< 0.01 * statistically highly significant (values are indicated in bold)

According to the obtained results, the weight of the fruit depends largely on the weight of the flesh (0.9813), which means that the weight of the fruit depends on 96.29% of the pulp mass. Also, the greater mass of the fruit is significantly affected by the length and width of the fruit in particular less (FW2), which is the result that most of the tested varieties have a small difference of these values, so that in cross-section they are almost regular round. Also, the larger mass of the fruit are significantly influenced by fruit's length, and especially with the smaller fruit width (FW2), which is a consequence that most of the examined varieties have a small difference in these sizes, so they are almost circular at the cross-section. The index of fruit's shape is in negative correlation in accordance to the length of the fruits (r = -0.8264), because the fruits with smaller length have a higher value of the fruit index, since it is expressed as a fruit width / length.

Table 3 – Principal Component Analysis (PCA) of morphological characteristcs

Parameters	PC1	PC2
FW	**0.961276**	0.197404
MF	**0.961309**	0.061758
SK	**0.806714**	0.529234

OS	0.481377	**-0.75788**
PF	-0.06489	**-0.9096**
PS	0.06489	**0.90960**
Explained variation	5.686404	4.17789
Eigenval	5.759079	4.105215
Total variance %	47.99232	34.21012
Cumulative variance	47.99232	82.20244

The results of the PCA analysis explains the larger part of the morphological variability between the tested varieties (82.20%). PC1 explains almost 48 % variability, and the highest correlation dependence is between the parameters of the weight of the fruits, the weight of the pulp, the mass of the skin and the largest and the lowest fruit width.

Conclusions

The investigated biferous fig varieties showed significant differences in morphological characteriscs. Some of the examined traits significantly contribute to easier identification of varieties. Further studies should be continued in the collection planted from vegetatively propagated trees of these varieties, in order to obtain more precise data on their agronomic value.

Abstract

Wheat endosperm storage proteins, particularly glutenins, are the major components of gluten that determine wheat dough processing qualities. The genetic variability of high (HMW) and low (LMW) molecular weight glutenins using Sodium Dodecyl Sulfate Polyacrylamid Gel Electrophoresis (SDS-PAGE) was analyzed for forty-three Morrocan wheat varieties including twenty three durum wheat (*Triticum durum*) varieties and twenty of bread wheat (*Triticum aestivum*) varieties. Gluten strength was assessed by SDS sedimentation test and Zeleny volume for durum and bread wheat respectively. The analysis of the glutenin composition for durum wheat revealed the presence of six alleles: silent "c" allele for the Glu-A1 locus noted in all durum wheat varieties and five alleles for the Glu-B1 locus: Glu-B1b, Glu-B1e, Glu-B1d, Glu-B1a and Glu-B1c alleles. For bread wheat varieties, electrophoretic analysis showed the presence of ten alleles: three alleles for the Glu-A1 locus; Glu-A1c, Glu-A1a, and Glu-A1b, five alleles at Glu-B1 locus; Glu-B1b, Glu-B1c and GluB1i and two alleles (a), (b) at Glu-D1 locus. Furthermore, results showed significant differences between the durum and bread wheat varieties for gluten strength. Significant association has been found between HMW and LMW glutenins subunits composition and gluten strength. Proteins HMW subunits Glu-A1b, Glu-B1c, Glu-B1i, and LMW-Type 2 subunits were found positively correlated with gluten strength. The allelic identification of glutenins subunits and their association with gluten strength constitute an important tool in wheat breeding program for the improvement of bread and pasta making quality of bread and durum wheat.

Keywords: *Wheat, Glutenins, Allelic diversity, Gluten strength.*

Introduction

Wheat is a major component of most diets of the world because of its agronomic adaptability, ease of storage, nutritional goodness, and the ability of its flour to produce a variety of foods. The unique viscoelastic property of dough produced from wheat flour is responsible for the universal use of wheat for a wide range of products such as bread, cakes, biscuits/cookies, pizza, noodles, pasta, couscous and many of traditional products. The quality traits are mainly determined by the quantity and quality of gluten proteins. Wheat storage proteins are the major protein components of gluten. The high molecular weight glutenin subunits (HMW-GS) are storage proteins synthesized in the seeds of wheat, they are encoded by the Glu-1 gene located on the long arms of the homoelogous group one chromosomes, with each locus comprising two linked genes encoding x and y-types subunits (Payne, 1987). Consequently, two loci (Glu-A1, GluB1) encoding four HMW-GS are present in tetraploid wheat (*Triticum durum*, 2n=4x=28, AABB) and three loci (Glu-A1, GluB1 and Glu-D1) encoding six HMW-GS are present in hexaploid wheat (*Triticum aestivum*, 2n=6x=42, AABBDD).
Electrophoretic studies have revealed appreciable polymorphism in the number and mobility of HMW-GS in both bread wheat (Branlard et al., 2001; Oury et al., 2010) and durum wheat (Brites et al., 2001; Gregová et al., 2012). Consequently, the Glu-1 loci present multiple alleles. Payne and

Lawrence (1983) summarized the range of the alleles at the Glu-1 loci as three allelic forms at the Glu-1A, 11 alleles at the Glu-1B, and six alleles at the Glu-1D. Since the publication of this catalog of alleles at Glu-1 loci, more have been identified. Furthermore, the main low molecular weight glutenin subunits (LMW-GS) are controlled by genes called Glu-3 located on the short arms of group 1 chromosomes. The allelic diversity of LMW-GS in durum and bread wheat has been largely studied (Carillo et al., 1990; Nieto-Taladrez et al., 1997).
The resulting multi-allelism of glutenins influences the rheological property of gluten. Indeed, the correlation between end-use quality of wheat and specific composition of seed storage prolamin proteins has been recognized (Payne, 1987; Martinez et al., 2005). Consequently, breeders have taken advantage of these protein-based markers to select for dough properties. Therefore, glutenins subunits composition could serve as indicators of quality in wheat breeding program when only small amounts of the material are available and fast quality prediction is necessary. Then, appropriate germplasm with favorable glutenins variants could be introgressed through breeding.
The aim of the present investigation is to analyze high (HMW) and low (LMW) molecular weight glutenins composition of Morrocan durum and bread wheat varieties. In addition, the correlation of prolamins alleles with gluten quality among genotypes is studied.

Materials and methods

Plant material

20 hexaploid (*Triticum aestivum*) cultivars and 23 tetraploid (*Triticum durum)* cultivars registered in the Moroccan catalogue were used to analyze the allelic diversity of glutenins subunits. All these cultivars were released by INRA wheat breeders. International cultivars standards have been used for allelic identification of HMW–GS (Table 2).

Electrophoresis

Polyacrylimide gel electrophoresis in the presence of Sodium Dodecyl Sulfate (SDS-PAGE) was carried out using the procedure of Singh *et al.* (1991). Ten seeds were used for each genotype; the seeds were crushed into fine powder mortar and pestle. Ten milligrams of each accession were weighed and taken in a microtube. A cleaning step with 50% *n*-propanol with intermittent vortexing was used to remove the gliadins. Glutenins were extracted and reduced from the residue in extraction buffer containing dithiothretol DTT 1%, 2% SDS, 40% Glycerol, 0.08M Tris pH 6.8 and 0.002% bromophenol blue. The extract was incubated at 65°C for 15 min and centrifuged at 10,000 rmp for five minutes. Proteins were fractionated by electrophoresis in a vertical SDS–PAGE gel of 14% acrylamide concentration in a discontinuous Tris–HCl–SDS buffer system (pH 6.8/8.8) at 18 mA for 18 h following the method of Laemmli (1970). The gels were stained overnight with 12% (w/v) Trichloro-acetic acid solution containing 5% (v/v) ethanol and 0.05% (w/v) Coomassie Brilliant Blue R-250. De-staining was carried out with tap water. The HMW glutenin subunits were identified using the numbering system of Payne and Lawrence (1983) and compared with the patterns of known genotypes (standards).

Gluten strength assessment

Wheat varieties were analyzed for humid gluten content by near-infrared reflectance spectrophotometry analysis using Infraneo Choppin equipment. Gluten strength appreciation was estimated by Zeleny values obtained by near-infrared reflectance spectrophotometry for bread wheat cultivars and by SDS sedimentation test following a standard method (NM, 1989) for durum wheat cultivars. Two replicate analyses were made for each genotype.

Statistical analysis

Statistical analysis was carried out using the SAS program (Statistical Analysis System version 9.1) for descriptive statistical parameters and analysis of variance. Associations between gluten strength and glutenins alleles were investigated using Power Marker Version 3.25 software.

Results and Discussion

Allelic diversity of glutenins for Moroccan wheat varieties

The frequencies of 10 alleles identified at the 3 loci Encoding HMWGs are shown in Table 1. Three alleles were identified at Glu-A1, five at the Glu-B1 and two at the Glu-D1 locus. At the Glu-A1 locus, three alleles were detected in bread wheat cultivars and only one in the durum wheat cultivars; among bread wheat varieties, Glu-A1 (b) was the most common allele with a frequency of 55%. The frequency of Glu-A1 (a) and Glu-A1 (c) was 25% and 20% respectively. On the other hand, all durum wheat cultivars contain the allele Glu-A1(c).

In Bread wheat, The Glu-B1 (i) showed the highest frequency (60%) followed by Glu-B1(b) and Glu-B1(c) representing 25% and 15% of cultivars, respectively. The subunit type (20) Glu-B1 (e) was the most present in durum wheat cultivars (43%) followed by the subunits type (7+8) Glu-B1 (b) and subunits (6+8) Glu-B1 (d) with 30% and 22% respectively.

At the Glu-D1 locus, two alleles were detected with Glu-D1 (d) being the preponderant allele in the bread wheat cultivars (80%) whereas Glu-D1 (a) was present only in four bread wheat cultivars (20%). At Glu-B3 loci encoding for LMW subunits glutenins, LMW-2 was the most common type with a frequency of 78% among durum wheat genotypes.

Gluten strength assessment of Moroccan wheat varieties and relationship with glutenins composition

Statistical analysis showed significant differences among durum and bread genotypes for gluten content and gluten strength. Gluten content, with a mean value of 30%, varied from 19% in "Chaoui" durum wheat to 39% in "Massira" bread wheat variety. Whereas, gluten strength appreciated by SDS volume for durum varied from 24 ml noted in "Faraj" cultivar to 42 ml observed in "Cocorit" cultivar with a mean value of 32 ml. For bread wheat, Zeleny volume average was 23 ml varying from 12 ml in "Potam" cultivar to 40 ml in "Sebara".

The association gluten quality–allelic composition is summarized in Table 3. Results showed significant association between low molecular weight glutenins and gluten content and gluten strength (P = 1%). Indeed, low molecular weight glutenin subunits play an important role in determining the quality of durum wheat (Porceddu et al., 1998). Thus confirming previous results obtained by Masci et al. (2000). Furthermore, the effects of the Glu-B1 (c) subunit are significant on gluten content; this allele contributes positively to strength and toughness of pasta according to Branlard (1999). For bread wheat, the effects of the Glu-A1 (b), Glu-B1 (b), Glu-B1 (i) and Glu-D1 subunits were significant on gluten content. The same findings were reported by Branlard et al. (2001).

Conclusion

The analysis of the glutenin composition for Moroccan wheat varieties revealed an important polymorphism. A total of ten alleles were detected in Glu loci. Six and seven different banding patterns were observed for bread and durum wheat respectively. The combination (2*, 17+18, 5+10) subunits is being the most common for bread wheat. The combinations (Null, 7+8, LMW-2) and (Null, 20, LMW-2) were more frequents in durum wheat varieties. Significant associations were found between some HMW and LMW glutenins subunits and gluten strength. The allelic identification of glutenins subunits and their association with gluten strength constitute an important tool in wheat breeding program for the improvement of bread and pasta making quality of bread and durum wheat.

Abstract

The on-farm conservation of hot pepper in Maleh valley in Morocco has been strengthened thanks to seeds exchange between farmers in relation to its notoriety linked to morphologic and organoleptic quality. The objective of this study was to optimize the genetic resources management and to make better use in plant selection according to consumers' criteria. Thus, genetic polymorphism among and within eighteen farmers' accessions of hot pepper meta-population was assessed using fifteen quantitative and eight qualitative traits of agro-morphological characters, seed storage proteins electrophoresis (SDS-PAGE) and the random amplified polymorphic DNA (RAPD) marker. Biometrical analyses of recorded data were performed to evaluate genetic variability and genetic structure of the meta-population of hot pepper from Maleh valley according to genetic parameters. The result showed high significant differences among genotypes, accessions and among sites for almost all agro-morphological characters. The result of biochemical and molecular analysis showed a large pool genetic according to alleles frequency (Na=1.480), Shannon-Weaver's Index (I=0.285), and expected heterozygosity (He=0.199). The hierarchical analysis of molecular variance shows that 30% of total genetic diversity was assessed among sites, while 44% was assessed within accessions and 26% was assessed among accessions. Moreover, the genetic differentiation between pairwise accessions (PhiPT=0.559**) was exhibited among sites (PhiRT=0.299**) and among accessions (PhiPR=0.370**). Otherwise, Nei genetic distance (NeiGD) approves a strong seed or seedling exchange within or among sites according to requested criteria.

Introduction

Pepper (*Capsicum spp*.) is one of the most important fruit crops primarily produced in the tropical and subtropical countries. The genus of *Capsicum spp.* was introduced in Morocco through Europe during the protectorate about 1924 in context of adaptation trials of tropical crops repatriated from the conquest of the new world in the 16th century. Some of adapted varieties were spread in some geographical areas delimited by their adaptation potential such as in Maleh river valley. In Morocco, pepper is produced from two cultivated species as *Capsicum annum* L. and *Capsicum frutescens* L. Its fruits are mainly consumed as a fresh or cooked vegetable, condiment or as culinary supplement. Furthermore, hot pepper is also used in traditional medicine as anti-inflammatory and antidiabetic, in food industry as food coloring or spicy taste, in phytosanitary industry as antiseptic, or as traditional insecticide agent, and as an ornamental plant (Berke et al, (2001); Bhadragoudar et al, (2011)).

The genus of hot pepper is diploid (2n=24), annual or perennial with an allogamic plant (15%). The average of allogamy can vary from 2 to 90% depending on the activity of pollinators (bees and trips) and synchronization of pollen and stigma maturity. The landrace of hot pepper produced in Maleh river valley is especially well adapted to salty soil. It is characterize by phenotypical variability particularly with regards to fruits. Hence, genetic diversity has to be described and measured in order to set a genetic resources management strategy towards strengthening the on-farm conservation of a valuable local genetic base. Nowadays, several genetic tools are used to assess genetic variability such as agro-phenotypical traits, denatured proteins and DNA restriction fragment markers. The agro-morphological characterization requires a large collection of samples, a large number of traits measured at maturity stage of the plant (Aniel kumar O. et al, (2010); Peeraullee et al, (2013); Nsabiyera et al, (2013)). Moreover, most of them are under polygenic control and therefore their expression depends on environmental factors as indicated by Geleta et al, (2005) and Bhadragoudar et al, (2011)). That's why the investigations on crop diversity were turned to biochemical markers methods based on seed storage proteins electrophoresis (SDS-PAGE) (Odeigah et al, (1999); Aniel kumar O. et al, (2010)) and to molecular markers methods such as the random amplified polymorphic DNA (RAPD) marker (Bhadragoudar et al, (2011); Troconis-torres et al. (2012); Peeraullee et al, (2013)). Indeed, molecular markers are more rapid and reproducible with the ability to generate large numbers of polymorphic genetic loci. Furthermore, their expressions are not influenced by the environment (Geleta et al, (2005)). DNA markers have been well used in plant genetic resources management mainly to assess genetic diversity ex situ and/or in situ conserved, to identify the valuable genes or genotypes that could be used in plant breeding. The molecular markers, as an additional tool of phenotypical traits, seems to be useful to assess the valuable genetic diversity of landraces on-farm conserved in increasing efficiency breeding efforts to improve crop productivity.

Thus, current study is based on an assessment of genetic diversity among and within farmers' accessions and the relationship between accessions of hot pepper meta-population on-farm conserved in Maleh river valley using morphological traits, biochemical (SDS-PAGE) and molecular markers (RAPD). This characterization might be useful approach in breeding for selecting performed lines or parents for hybridization.

Material and methods

Eighteen farmers' field accessions were randomly selected during 2014/15 growing season across three target localities of hot pepper production area in Maleh river valley. It concern Sidi Moussa Ben Ali ($Site_1$) (O 7° 22', 33° 35' N), Ech-challalate ($Site_2$) (O 7° 24', 33° 38') and Sidi Moussa El Majdoub ($Site_3$) (O 7° 23', 33° 37' N). At field level, six plants were randomly selected along field diagonal at regular intervals according to the standards reference in the practice guide of Marchenal (1994). Data of fifteen quantitative (Table 1) and eight qualitative (Table 2) agro-morphological traits was recorded from eight ripe fruits per plant of the six collected plants per field at first harvest according to UPOV Guideline TG/76/8 (2010). The polymorphism of twelve fruits collected from each farmer's field was assessed using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) as described by Laemmli (1970). Proteins bands were scored 1 or 0 depending on their presence or absence in the electrophoretic profile in the high-protein variation area between 80 KDa and 15 KDa. In addition, genetic diversity and genetic relationships between farmers' accessions was evaluated using random amplified polymorphic DNA (RAPD) marker. Total genomic DNA was extracted from young leaves using a modified CTAB method based on the protocol of Saghai-Maroof (1984). Sixty-two primers are used to evaluate genetic diversity and RAPD electrophoresis profiles of different farmer's accessions were converted into a matrix of binary data (1/0) depending on the presence or the absence of the band. Recorded phenotypical data were statically analyzed (ANOVA) using General Linear Model (GLM) ($\alpha = 0.05$) (SAS software (version 9.1), while matrix of binary data from both biochemical and molecular markers were subjected to variance analysis (AMOVA) using Gen Alex software version 6.1.

8	Shape of Fruit Apex	1: Very acute, 2: Moderately acute, 3: Rounded, 4: Moderately depressed, 5: Very depressed

Results and discussion

Quantitative and qualitative agro-morphological traits

Quantitative characters include plant and fruit features. Variance analysis showed a high significant variability of most of measured morphological characters within the meta-population which is structured within sites and within accessions. On account of coefficients of variation, high variability was observed for plant growth traits such as plant height (20.6%), number of vegetative nodes per plant (28.3%), stem length to first bifurcation (32.4%) and leaf size (24.4%); of yield components such as number of fertile nodes per plant (26.4%), number of fruit per plant (25.7%) and number of seeds per fruit (23.9%), and also of fruit characters such as fruit length (12.5), weight (18.2%) and thickness (15.6%), and number of locules per fruit (21.4%) (Table 3). High coefficients of variation for agro-morphological traits were also reported among pepper genotypes elsewhere by Adetula et al. (2006); Rodriguez et al. (2008); Sharma et al. (2010). Moreover, most performed traits related to plant vigor, plant productivity and fruit size were observed primarily within $Site_1$ and $Site_2$ accessions. Correlated analysis showed that fruits per plant were positively correlated with plant height ($R=0.199^{*}$), number of vegetative nodes ($R= 0.224^{*}$) and number of fertile nodes ($R=0.883^{***}$). According to variance analysis, most performed traits were observed within B_1 ($Site_1$); E_6 and E_7 ($Site_2$) and M_7 ($Site_3$) accessions for plant vigor; for plant productivity, and for fruit size. Rodríguez et al. (2008) have reported that fruit length, fruit weight and number of fruits per plant are the major yield component. Thus, B_1, E_6, E_7 and M_7 accessions might include genotypes with farmers and consumers' desirable traits concerning plant vigor, productivity and fruit characteristics. Furthermore, low morphological traits variability was revealed within E_6 and M_9 as a consequence of farmer's selection. Indeed, genetic diversity among farmers' accessions is, in one hand, related to their genetic composition of genotypes add to the degree of field hybridization, and in other hand, a consequence of genotype x environment constraints interaction and of genotype x farmers' selection impact interaction based mainly on fruit morphology (size, shape and color), sanitary and on fruit piquancy. Otherwise, natural hybridization concerns only 40-50% of the flowers which gives mature fruit. Thus, the Maleh hot pepper meta-population might be a useful source of candidate genes associated with desirable traits related to plant vigor, plant yielding and fruit size and shape.

Furthermore, most of qualitative fruit traits listed in table 4 showed a significant variation. Fruit color of unripe fruit was green, with a different level of color ranging from light to dark green. Red color of ripe fruit is related to capsanthin accumulation level; it varied from light to dark among accessions. According to farmers and consumers, the main selected criteria are related to dark (44.7%) and medium (41.3%) red color of ripe fruit produced mainly in Site$_2$ (67.9%***) and in Site$_3$ (55.7%***) respectively; high fruit brightness which concern 80.4%*** and 70.8%*** of measured hot pepper produced respectively in Site$_1$ and Site$_2$; narrowly triangular fruit shape (87.5%) with rounded apex (93.2%) and right pericarp (61.6%) (Table 4, Figure 1).

Biochemical markers (SDS-PAGE)

In addition to phenotypic information, biochemical markers were efficient to assess the average of polymorphism among the hot pepper meta-population (53%) which is ranged from 32% ($Site_1$) to 88% ($Site_2$) (Table 5). The highest rate of genetic variability was recorded for $Site_2$'s accessions with high percentage of polymorphic loci (88%) supported by high allele frequency (Na=1,880), high level of heterozygosity (He=0.334) and high Shannon genetic diversity index (SWI=0.492) (Table 5). However, lower genetic variability among $Site_1$ and $Site_3$ farmers' accessions might be related either to farmer's selection impact according to phenotypic preferences, or to genetic population size which is correlated to size of field production, or to seed/seedling exchange impact between farmers of the two sites. Indeed, the mean size of hot pepper production plot varied from 0.05 ha at $Site_3$ to 4.13 ha at $Site_2$ and genetic parameters as the importance of genetic diversity within sites (92%) than among site (8%), the short genetic distance between $Site_1$-$Site_3$ (0.061) and between $Site_2$-$Site_3$ (0.079) add to their low genetic differentiation (PhiPT) respectively (0.056^{ns}) and (0.046^{ns}) (Table 6) support seed/seedling exchange within or among sites.

Table 5: Genetic diversity parameters of hot pepper meta-population per Site

SDS-PAGE	P (%)	Na	Ne	He	UHe	SWI
$Site_1$	32	1,240	1.214	0,121	0.134	0,178
$Site_2$	88	1,880	1.582	0,334	0.350	0,492
$Site_3$	40	1,320	1.242	0,143	0.149	0,213
Mean	53,3±17.5	1,480±0.07	1.346±0.04	0,199±0.024	0.211±0.025	0,295±0.034

Na = Number of different Alleles, Ne = Number of Effective Alleles, SWI = Shannon's Index, He = Expected Heterozygosity, UHe = Unbiased Expected Heterozygosity where for Diploid Binary data and assuming Hardy-Weinberg Equilibrium ($p = 1 - q$).

Table 6: Genetic structure of hot pepper meta-population

Population	PhiPT	Nei Genetic Distance	Nei Genetic Identity
$Site_1$-$Site_2$	$0,144^{*}$	0,181	0,835
$Site_2$-$Site_3$	$0,046^{ns}$	0,079	0,924
$Site_1$-$Site_3$	$0,056^{ns}$	0,061	0,941

Molecular markers (RAPD)

Nine random primers were performed to assess genetic variability among and between accessions with an observed polymorphism ranged from 16.7 (OPL-08) to 62.5% (OPX-14) (Table 7). The mean polymorphism among hot pepper meta-population is 52% in accordance with biochemical markers which varied from 24% ($Site_1$) to 92% ($Site_2$) and among accessions from 7.1% (M_9) to 20.0% (E_6) as predicted by morphological traits analysis. The hierarchical analysis of molecular variance (AMOVA) shows that 30% of total genetic diversity was assessed among sites, while 44% was assessed within accessions and 26% was assessed among accessions.

The AMOVA derived diversity measurement SSWP/(n-1) was ranged from 0.67 (M_9) to 5.67 (E_6) with a mean of 2.9. The mean polymorphism observed within the meta-population (WP 52%) was supported by Nei's genetic diversity (SWI=0.287) which varied within accessions from 0.014 (M_9) to 0.124 (E_6), and between sites from 0.139 ($Site_1$) to 0.519 ($Site_2$) (Table 8). Otherwise, genetic diversity was greater within sites (89%) than among site (11%). In addition, Nei's genetic distance between $Site_2$-$Site_3$ and between $Site_3$-$Site_1$ was lower respectively 0.093 and 0.098 supporting farmers' seed/seedling exchange network in concordance with SDS-PAGE results. Otherwise, genetic differentiation within accessions (PhiPT=0.559**) was exhibited among sites (PhiRT=0.299**) in all $Site_2$ accessions and among accessions (PhiPR=0.370**) (Table 9).

Table 7: RAPD markers used to assess genetic diversity among hot pepper meta-population

PhiPT	53	150.75	2.844	2.844	44%	0.559	**

Conclusion

Genetic diversity provides farmers crop security in constraints environments. However, farmer's genetic diversity management is based on agro-morphological traits that are highly influenced by environmental factors, socio-economical and farmers' indigenous knowledge.

The agro-morphological variability observed among hot pepper accessions of Maleh valley was supported by biochemical (SDS-PAGE) and molecular markers (RAPD). Most of analyzed phenotypical traits related to plant vigor, yield components and fruit size and shape were found significantly variable among hot pepper meta-population. Variability within accessions might be useful to discriminate among genotypes according to farmers (productivity) and consumers (phenotype trait) criteria. Moreover, the study revealed a considerable genetic variability among accessions, among sites and within sites particularly within $Site_2$ and among B_1, E_6, E_7 and M_7 accessions that might include genotypes with both productive traits and fruit size and feature. Thus, the availability of genetic variability within hot pepper meta-population might provide breeders with genotypes or allelic variants of candidate gene(s) associated with desirable traits.

Abstract

Considering the importance of the cultivars performance in improving productivity, comparative study of ten new industrial tomato cultivars was conducted at the experimental field of Sidi Alla Tazi in the Gharb region of Morocco, for their phenological and production parameters. The objective of this experiment is to study the agronomic performance of 10 Tomato cultivars in order to seek the most adapted and high yield potential in the Gharb agro-climatic conditions. The cultivars trial was transplanted with dual lines and led by fertigation. The tested plant material consisted of cultivars with fixed growth. The adopted trial is a randomized block with four replications. Obtained results have statistically identified four cultivars; Num 0058 (120 t/ha), Artix (118 t/ha), Mariflor (117 t/ha) and Riotinto (116 t/ha), which differ by the best morphological, agronomic and technological criteria as: height, vegetative port, Leaf Area Index (LAI), yield, synchronized maturity, precocity and Brix. These cultivars expressing the highest yields and the best brix have shown the best performance of growth and development. The lowest yield was obtained by Heinz 2710 control (100 t/ha). In viewpoint of precocity, cultivars Num 0058 and NPT 63 are the earliest.

Keywords: *Performance, Cultivars, Brix, Industrial Tomato, Morocco*

Introduction

Two main types of tomatoes (Lycopersicum esculentum) exist, composed by indeterminate growth tomato and the growth fixed which is "dwarf" or so-called industrial tomato. Globally, the major producers of industrial tomatoes according to the International Association Mediterranean Tomato (AMITOM, 2010[1]) are; USA (12.6 million tonnes), China (6.2 million t.) and Italy (5 million t.). In Morocco, tomato area has experienced a constant evolution in the various regions where irrigation is possible (Oukabli, 1983; Atherton, 1986 quoted by Chleyah 2001). The production is currently concentrated in the Gharb and Loukkos regions on an area of about 5,000 ha and over 75% of the sowings exists in the Gharb region (ORMVAG, 2008). These crops present only 13% of sown areas, but they contribute to 54% of the total value of crop production (Green Morocco Plan 2008). Tomato sector provides 120 working days per hectare and ensures the continued operation of an emerging processing industry. The main part of production is converted into concentrated and derivatives by one of the important aggregator companies; Les Conserves de Meknes (LCM-Aicha) that convert more than 110,000 t/year (Anonymous, 2008; DPVCTRF, 2010). This study aims to contribute to the improvement of productivity by comparing ten new cultivars in order to propose the best ones to the farmers. This study was conducted in collaboration between INRA and LCM-Aicha.

(1) AMITOM: Mediterranean International Association of the Tomato.

Material and methods

1. Plant Material

The plant material used is composed of ten cultivars with determinate growth. All these cultivars namely; Num 0058, NPT 63, Num 0001, Num0051, Mariflor, Riotinto, Artix, NPT 65 and NPT 64, are produced by Syngenta and Nunhems companies. Cultivars of this experiment are sown in a peat substrate in trays cells. Heinz 2710 variety is used as control.

2. Soil Characteristics

The experiment was installed on a heavy soil in the experimental area. Results of physicochemical analysis show that the superficial horizons consist of alluvium depositing are rich of silt. Soil texture is clayey loam moderately provided organic matter (2.98%) and very rich in K (546 ppm). The pH (7.7) is slightly alkaline. Trial was conducted in fertigation for a yield of 100 t/ha. Fertilizers used are; 130U NO_2, 97U P_2O_5, 264U K_2O and 12U Mg.

3. Experimental setup

The experimental model is a randomized complete block with four replications. The basic plot with an area of 36 m^2 consists of three twinned lines spaced of 2 m. The plants stand is made of about 25,396 plants per hectare. Three plants are selected at random on the middle line of each plot. 120 plants were analyzed for vegetative characters such as: height; LAI; vegetative port; yield and its components; precocity score 1 to 6; number of clusters, number of flowers and number of fruits per plant. At harvest, the products were weighed and characters qualitative have been noted as caliber, weight, fruit shape; length; number of lodges; brix, pH and NaCl content were analyzed.

4. Statistical analysis

For each measured character as agronomic, technological and morphological, we have proceeded to the analysis of variance (ANOVA) by a single classification criterion. When a significant difference is found between cultivars for one character, the ANOVA is completed by Dunnett test.

Results and discussion

1. Phenological parameters

The variance analysis (Table 1) revealed a high significant HS difference for the height character and the LAI character respectively ($P \leq 0.0044$**) and ($P \leq 0.0043$**), but very HS for the vegetative shape character ($P \leq 0.0005$***). While the other characters are not significant, indicating existence of morphological diversity among the cultivars tested, with a low variation coefficient for all characters. So, the morphological characters are less variables.

Table 1. ANOVA of observed parameters

Variation sources (parameters)		Height (cm)	Leaf Area Index (LAI)	Vegetative shape (cm)	Yield (T/ha)	Fruit weight (g)
Cultivars (average± Type-Ecart)	Num 0058	72,91 ± 2,9ba	5.24±0.68ed	2.24± 0.31a	119.98 ±21.73a	85.08±9.14

(NB: For each character, values with the same letter are statistically equal according to Dunnett's test)

Comparison of heights average showed that cultivars such as Artix (76.66 cm), Num 0058 (72.91 cm) and Riotinto (72.91cm) give a remarkable growth in height greater than the control (69.58 cm), with a variation coefficient of 8.78% (Table 1). Indeed, this result justifies their adaptation to agro-ecological conditions of the region. The LSD test (6.03) at threshold $\alpha = 0.05$ allowed to classify cultivars in 3 homogeneous groups. The first one consists of Artix cultivar with an average height of 76.66 cm followed by Num0058 and Riotinto cultivars having an average of 72.91 cm and a last group including the control, not exceeding 70 cm. The comparison of leaf area index (LAI) was leading to estimate the biomass directly dependent on the photosynthesis that takes place in the plants stand. The density of leaf system has consequences on the health status of the culture and the reduction in evapotranspiration. This comparison shows that cultivars: Riotinto, Num0051, Artix and NPT 64 have shown greater leaf area index (>6) in comparison to control (<6) and therefore these cultivars have a denser biomass (Table 4). LSD test (0.74) at threshold $\alpha = 0.05$ has shown the existence of more homogeneous groups. The first consists of the Riotinto cultivar that comes out on top with a mean of 6.80 followed by Num 0051, Artix, NPT64 and other cultivars that overlap each other between 5.17 and 6. Comparison of vegetative shapes shows that cultivars Num 0058 (2.24), Num 0001 (1.96) and NPT63 (1.92) have a vegetative volume significantly higher than other cultivars including the control. LSD test (0.18) at threshold $\alpha = 0.05$ allowed to classify all cultivars in 4 homogeneous groups. The first one consists of the Num 0058 that ranks first with an average of 2.24 cm followed by the second group of the Num 0001 (1.96 cm). These genotypes tend to better display their vegetative port. An intermediate group of NPT63, Heinz 2710, Artix, Riotinto, Mariflor and NPT 65 cultivars whose averages overlap between 1.80 and 1.92 cm. The last group is composed by NPT 64, Num 0051 cultivars having a vegetative volume of about 1.76 cm only, and an erect vegetative port type.

2. Yield Components

Data on yield components (number of flower clusters/plant, number of flowers/plant, number of fruits/plant and yield) were submitted to principal component analysis (PCA) for discriminating and looking for correlations that might exist between components (Table 2).

Table 2: Counting data yield components

Cultivars* status: number of flower cluster (a), flowers (b), fruits (c) and yield in t/ha (d)											Mean	Type-Ecart
	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10		
a	43	31	34	24	36	47	42	55	22	31	36	10.32
b	295	109	103	103	190	220	167	149	124	140	159.5	61.18
c	140	50	85	41	71	117	65	125	44	68	76.6	36.76
d	120	114	105	101	117	116	118	112	102	100	111	7.72
Cultivars : Num 0058 (C1),NPT 63 (C2),Num 0001 (C3), Num 0051 (C4), Mariflor (C5), Riotinto (C6), Artix (C7),NPT (C8), NPT 64 (C9) and Heinz 2710 control (C10)												

According to the above analyze, cultivars have been classified on three homogeneous groups, the first one consists of the folowing cultivars as Num 0058, Mariflor, Riotinto and Artix. The best positive correlation is mentioned between Yield and the Flowers number (r^2=0.75), which constitute a good illustration for the best performance.

2.1 - Number of flower clusters

The number of flower clusters per plant varies widely between cultivars, of about 22 to 55. The best performances were recorded by the following cultivars: NPT 65, Riotinto, Num 0058 and Artix. The PCA for all yields components measured reveals a positive correlation between the number of flower clusters and other yield components like number of flowers, fruit number and yield. This relationship is confirmed between fruit number and yield, which establishes a significant correlation (r^2= 0.62). Therefore, this component explains strongly the performance of cultivars. Indeed, Num 0058, Riotinto, Mariflor and Artix cultivars have confirmed an abundant flowering compared to the rest of genotypes.

2.2 - Number of flowers per plant

The number of flowers per plant varies between cultivars; it changes from 103 to 295. The best performances were recorded by the cultivars: Num 0058, Riotinto, Mariflor, Artix and that showed superiority of flowering over the rest of the cultivars. The correlation between the number of flowers and the yield is significant ($r > 0.74$). The significance test of the correlation coefficient explained that the number of flowers determines greatly the yield parameter.

2.3 - Number of fruits per plant

The number of fruits per plant varies from 44 to 140 for the following genotypes NPT 65, Num 0058, Riotinto and Artix. Cultivars are shown remarkable regarding to the number of flowers clusters per plant, which ranged from 22 to 55 depending on the genotype. The correlation between the number of fruits and yield was significant ($r^2 > 0.62$) and therefore this component explains very well the cultivars performance. According to the control, the Num 0058, NPT65, Riotinto, Mariflor, Num0001 and Artix cultivars have given the best number of fruits. The highest fruits number was obtained by the Num0058, NPT65 and Rotinto cultivars.

2.4- Yields

At threshold α=0.05, ANOVA revealed no significant difference. LSD test has revealed three potentially interesting cultivars that are specially Num 0058, Artix and Mariflor. The highest yield was obtained by the followed cultivars Num 0058 (120 t/ha), Artix (118 t/ha), Mariflor (117 t/ha) and Riotinto (116 t/ha). The average yield of all other cultivars is of about 110.6 t/ha with a variation coefficient of 9.6%.

Note that the recorded performance levels (Table 2) range from 100 to 120 tonnes per hectare. These yields are very satisfactory compared to other similar experiments carried out in the region with other cultivars. The control gives only 90 t/ha. Moreover, cultivars Petoseed, Sun 6200, and Heinz 9661 have given yields comprise between 70 to 80 t/ha, while Boss, Sun 6235 and Heinz 8704 have given yields from 55 to 70 t/ha (El Atir et al, 2001). We thought that it is useful to make a classification for these cultivars in 3 homogeneous groups. The first and the best one consists of cultivars Num 0058, Artix, and Mariflor who gives the best yields.

3. Precocity, inter-cultivars maturity, size and technological quality

Monitoring flowering rate has determined the flowering period of the different cultivars. This period has a duration of 17 days. The evolution of flowering percentage allowed to a classification according to a gradient in the number of flowers, which gives an idea on the inter-cultivars precocity (Table 3). Thus, cultivars like NPT 63, Num 0058, Num 0001 and Mariflor are in advanced phase of nearly 15 days compared to other cultivars.

Table 3: Rating of flowering percentage according to studied cultivars

Obser./dates/cultivars	jours	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
pré-flowering (%)	0	3	4	1	-	2	1	1	1	-	1
Start- flowering (%)	3	30	30	20	5	10	5	3	2	2	1
Flowering (%)	7	40	45	30	10	25	10	10	8	8	10
Extend flowering %	10	45	50	35	10	40	15	12	12	12	15
Flow-blooming %	17	70	70	65	45	60	50	40	40	40	45
Total	17	188	199	151	70	132	81	66	63	62	72
Scale rating		2	1	3	6	4	5	6	6	6	6

Two harvests were conducted to observe if the cultivars expressing a grouped maturity. The first harvest was performed by 98 days after sow and the second after 15 days. Thus, compared to control, the others cultivars like Mariflor, Num 0058 and Num 0001 tend to have a grouped maturity and expressed more than 85% of their products in the first harvest (Table 4).

Table 4: Proportion of harvest in the parcelar global production.

Cultivars	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
1st. harvest (%)	87,8	86,8	87,2	80,9	90,1	82,9	81,2	86,9	86,4	88,4
2nd. harvest (%)	12,1	13,1	12,7	19	9,8	17	18,7	13	13,5	11,5
pH	4,18	4,02	4,09	4,06	4,24	4,22	4 ,22	4,2	4,2	4,08
degree of Brix	5	5	5	5,4	5,2	5	5,2	4,8	5	5
NaCl content	0,08	0,08	0,08	0,08	0,09	0,08	0,07	0,08	0,06	0,08

The percentage of the first harvest in the overall production ranged from 80.9 to 90.1% depending on the genotypes like Mariflor, Heinz, Num 0058 and Num 0001 tend to have a grouped maturity compared to other cultivars and expressed almost 85% of their products in the first harvest (Table 4). However, Num 0051, Riotinto and Artix cultivars presented 20% of their products 15 days after the first harvest. These cultivars have a relatively grouped maturity than other cultivars. The ANOVA of fruit weight showed no significant difference (P> 5%) between cultivars. The assessment of the form by the combination of the length and diameter of each fruit showed the existence of the rounded shape for the Num 0001 cultivar, the long rounded, and flattened for Num 0051cultivar and Heinz 2710. The rest of the cultivars have a long flat shape. Moreover, the lodges' number has been 3 for genotypes such as Num 0058, Num 0001, Mariflor, Riotinto F1, NPT 63 and Heinz 2710. However, the average of fruit weight is of around 92 g/fruit.

Brix is the most important criterion of the quality in tomato industry. It denotes the degree of dry matter, which determines the performance for processing. All cultivars have shown a brix above 5 except one genotype such as NPT 65 (4.8). Cultivars like Num 0051, Mariflor and Artix expressed the best brix between 5.2 and 5.4. The pH (4.18) and NaCl content (0.07) is relatively the same for all cultivars (Table 4).

4. Agronomic and morphological characteristics of cultivars

According to the results of these parameters (Table 5), it appears the existence of 3 cultivars that seem most appropriate and present the best performance. These cultivars are Num 0058, Artix and Mariflor, which expressed the best yields and the best brix. Also, they expressed the best growth and development performance. Concerning precocity, Num 0058 and NPT 63 cultivars are the best ones, while Num 0001, Riotinto F1 and Artix cultivars are later. In viewpoint of disease resistance, the Num 0058 and NPT 63 cultivars were free of diseases and physiological mosaic unlike Mariflor and Artix cultivars, which presented slight mosaic branches. We also observed that the Num 0058 cultivar presented a less dense foliage than other cultivars. Skiredj et al 2002 and El Alami, 1982, showed the same interpretation.

Table 5: Agricultural Features of the studied cultivars

Cultivars	Height (cm)	Veget. shape (m)	LAI	Precocity	Yield (t/ha)	Nbr. lodges	Brix	Diseases physio.	Mosaique	Foliar density
Num 0058	72,9	2,2	5,2	2	120	3	5	-	-	clair
NPT 63	67,0	1,9	5,6	1	114	3	5	-	-	very dense
Num 0001	65,4	1,9	5,1	3	105	3	5	+	-	dense
Num0051	65,4	1,7	6,4	5	101	2	5,4	+	2	very dense
Mariflor	66,2	1,8	5,6	4	117	3	5,2	+	1	dense
Riotinto F1	72,9	1,8	6,8	5	116	3	5	+	-	dense
Artix	76,6	1,9	6,0	6	118	2	5,2	+	-	dense
NPT 65	67,4	1,8	5,9	4	112	2	4,8	-	-	dense
NPT 64	65,4	1,7	6,0	6	102	2	5	+	2	very dense
Heinz 2710	69,5	1,9	5,9	5	101	3	5	-	-	very dense
(Precocity score= 1: very early, 2: early, 3: medium early, 4: fairly late, 5 late, 6: very late)										

Conclusions and recommendations

Gharb region is currently the first local production of tomato industry in Morocco. Obtained results have identified four cultivars statistically distinguished by the best morphological and agronomic technology criteria such as height, vegetative shape, LAI, yield, early maturity and brix. These cultivars are specially Num 0058 (120 t/ha), Artix (118 t/ha), Mariflor (117 t/ha) and Riotinto (116 t/ha). They expressed the highest yields and the best brix. They also expressed the best growth and the good development performance. In viewpoint of precocity, cultivars like Num 0058 and NPT 63 are the earliest. Concerning diseases resistance Num 0058 and NPT 63 cultivars were free of diseases and physiological mosaic. Num 0058 cultivar was observed with a less dense foliage than other cultivars has given the high level of yield. Adoption of these identified cultivars remains a promising project that could have a positive effect on increasing productivity in the irrigated perimeter. Although, industrial tomato becomes an opportunity for diversification of incomes for small farmers in this region. Therefore, it is recommended better sowing early culture when the agro-ecological conditions do not present significant risks.

Acknowledgements

Firstly, I would like to thank the General Director of the National Institute of Agricultural Research and the Manager of the Regional Center of Agricultural Research of Kenitra, for their assistance. In addition, we should be grateful for the financial support given by The "Les Conserves Meknes (LCM-Aicha)" group, in order to success all field trials.

Abstract

Utilization of Magnetically treated water has been investigated and applied in many countries such as Russia, Australia, Israel, China and Japan. Studies have shown that the magnetic field is used as a safe alternative choice to improve plant growth and development. Although the properties of magnetically treated water have received a great deal of interest in recent years, there are no studies conducted in Moroccan agricultural conditions. The present study aims at gaining more insight on the effect of magnetically treated irrigation water in the northwest region of Morocco, on the yield of strawberry plants (*Fragaria* × *ananassa* Duch. *cv. Camarosa*) and its components. The experiments were conducted in situ, during two crop seasons (2011-2012 and 2013-2014). The results confirm that physical treatment of irrigation water by a static magnetic field improve the yield of strawberry fruits. The percentage of increase in number of flowers, number of fruits and fruit yield per 100 plants were 27.4%, 30.9%, 34.8%, respectively compared with normal irrigation water (average over both crop seasons). These results suggest that irrigation with magnetically treated irrigation water improves the production of the strawberry plant, thus water use efficiency was enhanced. Therefore, the magnetically treated irrigation water can be considered as a promising technique for improvement strawberry production, but extensive research is still required.

Keywords: *Magnetic field, Irrigation water, Strawberry, yield components*

Introduction

Strawberries are one of the most popular cash crops from a commercial and economic point of view. Morocco ranks as the world's fifth largest strawberry exporter, with a total production of 145 233 tons (FAO, 2013). Appropriate strategies are to be developed to increase crop productivity while conserving water supply. One of the new strategies is physical magnetic treatment technology. This technique is safe, simple, and environmentally friendly without harmful effects. Besides that, it has low operating costs. The literature reports have shown an improvement of irrigation water quality and water use efficiency, crop yields and quality, soil improvement, scale prevention/elimination in water using systems, and water savings by using magnetic treatment (Eşitken & Turan, 2004; Grewal & Maheshwari , 2011; Mostafazadeh-Fard et al., 2011). In fact, it was reported that the magnetic treatment changes water properties due to displacement and polarization of water atoms (Dhawi et al., 2009). These changes result in a better assimilation of nutrients and fertilizers in plants during the vegetative growth period (Moon & Chung, 2000; Nawroz & Hero, 2010). It was found that the mobility of nutrient elements in root zone of citrus was improved greatly when using magnetic treatment (Hilal & Hilal, 2000; Eşitken & Turan, 2004). However, there are hardly any studies conducted in Moroccan agricultural conditions. The objective of our study is to investigate the effects of magnetically treated irrigation water in the northwest region of Morocco, on strawberry plant's (*Fragaria* × *ananassa* Duch. *cv. Camarosa*) yield and its components.

Material and Methods

This study was conducted in a farm named "DIRAFROST" located in the region of Laaouamra, 20 km south of Larache, Morocco[4]. A 2 ha field experiment was conducted, in situ, during two crop seasons (2012 and 2014).

The soil was classified as a frank sandy with a clay content of 5%; silt loam content of 15% and a sand rate of 80%. The amount of organic matter was 1.55% and a basic pH of 7.2. The electrical conductivity is 314µS cm^{-1}.

Camarosa bare root plants were planted on November 4th and 10th of the years 2011 and 2013 respectively, at the rate of 70000 plants per hectare. Strawberries were grown under low plastic tunnels. Water from a well was used for drip irrigation. In October, 3.2 litre of irrigation water was given daily, thereafter, watering was continued daily (30 $m^3.h^{-1}$ per hectare). Considerably, higher rates are required during prolonged hot and dry periods. The plants were fertilized weekly through the drip irrigation system. First and final harvests were performed between 1st of February and 30th of June for the two crop seasons.

Irrigation water was treated magnetically by passing once through a magnetic treatment device that was designed especially for field conditions. We have called the aforementioned treated water as magnetically treated irrigation water (MTIW).

The experimental field was formed by two adjacent plots. In each plot, there are three valves. Three sub-units were fixed in each plot (450 m^2), they coincide with the inter valve distance. Each sub-unit had 8 beds of 100 strawberry plants. The magnetic treatment device was installed in the front of the secondary pipe line in the plot irrigated with MTIW. Thus, water flowing downstream in the three valves has already treated by the static magnetic field. Statistically, the experimental system was performed as a completely randomized design with treatment (MTIW) at two levels and 3 replications (sub-units).

Quantitative traits such as the number of flowers and fruits per 100 plants, and fruit yield (kg/100 plants) were investigated for each treatment.

All data in the present study was subjected to the one-way analysis of variance (ANOVA) to test the main effects of the magnetic field and find the differences between the plants irrigated with MTIW and the control.

Results and Discussion

The number of flowers: the comparison of the number of flowers in the 2012 and 2014 crop seasons of strawberry plants, as affected by normal and magnetically treated irrigation water, are presented in Figure 1. The results show that the irrigation of strawberry plants with MTIW resulted in significant increases in the number of flowers compared with the plants irrigated with normal irrigation water. The results are highly significant for the plants corresponding with the 2012 crop season. On average, the increments were 25.6% in 2012 and 29.2% in 2014 (Figure 1).

[4] Coordinates: 35°1'16"N and 6°9'47"W in MSD (minutes and seconds degrees), latitude of: 35.0212059397254 and longitude of: 6.16293206440213 (in decimal degrees).

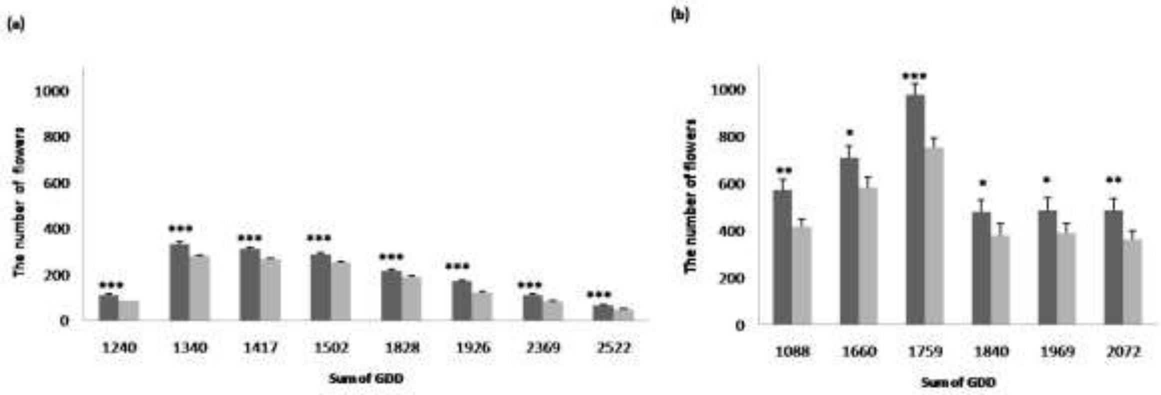

Figure 1: The number of flowers of 100 strawberry plants irrigated with normal ( ) and magnetically treated irrigation water ( ) for 2012 (**a**) and 2014 (**b**) cropping seasons. The data were presented as function of the sum of GDD (Growing degree days). *, ** , *** showed that the difference is significant at the 0.05 ; 0.01 and 0.001 levels, respectively. The vertical bars represent standard error of the means.

The number of fruits: the mean number of fruits of strawberry plants irrigated with normal and MTIW observed during the two crop seasons 2012 and 2014 are shown in Figure 2. The mean number of fruits of strawberry plants is strongly affected by the magnetic treatment. The percentages increase in the number of fruits was 43.5% (2012) and 27.4% (2014) when irrigated with MTIW.

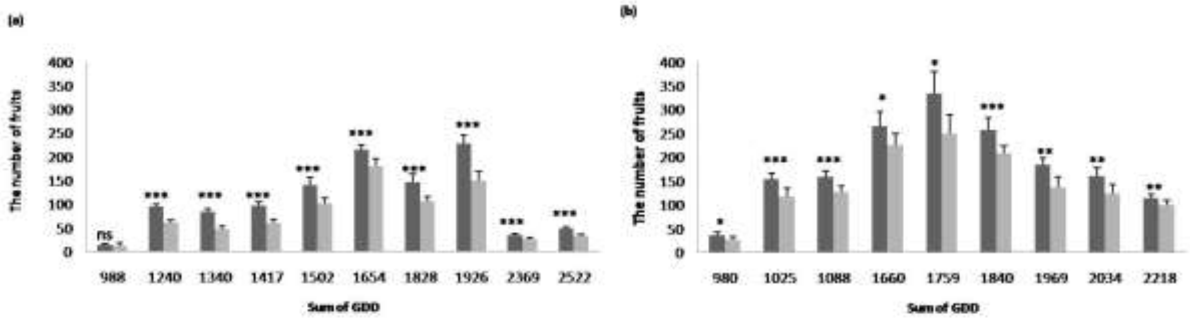

Figure 2: The number of fruits of 100 strawberry plants irrigated with normal ( ) and magnetically treated irrigation water ( ) for 2012 (**a**) and 2014 (**b**) cropping seasons. The data were presented as function of the sum of GDD (Growing degree days). *, ** , *** showed that the difference is significant at the 0.05; 0.01 and 0.001 levels, respectively. ns: not significant. The vertical bars represent standard error of the means.

The fruit yield: the mean fruit yield of strawberry plants irrigated with normal water and MTIW measured during the two crop seasons (2012 & 2014) are shown in Figure 3. The results show that irrigating strawberry plants with MTIW increased the fruit yield significantly, indeed extremely, over the control in 2012 and 2014 crop seasons. On average, in the different mentioned harvests, the increase reached 42% in the 2012 crop season and 27.7% in 2014 crop season. The stimulatory effect of irrigation with MTIW is evident, as represented in Figure 3. On the other hand, summing the fruit yield of all harvests recorded and then converted this sum to a production by hectare, we obtained, in 2012 and 2014 crop seasons, for the plot irrigated with MTIW, a production of 28.3 tons and 56.2 tons, respectively, over 20.2 tons and 44.6 tons, respectively, for the controls. So, these results indicate that we achieved an increase of 8.1 tons and 11.6 tons per hectare in 2012 and 2014 crop seasons, respectively.

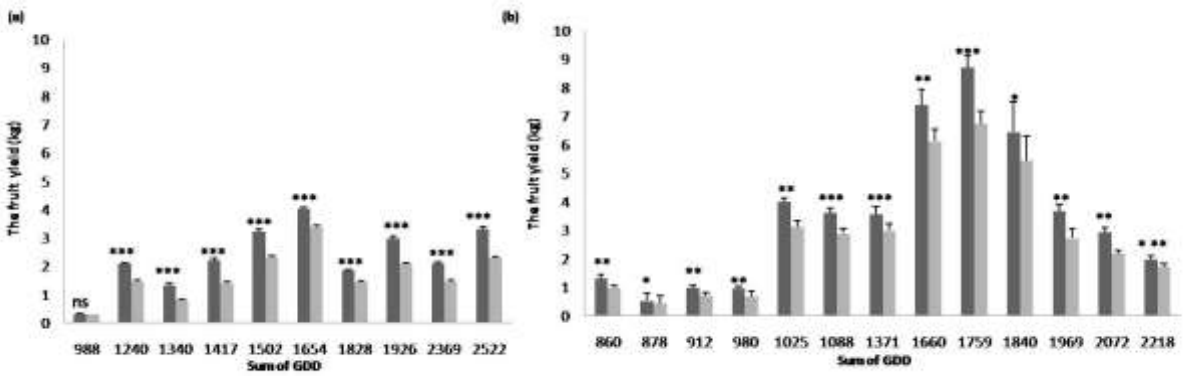

Figure 3: The fruit yield (kg) of 100 strawberry plants irrigated with normal ( ) and magnetically treated irrigation water ( ) for 2012 (**a**) and 2014 (**b**) cropping seasons. The data were presented as function of the sum of GDD (Growing degree days). *, ** , *** showed that the difference is significant at the 0.05; 0.01 and 0.001 levels, respectively. ns: not significant. The vertical bars represent standard error of the means

The results of this study confirm that physical treatment of irrigation water by a static magnetic field improved strawberry yield . These results were in line with those of Eşitken & Turan (2004), who found an enhancement of flowers number and total fruit yield of strawberry plants. The results value obtained from this study, corroborated with previous studies on cabbage and potato where magnetically treated irrigation water improved the quality of crops and gave a higher yield compared to the control (Taimourya et al., 2015; Taimourya et al., 2016). Similar enhancing effects of magnetically treated irrigation water have been reported abroad on other crops like pepper, groundnut, soybean, potato, canola and lettuce. In these studies the crop yield and quality were increased (Atak et al., 2000; Reina et al., 2001; Crnobarac et al., 2002; Marinkovic et al., 2002; Sevil & Günhan , 2002; Takac et al., 2002; Abdel-Ghany et al., 2005; Hozayn et al., 2016).
The stimulatory impact of magnetic treatment was attributed to the increase of the availability of minerals in soil through boosting the solubility of salts and minerals (Kronenberg, 2005). The magnetically treated irrigation water has a high solubility (Mohamed et al., 2013; Todeshki et al., 2015); therefore, nutrients are more soluble in water. In fact, magnetic treatment of water restructures the water molecules into very small clusters, each made up of six symmetrically organized molecules (Ali et al., 2014). The size of molecule groups gets reduced below the diameter of capillaries in the roots of plants thus it can easily enter the passageways in plant cell membranes (Ajitkumar, 2014). Various studies have demonstrated higher absorption of nutrients in crops irrigated with magnetically treated water (Eşitken & Turan, 2004; Grewal & Maheshwari, 2011; Mohamed & Ebead, 2013; Kamorudeen & Ayodele, 2015).

Conclusion

The current study has shown that using magnetically treated irrigation water could be applied as one of the most valuable physical growth stimulation approaches that can assist in improving yield and quality of strawberry crops. Magnetic technologies are ecologically friendly and non-polluting to the soil. In addition, the utilisation of magnetic treatment in agricultural production will enable intense and increased production in terms of both quantity and quality. It can also be used for conserving irrigation water and increasing the efficiency of added fertilizers. In conclusion, magnetic technology is a promising physical growth stimulation approach. However, further field and laboratory experiments are needed to overcome the field challenges and to gain knowledge about the working mechanism of the magnetically treated water.

Abstract

The experiment consisted of five varieties of field crops: wheat, barley, lentils, chickpeas and vetch. It was conducted in three different areas of the Gaza Strip (Palestine). The main idea of the experiment was to study the best varieties in terms of productivity in each target area according to the analysis of a number of different factors including climate and soil. The experiment was also aimed at determining the extent to which the Strengthening Livelihoods through Community Adaptation and Learning (SLCAL) project contributes to the productivity of field crops by comparing the productivity rates associated with the project interventions with control groups that were implemented without intervention.
The experiment relied on the experimental approach in the implementation process, which included zoning of experimental units and control units where the areas were divided according to the complete randomized sectors design. The eight target crops were planted in each experimental unit with one type of field crop per each preview unit. This mechanism was applied to all of the experimental areas. The project interventions included spraying of the Germination Inhibition Herbicide before starting the cultivation of the various crops. In addition, the compound fertilizer (NPK 13.13.13), herbicides were distributed to combat thin and broad herbs. Data was collected from primary sources including various control sites and readings were recorded for the various crop varieties in terms of seed weight, straw weight, total weight, length of the ears, numbers of branches, lengths of crops and weights of a thousand seeds. The same data was collected from the project intervention areas and soil samples were collected at a depth of 30 cm from all areas. The comparative quantitative method was used to analyze the results of the project and the experiment in another word the control without any intervention. The results showed positive effects of the project interventions at the level of productivity for all field crop varieties.

Introduction

According to the earth and human center for researches and studies (EHCRS) vision and objectives to enhance the role of scientific research in solving the problems of society through finding practical solutions using research tools, the center promotes these trends by translating field crop programs activities into research work based on experimental methodology to choose best options to cultivate the field crops, based on the opinions of experts and specialists in the technical committee, which recommended the needs to cultivate a specific area of agricultural land within targeted areas with the same crops that the project targeted but without intervention to identify best crops to cultivate in suitable areas. The Center conducted an integrated research experiment within the field crops program during the 2015-2016 agricultural season in order to determine the general agricultural policies for field crops in Gaza Strip to improve the productivity of agricultural sector in general and economic empowerment for field crop farmers in particular, through the use of various agricultural techniques, and these agricultural techniques have been tested during the project implementation period, which extended from the end of 2012 till now. These techniques proved their ability to increase the efficiency of agriculture production and in improving the abilities of farmers in facing climate changes.

This paper shows the most important results of the field crops program for the 2015-2016 agricultural crop season compared to the results of the experiment regions that carried out as a research work to test the feasibility of the SLCAL interventions in field crops.

Material and Methods

Methodology

Meanwhile, Oteng-Darko et al., (2013) reported in their study that most of agriculture experiments which concentrate on combine the soil, plant, and climatic systems to more accurately predict crop yield are very limited, the novelty of the present study relied on an experimental methodology through implementing a research experience in different regions by considering the soil texture and characteristics to judge the result of the experiment. Accordingly, standard comparison method has been adopted between the results of various interventions of SLCAL project and the result of research experiment for the same crops, which were cultivated without intervention to measure the impact of project interventions on the productivity of the targeted field crops compared with the experiment regions without intervention. The experimental methodology has been used to implement the experiment, which includes areas division into experimental units. These areas have been divided according to the design of complete random sectors by using R program (R software), and each experimental unit was divided into forty preview module with one square meter per each unit, then the eight targeted crops were grown in each experimental unit, and each crop has been cultivated in one preview module. This mechanism has been applied in all experimental regions which include Al-Qarara, Khozaa, Abasan, Al-Fokhary, Al-Shoka. About the project interventions; they included spraying of germination inhibition herbicide of type oxygal (Oxyflurufen 240gr/L) before starting cultivation of the different crops, in addition, there was fertilizers compound distribution of type NPK (13.13.13), and spraying agricultural pesticide to combat the herbs in different fields, finally, implementation of different trainings and awareness workshops about field crops management (Koba et al.,2015) .

Data collection methodology

The researchers depended on primary sources to collect the data, which included data collection from different experiment areas (control groups) (Dagher, 2007)., and recording the data for the different crops as seed weight, straw weight (hay), total weight, length of ears, number of branches, length of crop, weight of 1000 seed. And the same data has been collected from the areas of the project interventions in addition to collect soil samples at depth 30 cm from all regions (Al-Qarara, Khozaa, Abasan, Al-Fokhary, Al-Shoka).

Data analysis methodology

We used comparative quantitative method for analyzing the results of the project and the experiment, we used SPSS and Microsoft Excel program to extract the different results, and we used different statistical methods which included: repetition, graphs, One Way ANOVA, Post Hoc tests, and Pearson correlation coefficient between the components and the elements of the soil and the productivity rate (Almohamadi, 2011).

Results and Discussion

Average productivity of field crop seeds for the season 2015-2016

The results of field crops program indicate that there is a positive impact of the project interventions on the productivity of different field crops compared with the same crops which were grown without intervention from the project (experiments region). Depending on the calculation of the productivity rate of these crops, we showed that, the highest productivity rates of field crops was in wheat with its different types, where the average of productivity per acre in all intervention areas, which include the southern governorates of the Gaza strip (Rafah and Khanuonis), was 279.3 kg, while 97 kg for non-intervention areas (experiment),which indicates that there is an increase in wheat productivity rate with a ratio of 65.3% compared with non-intervention areas. VETCH was the second crop in productivity rates per acre in all intervention areas which reached 246.67 kg compared with 137.65 kg for areas with non-intervention (experiment), which indicates that there is an increase in VETCH productivity with ratio 44.2% in intervention areas compared with non-intervention (experiment). BARLEY was the third with general average equals to 243.8 kg per acre compared with 85.5 kg for non-intervention areas (experiment), which indicates that there is an increase in BARLEY productivity with ratio 64.9% in intervention areas compared with non-intervention. Finally, lentils and CHICKPEAS, 169.5 & 161.11 kg per acre respectively, compared with 60.85 & 90.65 for non-intervention area (experiment), which indicates that there is increase in LENTILS productivity with ratio 64.1%, and the productivity of CHICKPEAS with ratio 43.7% because of project interventions compared with different experiments areas.

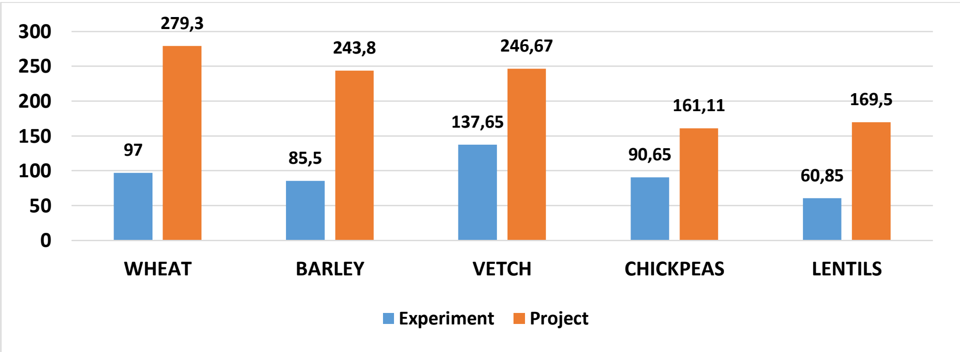

Figure 1. General average of seed weight for different crops and result of project and experiment.

Average productivity of seeds in intervention and experiment regions for barley

The figure below shows that the productivity rate for the intervention regions was high compared with experiment regions which implemented no interventions from the project. The highest productivity for BARLEY was in Al-Fokhary region with rate 328.33 kg per acre compared with 83 kg per acre in experiment region of Al-Fokhay region, which indicates that the productivity rate of BARLEY has been improved because of project interventions with ratio 74.7 % compared with non-intervention region. The BARLEY productivity rates between Al-Fokhay and Al-Qarara was convergent with difference of 10 kg, while the lowest productivity rate was in Al-Shoka and Khozaa regions with rate 108.33 & 185 kg per acre respectively.

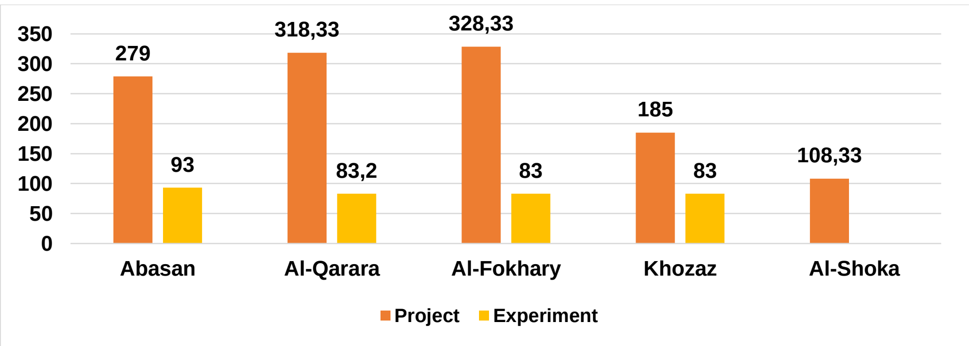

Figure 2. Productivity average for BARLEY in intervention and experiment regions.

Average productivity of seeds in intervention and experiment regions for chickpeas

The analysis results showed that the project interventions had a clear effect on productivity rates in different regions compared with experiment regions. The highest productivity rates for CHICKPEAS was in Abasan region with rate 211.67 kg per acre compared with 131.6 kg per acre in experiment region of Abasan region, which indicates that the productivity rate of CHICKPEAS has been improved because of project interventions with ratio 37.8 % compared with non-intervention region (experiment). The lowest productivity rate was in Al-Shoka region with rate 103.33 kg per acre.

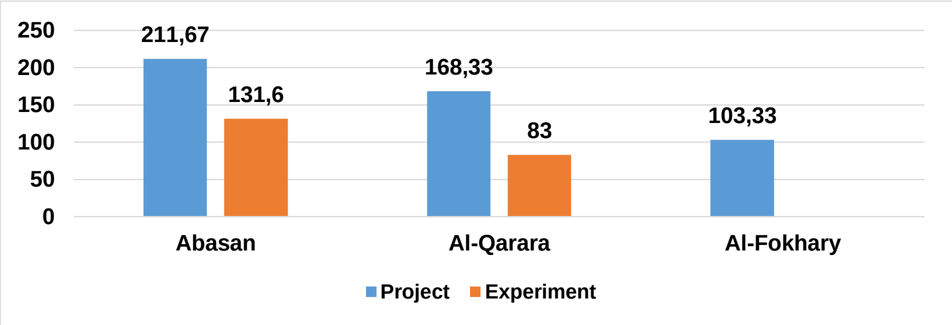

Figure 3. Productivity average for CHICKPEAS in intervention and experiment regions.

Average productivity of seeds in intervention and experiment regions for LENTILS

The analysis results showed that the project interventions had a clear effect on productivity rates in the different regions compared with experiment regions. The highest productivity rate for LENTILS was in Abasan region with rate 308 kg per acre compared with 54.4 kg per acre in experiment region of Abasan region, which indicates that the productivity rate of CHICKPEAS has been improved because of project interventions with ratio 82.3 % compared with non-intervention region (experiment). The LENTILS productivity rates between Al-Fokhay and Al-Qarara was convergent with difference 3.34 kg. The lowest productivity rate was in Al-Shoka region with a rate of 1110 kg per one acre.

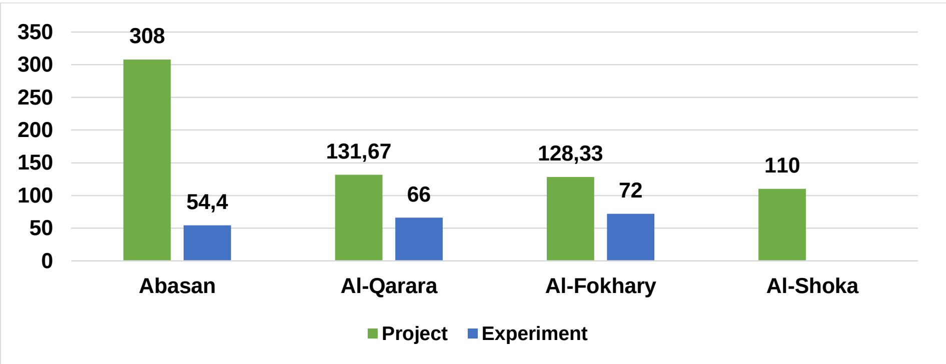

Figure 4. Productivity average for LENTILS in intervention and experiment regions.

Average productivity of seeds in intervention and experiment regions for vetch

The result showed that the productivity rate of VETCH seed was 246.67 kg per one acre in Al-Qarara compared with 108 kg per one acre in experiment region with non-intervention, which indicates that the productivity rate of VETCH has been improved because of project interventions with ratio 56.2% compared with non-intervention region (experiment). VETCH has been cultivated only in Al-Qarara region.

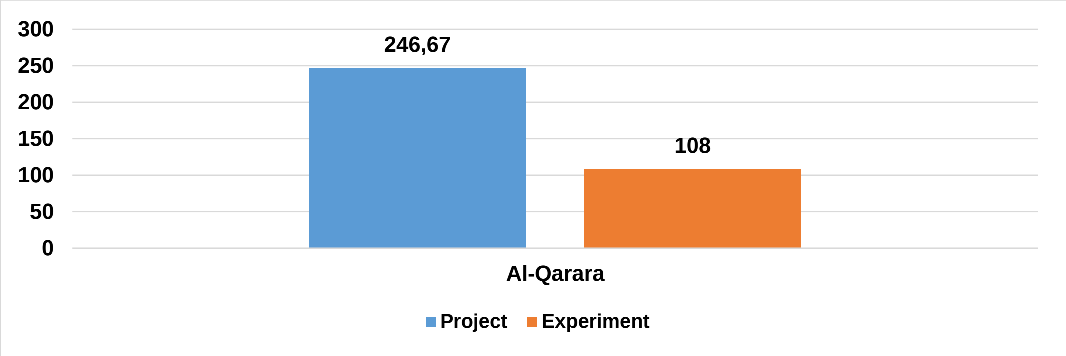

Figure 5. Productivity average for VETCH in intervention and experiment regions.

It is important to confirm here that Al-Shoka region has been targeted to implement an experiment to cultivate the field crops without any intervention, but because of external factors which damaged the experiment region represented in spraying germination inhibition herbicide of type OXYGAL by Israel planes the experiment failed, hence, we couldn't make a comparison between the intervention regions for the project and the other regions without any interventions by the project.

The results of seed weight differences tests for the various crops according to the region

As shown in the table below, there is no difference of statistical significance between the different experiments regions (non-intervention) for Ariel wheat, the level of calculated significance is 0.373 which is more than significance level .05. The productivity average of Ariel wheat was between 140 kg per acre in Al-Qarara region and 67 kg per acre in Al-Fokhary region, which means that there is no differences in productivity average which has statistical significance if this crop has been cultivated in any targeted region with non-intervention. Regarding AMIT wheat, the tests results showed that there is difference of statistical significance between different experiment regions (non-intervention), the level of calculated significance is 0.0, which is less than significance level .05. And to identify the nature of differences, we used PostHoc "LSD", which showed a difference between Al-Qarara region and Abasan, Al-Fokhay, Khozaa with differences of 156, 181, 166 kg per acre respectively, which means that Al-Qarara region is the best region for cultivation of AMIT wheat. As shown in the table below, there is no difference of statistical significance between the different experiments regions (non-intervention) for BLOND DEBYA wheat, the level of calculated significance is 0.244 which is more than significance level .05. The productivity average of BLOND DEBYA wheat was between 117 kg per acre in Al-Qarara region and 68 kg per acre in Khozaa region, which indicates that there is no difference in productivity average volume if this crop has been cultivated in any region with non-intervention. About YUVAL wheat, the tests results showed that there is difference of statistical significance between different experiment regions (non-intervention); the level of calculated significance is 0.004, which is less than significance level .05. And to identify the nature of differences, we used PostHoc "LSD", which showed a difference between Al-Qarara region and Abasan, Al-Fokhay, Khozaa with differences of 83, 91, 93 kg per acre respectively, which means that Al-Qarara region is the best region for cultivation of YUVAL wheat. Also the tests result showed that there is no difference of statistical significance between different experiment regions (non-intervention) for BARLEY; the level of calculated significance is 0.877, which is more than significance level .05. The productivity average of BARLEY was between 93 kg per acre in Al-Qarara region and 83 kg per acre in Khozaa and Al-Fokhary region.

Also the tests result showed that there is no difference of statistical significance between different experiment regions (non-intervention) for VETCH; the level of calculated significance is 0.413, which is more than significance level .05. The productivity average of vetch was between 93 kg per acre in Abasan region and 108 kg per acre in Al-Qarara region.

About CHICKPEAS, the tests results showed that there is difference of statistical significance between different experiment regions (non-intervention); the level of calculated significance is 0.001, which is less than significance level .05. And as shown in the PostHoc "LSD" results, there are differences between Al-Qarara and Abasan with a difference of 111 kg per acre for Abasan region. Also there are differences between Al-Qarara and Al-Fokhary region which differs 63 kg per acre for Al-Fokhary region. There are also differences between Al-Qarara and Khozaa region which differs 108 kg per acre for Khozaa region, which means that Abasan region is the best region for cultivation CHICKPEAS.

Also the tests result showed that there is no difference of statistical significance between different experiment regions (non-intervention) for LENTILS; the level of calculated significance is 0.627, which is more than significance level .05. The productivity average of lentils was between 72 kg per acre in Al-Fokhay region and 51 kg per acre in Khozaa region.

Table 1. The results of seed weight tests for different crops in the experiment for each region.

Crop	Region	Mean	Standard deviation	F-Test	Sig.	Comment
ARIEL Wheat	Abasan	101	55.95	1.113	0.373	No significant differences between the regions
	Al-Qarara	140	96.37			
	Al-Fokhay	67	32.33			
	Khozaa	91	55.95			
AMIT Wheat	Abasan	77	2.74	20.331	0	Significant differences between the regions
	Al-Qarara	233	81.36			
	Al-Fokhay	52	19.56			
	Khozaa	67	2.74			
BLOND DEBYA Wheat	Abasan	78	18.91	1.535	0.244	No significant differences between the regions
	Al-Qarara	117	62.31			
	Al-Fokhay	84	35.6			
	Khozaa	68	18.91			
YUVAL Wheat	Abasan	78	6.71	6.739	0.004	Significant differences between the regions
	Al-Qarara	161	71.1			
	Al-Fokhay	70	28.06			
	Khozaa	68	6.71			
BARLEY	Abasan	93	19.24	0.226	0.877	No significant differences between the regions
	Al-Qarara	83.2	17.92			
	Al-Fokhay	83	33.47			
	Khozaa	83	19.24			
VETCH	Abasan	160.6	36.64	1.012	0.413	No significant differences between the regions

	Khozaa	128	22.53			
LENTILS	Abasan	54.4	14.17	0.595	0.627	No significant differences between the regions
	Al-Qarara	66	27.02			
	Al-Fokhay	72	46.72			
	Khozaa	51	11.4			

The relationship between the productivity and the soil elements

According to the analysis results about the content of elements in the soil in all project regions, the results showed a positive relationship between the pH and productivity for all the crops except lentils, which means that the increasing of pH in the soil will increase the productivity for all the field crops except LENTILS. The productivity average of LENTILS decreases with pH increase because the productivity of LENTILS decreases with increase in the salts in the soil. LENTILS is sensitive to high load of salts in the soil and it gives the best productivity rate when pH ranges from 6 to 9. Also the results showed a positive relationship between the phosphorus element and the productivity average for all the crops except BLOND DEBYA wheat and BARLEY, which means that the increasing of phosphorus element in the soil will decrease the productivity for these two crops because the suitable pH for these two crops is from 6.5 to 7 as if if pH in the soil is more than 8, the absorption of phosphorus by these two crops is not easy, hence, the total productivity average of BLOND DEBYA wheat and BARLEY seeds has been decreased. In addition to the increase of salts in the soil in the regions that has been cultivated of these two crops, the regions that have been cultivated with BLOND DEBYA wheat have the highest percentage of dissolving salts (Al-Fokhary, Al-Shoka and Al-Qarara). There is an inverse relationship between the soil conductivity (EC) and the productivity average volume and there is the same relationship between the productivity and total dissolved solids (TDS) for all field crops, which means that the increase of EC and TDS in the soil cause decreasing in the productivity for all the crops except BARLEY, because BARLEY has the highest ability to bear the soil salinity compared with the other field crops that the project has grown. And we can notice that there is an inverse relationship between the productivity average and different elements in soil like NO_3, PO_4 and K, which means that the increase of these elements in the soil cause decreasing in the productivity. From practical side, the increase of these elements in the soil will cause increase in productivity average, but the decrease of productivity in this status maybe refer to existence of other effects which were not studied, caused the inability to absorb and get the benefits from these elements and these results contradict with the results of (Koba et al., 2015) which revealed positive relationship between the productivity average and different elements in soil like NO3, PO4 and K. The researchers justified that the soil characteristics in Gaza strip-Palestine is different in its pH, EC which effects on the absorption of NO3, PO4 and K, and this lead to hinder the level of absorption to these elements by plants which decreasing the crops productivity.

Table 3. Pearson correlation coefficient between soil nutrients and average productivity.

Soil Elements	Pearson correlation coefficient						
	ARIEL Wheat	**AMIT Wheat**	**BLOND DEBYA Wheat**	**BARLEY**	**CHICKPEAS**	**LENTILS**	**Crops as a whole**
pH	0.811	0.796	1	4	0.362	-0.111	0.434
EC	-0.562	-0.512	-0.363	0.501	-0.191	-0.674	-0.22
TDS	-0.613	-0.561	-0.45	0.475	-0.191	-0.656	-0.247
NO_3	-0.929	-0.902	-0.43	0.557	0.243	-0.238	-0.167
P	0.157	0.149	-0.597	-0.211	0.693	0.953	0.186
PO_4	-0.959	-0.985	-0.922	-0.133	-0.42	-0.565	-0.478
K	-0.789	-0.834	-0.738	-0.642	-0.982	-0.768	-0.542

Conclusions

The main conclusions of the field trial emphasized that there was variation in the productivity rate according to region, where the productivity average for wheat per acre was the highest productivity rate in all cultivated field crops. Al-Qarara was the best region for cultivation the ARIEL wheat; it has the highest productivity rate, while Al-Fokhay region has the lowest productivity for this crop.

Also, Al-Qarara region was the best region for cultivation the AMIT wheat; it has the highest productivity rates, while Al-Fokhay region has the lowest productivity for this crop. Al-Qarara region was the best region for cultivation of the Blond Depya wheat; it has the highest productivity rate, then Al-Shoka region. While, Al-Fokhay region has the lowest productivity in this crop. Al-Shoka region was the best region for cultivation of YUVAL wheat; it has the highest productivity rate, while Khozaa region has the lowest productivity for this crop. Regarding chickpeas, Abasan region was the best region for cultivation the chickpeas; it has the highest productivity rate, then Al-Fokhay region, while Al-Shoka region has the lowest productivity for this crop. Abasan region was the best region for cultivation of lentil; it has the highest productivity rate, while Al-Shoka region has the lowest productivity for this crop.

What interesting in the result that, there is positive relationship between pH and productivity for all field crops except BARLEY. As well, there is a positive relationship between phosphorus (P) and productivity for all field crops except BLOND DEBYA wheat and BARLEY. However, there is inverse relationship between soil conductivity (EC) and productivity, and the same relationship between total dissolved solids (TDS) and the productivity for all field crop except BARLEY. Also, there is inverse relationship between NO_3, PO_4, K and the productivity of field crops. Accordingly, the researchers recommended to continue the interventions of the project activities because it showed big differences in productivity rates between the interventions regions from the project, and non-intervention regions, for all various field crops without exception. To continue growing wheat of all cultivars (ARIEL, AMIT, BLOND DEBYA and YUVAL) because it gave highest productivity rates in all regions. To cultivate wheat of types AMIT, ARIEL and BLOND DEBYA because these types have the best productivity in Al-Qarara region respectively. To cultivate YUVAL wheat in Al-Shoka region, because it gave the highest productivity rate in this region. To cultivate BARLEY in Al-Fokhary region, because it gave the highest productivity rate in this region. To cultivate LENTILS and CHICKPEAS in Abasan region because they gave the highest productivity rate in this region. Finally, to conduct a large study on the factors that make difficult for the crops to get benefits from the soil elements and prevent crops to absorb and get benefits from nutrients, in spite of existence of these elements in the soil, like NO_3, PO_4 and K so, there was an inverse relationship between these elements and the productivity for the various field crop.

Abstract

The study was conducted on experimental plots between 2012 and 2015, in a completely randomized arrangement and with three replications. The aim of the experiment was to evaluate the effect of spent mushroom substrate and slurry on productivity and nutritional value of dry matter of hybrid alfalfa-grass mixtures. In the experiment three plant species were used: hybrid alfalfa, orchard grass, and perennial ryegrass. These species were sown as three legume-grass mixtures. Organic fertilizers, i.e. spent mushroom substrate and liquid manure, or slurry, were used in different combinations. In this paper, dry matter digestibility was estimated. Based on the fraction of neutral detergent fibre, acid detergent fibre, and dry matter intake (% body weight) were calculated. Additionally, relative nutritional value, which is an indication of relative feed value, was estimated. In comparison with mushroom substrate, slurry application resulted in higher digestibility of the legume-grass mixtures, higher dry matter intake, dry matter content, and relative food value. Forage of the ryegrass and alfalfa mixture had the most favourable dry matter intake and relative food value.

Keywords: *spent mushroom substrate, slurry, mixtures, relative feed value, dry matter intake*

Introduction

In crop rotation, growing grass after other crops repeatedly on the same field affects crop yields and soil quality in a positive way. In farming of this type the quality of the yield is also important; cultivation of legume-grass mixtures brings about a well-balanced fodder. Those mixtures play a large role in both integrated and organic production systems (Duer 1999). Thus, legume-grass mixtures are a source of very valuable fodder of balanced chemical composition (Krzywiecki *et al.*, 1997 and Gaweł, 2008), with components absolutely necessary in animal nutrition. According to Gaweł and Ścibior (2000) such crops are one of the cheapest fodder sources, and they have beneficial effects on follow-up crops, leaving the soil in good condition (Kryszak, 2003). In organic farming, it is also important to use organic fertiliser that will be safe for the environment, but at the same time, it should favourably affect the yield and quality of crops. Slurry and mushroom substrate can be used as such fertiliser. Poland is a leading producer of mushrooms, which leads to the creation of large amounts of mushroom substrate, an organic waste material which is a problem for the producers. At the same time it is an extremely valuable organic fertilizer which can be used in agriculture. The substrate removed from the mushrooms house as mushroom waste is a potentially a good fertilizer. It is an organic mass that is converted into humus in the soil. Wiśniewska-Kadżajan (2012) states that the content of macronutrients after mushroom cultivation in g kg^{-1} d.m. amounted to: nitrogen 13.0-26.0; phosphorus 1.0-10.0; potassium 5.0-25.0; magnesium 2.0-5,20; calcium 60.0-150.0; sodium 0.5-2.9. Mushroom substrate is also characterized by high contents of microelements and low heavy metals (Hackmann *et al.*, 2008). In the opinion of Wiśniewska-Kadżajan (2012, 2013) the used mushroom substrate is a valuable source of organic matter with a low C:N ratio. Many researchers have reported high variability and imbalance of the chemical composition of the mushroom substrate, which is an unquestionable drawback, which should

require their chemical composition to be continually controlled and the missing elements to be replenished to improve the fertilizer's properties (Polat *et al*., 2009). Another valuable fertilizer is slurry, which is completely different from manure both in terms of physical characteristics and effects on plants. Łabętowicz (2002) showed that the nutrients in slurry are present in forms more easily available to plants than in manure. That is why slurry is a fast-acting fertiliser.
The aim of the experiment was to evaluate the effect of spent mushroom substrate and slurry on the productivity and nutritional value of dry matter of hybrid alfalfa-grass mixtures.

Material and Methods

Set up in the autumn of 2012 and lasting from 2012 to 2015, the three-year research was conducted in the experimental field of the Department of Grasslands and Landscape Architecture Development, the University of Humanities and Natural Sciences in Siedlce. The experiment was replicated three times each year, with a split-plot arrangement and plots of 3 m^3 as experimental units. In the experiment, the main research factors were legume-grass mixtures and organic fertilizers with high organic matter content (mushroom substrate and cow slurry, used separately and in various combinations). The experiment consisted of the following units: control (no fertilization) (C); mushroom substrate (30 $t \cdot ha^{-1}$) (MS); slurry (60 $m^3 \cdot ha^{-1}$) (S); mushroom substrate (10 $t \cdot ha^{-1}$) + slurry (60 $m^3 \cdot ha^{-1}$) (MS10 + S60); mushroom substrate (20 $t \cdot ha^{-1}$) + slurry (40 $m^3 \cdot ha^{-1}$) (MS20 + S40); mushroom substrate (30 $t \cdot ha^{-1}$) + slurry (20 $m^3 \cdot ha^{-1}$) (MS30 + S20). These species were grown as three legume-grass mixtures: M1 - *Dactylis glomerata* cv. 'Bora'+ *Lolium perenne* cv. 'Info'+ *Medicago x varia* T. Martyn cv. 'Tula'; M2 - *Dactylis glomerata* cv. 'Bora'+ *Medicago x varia* T. Martyn cv. 'Tula'; M3 – *Lolium perenne* cv. 'Info'+ *Medicago x varia* T. Martyn cv. 'Tula'. In the above mixtures the proportion of each component was the same.
In the experiment, organic fertilizer was used in the form of slurry and mushroom substrate. Mushroom substrate was applied once at the start of the experiment, before the growing season, in different doses mixed with the soil. Slurry was used every year throughout the experiment, in equal doses after each harvest. Table 1 presents the chemical composition of slurry and mushroom substrate.

Table 1. Concentration of selected macro-elements ($g \cdot kg^{-1}$ DM) in mushroom substrate and slurry

Nutrient	Mushroom substrate	Slurry
N	24.50	48.00
P	9.50	12.64
K	13.20	43.16
Ca	58.20	30.75

The experiment was set up on soil with a granulometric composition of loamy sand, of the order of anthropogenic, the type of culture earth soil, and the subtype of hortisole. Chemical analysis of the soil showed high contents of absorbable forms of phosphorus and magnesium. However, absorbable forms of potassium were within the limits of the average content. Sielianinov's hydrothermal coefficient was calculated to determine temporal variation of meteorological elements and their effects on vegetation.
Optimal temperature and moisture conditions occurred only in April 2014 and in September 2015. In the remaining months of the growing periods, the weather conditions were not as favourable, varying from extremely dry in August 2015 to extremely wet in May 2013. Throughout the experiment the best conditions occurred at the beginning of each growing period. It can be concluded that the most difficult situation for plants occurred in 2015, when, apart from May and the end of the growing period, the weather ranged from moderately dry to extremely dry.

Table 2. The value of Sielianinov's hydrothermal coefficient (K) in the growing season

Year	Month						
	April	May	June	July	August	September	October
2013	2.56 (sw)	3.07 (ew)	2.11 (w)	0.84 (d)	0.78 (d)	2.53 (sw)	0.60 (sd)
2014	1.36 (o)	1.87(mw)	1.64(mw)	0.59 (sd)	1.92(mw)	0.64 (sd)	0.12 (ed)
2015	1.22 (md)	2.63 (sw)	0.87 (d)	1.08 (md)	0.18 (ed)	1.46 (o)	1.94 (mw)

$K \leq 0.4$ extreme drought (ed). $0.4 < K \leq 0.7$ severe drought (sd). $0.7 < K \leq 1.0$ drought (d1.0). $< K \leq 1.3$ moderate drought (md). $1.3 < K \leq 1.6$ optimal (o). $1.6 < K \leq 2.0$ moderately wet (mw). $2.0 < K \leq 2.5$ wet (w). $2.5 < K \leq 3.0$ severely wet (sw). $K > 3.0$ extremely wet (ew)

During each growing season all the mixtures were harvested three times. The fresh matter from each plot was weighed and a sample of 0.6 kg was taken. This was used to determine dry matter content and to perform chemical analysis. Dry matter digestibility was estimated. Based on the fraction of neutral detergent fiber *(*NDF) and acid detergent fiber (ADF), dry matter intake (DMI) (% body weight) was calculated and relative nutritional value (RFV), an indication of the relative feed values of the feed, was estimated – all the parameters were determined using the method of Linn and Martin (1989). The chemical composition of the plants was determined with near-infrared spectroscopy (NIRS) using the NIRFlex N-500 spectrometer. Data were analysed using analysis of variance. The Fisher-Snedecor test was used to determine the significance of effects of experimental factors on the parameters tested in the study. Tukey's test was used to compare means at the least significant difference - $LSD_{0.05}$ significance level. All the calculations were made with the Statistica 6.0 – 2001 program.

Results and Discussion

Digestibility is the percentage of feedstuff absorbed from the gastrointestinal tract into the body (Pawlak, 1990). According to Stachowicz (2010) roughage intended for ruminant feeding should be digestible at around 65%. Considering the relationship between dry matter digestibility and the fertilizer applied, organic fertilizers both in the form of mushroom substrate and slurry significantly improve digestibility. Forage from the plots where 20 t ha^{-1} of mushroom substrate and 40 m^3 ha^{-1} of slurry were applied had the highest digestibility (55.13%), while the lowest (50.91%) was for the forage from the plot without fertilizers. The mixture of hybrid alfalfa with orchard grass (M2) had the highest digestibility (56.39%) on the plot where only mushroom substrate was used (Table 3). The lowest (47.68%) was for the mixture of perennial ryegrass with alfalfa (M3) on the control plot. The mixture of hybrid alfalfa with orchard grass (M2) had higher digestibility if mushroom substrate was applied and it was lower when slurry was used. It was the other way round in the case of perennial ryegrass with alfalfa, the digestibility of which was higher on the plot with slurry than on the plot with substrate. However, the differences between the mixtures concerning dry matter digestibility were statistically insignificant.

Small differences in digestibility between mixtures of alfalfa with grasses and with other legumes were also observed by Gaweł (2008), but this was at a much higher level of digestibility (approximately 64%) than in the present experiment. It turned out that the addition of other legume plants (*Onobrychis viciifolia Scop.* or *Lotus corniculatus L*) to a mixture of alfalfa with grass increased fodder digestibility. A mixture of alfalfa with *Festulolium* in the experiment of Sosnowski (2012a) had a slightly higher digestibility (about 60.3%) than the mixtures in the present experiment. Borowiecki (1997) found that the presence of alfalfa in a mixture affected forage digestibility.

Martyn. The experiment consisted of the following units: control (C), mushroom substrate (MS), slurry (S). LSD - Least Significant Difference.

Forage quality largely depends on the plant development stage at the time when it is harvested. The older a plant is the lower its feed value. This is caused by an increase in fibrous fraction content in the biomass, and in consequence dry matter intake (DMI) also increases (Hintz and Albrecht, 1991). Studying the effect of different fertilizer combinations on dry matter intake calculated on the basis of the content of NDF (neutral detergent fiber) fibre fractions showed that ryegrass grown together with alfalfa generally had a higher NDF than the two other mixtures. Forage of the mixture with three plant species had the highest dry matter intake on the control plot, while orchard grass grown together with alfalfa had the highest dry matter intake on the plot with mushroom substrate. Sosnowski (2012a) demonstrated that ryegrass had a higher intake than orchard grass. Additionally, compared to the present experiment, Sosnowski and Jankowski (2013) and Sosnowski (2012b) observed somewhat lower values of DMI, about 2.5%, in a mixture of *Festulolium* with alfalfa. In another experiment Sosnowski (2012b) found that mixtures with red clover had a higher dry matter intake, and he also showed that increased doses of nitrogen reduced dry matter intake. In the present experiment the forage on the plot where 30 t ha^{-1} of mushroom substrate with 20 m^3 of slurry was used had the lowest DMI. It was highest for the mixture of ryegrass with alfalfa (Table 4) on the plot where 10 t ha^{-1} of mushroom substrate and 60 m^3 ha^{-1} of liquid manure were applied (3.30% of body weight) and on the plot with 20 t ha^{-1} of mushroom substrate with 40 m^3 ha^{-1} of liquid manure (3.27% of body weight). In the case of orchard grass with alfalfa the highest DMI was for forage from the plot with slurry (3.16% of body weight), while the three-plant mixture of orchard grass with perennial ryegrass and alfalfa had the highest value of dry matter intake (3.25% of body weight) on the control plot. The smallest DMI was found in the ryegrass and alfalfa mixture and in the three-plant mixture with orchard grass, perennial ryegrass, and alfalfa on the plot when only mushroom substrate was used (3.02% of body weight). Concerning the mixture of orchard ryegrass and alfalfa, the lowest DMI (3.01-3.03% of body weight) was in plants from the plots with both mushroom substrate and slurry applied.

The quality of roughage should satisfy the animals' requirements, which in turn depend on their species and performance. Based on the content of ADF and NDF fibre fractions, it is possible to calculate relative feed value (RFV), combining digestibility and feed intake in one parameter (Linn and Martin 1989; Jankowska-Huflejt and Wróbel, 2008).

The results show that only the following mixtures can be assessed as Class 2 perennial ryegrass with alfalfa on the plot where mushroom substrate was used (RFV of 147.96), orchard grass with alfalfa on all the plots where mushroom substrate was used together with slurry (RFV of 147.92, 148.59, 148.76), and the mixture of orchard grass, perennial ryegrass, and alfalfa from plots with mushroom substrate used both on its own (RFV of 148.34) and on the plots with 30 t of substrate with 20 m^3 of slurry (RFV of 148.63). Class 2 forage is adequate for high-producing dairy cows and young heifers selected for breeding.

Table 4. The effect of different forms of fertilizers on dry matter intake - DMI (% of body weight) and Relative Feed Value - RFV (average of all harvests)

Mixture (B)	Fertilizer (A)						Mean

Legume-grass mixtures: M1 - *Dactylis glomerata*+ *Lolium perenne*+ *Medicago x varia* T. Martyn; M2 - *Dactylis glomerata*+ *Medicago x varia* T. Martyn; M3 – *Lolium perenne*+ *Medicago x varia* T. Martyn. The experiment consisted of the following units: control (C), mushroom substrate (MS), slurry (S). LSD - Least Significant Difference.

Forage from the other plots was assessed as Class 1, which means that it can be used for feeding the best milking cows with very high productivity. Comparing relative feed value of the legume-grass mixtures used in the experiment with relative feed value of Class 3 and 4 grass from meadows and pastures, it can be concluded that the former is much better for ruminants than the latter (Jankowska, 2013; Jankowska-Huflejt and Wróbel 2008).

Conclusions

Forage from the plot with 20 t· ha^{-1} of mushroom substrate together with 40 m^3 ha^{-1} of slurry applied had the highest % digestibility. The highest dry matter intake (DMI) and the highest relative feed value (RFV) were obtained by applying 10 t· ha^{-1} of mushroom substrate with 60 m^3 ha^{-1} of slurry. Higher doses of mushroom substrate and lower doses of liquid manure resulted in a lower digestibility and relative feed value (RFV) of ryegrass with alfalfa forage. Generally, in comparison with mushroom substrate, slurry application resulted in higher digestibility of the legume-grass mixtures, higher dry matter intake (DMI), dry matter content, and relative food value (RFV). Forage of the ryegrass and alfalfa mixture (M3) had the most favourable dry matter intake (DMI) and relative food value (RFV).

THE EFFECTIVENESS OF DIFFERENT OVERDRILLING TECHNOLOGIES OF THE DRY MEADOWS IN CENTRAL POLAND

Maria JANICKA

Department of Agronomy, Warsaw University of Life Sciences – SGGW, Poland
*Corresponding author: maria_janicka@sggw.pl

Abstract

The nutritive value of bulk fodder produced from grassland is dependent on the botanical composition of sward and the proportion of valuable grass and legumes species. The aim of the study was to evaluate the effects of overdrilling of dry meadows depending on the treatment of the sward existing before renovation. The study was carried out in central Poland, in the valley of the river Pisia Tuczna (37 km west of Warsaw), on degraded permanent grassland, which had been extensively managed and fertilized. The competitiveness of the original sward before overdrilling (performed by a Vredo slot seeder) was reduced by: (1) low cutting without herbicides, (2) selective herbicides, (3) non-selective herbicide, (4) rototilling. The effectiveness of those treatments was compared with the control object which was not subjected to any treatment and was not fertilized. Dry matter yields, botanical composition of each cut and contents of the mineral macronutrients were measured according to Polish Norms or research procedures. The applied renovation technologies resulted in an increase in yields (in average from 86% to 125%) compared to the yield of the control original sward. The highest yields and the share of the sown species were obtained in the case of overdrilling preceded by rototilling (in average 6.62 $Mg \cdot ha^{-1}$ and 58.2% respectively) or spraying by non-selective herbicide (in average 7.09 $Mg \cdot ha^{-1}$ and 55% respectively). *Dactylis glomerata* L. was the most useful species to overdrilling of dry meadows, irrespective of technology (average 41-50% of sown species). The differences in the contents of macronutrients in the meadow sward were determined primarily by changes in species composition, which occurred to stay under the influence of the applied oversowing technologies and fertilization. The contents of phosphorus (0.36-0.40% P), potassium (1.44-1.68% K), magnesium (0.23-0.26% Mg), calcium (0.85-0.97% Ca) and sodium (0.20-0.23% Na) in the swards' dry matter fully covered the animals' feeding requirements.

Keywords: *Grassland renovation, yields, botanical composition, content of mineral macronutrients: N, P, K, Mg, Ca, Na, Poland*

Introduction

Grassland plant communities formed by sowing are unstable and become degraded relatively quickly. The causes of this phenomenon are unfavorable weather conditions, deteriorating soil conditions, and to a large extent improper management (Rutkowska *et al*., 1999; Kryszak *et al*., 2005; Warda and Kozłowski, 2012). In Poland as a result of twice-lower stocking density and reduced demand for animal forage (compared to the 1980-1990) the perennial grassland in many farms shows a low agricultural value. Their production capacity is often not even half-used (Jankowska-Huflejt and Domański, 2008; Stypiński *et al*., 2009). Depending on the degree of sward degradation and habitat conditions, the grasslands are renovated by various methods. Currently, overdrilling is the most recommended method to improve the economic value of both permanent and temporary meadows and pastures (Goliński, 2003; Baryła and Kulik, 2011; Janicka, 2012; Barszczewski *et al*., 2016). This method is appreciated primarily by farmers of large farms, in which simplified cultivation technologies are widely used on arable land (Hermenean *et al*., 2006; Mocanu *et al*., 2008). Strong interests in improving the methods of grassland restoration are shown by both farmers specializing in milk and in beef production. Regarding modern methods of oversowing with improved cultivars, mainly leguminous plants are of great importance for organic farms (Wolski, 2002; Komárek *et al*., 2007). The aim of the study was to evaluate the effects of overdrilling of dry meadows depending on the treatment of the sward existing previously.

Material and Methods

The study was carried out at the Jaktorów Experimental Station (central Poland), in the valley of the river Pisia Tuczna (37 km west of Warsaw). The experiment was established in moderately wet meadow habitat (water table between 50 and 80 cm), located at a distance of approximately 180-200 m from the river bed (geographical coordinates: 52°05′ N; 20°32′ E). It was carried out on degraded permanent grassland, situated on mineral soil (black earth) poor in potassium and with a high phosphorus and magnesium concentration, which had been extensively managed and fertilized. The reason for its renovation was low yielding, resulting from a very low proportion of valuable tall grass species (less than 10%), a lack of legumes and a high proportion of dicotyledonous herbs and weeds (more than 30%) in the sward (*Taraxacum officinale, Plantago lanceolata* and *Ranunculus repens* had the highest proportions). In addition, this area was characterized by the presence of a large number of empty places.

The experiment was designed as a randomized complete block with four replications. Each plot was 15 m^2 (2 m x 7.5 m). The mixture consisted of high grasses: *Festuca pratensis* cv. Pasja (20%), *Phleum pratense* cv. Kaba (25%), *Dactylis glomerata* cv. Astera (10%) and *Trifolium pratense* cv. Parada (15%) – 24.2 kg ha^{-1} was sown. Overdrilling was performed by a Vredo slot seeder (Type 120.10), the distance between rows was 10 cm and a sowing depth of 1-2 cm. Competitiveness of the original sward before overdrilling was reduced by: 1) low cutting without herbicides (cutting height about 3 cm) – PM, 2) selective herbicides: Starane 250 EC (1l ha^{-1}; active substance: fluroxypyr) + Aminopielik D 450 SL (3l ha^{-1}; active substance: 2,4 D + dikamba) – H+PM, 3) non-selective herbicide, and total sward destruction: Roundup 360 SL (5l ha^{-1}; active substance: glyphosate) – R+PM, 4) rototilling, one time, depth about 8-10 cm (without herbicides) – G+PM. The effectiveness of those treatments was compared with the control – old sward (SD), which was not subjected to any treatment and was not fertilized. In the sowing year two cultivation and two production cuts were made and in the subsequent years – three cuts per year. The following doses in $kg \cdot ha^{-1}$ of mineral fertilizer were applied: 180 N (in three equal doses for each cutting), 30 P (in spring) and 100 K (in two equal doses – in spring and after the first cut). Dry matter yields and botanical composition of each cut were measured. The species used in mixtures, other species of grasses, legumes and dicotyledonous herbs and weeds were separated. The sward samples taken from each re-growth were used to determine the content of mineral macronutrients: N, P, K, Mg, Ca and Na. These analyzes were done at the National Agrochemical Station in Warsaw according to Polish Norms or the accepted research procedures. The data was analyzed statistically by variance analysis (ANOVA). Verification of the significant differences was based on Tukey's test ($p \geq 0.05$).

Results and Discussion

The weather conditions during the vegetation periods were not favorable for growth and development of sown grass species and *Trifolium pratense*. This is supported by very low values of hydrothermal index of Vinczeffy (1984) calculated as the quotient of total precipitation to the sum of temperature. The values of this ratio ranged from 0.098 (second year) to 0.119 (first year) and were classified as extremely dry and very dry, respectively, while the optimal conditions for the growth and development of meadow vegetation occur when the index is 0.2 - 0.25 mm·$^{o}C^{-1}$.
In the first year, the sown grass species developed quite poorly and constituted a low share in the yield (Tab.1), which was a result of weather conditions (lack of rainfall) and high competition of the primary meadow sward' species, especially *Lolium perenne.* Similar results have been obtained in earlier studies (Janicka, 2004). In the following years, the development of the sown grass species significantly increased their share in yield to 51.6% (on average) in the last year of the studies (Tab.1). Irrespective of the year, they have the highest share in yields which were obtained in the treatments of overdrilling preceded by Roundup spraying or rototilling (45 and 51.5% respectively); the significantly lower ones were obtained in the others treatments (H+PM and PM).

* Figures indicated by the same letters are not significantly different

Dactylis glomerata L. was the most useful species to overdrilling of dry meadows, irrespective of technology (average 41-50% of sown species). It was characterized by increasing competitive ability and resistance to changing weather conditions. The usefulness of this species for overdrilling in Poland has been confirmed in numerous experiments (inter alia Grabowski *et al.*, 1996; Baryła and Kulik, 2008; Janicka, 2012). *Festuca pratensis* Huds. was not good enough, despite the rapid rate of development during the early period after sowing (in the first year 23% of sown species). In the following years it showed a high sensitivity to water deficiency and a declining ability to compete. *Phleum pratense* L. was the least useful species for overdrilling of dry meadows (Janicka, 2012). It was characterized by low competitiveness and sensitivity to drought (in the third year 9.5% of sown species). *Trifolium pratense* L. was well developed in the sowing year (47% of sown species) and limited the development of the old sward. This points to the usefulness of this species for overdrilling, regardless of technology.
The yielding was dependent on presence of the sown species in the sward. The highest yields on average for the studied period were obtained in the treatments where the primary sward was destroyed by non-selective herbicide (R+PM) or by rototilling (G+PM) and where the share of the sown species was highest (Tab.2). Lower productivity was obtained by the treatment with overdrilling carried out directly into sward (PM), and significantly lowest yield was taken from the

treatments with the use of selective herbicides (H+PM). This confirms the opinion that sufficient damage to the original sward is one of the most important conditions for the success of overdrilling (Tiley and Frame, 1991; Grabowski, 1992; Janicka, 2007). The yields of the meadow sward from the particular treatments were in average from 86% (H+PM) to 125% (R+PM) higher than the yields of the control sward (SD). The sown grasses influenced mostly the sward productivity. The results of yielding indicate that in moderately wet habitats positive effects of overdrilling may be obtained by mechanical limiting of the original sward competitiveness (G+PM), while in the moderately dry habitats the risk of significant drying out of the topsoil is relatively high (Baryła, 1996; Janicka, 2012).

* Total yields of II and III cuts;
** Figures indicated by the same letters are not significantly different

The total nitrogen content in the plant dry matter from the peculiar treatment amounted (on average) from 1.78% (G+PM) to 1.88% (H+PM). Lower content of nitrogen was found in the dry matter from the treatment G+PM and R+PM (Tab.3), what was probably linked to higher share of *Phleum pratense* in the sward from that treatment (the later species). The results of the other authors showed that the late species and varieties are characterized by lower protein content compared to the earlier ones (Dębska–Kalinowska, 1994, Kochanowska-Bukowska, 2001). Moreover, it is worth pointing out that the Astera cultivar of *Dactylis glomerata*, according to Łyszczarz and Dembek (2003), belongs to the later cultivars of that species and, according to the results of Kochanowska-Bukowska (2001) is characterized by a lower protein concentration in comparison to the earlier cultivars of that species. The significantly lower concentration of that component was found in the dry matter of the first re-growths in comparison to the others (the large share of the generative shoots) and in the second year (extremely dry). The high air temperature and lack of rainfall in that year limited use of nitrogen and gathering of that element in plants, which was found by many authors (i.a. Dębska-Kalinowska, 1994; Falkowski *et al.*, 2000; Borawska-Jarmułowicz, 2003; Łyszczarz and Dembek, 2003).
The average phosphorus concentration in the dry matter was a little higher than the value considered as optimum in animal feeding (0,3%, Brzóska, 2008), what was the result of high phosphorus content in the soil. The significantly higher amount of phosphorus was stated for the sward with PM treatment, in comparison to R+PM and G+PM (Tab.3). The significant differentiation in that element content was found depending on regrowth and the year of the study. The higher phosphorus concentration was stated in the summer re-growths (II, and the highest in III), probably due to the higher share of dicotyledonous in the yield in comparison with the first regrowth. Moreover, significantly higher content of phosphorus was stated in the sward from the first year – the year of the highest share of *Trifolium pratense*, being characterized by the high concentration of that element, in the yields.

* Figures indicated by the same letters are not significantly different

The average amount of potassium differentiated from 1.44% K in DM to 1.68%, so it was absolutely sufficient to the animals' requirements for that component (Brzóska, 2008). The excessive concentration of potassium (more than 2%) was not stated during the whole study period. The significantly lower content of potassium was typical for the swards from G+PM and R+PM treatments, what probably was the effect of higher dicotyledonous share in the yields. The significantly higher content of that element was found in the sward of the first regrowth. The lower potassium concentration – in the comparison to following years – was stated in the first year, as well as a higher share of dicotyledonous, especially *Trifolium pratense*.

The magnesium content in the sward dry matter differentiated in average from 0.23% to 0.26%. The differentiation of the magnesium content was relatively low, the highest concentration of that element was stated in the sward from the G+PM and R+PM treatments, and significantly lowest – in the sward from H+PM treatment (Tab. 3). It was determined by the differences in the dicotyledonous, which showed a higher magnesium concentration than grasses (Grzegorczyk *et al.*, 2013), as well as higher shares in the yields. The magnesium content in the dry matter was differentiated depending on the regrowth and the year of the study. In the sward of the later regrowths (II and III) the significantly higher concentration of the component was found, compared with the first regrowth. That fact was the result of the positive effect of higher temperature for magnesium input, as well as the higher share of dicotyledonous (herbs and weeds) in the yields (Kulik, 2009). The significantly higher share of that element was typical for the vegetation of the first year, with the highest proportion of dicotyledonous, especially *Trifolium pratense*.

The differentiation in the calcium content depending on the treatment was relatively low, the highest concentration of that element was found for the sward from PM and R+PM treatments, but the lowest – from the H+PM treatment (Tab. 3). That differentiation resulted from the differences in the share of dicotyledonous (*Trifolium pratense*, herbs and weeds) in the yields. Moreover the significantly higher content of that element was stated for the summer regrowths (II and III), with higher share of the dicotyledonous herbs and weeds, and in the first years of the study with the highest share of *Trifolium pratense.* Sometimes the calcium content exceeded 1% in dry matter, especially in the first year after overdrilling. This is a non-advantageous phenomenon, as a too high level of that component in the forage may limit the microelements' absorption, mainly the iodine and zinc (Falkowski *et al.*, 2000). It is worth stressing that often, extensive concentration of that element is found in the dry matter from the control treatment (SD).

The sodium concentration in the swards' dry matter was at the optimum level from 0.20% (H+PM) to 0.23% (G+PM) and covered the animals' feeding requirements for that element (Brzóska, 2008). That fact might be due to the effect of significant *Lolium perenne* (the species of primary sward, showing a large sodium concentration) share in the yields. The differentiation in that element content among the treatments was low; the highest sodium concentration was found for the G+PM treatment, and significantly lower – for the H+PM treatment (Tab. 3). This was the effect of the varied share of *Dactylis glomerata* in the yields (higher for G+PM treatment than for H+PM one). The highest sodium concentration was stated for the sward of the third regrowths, and significantly lower – for the first regrowths, which might be the result of the negative influence of potassium, lowering the sodium level (Falkowski *et al.*, 2000). The peculiarly high content of that element was stated for the III regrowth in the last year (0.32%), what was due to advantageous weather conditions in that period (rainfalls and optimal temperature), which determined the sodium intake by plants (Falkowski *et al.*, 2000). The significantly highest content of sodium was characteristic for the sward in the first year of the study, due to high *Trifolium pratense* (of higher concentration of that element in the comparison with grasses) share in the yields.
The reciprocal relations of macronutrients contents are of great importance from the animals' feeding point of view (Brzóska, 2008). Therefore, evaluating the nutritional value of sward after renovation should be taken into account. The relation of the potassium/sodium content was only in technology with the use of selective herbicides (H+PM) slightly exceeded the acceptable value equal to 10 (Brzóska, 2008). The proportion of calcium/magnesium content was lowly differentiated (3.6-3.9). Also the relation of calcium and phosphorus was advantageous. The values of that proportion were very lowly differentiated (2.2-2.5) and similar to the optimal one (Brzóska, 2008).

Conclusions

The applied renovation technologies resulted in an increase in yield from 86% to 125% when compared to the yield of the original sward. The highest yield and the highest share of the species introduced by overdrilling were obtained in the case of overdrilling preceded by Roundup spraying (in average 7.09 Mg·ha^{-1} and 55% respectively) and rototilling (in average 6.62 Mg·ha^{-1} and 58.2% respectively). *Dactylis glomerata* L. was the most useful species to overdrilling of dry meadows, irrespective of technology (average 41-50% of sown species).
Taking into account the animals' requirements for mineral nutrients, the best forage nutritional value was characterized by the treatments with overdrilling after either rototilling or Roundup spraying. The contents of phosphorus (0.36-0.40% P), magnesium (0.23-0.26% Mg), calcium (0.85-0.97% Ca) and sodium (0.20-0.23% Na) in the swards' dry matter fully covered the animals' feeding requirements. Due to the higher dicotyledonous' share in the yields, the higher concentrations of those elements occurred in the summer regrowths.

Abstract

Bell pepper is grown in Romania as an annual plant, cultivated both for fresh consumption and processed products. To aid Romania in enriching its assortment of bell peppers, new cultivars are being developed for local climatic conditions and for supporting the industry demands. Any breeding process can only be initiated if there is available a valuable biological material, which means that there is a sufficiently large variability of the characters and attributes that characterize the material in order to choose the genotypes in accordance with the objectives pursued. That is why research begun with the evaluation of the biological material held in the germplasm collection. Based on that evaluation, it was found that from the total of 214 *Capsicum spp*. genotypes, a number of 42 genotypes demonstrated genetic stability in the descendant, a number of 54 genotypes were included in genetically advanced accessions group and a number of 118 genotypes had been proved to be segregant. During the breeding work a number of 42 genetically stable genotypes were used as initial material for achieving new cultivars. The research undertaken within the breeding program was completed with two new crops that had been tested for 3 years in open field and cold greenhouses. The control variant used in this experiment was a well known Romanian bell pepper variety, Galben Superior. Two new varieties, Ideal (A3) and Carmin (A70) which have shown valuable characteristics and are in conformity with the international standards imposed by the DUS test are currently in the process of being patented.

Keywords: *Capsicum annuum* L., *Carmin, Ideal, Breeding, Variety.*

Introduction

Bell pepper is cultivated worldwide for vegetable, spice and processed products (Crosby, 2008) and is grown in a wide range of climate as an annual and/or perennial crop (Bosland and Votava, 2012). Bell pepper is a good source of vitamin C and E, provitamin A, ascorbic acid and carotenoids, like 5.8 µgm/gm of fresh green wt. (Materska and Perucka, 2005). The nutritional and health value of ascorbic acid (AsA) is of great importance in the human diet, in order to "fight" diseases such as scurvy, to maintain collagen, to reduce stress damage, and as an antioxidant. Ascorbic acid is important in the biosynthesis of amino acids, formation of adrenaline, and detoxication in the liver (Smirno,1996). Total ascorbic acid was higher in bell pepper than in tomato fruit. In pepper fruit, the level of ascorbic acid increased rapidly during its development, reaching a maximum of 136.1 mg/100 g at 51 days from fruit set and then decreased suddenly, reaching a minimum of 65.5 mg/100 g at 64 days. (Yahia et al., 2001). In Plant Variety Catalogue there are numerous cultivars achieved by breeders in different parts of the world. Because there is a lack of competitive peppers varieties in Romania, farmers tend to buy the seeds from foreign companies. But, the attempt to introduce foreign origin varieties into Romanian crop proved to be a solution for the moment, since parameters of production from the country of origin are not always attained, due to ecological plasticity. Vegetable Research and Development Station was found in 1957 and has always been producing and selecting vegetable seeds, also obtaining new cultivars and hybrids. Since 1996 has begun the increasing of germplasm collection of peppers and not only. During the evaluation of

germplasm collection, a number of eight valuable genotypes of chilli peppers, having a different measurement of pungency (SHUs) and a dwarf port, suitable for pots and jardinière were selected (Barcanu Elena et.al., 2017). In order to meet the requirements of a biological material with high breeding value, one of the main features of germplasm collection is variability (Leonte C., 2011).
Huge variability of characters from germplasm collection and also the *Capsicum spp.* genus variability has allowed the extraction of new genotypes of bell peppers. And the germplasm collection still has plenty of valuables genotypes. In order to increase horticultural crop and improve its quality, it is recommended to introduce new cultivars and replace the existing one, with better aspects as quantity and qualitative yield, resistance to the environmental factors and tolerance to pathogens. That is why our aim is to achieve new assortment varieties created under the specific climatic conditions of our crop area and also for supporting the demands of the industry.

Material and Methods

Any breeding process can only be initiated if there is available a valuable biological material, which means that there is a sufficiently large variability of the characters and attributes that characterize the material in order to make possible choosing genotypes in accordance with the objectives pursued. That is why research begun with the evaluation of the biological material held in the germplasm collection. Based on this evaluation, it was found that from the total of 214 *Capsicum spp.* genotypes, a number of 42 genotypes demonstrated genetic stability in the descendant, a number of 54 genotypes were included in genetically advanced accessions group and a number of 118 genotypes had been proved to be segregant. During the breeding process, a number of 42 genetically stable genotypes were used as initial material for achieving new cultivars. The breeding methods used have been: repeated individual selection in local populations, bulk method, hybridization and segregation. The control variant used in this experiment was a well known Romanian bell pepper variety, Galben Superior. This control variant was chosen because there is a need for improving quantity and quality of yield. Over the growing season, phenological and biometric observations have been made on plant and fruits, and also an analysis of variance (ANOVA) for the determination of the agronomic value for the perspective genotypes in comparative cultures. Valuable genotypes have been studied for 3 years, during 2014-2016, under two conditions: in open field and greenhouse. Peppers were grown under the same technological conditions used for bell pepper production.

Results and Discussion

The researches undertaken within the breeding program, having the main objective the achievement of new bell pepper varieties suitable for current climatic conditions and also for growers demands, processors and consumers, had been completed with two new cultivars that were tested for 3 years in open field and greenhouses. In order to highlight the results, in both crop systems has been used Galben Superior as control variant. Main plant characteristics can be found in table 1.

Table 1. Main plant characteristics

Varieties	UM	A3 (Ideal)	A70 (Carmin)	Galben Superior (CV)
Plant height	cm	85	105	95
Number of main shoots	no	3	4	3
Plant diameter	cm	73	67	74
Fruit length	cm	12,3	10,5	9,6
Fruit diameter Base-middle-top	cm	5,3 – 4,8 – 1,2	7,9 – 6,2 – 4,4	7,2-6,1-4,2
Fruit weight	(g)	130,5	105,6	102,3
Total number of fruits/plant	no	20	11	9

Accession 3 has shown three important features: earliness, productivity and a very good flavour, which is the reason for patenting under the name of „Ideal”. Early variety, with slightly conical, pendulum fruits, can be eaten both in green as in red. The average fruit weight is of 130.5 g with a 0.6 mm thick pericarp.
Accession 70 is a medium earliness variety, characterized by a medium-sized bushy plant, with erect fruit having 3-4 fleshy lobes. The fruit color turns from yellow-green to red carmine at physiological maturity. Fruits can also be eaten at the green stage. Fruit length is of 10 cm and 4.4 cm in diameter, and the thickness of the pericarp is of 0.7 mm. Due to the positive results achieved at this accession in 2016, it has been patented under the name of „Carmin”.
According to Table 2 and Table 3, the average yield potential for the studied genotypes showed a significantly growth compared to the control variant, both in the open field and in greenhouse.

Table 2. Average yield potential of bell pepper varieties in field, years 2014-2016

Varieties	**Yield**		**Differences t/ha**	**Level of significance**	
	Absolute t/ha	Relative %		Compared to S^2E error	Compared to S^2VxA interaction
Accession 3 (Ideal)	48,57	153,8	17	xxx	Xxx
Accession 70 (Carmin)	41,8	132,4	10,23	xxx	Xx
Galben Superior (control variant)	31,51	100	-		

For S^2E
LSD 5% = 2,76
LSD 1% =3,69
LSD 0, 1% = 4,82

For S^2VxA
LSD 5% = 4,79
LSD 1% = 6,49
LSD 0,1% = 8,47

Table 3. Average yield potential of bell pepper varieties in greenhouse, years 2014-2016

Varieties	**Yield**		**Differences t/ha**	**Level of significance**	
	Absolute t/ha	Relative %		Compared to S^2E error	Compared to S^2VxA interaction
Asscession 3 (Ideal)	58,8	154,7	+20,8	xxx	Xxx
Asscession 70 (Carmin)	52,0	136,8	+14	xxx	Xx
Galben Superior (control variant)	38,0	100	-	-	-

For S^2E
LSD 5% = 1, 74
LSD 1% = 2, 39
LSD 0, 1% = 2,58

For S^2VxA
LSD 5% = 5, 47
LSD 1% = 9, 06
LSD 0,1% = 16,9

Conclusions

Diversity is one of the most valuable resource of plant genetic. If is better perceived and evaluated the genetic diversity germplasm can offer more chance of getting new cultivars. Starting from these premises, researches have been completed so far with the improving and evaluation of the biological material held in the germplasm collection consisting of 214 genotypes. Two new varieties, Ideal (A3) and Carmin (A70) which have shown valuable characteristics and are in conformity with the international standards imposed by the DUS (Distinctness, Uniformity and Stability) test are currently in the process of patenting.
The yields obtained during 2014-2016, both in open field and greenhouses were clearly superior to the control variant, Galben Superior.

Abstract

The paper aims to provide analysis of interaction between a simple rectangular tillage tool moved with constant speed in a soil model without cohesion (coarse sand). For simulation, the LS-DYNA finite element method (FEM) analysis was used. For the geometric model with length 400 mm, width 300 mm and depth 500 mm, the soil material model 147 was chosen. The element grid has 9305 nodes and a network of 8010 solid rectangular elements. For base surface and lateral surfaces appropriate boundary conditions were imposed. The tillage tool is a rectangular prism with length 322 mm, width 20 mm, in vertical position at a depth of 222 mm. The tool speed was imposed to 1.5 m/s alike experimental test rig tool. The experimental test rig allows the movement of 4 tools on circular trajectory with diameter 1700-2000 mm, at maximum depth 900 mm. The interface contacts between the tool and the soil material was modeled automatically by the application software. Tension wave propagation in the soil, speed and accelerations of soil and tool nodes can be obtained and visualized. Soil displacement in three directions shows good similarity with experimental results. Natural tool vibration and soil acceleration was also investigated to reduce the drag force. The simulation shows a lower drag force than experimental result, thus further investigation is needed on FEM modelling. The reduction of the drag force will decrease the required energy in the tillage process, thus reducing the fuel consumption and the environmental pollution.

Keywords: *tillage tool, FEM model, soil resistance, soil disturbance, soil-tool interaction.*

Introduction

Study of soil-tool interaction starts with understanding of the soil break fundaments and the factors which influence that. Tool geometry and soil properties must be considered together when study soil-tool interaction. When finite element methods FEM is used to evaluate the process, several disadvantages or lacks of analytic models can be overpass. The FEM method can estimate drag resistance without preliminary simplification of soil rupture model and can calculate fields of displacements, tensions, speeds and accelerations. Several investigations with 3D models related to soil-tool interaction have been made (Kushwaha, 1993 and Liu, 1985). The key to understand this includes soil material constitutive relation and a model of interface between soil and tool. Among the most used constitutive relations are the one established by Duncan and Chang, 1970, Kushwaha and Shen, 1993, cap model of Drucker at all, 1955 etc. Mouazen and Nemeny, 1999, are between the first who have studied the interaction of a real tool with the soil from FEM analysis perspective. Another important element in understanding the soil-tool interaction is tied by the ratio between working depth and working depth of tillage tools. For a given soil material, the ratio value allows to obtain the desired effect in the soil. For that, the present investigation is trying to obtain the correlation between a simple vertical tillage tool model and the corresponding drag and soil disturbance and to compare with similar test rig experiment in order to understand the soil tool interaction and to be able through simulation to obtain efficient tillage tools.

Materials and methods

One of the most difficult tasks associated to FEM modelling is represented by appropriate selection of properties of the materials used, in order to represent as accurate as possible their physical behavior. It is desirable that the materials input parameters to be determined through physical tests and more than that, the selection and proper use of input parameters or variables to be based on profound understanding of those.

Taking into consideration the implications of designing a soil constitutive model, in order to obtain appropriate results through FEM analysis, a constitutive model developed and evaluated with the LS-DYNA solver by the Federal Highway Administration, US Department of Transportation, has been chosen to be used, respectively the soil material model 147. This material model has been chosen for, in order of priority, accuracy, robustness, high computational speed and very important its ease of use.

The not null values of the input parameters used to define the material used, a coarse sand, with the LS-DYNA solver, version 970, can be found in the table below. The complete theoretical fundaments and the evaluation of the constitutive model based on standard soil tests (i.e. triaxial shear test and uniaxial strain tests) can be found in the manual respectively the evaluation of LS-DYNA Soil Material Model 147.

Soil parameters used for FEM model — Table 1

Symbol	Unit	Value	Description
Elastic and Soil Characteristics			
K	N/mm^2	3.25	Nonporous bulk modulus
G	N/mm^2	6.22	Shear modulus
γ_{sp} – Spgrav	-	2.65	Specific gravity
m_c – Mcont	%	0.034	Moisture content
ρ – Ro	Kg/mm^3	0.02082	Density of soil
Plasticity			
φ – Phimax	rad	1.1	Friction angle
c – coh	N/mm^2	0.0062	Cohesion
ahyp	-	0.0001	Coefficient for modified Drucker-Prager surface
e – eccen	-	0.7	Eccentricity parameter for third invariant effects
Strain Softening			
ξ_0 – Dint	-	0.01	Volumetric strain at initial damage threshold
G_f – Vdfm	Nmm	0.00006	Void formation energy
φ_{res} – Phires	rad	0.001	Minimum internal friction angle used for residual strength
Strength Enhancement Caused by Strain-rate Effects			
n – vn	-	1.1	Viscoplasticity parameter, strain-rate enhanced strength
Element deletion			
Damlev	%	0.99	Level of damage that will cause element deletion
Epsmax	-	0.8	Maximum principal failure strain
Miscellaneous			
Nplot	-	1	Element plotting variable to put into effective plastic strain variable
Rhowat	Kg/mm^3	0.01	Density of water in model units, used to determine air void strain (saturation)
Itermax	-	10	Maximum number of iterations used in plasticity iterations

The material model 147, based on modified Mohr-Coulomb surface, corresponds to an isotropic material, well graded and not stratified. It also allows elements deletion and it's available for solid elements in LS-DYNA.

The geometric model is a rectangular volume with defined dimensions respectively 400 mm length, 300 mm width and 500 mm depth. The element grid is using 9305 nodes, formed by a network of 8010 solid rectangular elements. The base surface and all the lateral surfaces have imposed appropriate boundary conditions.

The simulated tillage tool is a rectangular prism with a length of 322 mm, a width of 20 mm working in vertical position at a depth of 222 mm. The speed of the tool is imposed to be 1.5 m/s as on the real tool on experimental test rig. The interface contact between the tool and the soil material was modeled automatically by the application software for the two parts, surface to surface type.

Fig. 1 Experimental test rig

The experimental test rig design used to confirm the results from the simulation is presented in fig. 1. It allows to mount up to 4 tools, with multiple adjustments, which can move on circular trajectory with a diameter between 1700 mm and 2000 mm, a maximum depth of 900 mm and was equipped with a data acquisition system based on HBM Spider 8 amplifier.

Results and discussion

Part of the results from the numerical analysis can be found below, a deeper analysis being possible based on LS-DYNA model simulation. For all the images obtained, the representation scale is the same in order to process the visual information in a more intuitive manner.

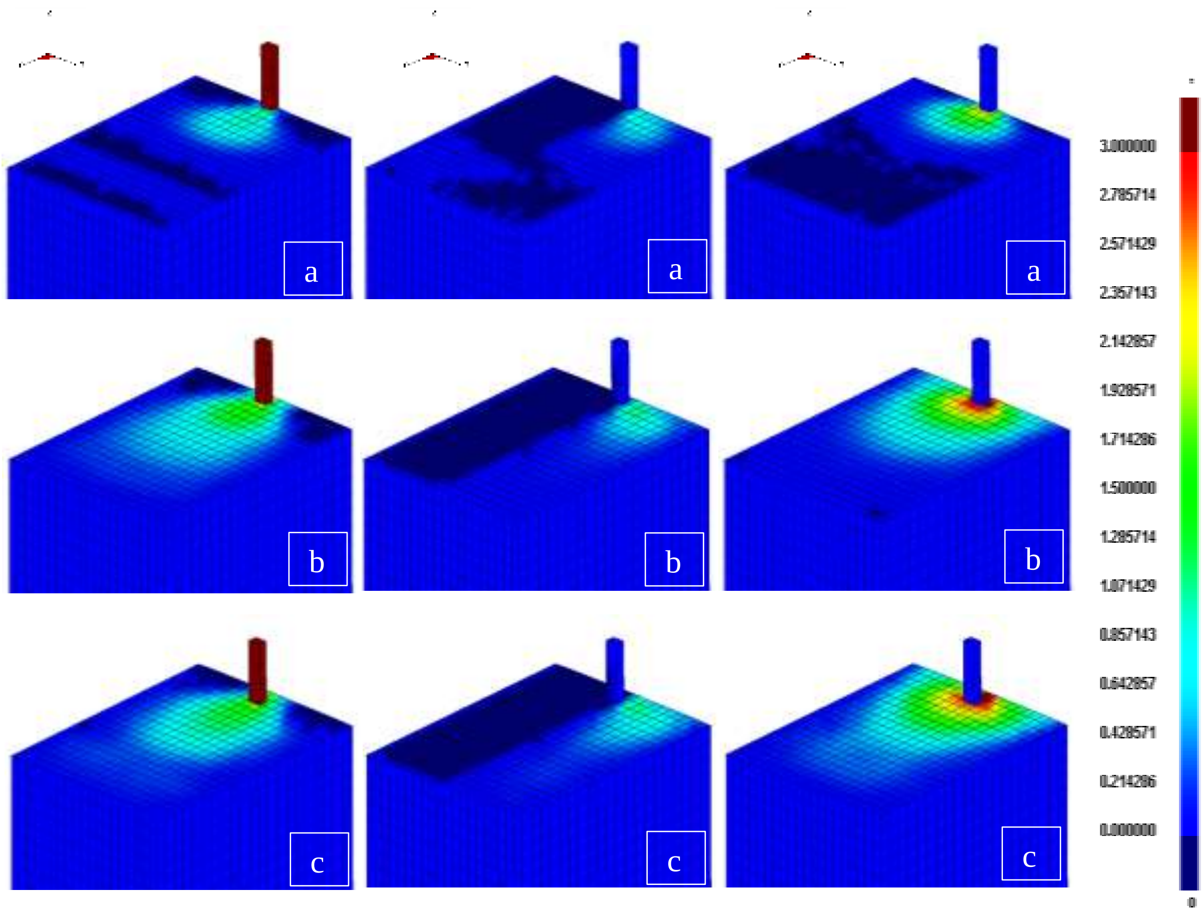

Fig. 2 Elements displacement in top plane along x direction after a) 10 ms, b) 20 ms and c) 30 ms

Fig. 3 Elements displacement in top plane along y direction after a) 10 ms, b) 20 ms and c) 30 ms

Fig. 4 Elements displacement in top plane along z direction after a) 10 ms, b) 20 ms and c) 30 ms

For the representation along Y direction, the images must be perceived as mirrored.
Regarding the influence of tillage tool over the soil, respectively the soil disturbance, the results can be graphically visualized in figures 2, 3 and 4. Considering the top soil layer in three different

position in time, at 10ms, 20ms and 30ms, after the start of the tillage tool movement in the soil at the specified speed the results show a high disturbance of the soil in vertical direction, an effect desired as it's loosening the soil. Another effect of tool movement into soil can be seen in fig. 3, the soil disturbance in y direction. Based on this values the optimum distance between the tools in a row can be established.

Analyzing the soil elements displacement in the other two planes, as can be seen in fig. 5 and 6, the critical angle β_x, β_z and the critical depth h_{crit} of the soil-tool interaction can be visualized and determined. As stated by other authors (Godwin,1977; Payne, 1956 and Spoor, 1978) the soil disturbance profile is determined by the ratio between working depth and width and also by the tillage tool angle of attack. For the chosen tool the effect is as the one observed in laboratory experiment in which the lateral effect and the loosening of the soil of the narrow vertical tool is significant in the upper part of the soil.

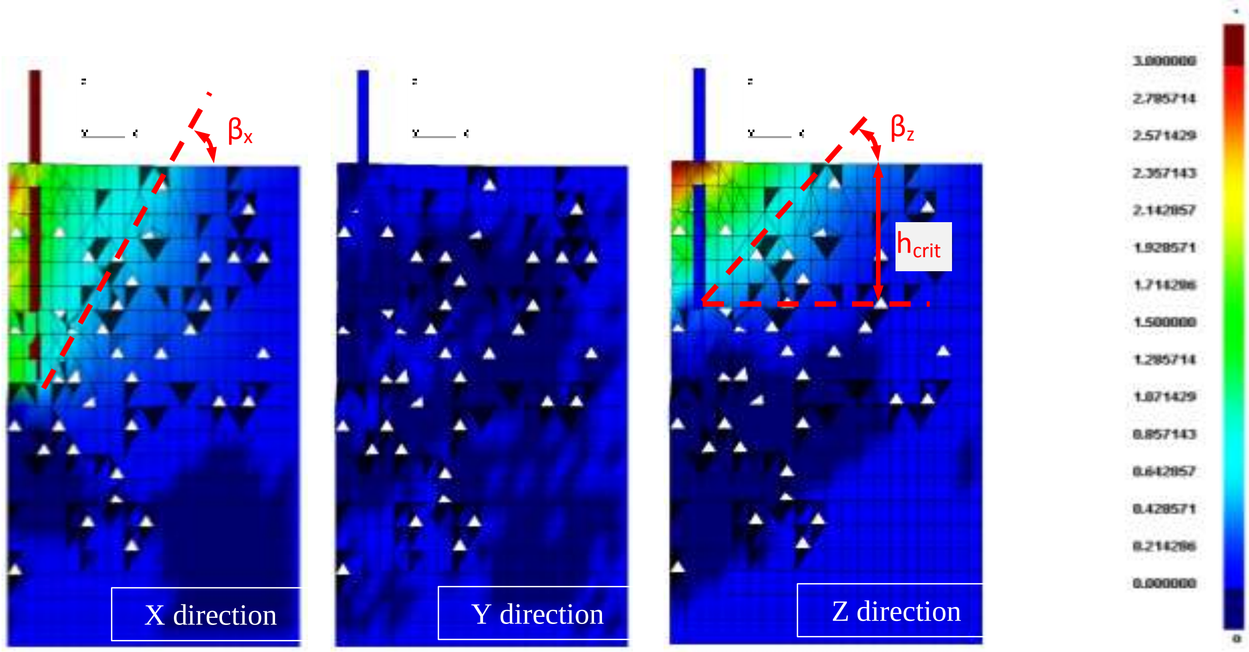

Fig. 5 Elements displacement in symmetry longitudinal plane along X, Y and Z direction after 30 ms

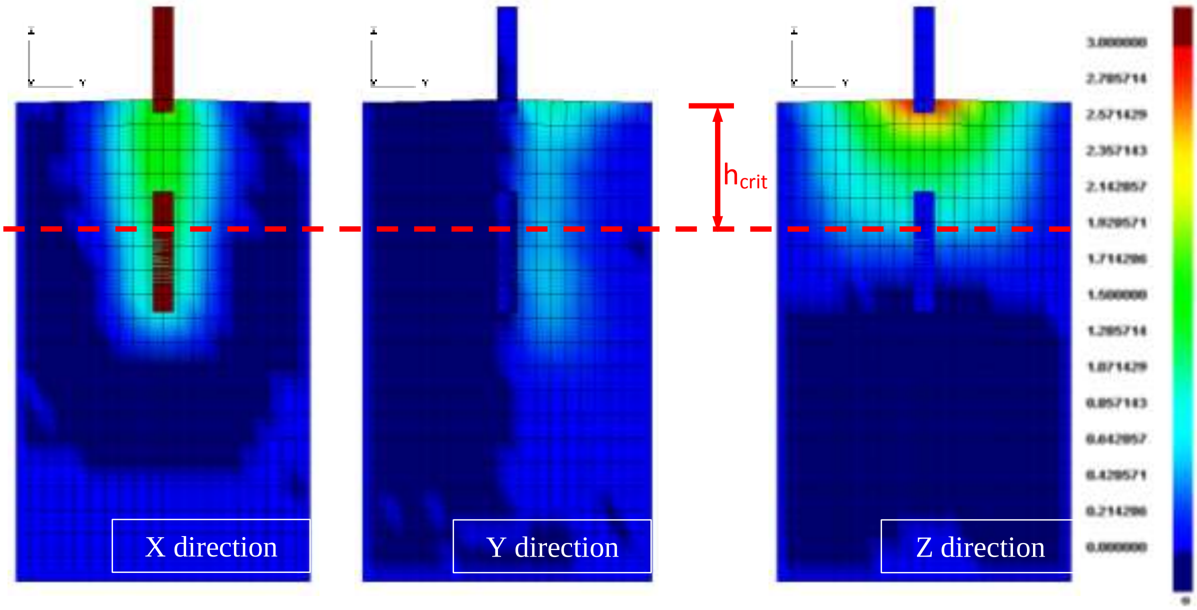

Fig. 6 Elements displacement in tool active surface plane along X, Y and Z direction after 30 ms

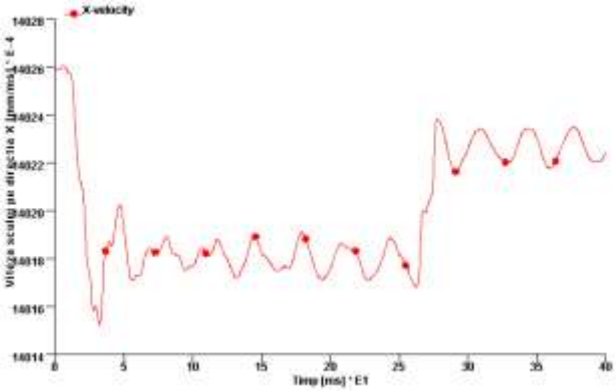

Fig. 7 Tillage tool speed variation in FEM model

In a similar way, the speed and accelerations of the nodes, for either the soil or the tool, can be obtained and visualized for all three directions. For that, fig 7 shows a speed variation of the tool, in which the oscillations are due to the load and the elastic behavior of the tool material as in real conditions. At the soil level, for the top layer, the total acceleration of the soil nodes was represented (fig. 8) and the results show the manifestation of a shock wave due to speed variation of the tool similar to vibration tool. The effect can be use in an advantageous way by lowering drag resistance if fine tuning is made regarding the tool parameters, working speed and real soil characteristics. Related to the results presented above, figure 9 shows the propagation of a tension wave in the soil whose existence was validated by Hendrick and Gill, 1973. Due to reflective properties of the boundary conditions, for a longer simulation, the results obtained are unreliable. In order to eliminate that, a solution can be the selection of a higher soil volume which increase the computation resources and time or inserting impedance at the boundary limits.

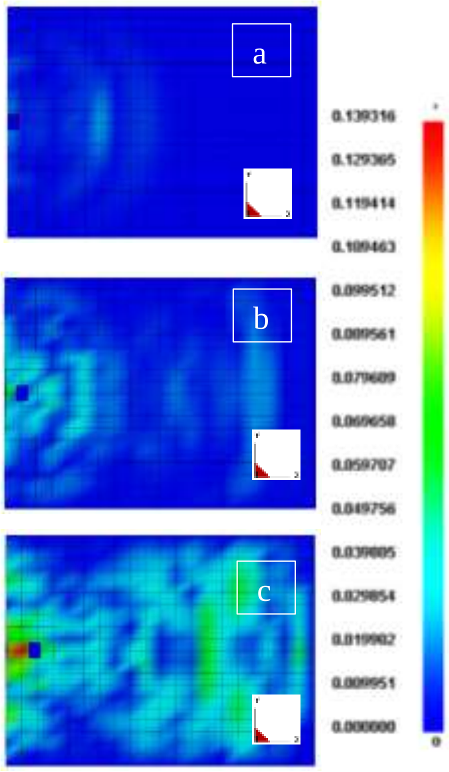

Fig. 8 Total acceleration at soil surface :
a) 10 ms, b) 20 ms, c) 30 ms

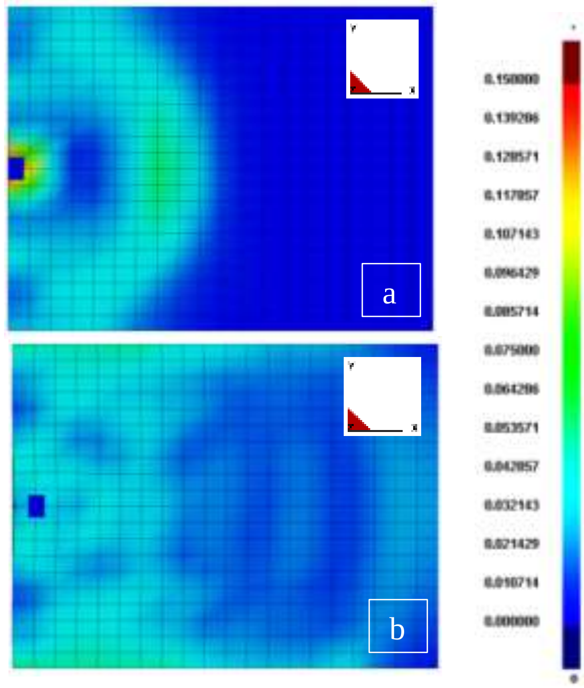

Fig. 9 Tension wave propagation in soil:
a) 10 ms, b) 20 ms

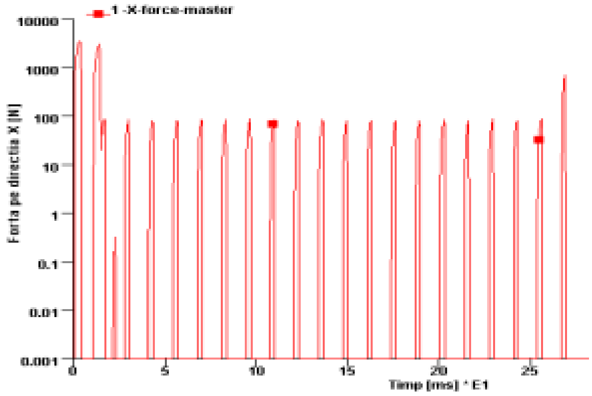

Fig. 10 Simulated drag resistance

Regarding the drag resistance, the force the moving tool needs to overcome the soil resistance, the values obtained are around 100 N according to the simulation with a spike of 1500 N that can be seen in fig. 10. Comparing the results obtained in the numerical simulation with the experimental results from the test rig, it can be stated that a similarity can be observed between the two analyses.

Conclusion

The influence of a simple rectangular vertical tillage tool moved with constant speed through soil – coarse sand – was simulated using the finite element method in dynamic transient process. The result: soil displacement in the three direction can be used to determine the soil disturbed by the tool with good approximation compared to the results obtained on an experimental test rig. Natural tool vibration and soil acceleration was also investigated in order to reduce the drag force. The reduction of the drag force will decrease the required energy in the tillage process, by thus lowering the fuel consumption and the environmental pollution.

The force obtained numerically was lower than the one obtained in the experiments, for that further investigation are needed from the perspective of FEM modeling.

The purpose of the investigation made in this paper is to enhance the information-needed to obtain a tillage tool which can respond to the needs of the user from an engineering point of view regarding agro-technical and efficiency parameters.

Abstract

Experiment set up in 2014 aims to investigate shortening of sweet corn growing period with application of some technological elements: propagation time, propagation method, floating row cover. The choosen variety was a conventional sweet corn hybrid, very early ripening 'Spirit'. The following growing technologies were compared: 1. Plants transplantation with floating row cover, 2. Direct sowing of plants with floating row cover, 3. Direct sowing of plants with no row cover (regarded as control). The transplanted plants had shorter growing period 19 days, compared to direct sowed covered treatment and were 21 days earlier harvested than control. Interaction of growing technology and plants covering had also a favourable effect on some important morphological properties of ears such as weight of husked and unhusked ears, ear length, ear diameter, length of kernel.

Key words: *earliness, sweet corn, transplantation, fleece covering*.

Introduction

Based on its present growing area, the sweet corn is the vegetable which is grown on the greatest area in Hungary. After dates of Hungarian Fruit & Vegetable Interprofessional Organization in 2016 the growing area was about 32,000 hectares. After 2003, greatest cultivated area about 38,000 ha, followed a sudden and sharp decline. After diminishing, the plant returned in rise, in 2006 against over 30,000 hectares, excepted 2010, 18,000 ha. The recession mentioned above affected not only Hungary but also the holdings of the USA and Western Europe. In the case of the former, however, the increase in fresh consumption partly counterbalanced the rate of decrease. Near 50% of world sweet corn production came from US (Slezák *et al.*, 2012). In 2013 the growing area was 34,000 hectares, less with 1,000 ha, compared to 2012 (Avar, 2013).

In order to promote fresh consumption, as well as to maintain and increase the sweet corn exports, it is necessary to promote investigations so as to be able to ensure a further increase in the growing area and yields of sweet corn with the help of the experiences. The literature mainly is concerned with maize growing technology, but a lot of dates could be used by sweet corn. Of the production technology elements, a number of researchers studied are currently studying the sowing time of sweet corn.

As early as at the ending of 19^{th}- and the beginning of the 20^{th} century some researchers (Cserháti, 1901) highlighted the importance of the sowing date. Ripening can occur earlier when sowing earlier and using high quality seeds as compared to normal or late sowing.

Several techniques are known in the art for the purpose of early fresh market shipments: seedling growing or direct seeding with temporary plant cover (Hodossi, 2004).

About the covered early sowing as a technological variation, Aylswirth (1986) mentioned, that from an early sowed crop, made in first week of April, arranged in twin rows (42 cm) and covered by plastic, we could harvested marketable cobs by the fourth of July.

According to Takácsné-Hájos and Gyökös (2011) sown on 14^{th} April under movable plastic tent some super sweet varieties, Dessert 70 F1 and Signet F1, could be harvested as early as the 1^{st} of July. In this way the adverse effect of considerable precipitation quantity and decrease in

temperature in the year 2010 could be prevented and in the same time harvest occurred 7–10 days earlier than in the covered field production.
The most widespread method of seedling production is the use of soil blocks (Pereczes, 1999) which can also significantly increase earliness. The combined application of seedling growing and floating row cover can advance harvest by three weeks as compared to the traditional technology and can give farmers a three to four times greater income (Kurucz, 1998). Rattin et al., (2006) compared direct sowed and transplanted sweet corn varieties, without covering and concluded no difference, in ear weight and ear length, between transplanted treatments plant's, in comparison to direct sowing treatments plant's.

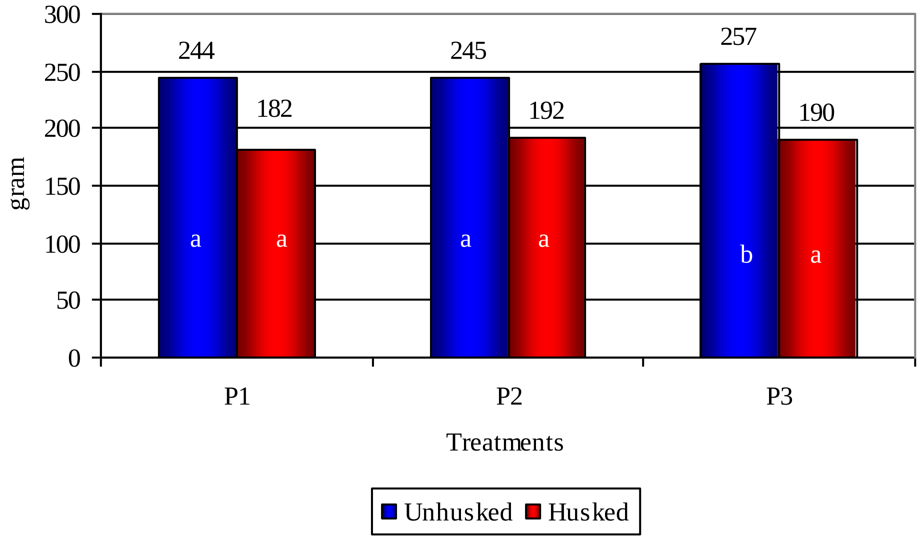
Materials and methods

The experiment was set up in 2014 on an area eqiupped for irrigation at Tg-Mures, Mures County, situated in Central part of Romania. Conventional, reliable and sufficiently known among growers sweet corn variety, Spirit, was used as a reference variety in the variety comparison trials of the Central Agricultural Office. Hybrid has short growing period of 85 days and yellow kernels. Average height of plants is 159 cm, average ear height is 37 cm, ear length 19.6 cm and average ear weight is 245 g. The variety was granted official recognitions in 1988 and has been the dominant variety of the early ripening category till now. In the year prior to the experiment the area was under wheat.
The following treatments, each with four replications, were applied during the experiment:
P1 = plants transplantation with floating row cover, normal period (25th April)
P2 = direct sowing of plants with floating row cover, normal period (25th April)
P3 = direct sowing of plants without row cover, normal period, regarded as control (25th April)
For the frame structure of the treatments with cover we used ø 4.2 mm zinc coated wire coils. The fleece, 60 cm in width, was stretched over a small tunnel of 40 cm in height and then its edges (25-25 cm, respectively) were covered with soil using a hoe and the its ends were tied to the stakes hammered down. The construction of the frame structure and the setting out of the fleece cover were carried out at the same day as direct seeding and out planting.
For the purpose of seedling growing, the seeds were sown on 4th April 2014, in trays with rigid walls having 3.7x4x5.4 cm size. For growing the seedlings, commercial mix made of white peat 10-20 mm, PG Mix 1 kg/m^3 + micro nutrients, bentonite 40 kg/m^3, pH 5.5-6.5 was used. The seedlings were planted out at the 3 to 4 leaf phenological stage. At the two propagation times the treatments P1 and P3 were covered with Novagryl floating row cover, having a weight of 19 g/m^2, (using the small tunnel technique) in order to enhance earliness. The stand was created to contain 60,607 plants per hectare, according to the recommendations of the owner of the variety, at a spacing of 110+40x22 cm in twin rows. Each plot had an area of 6x3.5m (8 parallel rows and 16 seeds sown in each row). Sowing depth was 3 cm. The edge was the respective outer rows of the 4 twin rows of the plot.
In October 2013, 35 t/ha of farmyard manure was worked into the soil with ploughing on area. Nitrogen fertilizer (120 kg/ha) was applied at the 6-7 leaf stage, the form of top dressing. The fertilizer application was worked into the soil with a rotary hoe.
Ears were harvested together with the husks, from the two central twin rows. Twenty ears were selected from each row and the following measurements were carried out:
weight of unhusked and husked ears (g);
total ear length (cm);
length of seeds (mm);
ear diameter (mm).
The statistical analysis of the results was carried out by using the programme *RopStat 1.1.* When the standard deviations were identical the mean values were compared by pairs using the *Tukey-Kramer* test, while in the case of the non identical standard deviations the means were compared using the *Games-Howell* test (Vargha, 2007).

Results and discussion

According to obtained results, harvesting time (measured in days) was the shortest in the treatment P1 and P2, merely 64 (VI. 28.), respectively 83 (VII. 17.) days, i.e. the corns became ready for harvest 21, respectively 19 days earlier compared to P3 (control) (VII. 19.). In case of P2 treatment, harvesting began 2 days earlier compared to P3 (control).

Results of the one of the major characteristics in connection with yield rating, unhusked and husked ear weight, are summarised in Figure 1.

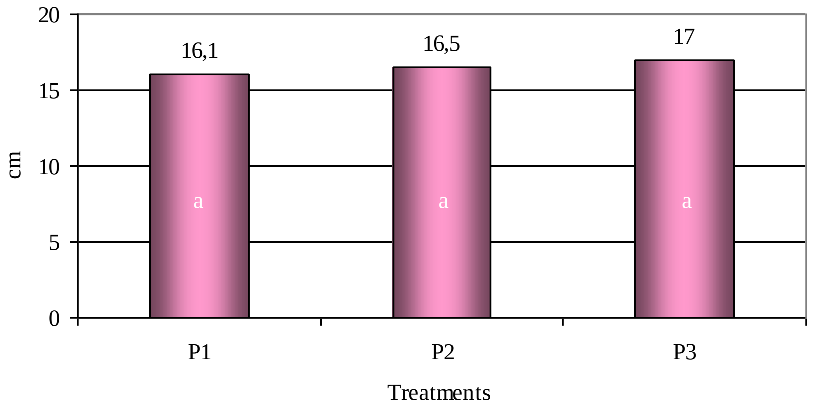


F(5;176)=2,856
F(5;174)=7,201
Sd=99%

Figure 1. Unhusked and husked ear weight (g)

Analysing the data measured for unhusked ear yield, it is noticeable the average weight of the ears of transplanted covered P1 and direct sowed covered P2 treatments was significantly (at *p<0.01* level) lower as compared to direct sowed, uncovered P3 (control) treatment. Covered treatments P1 and P2 unhusked ear weight compared to each other presented no difference. Measured highest value of husked ear weight, but not significant statistically was observed by ears of covered, direct sowed (P2) treatment.

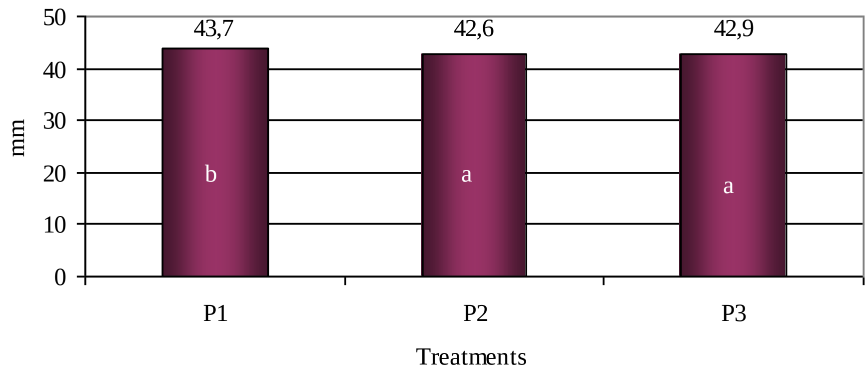
The data concerning an important characteristics for market appeal (total ear length) are contained in Figure 2.



F(5;174)=11,000
Sd=99%

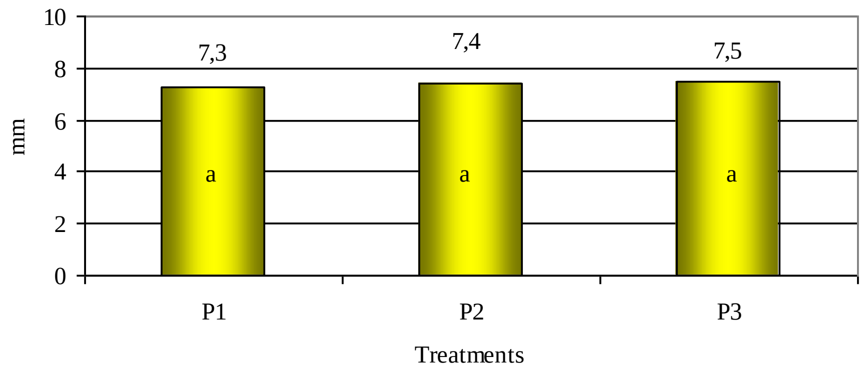
Figure 2. Total ear length (cm)

The length of the covered, transplanted treatment P1 shorter compared to the ear length of direct sowed, covered (P2) and direct sowed, uncovered (P3, control) treatments. No statistically demonstrable difference was found between ear lengths of covered, direct sowed P2, uncovered direct sowed P3 (control) treatments.
Total ear length, average ear length 19.6 cm as measured in the variety comparison trials, had been not achieved by the above mentioned treatments.
Other important characteristics for market appeal (total ear diameter) is presented in Figure 3.



F(5;174)=4,440
Sd=99%
Figure 3. Total ear diameter (mm)

The measured values were significantly (at *p<0.01* level) higher in case of transplanted, covered treatment P1 compared to covered, sowed treatment P2 and uncovered, sowed treatment P3 (control) treatments. Total ear diameter of covered, sowed treatment P2 and uncovered, sowed (P3, control) treatment presented no significantly differences.
Length of seeds is an important characteristic for yield quantity is presented on Figure 4.



F(5;174)=1,248
Sd=99%
Figure 4. Length of seeds (mm).

The measured length of seeds values were higher in case of covered and uncovered, sowed treatments P2 and P3 (control) compared to covered, sowed P1 treatment. Length of seeds of transplanted, covered treatment P1 and covered, sowed P2, uncovered, sowed P3 (control) treatments no significantly differences were found.

Conclusions

Based on the results of the 2014 year experiment, the following conclusions can be made:
The growing period was significantly shortened with transplantation of sweet corn plants compared to direct seeded.
Harvest time occurred 21 days earlier in the case of normal time, transplanted and floating row covered (P1) application compared to normal time, direct sowed, uncovered, control (P3) treatment, and 19 days earlier compared to normal time, direct sowed, covered P2 treatment.
At the same time the floating row cover produce 2 days shortening in the growing season between P1 (transplanted plants with floating row cover) and P2 (direct sowing of plants with row cover) treatments.
The fleece covering had favourable effect on studied morphological characteristics of plants that are transplanted and floated with row cover.
In case of direct sowed treatment (P2) the effect of covering had positive effect on unhusked and husked ear weight, length of ears and length of seeds.

Abstract

The purpose of research is to highlight the content of vitamin C, beta-carotene, potassium and phosphorus in the eight local pepper populations in southern Oltenia, Nettle and Ianca localities Romaniaon two different soils as a structure. Because the soil plays a decisive role in the cultivation, development and production of significant crops in the pepper crops studied, the agrochemical determinations carried out on the soil confirm the importance of knowing its composition and especially the accessibility of the nutrients from the organic soil reserve.
The actuality of this research results from the need to fully know the nutritional value potential of pepper in the areas studied. Acquiring these results will help future vegetable and nutritionists, develop a broad range of organic products for food, cosmetics, pharmacy and health.
In this way, the knowledge of the biochemical composition of the peppermint fruit comes in addition to the vitamin requirements required by our body but also used as a biostimulator of blood circulation in treating various colds, sore throats, relieves rhinitis, treats gingivitis, regulates Blood pressure, intensifies poor peripheral circulation, prevents gastric ulcer and especially in rheumatic treatment.The naturist remedies as well as the culinary ones recommend the pepper to be enumerated as one of the main vegetables from Romania which are very sought and consumed.
The purpose of the paper is to develop the theoretical and practical bases for highlighting the role of chilli pepper in the development of the food industry, the pharmaceutical industry, cosmetics and health, the use of the biochemical composition of chilli peppers, the determination of the growth potential of these industrial branches and the argumentation of some proposals for efficiency Use of chilli pepper properties for multiple purposes.

Keywords: *Pepper, Beta-carotene, Potassium, Phosphorus.*

Introduction

Capsicum annuum L is an annual plant of the solanaceous family. Being a plant known to many of us, but not knowing how beneficial it is that the herb or pepper can be used even as an ornament plant. Hot pepper is perhaps the plant with the most health benefits, and its consumption prevents certain diseases.
There are many vegetables with real therapeutic properties, but hot pepper is a real drug, and the what do you mean with quicker it is, the richer it is in substances beneficial to the body.
Beta-carotene from chilli pepper is not only a powerful antioxidant but can be converted into vitamin A, a vital nutrient for the health of all epithelial tissues. Beta-carotene may be useful in reducing the symptoms of asthma, osteoarthritis and rheumatoid arthritis.
Amongst the known vegetables, pepper has a multitude of benefits for human healthy (Ciofu R., et al., 2002). Pepper takes part of the genus*Capsicum* and is known as *Capsicum annuum L*. It is a source rich in vitamin C, the most known vitamin, which is an antioxidant being important in infections prevention and treat.Vitamin C treats colds, removes the fatigue and anxiety sensation and strengthens the immune system. The vitamin C necessary for an adult varies between 60-80 mg/day. A particular importance for the organism is also represented by beta-carotenewhich is

taken from fruits and vegetables and when it reaches inside the organism is transformed in vitamin A, being acknowledged for improving the immune system and the sight. There is not a daily quantity recommended by specialists until now (Bosland P.W., 1999; Enăchescu G., 1984).
Because the proteins are part of every cell from the organism, being implicated in all its functioning processes, the knowledge of vegetal protein quantities existent in every aliment is important, because the daily necessary is 1g/kg of body depending on gender and age, and the pepper fruits have also in their composition small quantities of protein (Sărăcin I., et al., 2010; Somoș C., 1967).
The consumption of pepper combats cancer, stimulate the pancreas and helps at lungs function. Last, but not least, the pepper is used with success in diet, helpful at weight loss. It helps to the stimulation of our metabolism, through the action on vein structure (Lazăr V., 2006). Pepper is one of the most adequate remedies for high blood pressure, cleans arteries and has contribution in decrease of bad cholesterol or triglycerides(Ulrich A., 1996).
Given that the cardiovascular diseases are the first cause of death on globe, the proprieties of pepper are particularly important. Pepper is beneficial both for stomach and gastrointestinal tract, because it stimulates the peristaltic movement, helps to eliminate feces and contributes at the construction of stomach tissue, easing the heal of stomach injuries and intestinal ulcers(Sărăcin I., et al., 2010).
When pepper is consumed, it triggers a heat sensation in the whole body and for this reason it was recommended in case of frostbites. Sharply and spicy, pepper is added in different types of tasty food from all over the world.
Depending on the nutritional values peppers can be recommended for consumption fresh, canned or dried, for pharmaceuticals and herbal medicine or both,knowing that natural medicine is making giant steps in improving or curing serious diseases or diseases for people's health, where chemically prepared preparations are successfully replaced with herbal preparations or medicinal, aromatic or spontaneous plants.

Material and Methods

The carried out by placing chilli peppers from the local communities of the two communes in southern Oltenia, namely Urzica and Ianca, where we monitored the contents of vitamin C, beta-carotene, potassium and phosphorus of pepper harvested in technical maturity. Because soil has an important role in crop technology, we also performed soil analyzes before the cultivation began, namely April 12, 2015.
The chemical composition of the plant is a synthetic indicator that reflects the plant's biological peculiarities, and the correct interpretation of plant analysis results can only be made taking into account agrochemical soil indicators.
Methods of work used for physiological determinations of plants targeting the production of hot chilli peppers from the eight popular cultivation will be subjected to biochemical analyzes for the determination of vitamin C, beta carotene, phosphorus and potassium.
The nutrition conditions in the soil, determined both at the level of natural fertility and applied technologies, are another important factor of variability of the chemical composition of chilli plants, which requires soil agrochemical analysis prior to the establishment of crops experimental.
The soil samples were harvested using an agrochemical probe at depths of 0-10 cm and packed in plastic bags until they were brought into the laboratory. The sampling took place on 17.07. 2015 for the two communes of Urzica and Ianca.
Samples of hot chilli peppers harvested in the technical maturity phase are packed in perforated plastic bags and taken during the same day in the laboratory.
The P-content in the extract obtained by the mineralization is colorimetric with ammonium vanadate and the P content of the vegetal material is expressed in% P from the dry matter and is calculated by the relationship (Bergman et al., 1976):

P% = C x Vt x 100 / Va x m x 1 000 000

in which:
C - The content of P in micrograms of the aliquot used for colorimetry
M - The amount of vegetal material used for mineralization in grams
Vt - Total volume of the extract obtained from the mineralization in ml
Va - Volume of the aliquot part used for colorimetry
100 - Percentage reporting factor
1 000 000 - Transformation factor of micrograms in grams
The determinations for K was carried out by flame emission photometry and the results obtained from the K-dosing of the plant material are expressed as a percentage of the dry matter as follows:

K% of SU = C x V x r x 100 / m x 1000 000
K% of SU = C x V x r / m x 10 000

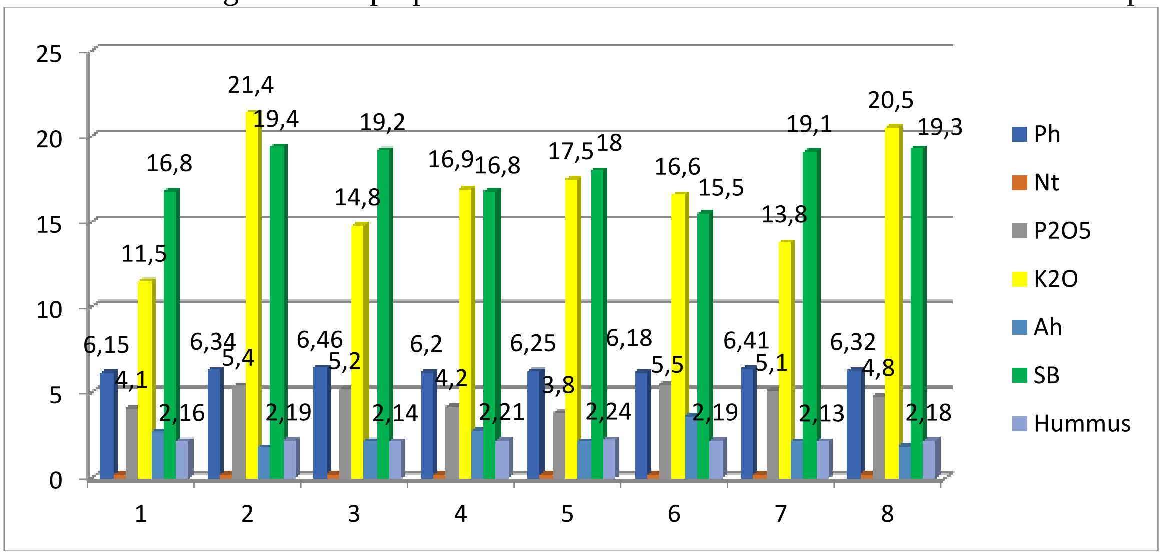
where:

C - Concentration in micrograms K / ml, found on the calibration curve
V - Volume of the diluted solution used for dosing in ml
R - The dilution ratio used
M - Amount of vegetal material used in mineralization expressed in grams
For the determination of the vitamin C content of the pepper, the titration method was used and the titration result multiplied by the coefficient 8,8 being expressed in mg of ascorbic acid per 100 g of fresh substance (mg%). Beta-carotene was obtained using the photocolorimetry method.
Chemical and hydrophysical analyzes were performed on the soil, so pH determination was performed by potentiometric methods, Ah - the soil was treated with the solution of an alkaline hydrolyzate state and 0.1 N sodium hydroxide in the presence of phenolphthalein.
Sb was determined by Kappen method, phosphorus and potassium by the Enger-Riehm-Domingo method, Walkle and Black humus and Nt by the Kjeldahl method.

Results and Discussion

Analyzes and results are presented in the tables below, with soil samples being collected from eight different sites. The soil of the Ianca commune is a cambic faeoziom (cambic cernoziomoid soil), and the Urzica commune is an argil faeoziom, ie an argiloiluvium chernozem.

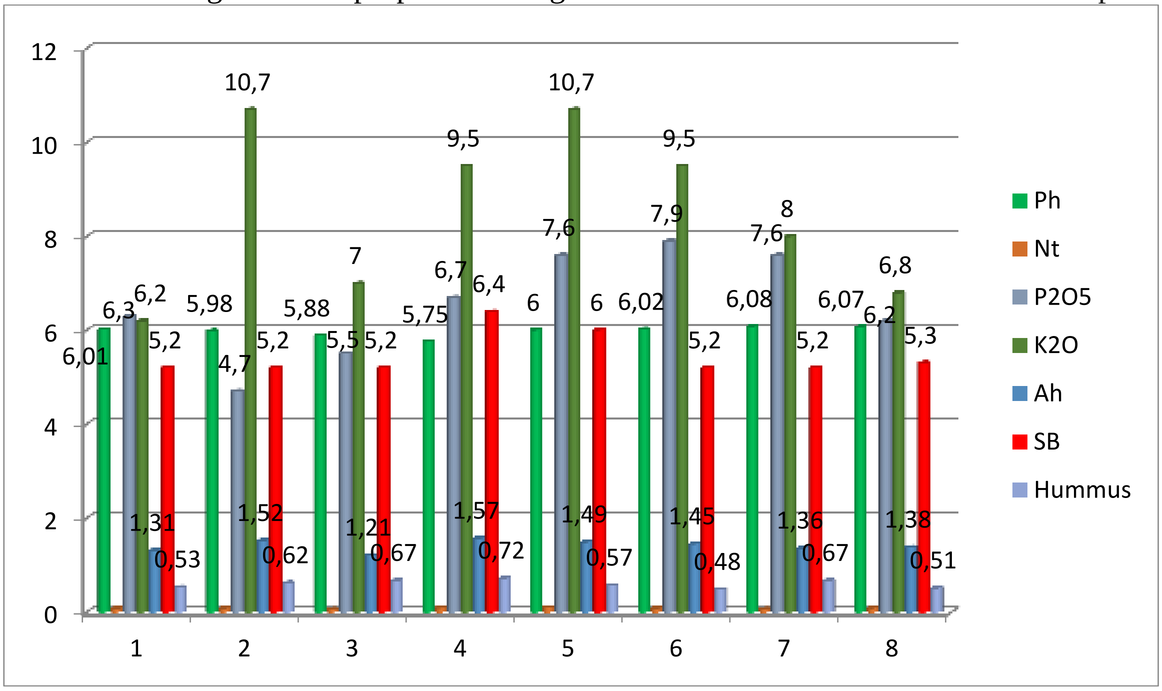
Figure 1. Determining chemical properties of cambic chernozem from Ianca at 0-10 cm deep



*Source: Elaboration by the author

Soil from Ianca village, Olt, has a good pH, accessible to vegetable crops, and the humus content gives a high profitability by producing increased yields.

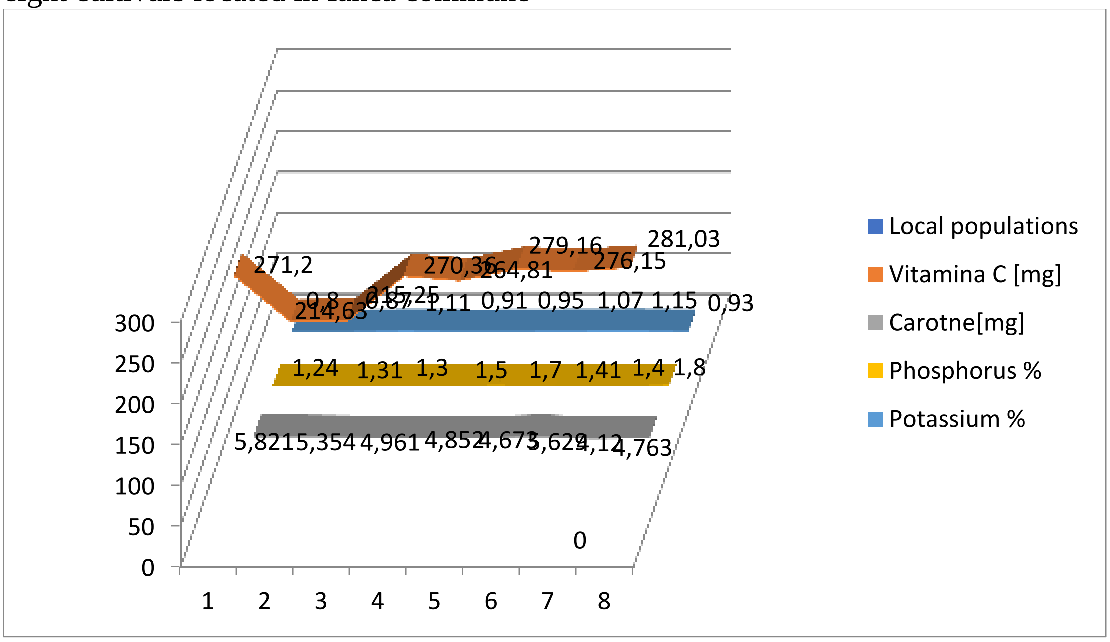
Figure 2. Determining chemical properties of argic chernozem from Urzica at 0-10 cm deep



*Source: Elaboration by the author

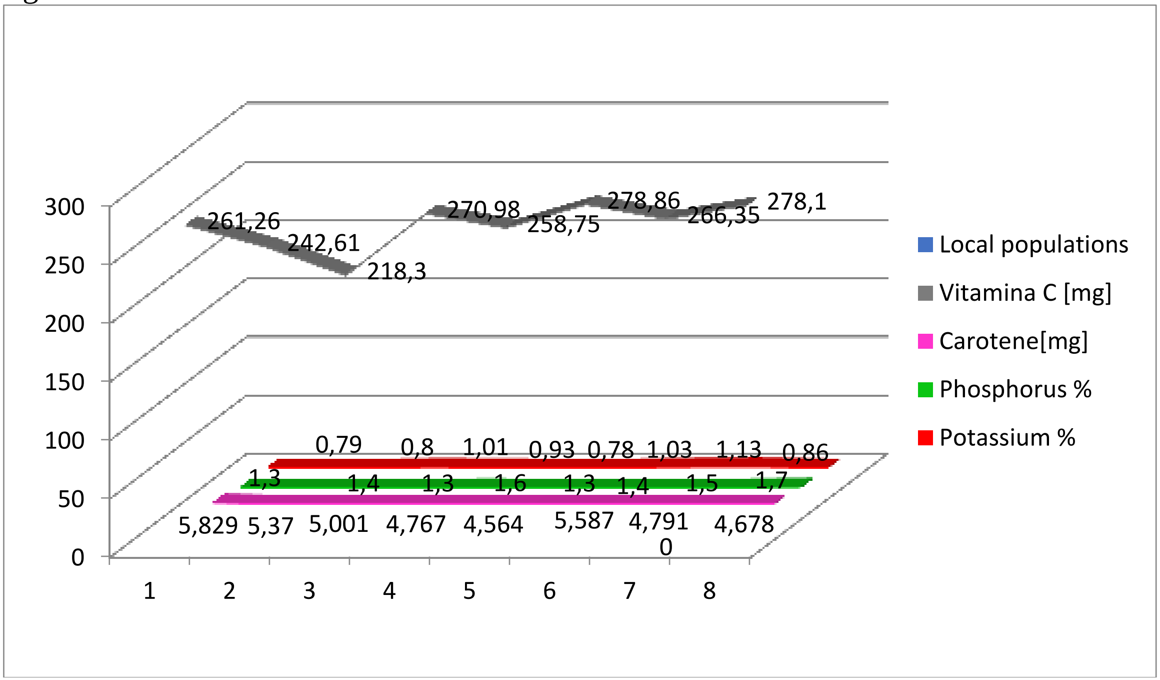
The differences between the two soil types are relatively small and difficult to identify on the ground but are highlighted by laboratory analytical data. In terms of chemical properties, the two soils studied have high phosphorus and potassium content, which gives them a good natural fertility. When determining the four active principles obtained from the biochemical analyzes of the hot pepper, it can be ascertained that the best results were obtained for vitamin C, cultivar number 8 from Ianca commune, and for carotene was evidenced the cultivar numărul 1, for the phosphorus cultivar number 8 and for the potassium cultivar number 7.

Figure 3. Determination of the vitamin C, beta-carotene, phosphorus and potassium content of the eight cultivars located in Ianca commune



*Source: Elaboration by the author

Figure 4.Determination of the vitamin C, beta-carotene, phosphorus and potassium content of the eight cultivars located in the commune of Urzica



*Source: Elaboration by the author

The results obtained from the cultivars located in Urzica commune, vitamin C is found to be higher at cultivar number 6, carotene in cultivar number 1, phosphorus at cultivar number8 and potassium at cultivar number 7. bFollowing the obtained, the active principles determined from the eight cultivars in both communes, behaved almost similarly in both communes. These results obtained by biochemical determinations are necessary materials which will represent the study object for obtaining pharmaceutical products which have components obtained from pepper as active substance, knowing that the replacement of chemical-obtained products with naturist products is tried with success. The modern agriculture from nowadays, along with all the sectors related to it in Romania, make the scientists to do different studies and put into practice the obtained results for promoting naturists products in alimentation as well as in naturist and beauty medicine.

Conclusions

The local cultures studied have succeeded in achieving the proposed goal. Nutritional values are influenced by soil, climate, color, and harvesting. Following the analysis for the determination of vitamin C from the eight cultivars located in the two communes, the best results were obtained by cultivars number 8 and number 6. Determination of carotene from the chilli pepper to the eight cultivars, the most significant results for carotene belonged to cultivar number 1 for both ommunes. Determinations of phosphorus and potassium content in cultivars number 8 and number 7 for both communes yielded the best results. As a result of the results, it was found that the majority of the local poppy cultivations behaved very well in the described locations, so we recommend their acceptance as varieties with a local name in the vegetable culture, for the diversification of the peppermint varieties in our country, for the enlargement food, natural and pharmaceutical, and the benefits of certain active principles underlying the composition of hot pepper.

Abstract

The research is circumscribed to the latest global concerns. We note that the field research has evolved a lot, due to several reasons:
the importance of ensuring sustainable development;
the role that agriculture has in the economy and society;
growth of risks in agriculture due to climate change;
high volatility of outputs, costs, prices and incomes on farms.
In this respect, in order to carry out this research, a significant role belongs to the identification of the different types of severe meteorological phenomena and the agro-climatic risk aspects. Thus, first of all, the phenomenon of agricultural drought will be described, starting from a general look at the definitions, concluding that at the conceptual level in the literature the definitions of drought are numerous and are based on the meteorological parameters, singular And/or in combination, but in direct correlation with the moisture requirements of the plants during the main phases and specific interfaces of vegetation. A drought-related damage dimensioning is also carried out according to the intensity and duration of disturbing factors (winter drought, spring drought, summer drought, autumn drought). Also, the characterization of the above-mentioned phenomenon is made, starting from agrometeorological/agro-climatic parameters of risk/thermal, atmospheric and hydric stress, defining, characterizing and identifying the singular and/or complex production of the agricultural drought phenomenon. The following result, the selection of the agro-climatic risk types according to the main characteristics of production and effects (materialized in a risk taxonomy), was obtained on the assumption that an overview of some definitions of the agro-climatic risk types defined by the indices Agrometeorological and agro-climatic shows that the risk/thermal stress or water stress can be classified according to the basic criterion used in the analysis and assessment of the effects on each agricultural species. It was also considered that agrometeorological/agroclimatological literature specifies the agro-climatic risk types based on agrometeorological/agro-climatic parameters singly or in combination and in direct correlation with the requirements for plant vegetation conditions by phases and Specific interfaces, as well as the active season as a whole. Thus, the types of thermal and hydric risk, respectively the heat, rainfall and atmospheric, pedological and agricultural drought, defined and characterized according to the specific criteria of analysis, the taxonomy of the risks was made. For each type of agro-climatic risk, three levels of risk characterizing vulnerability to thermal and hydrological risk have been identified - excessive, strong and moderate risk.

Introduction

Recent research by ANM researchers, which we are grateful for the research made available as well as for the data we later used in the construction of the Seleanynov indices.
The scenarios on the impact of climate change in the Caracal micro-zone on wheat and maize crops have taken into account the models CERES-Wheat (DC Godwin et al., 1989) and CERES-Maize

(JT Ritchie et al., 1989). Daily basic biophysical processes occurring at the soil-plant-atmosphere interface in response to the variability of environmental factors.
The impact assessment of climate change on autumn wheat and maize crops was based on climatic scenarios derived from regional climatic models (RegCM) for two distinct periods, namely: 2021-2050 and 2071-2100.
These scenarios predict future climate change by modifying monthly averages of monthly air temperature, rainfall, and solar radiation values that have been applied to the current climate adjustment. The simulated results under conditions of climate change were compared with those simulated under the current climate and the changes in the production levels and the length of the vegetation period were thus quantified.
As a secondary objective, we intend to analyze the evolution of the areas, production and average production during the period 2004 - 2012, at the Caracal micro-zone and the localities of this micro-zone, for wheat, corn and sunflower crops and to see to what extent They were affected by changes in climatic factors. Research on the impact of climate change on sustainable development is achieved through a complex and integrated approach to information in a comparative system of analysis and identification of risk situations in the agricultural field. As far as the impact of climate variability on growth, development and training of agricultural crops is concerned, it is quantified by the potential of meteorological parameters to ensure optimal vegetation conditions or unfavorable effects, depending on the degree of intensity of the disturbing factor, the mode and duration of action, The vulnerability of plant species to extreme weather events. In Oltenia, in general, there were no studies of physiological processes determined under different environmental conditions, respectively water year (2002) and climatic normal (2003), for corn culture "presented in his paper By Pandia Olimpia (2006). Thus, Barrett (1999) puts the issue of environmental regeneration as an objective and major necessity that arises from the irrational exploitation of resources (which becomes anthropogenic risk, which is a potential risk factor for other risks, with a direct impact on development Durable), a problem that must be thought globally, at the level of spatial and temporal dimensions that satisfy, for at least a long time, the human collectivity.
Sorocovschi (2003) highlights the functional complexity of risks and catastrophes resulting from a large number of factors, components and impacts, reflecting their multidisciplinary and interdisciplinary character. An interesting contribution is the dual risk approach, meaning both the losses and the earnings they produce (Denmead 1960). Another interesting contribution is presented by Berbecel (1980) and Iagăru (2001), which highlights the extent of human risks related to climatic and environmental risks. At present, atmospheric pollution is increasingly "incriminated" by the global climate change, which, if produced, would be the most dangerous natural hazard possible for mankind. In the year (2013), Sărăcin Ion and his colleagues report "The result of poor agricultural practices regarding the quality of sandy soil in southern Oltenia", due to all the climate changes and the mistakes of applied agricultural technologies.

Material and Methods

The studies and researches were carried out in the Caracal micro-region of Olt, Romania, which includes 8 communes (Brastanovatu, Bucinişu, Deveselu, Obârşia, Redea, Rotunda, Traian and Vlădila) besides the city of Caracal. Agriculture in the localities of this micro zone is well represented, the data presented being eloquent.
The year 2012, reported at the level of Olt county, with a total area of 549,828 ha, the area of the micro-region was about 47,696, or about 9%. A similar share also holds in terms of the agricultural area, Caracal microzone, with about 41,416 ha, accounting for 9.5% of the agricultural area of Olt County. As for the arable land, the Caracal microzone with the 40,532 ha had, at the level of 2012, a share in the county of over 10% of the total arable area.
A first category is represented by qualitative research methods such as: analysis, synthesis, comparison, use of induction and deduction analysis couple, and comparative analysis.

Another set of tools are the quantitative models: statistical processing, accompanied by specific research tools, such as: sorting, structural analysis and dynamics, then statistical and economic analysis, econometric models.
Thus, we have identified the statistical links, links and interdependencies that are formed between different phenomena and processes and the degree of correlation as a method by which we studied the relation and the interdependence between two phenomena or characteristics of a phenomenon expressed numerically.
When increasing the values of a characteristic is accompanied by an increase in the value of the other characteristic, the correlation is direct. When increasing the value of a characteristic corresponds to a decrease in the value of the other characteristic, the correlation is inverse.
We have also identified the degree of functional dependence, that is the correspondence that can be established between two variable sizes, so that, given an arbitrary value of one of the two sizes, it uniquely determines the value of the other magnitude. The two functionally dependent variables can be qualitative or quantitative characteristics.
The most commonly used climate change indicators (temperature, precipitation, and mixed) were selected, among which we chose Seleanynov, which are considered to be representative of our research.
We compute the Seleanynov agro-climatic indices using the formula:

$$SHR = \frac{\sum \text{rainfall}}{0.1x\sum \text{temperature/medium}} \tag{1}$$

The index is one of seasonality, measuring variations in phenomena in different periods of the year. These are phenomena that normally have seasonal oscillations (temperature and precipitation).
The average index was calculated as the average of the individual indices showing the variation of the same characteristics across the different groups of units.
These were determined for three important crops for the analyzed micro-zone: wheat, maize and sunflower.
We used the calculation of agro-climatic indexes of Seleanynov type in regression functions, which analytically describe the dependence between a resolving characteristic and a factorial characteristic. With this help we synthetically expressed the character and the direction of the connection between the phenomena.
The regression function mirrored the way in which the resolving characteristic changed under the incidence of the change in the factorial characteristic, leaving out the influence of other characteristics considered random and consequently not included in the analysis.
In our analysis, the regression function was a linear one, the resolving characteristic changing evenly under the influence of the change in the factorial characteristic, the linear function we used with the formula:

$$Y = a + b\,x. \tag{2}$$

Where the values of the resolving characteristic y depend only on the values of the factor x. All other factors are considered constant.
Geometric, the regression coefficient b represents the straight line slope. In the theory of correlation, he shows how large the change of y is, as a result of changing the variable x, by a unit. Therefore, if x increases with a unit, the value of y changes exactly to the size of b.
The regression coefficient b was calculated by applying the smallest squares method.
Between the linear regression coefficient b and the correlation coefficient r was the relation:

$$b = \frac{\sigma y}{\sigma x}\,\mathrm{r} \tag{3}$$

Where σy and σx are the quadratic mean deviations of the y, respectively x, σy and σx concrete characteristics, expressed by a certain unit of measure.

From their report, the linear regression coefficient shows how many units of the variable y return to a unit of the variable x. In our case the coefficient has an inverse correlation.
The correlation coefficient used to determine the correlation intensity was calculated according to the formula:

$$r = \frac{\sum(x-\bar{x})(y-\bar{y})}{n\sigma x \alpha y} \qquad (4)$$

in which:
X - the values of the factorial characteristic;
Y - the values of the resolving characteristic;
Σ x - the average square deviation of the x characteristic;
Σ y - the mean square deviation of the y characteristic;
N - the number of observed values pairs of the x and y characteristics;
or

R = xy - x - y σxσy (5)

in which:
Xy - mean of products xy (xy = xyn)
X and y - the x and y attribute averages. For the calculation of the correlation coefficient the following formula was used:

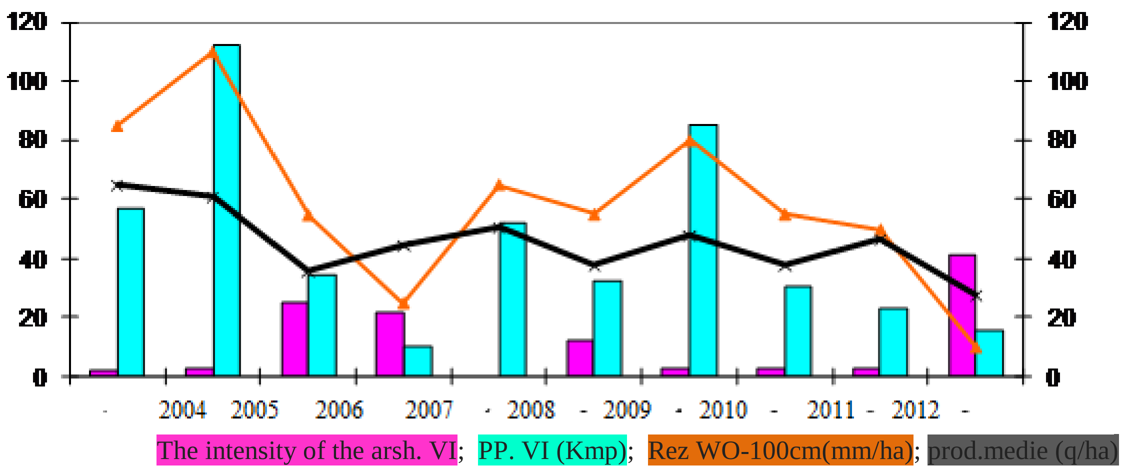
R = nxy-x (y) [nx2- (x2)] [ng2- (g) 2] (6)

We then determined the adjustment curve, which was useful, and had to be done taking into account the character of the data to be adjusted. For this, a continuous function, adjustment function, was used with a number of three parameters: temperature, precipitation, production.
The methodology for determining the tendencies and anomalies of the thermal and pluviometric extremes in the Oltenia region aimed to determine and analyze the trends and thermal anomalies of the maximum and minimum monthly temperatures as well as the tendencies of the maximum precipitations within 24 hours in the Oltenia region. For this, we took into account the homogeneous data series for the period 1961-2000 at the meteorological stations in the analyzed region.
Methodology: The monthly average monthly temperature (TXL), monthly minimum temperature (TNL) averages and monthly monthly precipitations in 24 hours (CPT) were determined and analyzed.
The simulation models used to develop climate change scenarios and influence on agricultural crops were those used in NMA research and are CERES (Crop-Environment Resource Synthesis), developed under the auspices of the IBSNAT (International Benchmark Sites Network For Agrotechnology Transfer).

Results and Discussion

Annual fluctuation of climatic factors leads to significant variations in agricultural output from one year to another, and knowledge of the impact of climate variability on vegetation and yields is one of the direct applications of agro-meteorological scientific research in agriculture.
The use of plant protection measures in order to reduce the limiting effect of climatic conditions, especially temperature and precipitation, is clearly reflected in the level and quality of the yields obtained in any area of culture, especially the drought, both irrigated and irrigated.
The analysis of the fluctuation of agro-climatic resources through the dynamic evolution of agro-meteorological/agro-climatic factors is the basic criterion in quantifying the impact of agricultural drought on the state of vegetation and the productivity of agricultural crops.
This way of characterizing and assessing the influence of climate variability on cultivated species/species requires the monitoring of meteorological/climatic factors in terms of evolution of vegetation accumulations (duration and passage of phenological phases) corroborated with

agricultural practice, and differentiated cultivation technology differentiated according to specific agropedoclimatic conditions.
The Caracal Plain, which is the area of interest of this paper, is an agricultural area with a generally dry climate, especially the autumn and summer season, the frequency and severity of droughts produced in these seasons being increasing.
In the agrometeorological research activity, the impact studies in the agricultural field are based on meteorological/climatic data from agro-meteorological programs and the archive of climatology (INMH archive), as well as on the basis of specialty, phenology, biometrics and production measurements carried out Both in the standard platforms of meteorological stations and agrometeorological programs, as well as in production fields located near the weather stations.
For the agricultural area of the Caracal Plain, the Caracal Meteorological Station with agrometeorological program is considered representative and meteorological and agrometeorological meteorological and meteorological observations are monitored for a minimum 30-year reference climate according to the WMO guidelines and norms.
Therefore, in order to assess the influence of climate variability on the vegetation state and yields on the main cereal crops in this area, namely autumn wheat and maize, with a significant weight in the structure of the field crops in the south of the country, meteorological data were used And agrometeorological data from 2004-2012.
From the Meteorological Station Caracal and specialized/technological data, respectively average production/ha, from the Caracal Agricultural Research Station and OLT County Department of Agriculture.
Combined action of agro-meteorological parameters of thermal and hydric stress, respectively days with maximum temperatures in air that exceed the biological critical threshold of 32 ° C of wheat plants associated with absent or insufficient rainfall (<10 l/mp/month) determines the significant decrease Of the soil water reserves up to values that characterize the occurrence of pedological drought with varying degrees of intensity, the annual variability and the decrease of crops being in evident correlation with the evolution of the climate (fig.1).
Reference data/figure 1: Extreme/drought-free agricultural years are highlighted:
2004-2012:
• the intensity of "heat": VI = 25,3 units of heat;
Precipitations: VI = 34.3 (l/mp;
• Soil water reserve/0-100 cm: VI = 54.8 mm/ha;
• Medium production: 85: 36.0 q/ha
Figure 1. Influence of thermal and hydro stress conditions on wheat yields.



*Source: Author

The combined and sustained action of agrometeorological stress and corrosion parameters in maize, respectively, the days with maximum air temperatures exceeding the critical biological threshold associated with insufficient rainfall (<10l/mp/month) caused a significant decrease of the reserves Water from soil to values that characterize the occurrence of pedological drought with varying degrees of intensity, the level of crops thus being in evident correlation with their evolution and duration (figure 2). Reference data/figure 2, which highlights agricultural years of excessive drought:

2006:

• the intensity of the "heat": VII = 46.1 units of heat; VIII = 41.2 units of heat
• precipitation: VII = 6.7 l/mp; VIII = 16.8 l/mp;
• soil water reserve/0-100 cm: VII = 25.0 mm/ha; VIII = 10.0 mm/ha;
• average yield/F 376: 40.8 q/ha

2012:

• intensity of "heat": VII = 78,4 units of heat; VIII = 55.4 units of heat;
• precipitation: VII = 26.1 l/ mp; VII = 1.3 l/mp;
• soil water reserve/0-100 cm: VII = 10.0 mm/ha; VIII = 5.0 mm/ha;
• average yield/F 376: 30.3 q/ha.

Conclusions

The amount of precipitation and its distribution on months and critical vegetation intervals varies from year to year compared to the optimum limits specific to each month, season or agricultural year as a whole, significant negative deviations from them leading to unfavorable conditions for growth and development Plants during vegetation;

The frequency of droughts, giving the agricultural area a dry climate, which requires an increased attention in the choice of autumn wheat varieties, and in the crop technology, the adaptation of the agro-technical measures specific to these conditions, namely the sowing, density, cropping, fertilization, and so on

In the period with maximum requirements of maize plants relative to the temperature factor (july-august), the production of the thermal stress quantified by the phenomenon of "heat" varies in intensity and duration, being differentiated from one year to the next, these cases being considered Extreme thermal risk situations with complex consequences on the state of vegetation and the productivity of crop plants;

The combined action of the heat stress factors ("arsita") and hydric (moisture deficiencies) in july-august, with maximum requirements of maize plants relative to the temperature and humidity resources, respectively the intensity and duration of the phenomenon of "heat" , The amount and distribution of precipitation and the degree of water supply of soils is reflected significantly in vegetation and production levels, depending on the extreme characteristics and prevalence of

intensity, duration, mode of action and persistence of limiting stress factors, drought-specific indicators agricultural;
The results of the research in the Caracal area can be considered significant for the entire southern area of the Romanian Plain through both the approach of the agricultural drought phenomenon and the adaptation of agricultural measures and practices to the risk situations due to this dangerous phenomenon for agriculture.

Abstract

The paper presents how to make an equipment for sowing small seed drill, how to use it and the advantages of using it. The equipment consists of the following: cylinder with pressure chamber and piston, vacuum generator, nozzle distribution ramp and other auxiliary components. The small and very small dimensions of some seeds require a small sowing depth and a distance between seeds to ensure germination and vegetative space after emergence. Typically, these seeds are sown in hand-drawn gutters through scattering. Thus the depth of sowing and the distance between the seeds could not be ensured, and after sunrise it is necessary to repace the work, also by doing that it increases the quantity of seeds per unit area, increases the seed expenses and at the same time it requires a high consumption of labor. To ensure very low seed sowing and seed spacing to minimize seed consumption and minimize labor costs to increase productivity to ensure maximum seed growth and seed growth after emergence , small and very small seed equipment have been developed to ensure that the seeds are placed at the depth technologically set and alsoat the tecnological distance, safe and fast. With its simple construction, the equipment has a low price, is easy to make and use, does not require the user's training and even adapts to automate the sowing process.

Keywords: *sowing, equipment,seeds,depth, distance*

Introduction

The sowing of the small seeds in the seedlings requires the amount of manual force required to carry out the work, the amount of seed used on the surface unit is high, the expenditure is very high, the growing space of the plums is not ensured, the unevenness of sowing and emergence is also high.
The use of the equipment proposed for sowing small seeds in seedlings reduces the amount of manual force required to carry out the work, decreases the amount of seed per unit area, eliminates the performance of works, thus reducing the costs of obtaining the seedlings [Oprean A., 1982; Saracin I., 2009].
The depth of sowing and uniformity of plant growth is also ensured. Equipment is made using plastic materials or components of existing installations and appliances that can be reused.
Experimental studies and trials on production indices, consumption norms, degree of emergence and percentage of plants suitable for planting will continue. On the basis of the rules on influence factors to achieve optimal density, it is possible to determine by crop species, by crop schemes, production implications that ultimately express productivity [Hulea A., 1962; Navid, H., 2011].
The observance of the quality indices of the sowing works contributes to the increase of the agricultural productions both qualitatively and quantitatively. To ensure seed quality, the following requirements must be met:
- compliance with sowing rules;
- Incorporation of seeds at the established depth;
- Ensure optimal sowing density by observing uniform line spacing and seed distribution uniformity.

With the aim of making the sowing density as rigorous and easier as possible, it is proposed to establish a new method of assessing the uniformity of sowing, which can also be used for small seed sown in frequent rows.

Material and Methods

The studies carried out in order to develop equipment that could be used to set up specific crops from small seeds, forestry, floriculture and vegetable species started and takes place in the mechanization laboratories of the Faculty of Horticulture and Agriculture Craiova [Saracin I., 2002 -2004; Scripnic V., Babiciu P., 1979].
To this end, some of the methods used for the sowing of small seeds, whether manual or mechanized, have been studied in the country and abroad (Figure 1); [Valentin D.C., 2012].

Figure 1. Sowing in gutters by hand

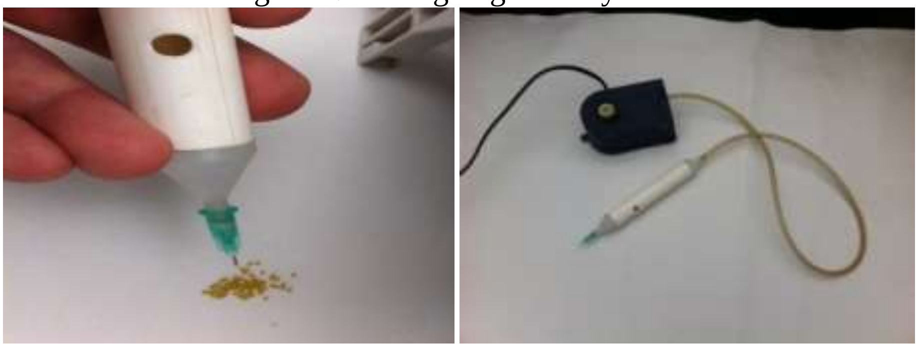

Figure 2. First equipment for seed drilling with seed

For the beginning, some characteristics of the seeds of the forest, floricultural and vegetable species have been studied, shown in the figure below.
The documentation and studies also took into account the following:
- Possibility of sowing directly in the alveoli;
- Successive sowing in several alveoli at the same time;
- Possibilities of adjusting the depth of sowing; [Saracin I., Olimpia Pandia., 2010];
- Possibilities to automate the process of sowing small seeds in the alveoli [Valentin D.C., 2012].

On the basis of the rules on influence factors in achieving optimal densities, production indices which ultimately express productivity can be established by species, by crop type, by crop schemes. Research and experimentation on production indices, consumption standards, will continue. [Saracin I., Olimpia Pandia., 2010; Saracin I., 2002 -2004].
As a result of recent research results, seed consumption norms for seedlings must be established in relation to the average soil emergence index, germination determined in the laboratory, plant maintenance index and percentage Of suitable plants.
The sowing rule can be calculated as follows:
A) Sowing standard in number of seeds per linear gauge, after relation (1):

$$N = i * \frac{100}{R} * \frac{100}{M} * \frac{100}{A} = I * \frac{1.000.000}{R*M*A} \quad \text{seeds/m} \qquad (1)$$

or:

$$N= \frac{I}{L} * \frac{1.000.000}{R*M*A} \quad \text{/ seeds /m} \qquad (2)$$

in which:
N = sowing standard, number of seeds or number of seeds to be sown per meter / m^3/ m;
I = production index per gully meter, / buc / m;
R = the index of emergence; %
G = the technical germination or germination potency indicated in the analysis bulletin %;
M = plant maintenance index;
A = percentage of plants fit for planting. %
b) Sowing standard in grams of grain per meter, after the relationship (2):

$$q = n * \frac{G1000}{1000} * \frac{100}{P} = n * \frac{G1000}{10*P} \quad \text{/ g/m} \qquad (3)$$

and / or

$$q = \frac{I}{L} * \frac{1.000.000}{R*M*A} * \frac{G1000}{10*P} = I * \frac{1.000.000*G1000}{R*M*A*P} \quad \text{/ g/m} \qquad (4)$$

in which:
q = consumption standard (sowing rule) in grams of grain or grain quantity to be sown on the linear meter;
G 1000 = the weight of 1000 seeds, indicated in the analysis bulletins, also indicating the average number of seeds per kilogram - NK;
P = seed purity [%], in the analysis bulletins.

Method of research

The computer application developed in Mathcad determines the number of seeds on a surface converting that image into a binary number system by means of specific mathematical formulas. [Valentin D.C., 2012].
To achieve the uniformity of distribution of a surface sown under laboratory conditions, three distinct steps will be taken:
- calibration of the measuring system;
- collecting experimental data;
- data processing using the computing technique.

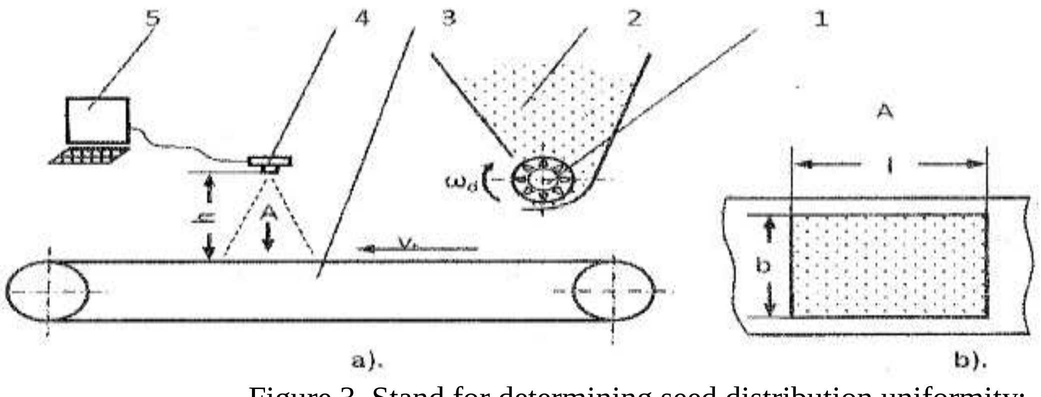

Figure 3. Stand for determining seed distribution uniformity:
a-side view; b-front view

The test stand of the distribution apparatus (Figure 3) consists of:

A. The seed box (1) and the dispensing device (2) driven in rotation with an electric motor (ωd-adjustable);
B. The seed collection system materialized by the belt conveyor (3), simulating the linear movement of the seed drill (vt - adjustable). The adherent surface of the conveyor belt secures seeding to its surface;
C. The WEB camera (4) captures the images at a predetermined frequency according to the speed vt and the angular velocity of the distribution device ωd to avoid overlapping the images. The computing system (5) is used for image storage and experimental data processing.
Calibration of the measurement system consists in determining the position of the WEB camera relative to the conveyor belt through tests. The height h is set so that the width b of the image is equal to the distance between the seed rows b.

Results and Discussion

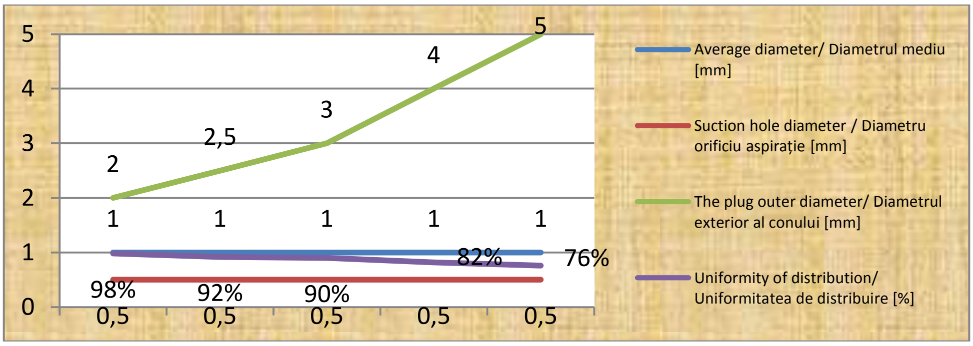
Made of a 35mm diameter cylinder, fitted with a rod-shaped pistol that seals the cylinder and pa that divides it into two chambers. The upper chamber called the atmospheric pressure chamber and the lower chamber called the depression chamber. The atmospheric chamber is connected to theatmosphere through a hole which can be closed or opened by the piston that moves inside the cylinder. The depression chamber is in relation to A vacuum generator and can be closed or opened by the same piston, but also with the distribution ramp of the apparatus.
The distribution ramp is the part of the apparatus provided with nozzles of different diameters depending on the smallest size of the seed to be sown. The nozzle diameter of the nozzle is about 0.7 of the smallest seed size.
The number of nozzles on the ramp is equal to the number of alveoli on the sowing tray. The nozzles may be provided with one or more apertures depending on the need of the culture to be set up. Also, the nozzle support rod allows movement of the nozzles to Adjusting the distance between them, depending on the size of the alveole.
In the lower part of the cylinder is mounted a plastic limiter that serves the user to adjust the depth of sowing.

b.

c. d.

Figure 4. Sowing equipment in alveoli, a and d with multiple distributor, b and c mono distributor

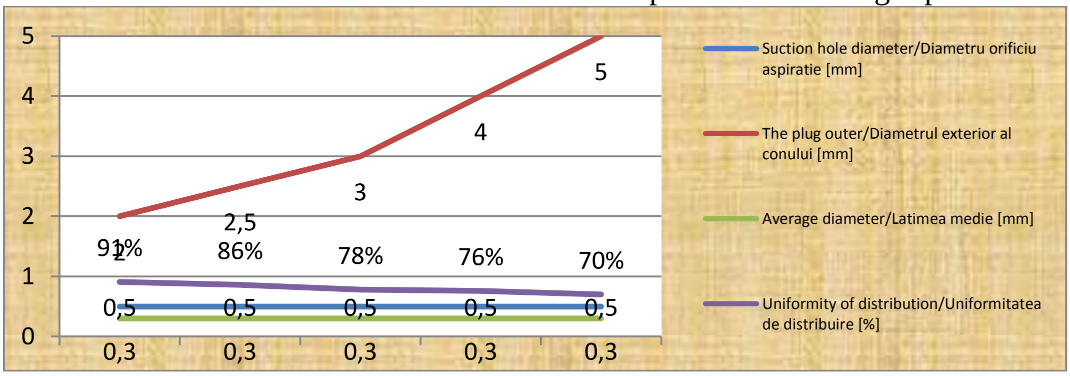
The results obtained in the laboratory regarding the distribution uniformity for the saplings of eggplant, eggplant and tobacco are presented in the graphs of figures 5, 6 and 7:



*Source: Elaboration by the author

Figure 5. Uniformity of distribution for small sprouts with 1 mm diameter diameter and 0.5 mm suction hole diameter

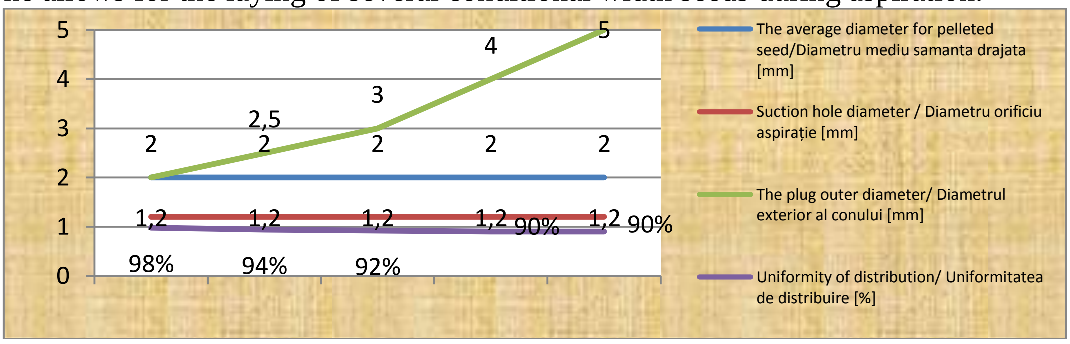
From the graph shown in Figure 5, it is noted that the seed distribution uniformity decreases with the increase in the outer diameter of the cone. Probably due to the fact that the surface between the orifice and the outside of the cone allows more seeds to be placed on it during aspiration.



*Source: Elaboration by the author

Figure 6. Distribution uniformity for small eggplants with an average diameter of 1 mm and a suction hole diameter of 0,5 mm

From the graph shown in figure 6, it is noted that the seed distribution uniformity decreases as the cone's outer diameter increases. Probably the resulting surface between the orifice and the outside of the cone allows for the laying of several conditional width seeds during aspiration.



*Source: Elaboration by the author

Figure 7. Distribution uniformity for small-sized tobacco seeds with average diameter of 1 mm and inlet diameter of 0.5 mm

From the graph shown in figure 7, it is noted that the seed distribution uniformity decreases with the increase in the outer diameter of the cone. Perhaps by dragging, the outer diameter of the seeds increases, and the surface between the cone and the orifice does not allow the seed to settle more during the aspiration.

Conclusions

In order to achieve production clues, it is necessary to carry out the following technical instructions on the minimum required works to be executed in the pavements:
• In seed preparation: seed quality verification; Establishing sowing rules; Specifying the sowing mode; Seed preparation according to the specificity of each species;
• When sowing: the soil temperature at sowing time must be between + 9 ° C ... + 15 ° C;
• In the seed coating: seed cover with the humus and sandpot mixture; Easy application of humus after soil cover;
• The equipment can be used in small spaces, making it easy to handle and use;
• The vacuum generator can be operated either electrically or with a thermal motor;
• Depression in the plant does not require high values because of the small seed mass;
• The proposed method is recommended primarily for research under laboratory conditions;
•This can be generalized for the comparative study of the performance of different types of distribution apparatuses and for the study of the influence of functional seed parameters on the uniformity of distribution;
•The use of modern digital imaging systems and computational techniques for processing results reduces the time needed to test sowing machines;
• The method of determining the distribution uniformity developed in the paper presents the advantage of appreciating the uniformity of sowing density compared to current methods that take into account the uniformity of seed mass flow.

TARRAGON CULTIVARS (*ARTEMISIA DRACUNCULUS* L.) OF THE NIKITA BOTANICAL GARDENS BREEDING

Nadezhda BAKOVA, Lidiya LOGVINENKO, Oksana SHEVCHUK

Federal State Funded Institution of Sciences "The Labour Red Order Banner Order Nikita Botanical Gardens - National Scientific Centre of RAS",
Yalta, the Crimea
*Corresponding author: oksaana_shevchuk1970@mail.ru

Abstract

Tarragon or estragon (*Artemisia dracunculus* L.) is a promising food, a spicy, aromatic and medicinal crop for an industrial cultivation in the Crimea. Long-term breeding tests of the samples of a different geographical origin in the Nikita Botanical Gardens have made it possible to study the special features of development, a plant morphology, productivity, a mass fraction and a component composition of essential oils. Estragon selection was aimed at determination of high productive and high essential oil yield forms with a valuable component composition of essential oil and compact bush shape. It has been found out that raw biomass yield of the studied samples was 110-116 cwt/ha, a mass fraction of essential oil is 0.22–0.61% of fresh biomass and essential oil yield was 24.2-57.2 kg/ha. The main components of essential oil is sabinene - up to 41%, elemicin - up to 30.3%, trans- isoelemicin - up to 32.7%. The valuable components of estragon essential oil are methyl chavicol ($C_{10}H_{12}O$) and its derivates such as methyl eugenol, elemicin, isoelemicin. Two highly efficient cultivars - "Smaragd" with a high content of essential oil promising for use in medicine as a restorative remedy and "Travneviy" that could be used in the food industry as spice, have been created. During the mass blossom the cultivar "Smaragd" plants accumulated a maximum amount of essential oil (up to 0.61% of raw biomass), the main component of essential oil is methyl chavicol mass fraction of which was up to 91%. Mass fraction of essential oil in heads was 0.8%, in leaves - 0.6%, in stems - 0.03% of raw biomass. The raw biomass productivity for "Travneviy" cultivar was 123.4 hw/hectare, mass fraction of essential oil - 0.08% of fresh biomass, essential oil yield - 10.7 kg/hectare. The main components of essential oil are sabinene (40.0%), trans-iso-elemicin - 26.1%.

Keywords: *Artemisia dracunculus L., spice, essential oil, methyl chavicol, sabinene*

Introduction

Tarragon or estragon (*Artemisia dracunculus* L.) is a perennial herbaceous plant from Asteraceae family. It is native for Western Europe (except its northern part), the Caucasus, Asia Minor, Central Asia, Northern China, Mongolia and the west of North America, mostly in the floodplain meadows, virgin and saline lands in the steppe and forest steppe zones (Vulph, Nilov, 1937). It is cultivated everywhere in Europe, India, USA, Brazil (Libus et al., 2004).

Tarragon is a promising spicy-aromatic crop (Bakova, Rabotyagov, Marko, 2010). Its tender aboveground green parts can be used fresh and after some maturing for canning and pickling vegetables. It is a component of the flavoring composition for processed cheese production; water-alcohol extract of tarragon is the main component of a soft drink "Tarhun" which is a tonic drink of a high quality (Bakova, Logvinenko, 1995).

Tarragon is widely used as a carotene-containing and antiscorbutic agent in dietary nutrition. Tarragon herb stimulates secretion of a gastric juice, improves appetite, and normalizes the functions of endocrine glands. Consumed young herbaceous shoots with leaves containing up to 190 mg /% vitamin C, 15 mg /%, carotene, 170 mg /% rutin, as well as macro- and microelements:

1.9 mg /% calcium, 2.11 Mg /% magnesium, 1.32 mg /% iron, 226.5 mg /% phosphorus (Vulph, Nilov, 1937; Botanico-pharmacognostic ..., 1990; Libus et al.., 2004).

In ethnoscience medicine, tarragon is considered as an effective diuretic and it is used against worms, with swelling. In Tibetan medicine estragon is recommended for the treatment of pulmonary tuberculosis, pneumonia, bronchitis. In the official medicine, the herb is used as a stimulant for the secretion of a gastric juice and bile, remedy for diuresis increasing and cure with a general strengthening effect (Logvinenko, Rabotyagov, Bakova, 1995; Bakova, Logvinenko, 1995).

Estragon essential oil has an anti-inflammatory, choleretic, diuretic, spasmolytic, antiparasitic, sedative, wound-healing, antiseptic, restorative, antiallergic effect (Libus and oth., 2004). It can be used in the development of phytopreparations of preventive and sanitary-hygienic trends, as well as an odor in perfume and cosmetics industry.

Material and Methods

The objective of our research was to study developmenl features as well as the content and component composition of the essential oil in *Artemisia dracunculus* samples of a different geographical origin under the conditions of the Southern Coast of the Crimea, either to create new cultivars.

The original plant material had been obtained from the botanical gardens of France, Germany, Austria, Czech Republic, Italy, Switzerland, Hungary, Poland, Belarus, Armenia, England, and also collected during the scientific expeditions in the Crimea and the Caucasus. The subjects of the study were 13 samples; each of them was represented by at least 10 plants.

Introductory and breeding studies were carried out on the experimental plots of aromatic and medicinal plants collection in the Nikita Botanical Gardens using common methods and methodological developments (Introduction .., 2009). An organoleptic testing of the essential oil was carried out on 5-point scale (Introduction .., 2009). The mass fraction of the essential oil was determined by a hydrodistillation method from a fresh raw biomass. (Ermakov, 1962). The essential oil composition was tested on Agilent Technology 6890N chromatograph with 5973N mass spectroscopy detector (Jennings, Shibamoto, 1980).

The promising varieties were isolated by the method of a positive individual selection. Breeding was aimed at creation a high-yield cultivars with high quality of the essential oil and suitability for harvesting machine.

The Southern Coast of the Crimea is a region with a dry subtropical climate and well-preserved elements of the Mediterranean landscape. Average annual temperature is 12-15^{o}C, the absolute minimum in winter is 7-10^{o}C, the maximum in summer is 36-38^{o}C. Average daily temperature transition of 5^{o}C occurs in the first-second decade of March, and temperature transition below 5^{o}C – is in early December. Periods with stable average daily air temperatures below 0^{o}C are rare. Precipitation amount is up to 560 mm (Fursa, Fursa, 1992). The soil type is brown carbonate, medium-humus, powerful, light-clay (Soils .., 1963).

Results and Discussion

Under the conditions of the Southern Coast of the Crimea, tarragon is a perennial herbaceous plant up to 120 cm height, with a lignified, well-developed rhizome located in the upper soil layers. Stems are erect, pubescent, ribbed, lignified at their lower part, highly branching. Branches are of medium length, pinned to the stem, the average number of the first order branches is 8-10 ones. Leaves are slightly pubescent, linear-lanceolate: in the middle and upper parts of the stem they are whole, in a lower part - two-threefold. Flowers are yellow combined in numerous small spherical heads organized in narrow-clustered inflorescences, the length of which is up to 6 cm, the number of heads per the inflorescence is up to 50 ones, the number of inflorescences of a single plant is 2-3 ones. Fruit is an oblong seed. Seeds are small, compact, obovate, light brown in color. In contrast to the other wormwood species, tarragon is completely devoid of bitterness. This low temperature-

resistant plant is characterized by resistance to diseases and pests (Mashanov, Logvinenko, 1991). The studied samples form bushes of various shapes: a spread bush (diameter 80-90 cm), compressed (diameter 25-30 cm) and pyramidal ones (diameter 60-70 cm) (Bakova, 1997). Beginning of vegetation in plants of all the studied samples occurs during the first decade of March. The period of flower budding is short - from 12th to 26th June. The phase of a mass blossom is observed from July 9th to August 21st. A large range in the terms of the mass blossom phase start in different tarragon forms is associated with their individual characteristics. The longest flowering period is 45 days, the shortest - 36 days. An average period of vegetation of estragon was 164 days, the maximum - 169 days, the minimum - 147 days. The terms of seed ripening did not differ significantly. The weight of 1,000 seeds was 0.18-0.22 g. The seeds retain their germination capacity for 1-2 years. The essential oil is produced in the aboveground parts of estragon plants. The aboveground parts of the plants are used as the raw biomass and harvested during the period of a mass blossom. The yield of a plant raw biomass in the studied samples varied within 39.6-166.6 hw/hectare. In the most productive samples, the raw biomass yield was 110-166 hw/hectare (table).
A produced essential oil is a colorless or yellow-green liquid with a peculiar aroma. The density d_{15}^{o} is 0.900-0.945, the refractive index is 1.504-1.526, the acid number is up to 1; ether number is 1-9; ether number after acetylation 15-22; soluble in 6-11 volumes of 80% alcohol with a slight turbidity, as well as in 0.6-1.5 volumes of 90% alcohol. The mass fraction of essential oil in the aboveground biomass of the studied samples varies from 0.12 to 0.61% of a fresh biomass. The smell of the essential oil is fragrant and it is determined by its main ingredients. Organoleptic evaluation allowed identifying the following flavor trends: sagebrush, carrot, cineol borneol, ginseng, eugenol, methyl eugenol, methyl chavicol (estragole) and bitter grapefruit. The taste is burning. The main components of the estragon essential oil were methyl havicol (estragole), elemicin, trans-isoelemicin, sabinene, myrcene, octanone-3, linalool, caryophyllene. Cis-ocimene, trans-ocimene, phellandrene, nerol, 1,8-cineole, myrcene, eugenol and other compounds were also presented in the oil (Grebennikova and oth., 2014). Tarragon essential oils differ in combination of methoxylated forms of methyl chavicol - methyl eugenol, elemicin, sabinene, etc. There are several basic tarragon varieties, which differ in chemical composition of essential oil and its yield - Russian (Caucasian), German, French, English, Japanese (Wormwood tarragon). The original tarragon contains 80-90% methyl chavicol (1-methoxy-4-allylbenzene) and some of its forms accumulate methyl eugenol (1,2-dimethoxy-4-allylbenzene) or its methyl iso-eugenol isomer. The other forms of original tarragon contain elemicin (1,2,6-trimethoxy-4-allylbenzene) and isomer isoelemicin. There is a known tarragon chemotype containing a significant amount (up to 35%) of the methyl chavicol isomer anethole (1-methoxy-4-propenylbenzene) (Wormwood tarragon). In the essential oil of the tested samples, the content of the main components has a wide range of variability. Thus, concentration of methyl chavicol ranges from 0.23 to 90.98%, elemicin - from 4.43 to 30.35%, methyl eugenol - from 0.49 to 70.53, isoelemicin - from 17.45 to 29.26%, sabinene - from 6 to 40%, which suggests that all variants of metaxylated forms of methyl chavicol are presented (table). The following chemotypes have been determined: methyl chavicol, methyl eugenol, elemicin and sabinene. The criteria for breeding improvement of tarragon are the raw biomass yield, the essential oil yield, essential oil component composition and possibility for its industrial cultivation (Rabotyagov et al., 2007; Logvinenko, Logvinenko, Bakova, 2008). The suitability for industrial cultivation is determined by the compact bush shape and shoots attachment to the main stem high above ground. Based on the analysis of all the studied samples according to these criteria two promising samples gave been selected: № 98086 – cultivar "Smaragd" is characterized by a high yield of methyl chavicol essential oil, and № 33188 - "Travneviy" - with high aerial biomass yield, essential oil of sabinene chemotype and clove-muscat aroma (Rabotyagov et al., 2007; Rabotyagov et al., 2011). Their full description is presented.

Table. Morphological and economically valuable features of *Artemisia dracunculus* L. samples

The introductory number and origin of the sample	Morphological features	Productivity, **(hw/hectare)**	Mass fraction of essential oil, % of fresh weight	Essential oil yield, kg/ha	Aroma, organoleptic evaluation (points)	The main components of essential oil,%
Methyl chavicolic chemotype						
98086 Armenia	height 72±6,5 cm, compact bush, diam. 27±3 cm, scions attached to the stem high above ground	94.9	0.61	57.2	mint-chavicol, 5	**methyl chavicol – 90.98**; trans- ocimene – 8.87; cis-ocimene - 7.78; linalool – 0.29; methyl eugenol – 0.49; limonene - 4.3
Methyl eugenol chemotype						
131187 France	height 100±7,8 cm, spread bush, diam. 78±9 cm, scions attached to the stem low	126.6	0.23	28.5	methyl eugenol, 5	**methyl eugenol – 70.53;** methyl chavicol – 16.48; linalool - 0.36; isoelemicin - 17.45
45992 Austria	height 90±4,8 cm, compact bush, diam. 23±2,3 cm, scions attached to the stem high above ground	110.6	0.25	27.7	methyl eugenol, 5	**methyl eugenol – 57.51;** elemicin – 17.45; linalool – 0.27; methyl chavicol – 0.77; sabinene – 1.43
Sabinene chemotype						
33188 Caucasus	height - 105±10 cm, pyramidal bush, diam. 84.5±2 cm; scions attached to the stem high above ground	166.6	0.25	41.65	eugenol, 5	**sabinen – 40.09**; **trans-iso-elemicin – 26.1;** methyleugenol – 1.34; linalool – 0.91; methyl-havicol – 0.23; elemicin – 4.43;
90888 France	height - 87±10 cm, compact bush, diam. 25±6.3 cm**;** scions attached to the stem high above ground	54.1	0,55	29,75	cineol-borneol, 4	**sabinene – 41.1; elemicin – 30.3;** methyl chavicol – 0.44; methyl eugenol – 2.54; linalool- 1.32
Elemycin chemotype						
33288 Crimea	height - 112±6,3 cm, compact bush diam. 46.4+2.3 cm, scions attached to the stem high above ground	166.6	0.05	8.33	bitter grapefruit, 5	**elemicin – 32.8;** sabinene – 16.9; linalool – 0.57; methyl chavicol – 0.64; methyl eugenol -7.6
80588 England	height - 93±6.3 cm, pyramidal bush, diam. 69.5±1.3 cm, scions are attached to the stem low	83.3	0.12	9.99	eugenol, 5	**elemicin – 47.23;** methyl eugenol – 16.78; isoelemicin – 13.76; sabinene – 6.45

Cultivar 'Smaragd' – the bush 70-78 cm height, compressed in a shape, the bush diameter is 50-56 cm. The straight stems are densely leafy. The lower leaves are mainly tripartite, the upper are linear-lanceolate, bare, up to the flower budding stage soft and tender, at the beginning of blossom become stiff. Yellowish flowers collected in spherical small heads in their turn organized in narrow-clustered inflorescences. Seeds are small, brown, flat. The mass of 1000 seeds is 0.2 g. Vegetation is 150-160 days. Mass blossom occurs in the second decade of July, the harvest period is 20 days. The cultivar is propagated vegetative (bush fragmentation) and with seeds. It grows well on flat, open areas with loose, fertile soils.

During the period of a mass blossom, the plants of this cultivar accumulate the maximum amount of essential oil (up to 0.61% of fresh biomass), the main component of the essential oil is methyl chavicol, its content is up to 91%. A mass fraction of the essential oil in flower heads is 0.8%, in leaves – 0.6%, in stems 0.03% of fresh weight. Accordingly, the raw biomass for producing essential oil is the aboveground parts (stems, leaves and inflorescences) cut at 15-20 cm height above the ground. This cultivar is promising as an essential oil crop for use in the pharmaceutical and perfumery-cosmetic industries.

Cultivar 'Travnevy' is 110-115 cm height, the bush is pyramidal erect, 84-86 cm in diameter. The stems are densely leafy, the stem thickness is 0.9 cm. The leaves are slightly pubescent, linear-lanceolate: in the middle and upper stem parts are entire, in the basal stem part - 2-3-parted. The flowers are yellow in numerous small spherical heads collected in narrow-clustered inflorescences, the inflorescence length is 5.7 cm, the number of heads in the inflorescence is 49-50 ones. The beginning of blossom was noted in the second decade of July, mass blossom - in the first decade of August. Fruiting is in September - October. The seeds are small, flat, ovate, brown. Vegetation is 169 days. It grows well on flat, open areas with loose, fertile soils, drought-resistant.

The raw biomass yield is 123.4 hw/hectare, the mass fraction of essential oil is 0.08% of fresh biomass. Raw biomass is harvested at the beginning of blossom. The main component of the essential oil is sabinene - 40.0% and trans-iso-elemicin - 26.1%. The cultivar is promising for use as food and canning spice with nutmeg aroma (Patent, 1998).

For preservation of the special cultivar characteristics, a vegetative propagation (bush fragmentation) from the third life’s year, in early spring or in autumn, after the harvesting, is suggested. Essential oil and raw biomass of the created tarragon cultivars conforms to the requirements of international standards (ISO 7926: 1991).

Conclusions

The complex studies of estragon samples from the collection of aromatic and medicinal plants of the Nikita Botanical Gardens demonstrated that in the conditions of the Southern coast of the Crimea productivity of the studied samples raw biomass was 39.6-166.6 hw/hectare and the mass fraction of essential oil in the aerial parts was 0, 12-0.61% of fresh biomass.

The Samples of methyl chavicol, methyl eugenol, elemicin, and sabinene chemotypes are presented in the collection. Two new cultivars have been created: cultivar 'Smaragd' characterized with a high content of methyl chavicol chemotype essential oil for use in the pharmaceutical and cosmetic industries, and cultivar 'Travnevy' - a high-yield, drought-resistant, of spicy-aromatic trend with essential oil of the sabinene chemotype.

Abstract

The plant cell and tissue culture *in vitro* is the one of promising approaches for modern breeding programs in vegetable crops. The double haploid lines (DH-lines) were produced thought isolated microspores in species of Brassicaceae, namely in Chinese cabbage, broccoli, white head cabbage, red head cabbage and kohlrabi, where the yield of embryoids was up to 40 per a flower bud. Moreover, DH-plants were produced in such species as *B. alboglabra* and *B. purpuraria* with the yield of embryoids up to 200 per a flower bud. DH-lines in different varieties and interspecific hybrids of pepper were obtained through the culture of isolated anthers and microspores with the yield of 54.5 embryoids per 100 anthers cultured. The technology of the DH-line production was optimized for different carrot breeding accessions and totally 84 embryoids per one Petri dish were obtained in culture of isolated microspores. The regenerated plants of carrot showed game to clonal variation confirmed by morphological and DNA analyses. The technology of DH-plant production from isolated unpollinated ovules and ovaries have been developed in plants of Cucurbitaceae family such as cucumber, marrow, pumpkin with the yield up to 20, 55 and 9 embryoids per an ovary respectively. Additionally, plants originated from unpollinated ovule culture were obtained in carrot, onion and red beet. As a result of breeding program realized with the use of DH-lines, hybrid F1 of kohlrabi 'Dobryniya', sweet pepper 'Nataly' and 'Gusar', and a carrot variety 'Sonata' have been released. Meristem plant culture was used to produce polyploid virus-free breeding accessions in garlic. Clonal micropropogation technique was developed to multiply plants in large quantity with male sterility in cabbage. Furthermore, the technologies of micropropagation in eggplant and sweet pepper served as basis to develop the method for embryo rescue used for production of their interspecific hybrids.

Keywords: *DH-plants, microspore culture, unpollinated ovary culture, micropropagation.*

Introduction

Currently biotechnological methods of *in vitro* plant cell culture process are of applied significance in agriculture rather than just play an important role in basic research in genetics, physiology, molecular biology and plant cytology. Vegetables are important component of the population nutrition patterns. Selection charged with the task of creation of new varieties and hybrids is essential for improvement of vegetable production efficacy. The following approaches may be used for incorporation of biotechnological methods into selection process of vegetable crops: 1. Biotechnological methods accelerating production of parent material for heterotic breeding of the vegetable crops with the use of andro - or gynogenesis; 2. Clonal micropropagation to maintain sterile or self-incompatible lines and unique samples of vegetable crops and also to obtain virus-free planting material; 3. *In vitro* use of embryo culture methods to overcome postgamic incompatibility during the processes of cross-species hybridization and induced apomixis. In this article we report our results achieved due to the use of biotechnological methods in vegetable crop breeding.

Materials and methods

The study was carried out with breeding accessions taken from collection of All-Russian Research Institute of Vegetable Breeding and Seed Production (VNIISSOK), Moscow region, Russia. The accessions of *Brassica oleracea* L. var. *alboglabra* (L. H. Bailey) Musil and *Brassica rapa* L. subsp. *chinensis* (L.) Hanelt var. *purpuraria* (L. H. Bailey) Kitam. were kindly provided from the N. I. Vavilov Institute of Plant Genetic Resources (VIR), Saint-Petersburg, Russia. Donor plants were grown in a climate chamber at 18^0C around the clock, 16L8D, where L is light time and D is dark, and light intensity was 9000 lx. Plants of white head cabbage, red head cabbage, carrot and red beet were vernalized in cold room, maintained at 4-6^0C under a 16h photoperiod with 5000 lx for 9 weeks. After floral differentiation and the start of generative development, plants were transferred to a climate chamber.

Bud and plant explants were sterilized for 60s in 96% ethanol, then for 5 min in a 50% aqueous solution of the "Belizna" (Russia) commercial preparation with the addition of Tween 20 (Panreac, Spain), followed by washing three times with sterile distilled water.

Anther and ovule culture: for induction of gynogenesis the sterilized carrot buds used as explants were pre-cultured on MSM medium (Masuda et al., 1981) with 0.2 mg L^{-1}2,4D and 0.2 mg L^{-1} kinetin for 2-3 weeks at 25^0C in darkness. Then ovules were taken out of ovaries and placed on fresh MSM medium of the same composition under light until the gynogenic calluses or/and embryoids appeared. Embryoids and parts of callus were then transferred to new tubes with MSM medium with 0.1 mg L^{-1} kinetin for process of organogenesis. The experimental procedure for carrot anther culture, onion and red beet ovule culture was generally similar to ovule culture in carrot and Cucurbitaceae family, and performed according to the protocol previously described (Tyukavin et al., 1999; Domblides, 2016).

Microspore culture: sterile buds were placed ½ NLN medium, pH 5.8 (Lichter, 1982), with 13% sucrose and homogenized using a magnetic stirrer. The microspore suspension was filtered through a nylon filter with a mesh size of 40 microns and pelleted for 5 min using an Eppendorf 5804R centrifuge (Germany) at 125g. The pellet with microspores was resuspended in NLN medium and then centrifugation was repeated. Microspore washing was performed twice. After isolation and washing, microspores from 5 buds were placed in a Petri dish (6 cm in diameter) with 5 mL medium as mentioned above and incubated at 32°C in the dark for 1-2-3 days. Further incubation was at 25°C in the dark until embryos were formed.

The detailed protocols for the research performed were published in our articles, as cited below in the result and discussion.

Results and discussion

Laboratory of Biotechnology was established in VNIISSOK in 1987 and contributes to creation and maintenance of valuable vegetable breeding material through the use of various biotechnological methods (Fig. 1) (Shmykova, 2015). Production of DH-plants in one of the main fields of activity of our laboratory. The first double haploid plants were produced by VNIISSOK laboratory of biotechnology in the anther culture of carrot (Fig. 2A) and white cabbage (Taganov, 1991; Semova, 1992). Cytology of embryogenesis in the culture of carrot anther revealed the patterns of embryod formation from microspores; we showed that the ploidy change starts at early stages of primary embryoid formation (Tyukavin *at al*., 1999). With the use of our method the number of embryoids formed in the carrot anther culture in

MSM medium containing 2,4D in amount of 0.2 mg/L may reach 544/100 anthers (Tyukavin, 2007). Obtained plant-regenerants demonstrated clonal gamete variability, which was verified by morphological, cytological (Fig. 2E) and molecular-genetic assays (Tyukavin, 2007; Domblides, 2017). Carrot variety Sonata was created with the use of produced DH-lines. Despite numerous studies throughout the world, which was aimed on creation of double haploids in a carrot anther culture (Andersen, 1985; Adamus, Michalik, 2003), the success in development of microspore culture technology for this important vegetable crop was achieved only during the recent years (Gorecka *et al*., 2010; Li *et al.*, 2013).

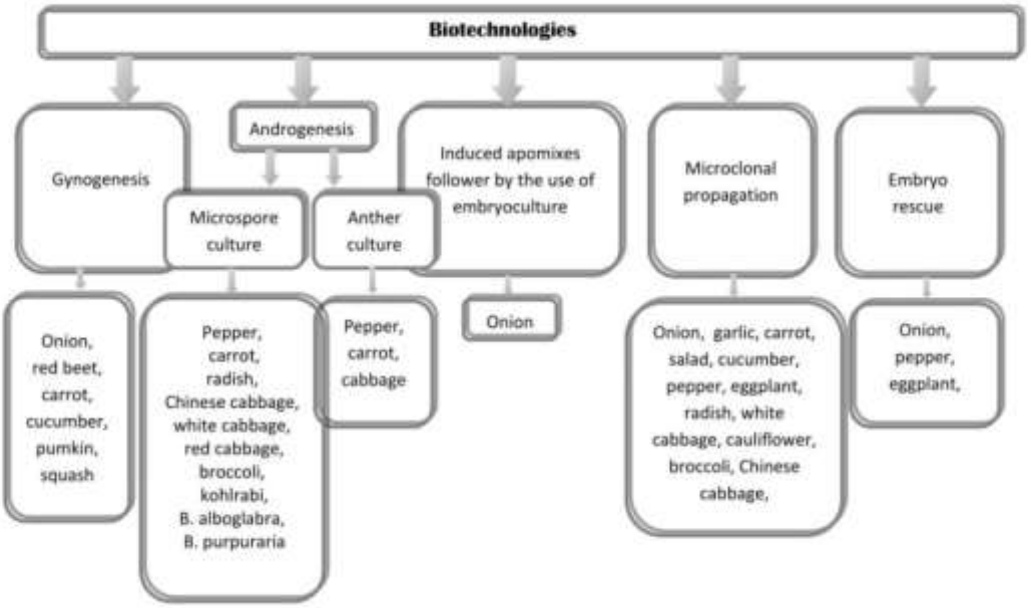

Figure 1. Biotechnological methods used in the creation of agricultural varieties in the All-Russian Research Institute of Vegetable Breeding and Seed Production (VNIISSOK)

Production of DH-plants in carrot through microspore culture is also developed at our institute (Fig. 2C), and the plants-regenerants from the varieties 'Nantskaya' and 'Shantane' have been already created (Vjurtts *et al*., 2016). As a result, 84 embryoids per one Petri dish were obtained in culture of isolated microspores. The main challenge we have faced is the production of large amount of albninotic regenerants (Fig. 2D).

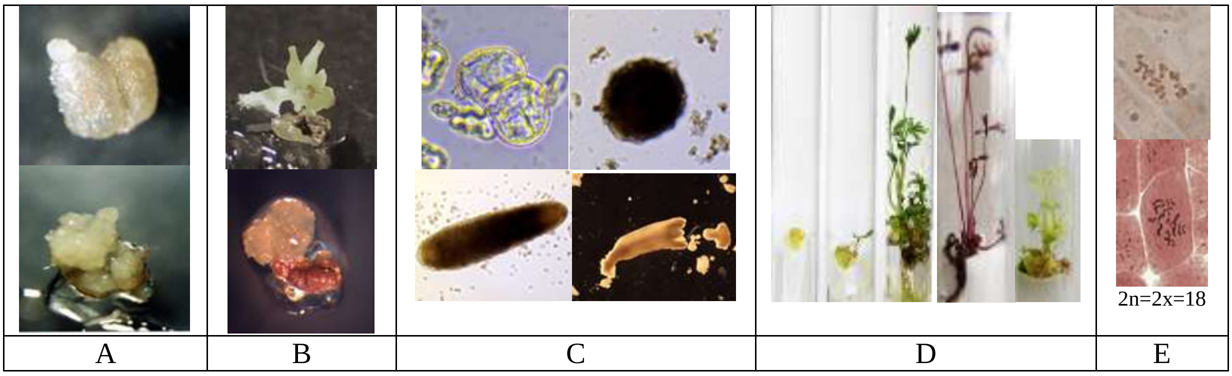

Figure 2. Obtaining carrot (*Daucus carota* L.) DH-plants in anther culture (A), unpollinated ovules (B) and microspore culture (C); regeneration plants (D); cromosomes in a root apex cell of a diploid planlet (E)

The species of Brasssicaceae family are of great importance among vegetable crops, and the work aimed on optimization of production technology of double haploids in microspore culture is ongoing throughout the world (Takahata, Keller, 1991; Bhatia et al., 2016). Laboratory of Biotechnology optimized a basic protocol of rape microspore culture (Custers J.B.M. (2003), and this led to creation of double haploid lines of Chinese cabbage (Shumilina et al., 2015), broccoli, white head cabbage (Pivovarov, 2017), red head cabbage and kohlrabi, which are included into breeding process of heterosis hybrids. After the method was optimized for some genotypes the yield reached 40 embryoids per one cultivated flower bud. Hybrid kohlrabi 'Dobryniya F1' was created with the use of double haploid lines. DH-plants were produced in such species as *B. alboglabra* and *B. purpuraria* with the yield of embryoids up to 200 per a flower bud (Fig. 3).

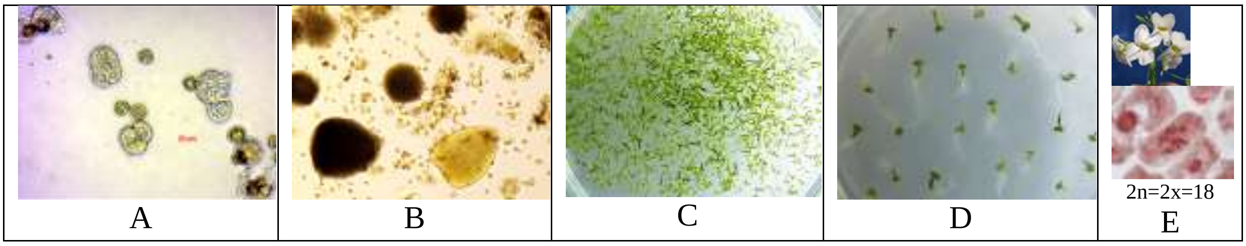

Figure 3. *Brassica oleracea* L. var. *alboglabra* (L. H. Bailey) Musil microspore culture. First division of microspore (A); embryoids after 14 days of culture (B); torpedo and cotyledonary embryods after 21 days of culture (C); embryos after 5 days on regeneration medium (D); chromosomes in a root apex cell of a diploid plantlet (E)

Radish is considered to be one of most recalcitrant species for microspore culture among Brasssicaceae crops. However, we succeed in selection of optimum nutrition medium M1 and obtained DH-lines originating from 4 varieties (Rodos, Teplichny Gribovsky, RBK, and Sonata). The yield comprised from 0.2 to 2 embryoids per 1 flower bud (Fig.4).

Figure 4. Microspore culture of radish (*Raphanus sativys* L.)

We developed the technology of pepper double haploid line through the anther/microspore culture by cultivation of double-layer medium (Shmykova *et al*., 2012; Shumilina *et al*., 2013), and created the double haploids of various pepper varieties and pepper inter-species hybrids based on this technology. This technology is up to the best foreign analogues for hot pepper (Supena, 2006; Kim, 2008). The losses in amount of haploid and double haploid pepper plants often take place at the stage of embryoid development into the seedling. For pepper species the formation of radiciform embryoid is typical, which does not develop into normal plants-regenerants. We managed to solve this problem partially through the use of gibberelic acid, which allowed to avoid rosette formation in regenerants, and through the use of benzylaminopurine for stimulation of secondary embryogenesis (Shmykova et al., 2012). The hybrids of sweet pepper 'Natali F1' and 'Gusar F1' were created with the use of DH-lines.
Female gametophyte can be also used for production of DH-plants. In vitro cultivation of unpollinated ovaries and ovules allows producing haploids from the plants with cytoplasmic male sterility, and when anther or microspore culture does not result in satisfactory yield (Chen *et al*., 2011). At present haploid plants in the culture of unpollinated ovaries have been produced in vitro for more than twenty plant species and used in breeding programs of sugar beet, rice, gerbera, onion, and other plants (Mukhambetzhanov, 1997). It is known that DH-plants have been produced through cultivation of unpollinated ovaries in such vegetables as onion (Bohanec *et al*., 2002), cucumber (Gemes-Juhasz *et al*., 2002), pumpkin (Mohamed, Refaei, 2004), marrow (Shalaby, 2007), carrot (Kielkowska, Adamus, 2010), red beet (Michalik, Baranski, 1992). VNIISSOK has also participated in investigation in this field for the last 20 years. Double haploids production in the culture of unpollinated ovaries of carrot *Daucus carota* L. was one of the first developed technologies in this field (Fig 2B). Cytological study of embryo sac development under in vitro cultivation was carried out, and optimal stage for gynogenesis induction was detected (Tyukavin, Shmykova, 1996; Domblides, 2001; Tyukavin, 2007). At present this work is ongoing, and this method is successfully used on new carrot genotypes (Vjurtts *et al.*, 2016). Double haploids were obtained in the culture of unpollinated ovaries of red beet, onion (Stuttgarter Riesen variety) and interspecies hybrids of Allium genus (Shmykova, 2006). Technology of *in vitro* production of the cucumber DH-lines in the culture of unpollinated ovaries has been developed (Shmykova, Suprunova, 2009). The use of 0.2 mg/L TDZ together with 10^{-7}M epibrassinolid for gynogenesis induction allowed to enhance regeneration capacity of the ovaries. This technology was upgraded and successfully used for Cucurbita genus plants – pumpkin (Shmykova *et al*., 2015) and marrow (Domblides, 2016) (Fig. 5). The greatest number of embryoids per an ovary comprised 55, 20, and 9 embryoids for marrow, cucumber, and pumpkin, respectively. All produced plants have been included into selection process aimed on creation of the hybrids.

Figure 5. Obtaining summer squash (*Cucurbitata pepo* L.) DH-plants in unpollinated ovules

To achieve uniformity of segregating populations in the process of new selection form creation the method of induced apomixis can be used as well. We used this method for vegetable crops of Allium genus. The plants *A. odorum* L. were employed as apomixis inducers. Maternal plants were pretreated with gibberellin solution (0.1%) and 2.4-D solution (0.5 mg/L). *In vitro* embryoculture method was successfully used for creation of onion BC1 (F5(*A. cepa* × *A. fistulosum*) × *A. cepa*) interspecies hybrids and varieties of 'Odintsovets' and 'Danilovsky 301' of bulb onion (Romanov, 2008).

Clonal propagation helps to maintain and preserve valuable material to the plant breeders. Biotechnological task is to achieve the high propagation index *in vitro* without compromising of genetic stability. For some species of the vegetable crops this task was solved many years ago (carrot, eggplant, cucumber), while for some scarcely responsive species (for instance, pepper, cabbages) effective protocols were developed just recently (Yang et al., 2005). In VNIISSOK Laboratory of Biotechnology developed the technology of clonal micro-propagation of cauliflower with the use of perifloral meristem (Ibragimov, 1991). Later an effective technology of clonal micro-propagation of white cabbage with male sterility was developed, which allows producing the plants in infinite amount. This technology comprises four stages (sprout formation induction, sprout formation, sprout growing, and sprout rooting). The whole cycle lasts for 8-11 weeks. The sprout development begins from the stage II; propagation index may range from 10 to 30 depending on an explant. After stage III propagation index increases 2-3-fold, while stage III may be repeated several times (Bunin, Shmykova, 2004). The F1 hybrid of Chinese cabbage 'Pamyati Popovoy' was created with the use of microclonal propagation technology.

The elements of microclonal propagation technology of the plants *Raphanus sativus* L. have been tried and tested. MSM medium with 0.2 mg/L of growth regulators such as naphtyl acetic acid (NAA) plus thidiazuron (TDZ) or NAA plus BAP was used to initiate radish shoot regeneration processes. To increase the number of the plants-regenerants per explant hypocotyls were pretreated with 0.1% of silver nitrate for 1 hour that resulted in 1.2-5 fold increase of propagation index (Zayachkovskaya, 2005).

Clonal micro-propagation method can be used for production of virus-free plant material rather than just for replication of difficult-to-propagate plants. For instance, we use clonal micro-propagation to obtain revitalized garlic plant material (Fig. 6). Garlic is a sterile plant that propagates slowly in the field, and most of the plants are infected by viruses. Viruses can be eliminated through meristem-tip culture and the resultant virus-free plants give 10 to 70% higher yield (Nagakubo *et al*., 1997). We also used *in vitro* polyploidization method treating the callus with 0.05% and 0.1% colchicines solution to improve genetic diversity of garlic intended for breeding process. Our work resulted in inclusion of 12 produced lines into breeding program.

Figure 6. Micropropagation of *Allium sativum* L. (Garlic)

Technology of clonal micro-propagation in eggplant, which was developed in our laboratory (Verba *et al*., 2010a), provided the basis of embryo culture enabling embryo rescue in the process of inter-species hybridization. VNIISSOK performs the studies aimed on involvement of eggplant wild species into breeding program in order to transfer the resistance abilties to abiotic stressors. Inter-species hybrids of *Solanum melongena* L., *S. integrifolium* L. and *S.aethiopicum* L. are already available, where interspecies barriers were overcome with the use of *in vitro* embryo culture method (Verba *et al*., 2010b). The method of *in vitro* cultivation of immature embryos of the pepper inter-species hybrids enabled to obtain the following inter-species hybrids: *C. baccatum x C. chinense, C. annuum x C. chinense, C. baccatum x C. annuum, C. frutescens x C. chinense, C. frutescens x C. annuum, C. annuum x C. frutescens*. Produced interspecies hybrid combinations were used in creation of pepper breeding material, which is resistant to viral diseases (Bunin *et al*., 2008).

Conclusion

Wide application of biotechnological methods in current breeding programs allows breeders to develop very competitive and marketable varieties and hybrids of vegetable crops. Such biological features of plants as development from gametic haploids cells and as well as regeneration from somatic cells have served as valuable source of genetic variation, which can be used both for breeding program and genetic studies. As it has been shown in the study the process of DH-plant production can be launched in many plant species by optimizing only the standard protocol invented previously. Consequently, the involvement of biotechnological methods into breeding process will result in 2-3 fold reduction of time and labor expenses required for creation of new competitive hybrids and varieties of vegetable crops, thus enabling the plant breeder to response promptly to changing and growing market demands. As a result of breeding program realized with the use of DH-lines, hybrid F1 of kohlrabi 'Dobryniya', sweet pepper 'Nataly' and 'Gusar', and a carrot variety 'Sonata' have been released. The F1 hybrid of Chinese cabbage 'Pamyati Popovoy' was created with the use of microclonal propagation technology.

Abstract

The impact of increasing rates of mineral fertilizers on Falenskaia 4 winter rye yield. agrophysical and agrochemical properties of the ploughed soil layer was determined in 2011-2013 as part of long-term field test trials, founded in 1972-1974.The field experiment was carried out on heavy loamy sod-podzolic soil with humus content 1.54%, pH $_{KCl}$ – 5.4, high P_2O_5 and K_2O content. Long-term (over 40 years) fertilizers application ($N_{60}P_{60}K_{60}$ ha $^{-1}$ and more) caused the humus level to rise from 1.54 to 2.18 %, labile phosphorus - from 296 to 399, soluble potassium - from 187 to 324 mg/kg with slight soil acidification (pH_{KCl} varied from 4.82 to 5.12) and improvement of soil agrophysical properties, including the valuable silt fraction and an increase in water-stable particles. Mineral fertilizer applications had no direct effect on soil density, which was more influenced by phase of the vegetation period : increasing from 1.18÷1.23 during the tillering stage to 1.54÷1.61 g/cm³ during the grain milk- ripe stage.

Improved nutritional conditions due to the joint impact of mineral fertilizers and organic matter from the root remains and crop residues promoted raised the yield of winter rye by 1.15 – 1.47 t ha $^{-1}$ compared with the control (no fertilizers). Maximum yield and crop return in the field trial found in the treatment $N_{60}P_{60}K_{60}$ ha $^{-1}$ – 4.48 t ha $^{-1}$ and 8.2 kg of grain – respectively for 1 kg of mineral fertilizers active substance. Further increment of mineral fertilizers rates to winter rye caused plant lodging. and losses while harvesting and yields decreased as a result.

Key words: *winter rye, mineral fertilizers, agrophysical, agrochemical soil properties. yield.*

Introduction

Winter rye provides the most stable yields among cereal crops in the Perm Region as well as in the Non-Chernozemic zone of Russia and other countries. (Arseniuk and Oleksiak, 2003; Bragin and Yumashev, 2012; Raun and Solie, 2005). Winter rye is widely used and possesses an extremely high food value. Its wide application is due to its high content of valuable proteins, carbohydrates and vitamins in the grain (Ismagilov, et al, 2001; Kedrova 2000). The amino-acid content of winter rye protein is more balanced compared with other cereal crops [Kobylyansky and Solodukhina, 2012; Sherstnyov. 1980; Sysuyev and Kedrova,2000).

Winter rye is one of the best preceding crop as it is harvested earlier than other cereals, that making it possible to carry out skimming for better weed control. This crop is the most adaptive and stress-tolerant of the small-grained cereals. Winter rye efficiently uses water during autumn and winter, reduces the growth machinery work load during the spring and summer. It is also better-adapted to poor sod-podzolic soils- than other cereals, and has a high nutrient uptake capacity. It is a reliable crop insuring a steady yield of food grain, regardless of weather conditions (Frank, 1992; Panasiewicz, et al, 2016; Sysuyev et al, 2007].

Therefore, the extension of winter rye crops is conditioned by economic, agricultural, and environmental reasons. Many new cultivars of winter rye have now been introduced into arable farming, including those highly responsive to mineral fertilizer applications, such as Falenskaya 4, and others. Therefore, the elaboration of a rational and profitable fertilizer system for winter rye - is very relevant.

The aim of this research was- to determine optimum fertilizer rates for Falenskaya 4 to provide steady harvests and stable soil fertility.

Materials and methods

Fertilizer utilisation efficiency on winter rye was studied during 2011-2013 as part of a long-term, stationary experiment founded in 1972-1974. The experimental plots located on shallow- sod podzolic heavy loam soil with humus content 2.01 %, pH_{KCl} =5.4, H_A = 2.2 mmol/100 g soil, S= 20.3 mmol/100 g soil, high content of labile phosphorus (P_2O_5), soluble potassium (K_2O), respectively 182 and 190 mg/kg (before starting the experiment).

Experimental Design:

1. Control (no fertilizers)
2. $N_{30}P_{30}K_{30}$
3. $N_{60}P_{60}K_{60}$
4. $N_{90}P_{90}K_{90}$
5. $N_{120}P_{120}K_{120}$
6. $N_{150}P_{150}K_{150}$

Treatments were located systematically, with each treatment having four replications for each of three replicate years. The total area of each plot was 100 m². calculated area 63 m². Field trials were carried out using a crop rotation as follows: bare fallow, winter rye, potato, spring wheat as a shelter crop for meadow clover, first year clover, second year clover, spring barley, oat. Certified seeds were used for sowing. The studied culture – winter rye (Secale sereale. Z. var. vulgare), cultivar - Falenskaya 4 (selected in North-East Zonal Agricultural Research Institute after N.V. Rudnitskiy).

The forms of fertilizers used were ammonium nitrate, single superphosphate, potassium chloride. PK fertilizers were applied in the autumn before pre-sowing cultivation, nitrogen fertilizers: fractionally N_{30} in the autumn, N_{30-120} in the spring. as a top dressing.

Soil and plant chemical analyses were carried out in an analytical laboratory of the Perm Agricultural Research Institute according to national standards: humus content - GOST 26213-84; pH_{KCl} - GOST 26483-85; hydrolytic acidity - GOST 26212-91; sum of exchange bases - GOST 27821-88; labile phosphorus and soluble potassium - GOST 26207-91. Data processing included analysis of variance and determining correlation coefficients. Crop ruturn parameter was determined as a difference between yield in the control treatment and the one with fertilizer applications per 1 kg of mineral fertilizers active substance:

$(Y_{NPK} - Y_{Control}) / \text{NPK rate}$

Weather conditions during the experiment were typical for the Ural Region and suitable for winter rye.

Results and discussion

Balanced mineral nutrition of winter rye plants is the most important factor for stable yields. Unlike other cereals. winter rye has a well-developed root system and high nutrient uptake capacity. This crop needs phosphorus and potassium in the autumn, and moderate nitrogen rates in the spring.

Well-balanced plant nutrition allows the crop to provide high crop yields with good quality characteristics of the grain and straw and indirect improvement of soil agrophysical parameters due to winter rye's strong root development (Sysuyev et al, 2007). Soil agrophysical parameters are very important in the context of extreme climate changes as they control edaphic processes and have a directive effect on winter rye yield. Water, thermal conditions and nutritional status depend significantly on the soil texture expressed by volume weight or soil density. During the three years of the experiment no significant compacting was noted in autumn or in winter as the soil was frozen deeply enough and therefore did not shrink. Soil density at the tillering stage of winter rye varied from 1.22 to 1.26 g/cm³ over the three years. which is close to optimum values for cereals. Mineral fertilizer applications had no direct effect on soil agrophysics. A vigorous increase in vegetative and root masses was caused by a complete (NPK) fertilizer at rates of 60 kg and more of active substance, that reduced soil density significantly compared with the control as a result (least significant difference 0.02 g/cm³). Abnormal climatic events (air temperature fluctuations. droughts during the winter rye vegetation period) resulted in puddling from the tillering stage (1.35 to 1.40 g/m³) to harvesting (1.52 to 1.63 g/m³). However, a well-balanced soil dressing using a complete mineral fertilizer (60 kg FAS or more) provided a friable topsoil texture. due to powerful root system growth. Soil structure is one of the important fertility parameters. The process of soil aggregation is influenced by many factors, first of all connected with climate. Mineral fertilization in our experiment increased the proportion of valuable fractions, especially the silt fraction. The formation of soil structure was due to microbiota activity as influenced by the nutrition provided. The most important structure parameter is the quantity of water-stable particles, which depends on climatic factors, microbiological activity and organic matter input with crop and root residues (Fig 1).

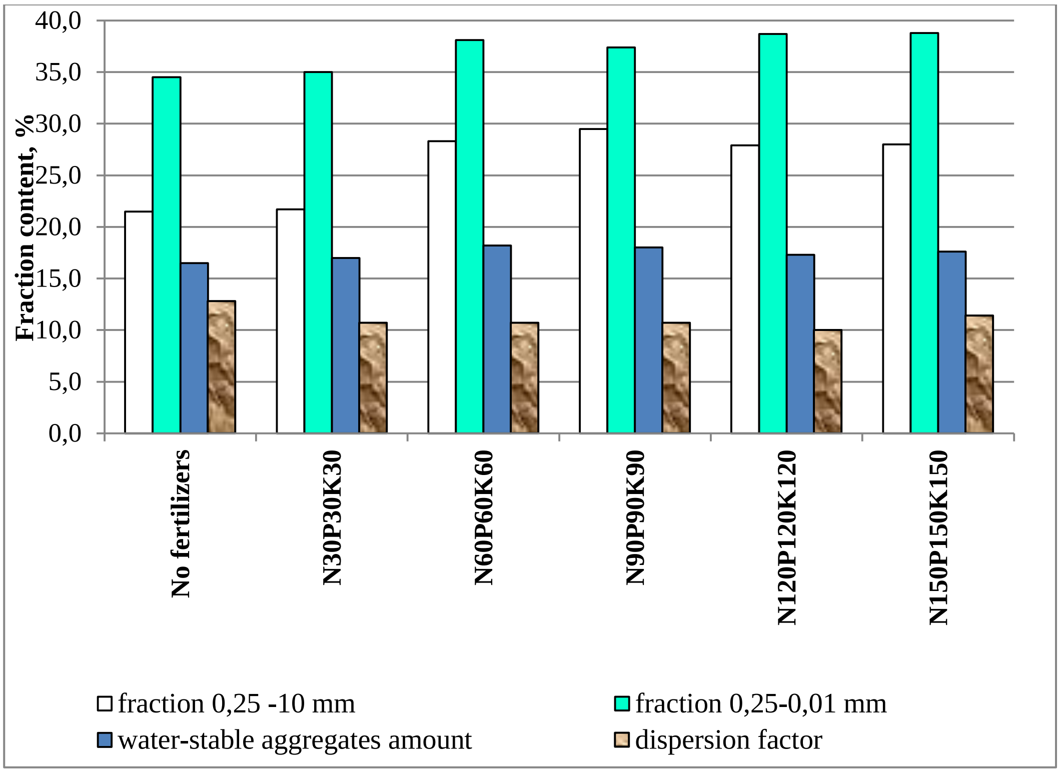

Fig. 1. The structure of sod-podzolic- soil in 0-20 cm layer.
average for 2011-2013.

Long-term mineral fertilization promoted an increase in soil humus from 1.54 to 2.18%, labile phosphorus from 296 to 399 mg/kg of soil, soluble potassium from 171 to 324 mg/kg of soil

(Table 1). High rates of mineral fertilizers ($N_{90}P_{90}K_{90}$ and more) caused soil acidity to increase: pH decreased, hydrolytic acidity (H_A) increased.

Table 1. Effect of mineral fertilizers rates on soil fertility parameters (0 - 20 cm layer).

Treatments	Humus. %	pH_{KCl}	mmol/100 g soil		Content. mg/kg	
			H_A	S	P_2O_5	K_2O
No fertilizers	1.54	5.01	2.20	19.8	296	187
$N_{30}P_{30}K_{30}$	1.66	5.12	2.18	20.3	303	171
$N_{60}P_{60}K_{60}$	2.08	5.00	2.30	21.7	330	213
$N_{90}P_{90}K_{90}$	2.12	4.94	2.67	21.3	385	293
$N_{120}P_{120}K_{120}$	2.18	4.91	3.01	20.7	391	305
$N_{150}P_{150}K_{150}$	2.17	4.82	3.05	20.5	399	324
LSD_{05}	0.41	$F_a < F_t$	0.10	$F_a < F_t$	56	60

Thus, increases in soil humus, labile phosphorus and soluble potassium and better soil agrophysical properties promoted winter rye yield to more than 3.5 t ha^{-1} (Table 2) in spite of water-deficient during certain vegetation periods. Increases of winter rye grain yield varied from 0.31 to 1.47 t ha^{-1} compared with the control ($LSD_{0.05}$ = 0.53 t ha^{-1}).

Table 2. The influence of mineral fertilizers rates on winter rye yields. t ha^{-1}

Treatments	Years			Average	Deviations		Crop returns 1 kg NPK/kg
	2011	2012	2013		t ha^{-1}	%	
Control	3.67	3.05	2.31	3.01	-	-	
$N_{30}P_{30}K_{30}$	3.87	3.22	2.87	3.32	0.31	10.3	3.4
$N_{60}P_{60}K_{60}$	5.10	3.94	4.39	4.48	1.47	48.8	8.2
$N_{90}P_{90}K_{90}$	4.84	3.87	4.03	4.25	1.24	41.2	4.6
$N_{120}P_{120}K_{120}$	4.92	3.92	3.65	4.16	1.15	38.2	3.2
$N_{150}P_{150}K_{150}$	4.97	3.95	3.61	4.18	1.17	38.9	3.2
LSD_{05}	0.51	0.34	0.42	0.53			

In the treatment with $N_{30}P_{30}K_{30}$ applied in the spring as a top dressing, growth retardation of winter rye plants was noted, as well as poor tillering compared with NPK addition at higher rates. That may be explained by the early resumption of vegetative growth in winter rye, when soil microbial activity is weak. Nitrogen release is slow and plants are stressed from nitrogen deficiency.

Moderate ($N_{60}P_{60}K_{60}$) and high fertilizer rates increased grain filling and 1000 grain mass. Maximum winter rye yield 4.48 t ha^{-1} was achieved in the treatment $N_{60}P_{60}K_{60.}$ Crop return reached 8.2 kg (Table 2). Higher fertilizer rates caused crop lodging and losses while harvesting and yields decreased as a result.

Conclusion

Non-uniform distribution of warmth and rainfalls during vegetation periods in 2011-2013 caused degeneration of the soil agrophysic properties. Topsoil density increased from 1.18-1.23 during the tillering stage to 1.54-1.61 g/cm³ during the grain milk-ripe stage.

Long-term mineral fertilization ($N_{60}P_{60}K_{60}$ and more) caused soil humus content to increase from 1.54 to 2.18 %, mobile phosphorus and soluble potassium to accumulate and soil acidity dimensions and soil agrophysical properties to improve, including the silt fraction and water-stable particles to increase.

A maximum winter rye yield of 4.48 t ha^{-1} was obtained using $N_{60}P_{60}K_{60}$. The highest crop return 8.2 kg was also noted in this treatment. The higher fertilizers rates caused crops to lodge and losses occurred while harvesting and yields decreased as a result.

SEED LIFE CYCLE MANAGEMENT

Sergej V. GONCHAROV

Crop breeding Department, Voronezh State Agricultural University, 1 Michurin Str., 394087, Russian Federation
Corresponding author: slogan1960@mail.ru

Abstract

Seed lifecycle management of corn, sunflower and sugar beet is discussed from marketing standpoint; and includes the market introduction phase, growth, maturity, and decline one. The market needs pipeline of varieties with higher added value, i.e., with competitive advantage compared to existing ones. The breeder has to be aware about value chain needs and pain points, and processing industry ones as well. Improve the return of investment to the breeding program based on improved turnover of seeds, royalty collection harmonization for certified seeds, and for the farm-saved seeds too. Knowledge of seeds life cycle characteristics allows to be more efficient in portfolio management, i.e. to adjust product pipeline to value chain needs. Variability of life cycle stages is one of its strategy implementation disadvantages. Recommended for specific stage strategy does not always aligned with expected result due to some uncertainties related with them.

Keywords: *Seed lifecycle, royalties, return of investment, breeding.*

Introduction

The seeds business is possible to explore from the standpoint of marketing, i.e. as the life cycle length of a product. The actual length of a variety availability at the market is considered as duration of its commercial use, or period of charging from the product market introduction till its withdrawal. Also, it is considered as an average period of the variety listing.

The shorter is life cycle of the product, the faster market growth is in the conditions of high competition on the seeds market, high-input technologies, and goals of profitable crop production. New generation of cultivars with better adding value (greater yield potential, better goods quality and proper adaptation) is able to increase the profitability of whole value chain from breeder till processor.

Fairness of the variety registration, patent protection and complicated certification are reducing varieties flow at the National register and enlarge their life cycle. Russia and the EU have common approach to the protection of intellectual property of seeds, and National registers populating by cultivars. Comparison of life cycle duration between field crops explains some details of crop competitiveness, attractiveness of markets for seed and other commercial products.

Materials and Methods

Lists of registered corn, sugar beet, and sunflower varieties were used as testing subject. Updated data of the National Register of Belorussia, Kazakhstan. Russia, and Ukraine in 2016 [National Register of Varieties and Ornamental Crops, 2016; National Register of Breeding Achievements (2016], have been interpreted with the author's method of variety life cycle duration assessment [Goncharov S.,2017]. The marketing approach was applied to identify stages of seed life cycle.

Results and discussion

Seed life cycle is the set of processes from identification of the consumer needs in food / feed products till their satisfaction. It is unique for every variety, and generalizes income in process of seed commercialization. It helps decision-making for identification of needs in the variety promotion support, or vice versa, if it makes sense to make solution about its withdrawal.

The seed life cycle describes the dynamics of the processes associated with the commercialization of varieties: investments, seed sales, profit generalization from trading and the royalties transfer. It consists of the phases of the market introduction (start of sales), growth, maturity and decline (Figure 1). The variety commercialization precedes breeding program (which takes 10-12 years). Although the breeding goals seemed to be common (yield, quality, resistance to stress, etc.), the market needs products with added value, and better return of investments (ROI) i.a. innovation [Goncharov S., 2017].

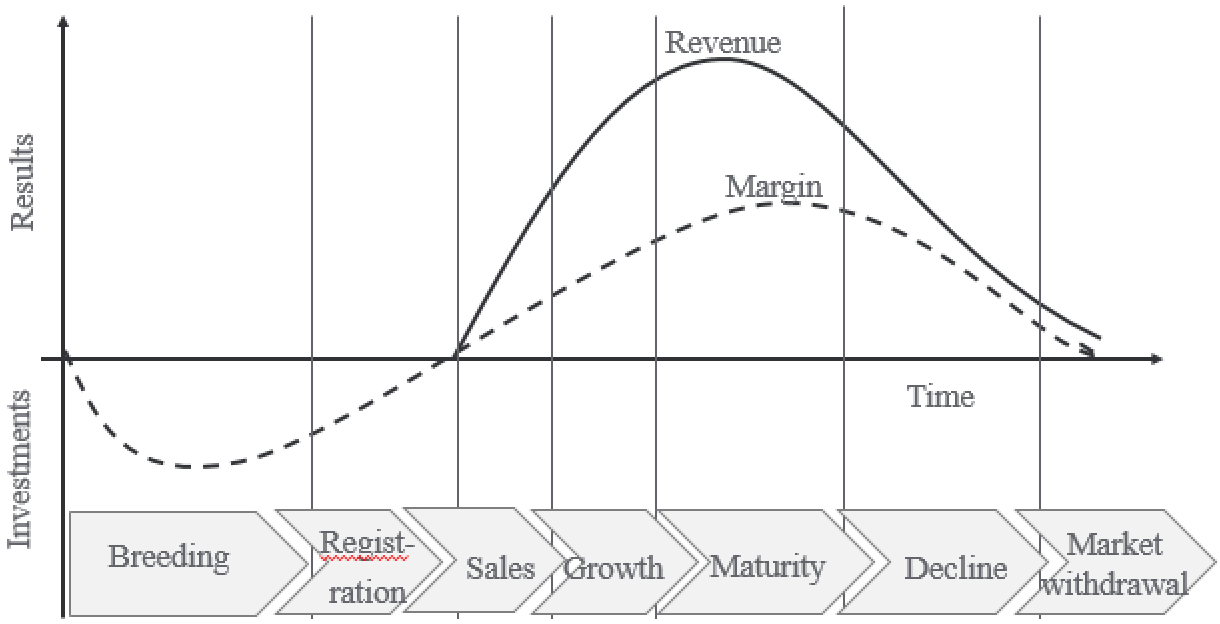

Figure 1. Seed life cycle stages

Every variety as a product has its own life cycle and it will pass through the stage of decline someday. But through effective product line decisions and other strategies its profitability period may be extended for the breeder benefit. Planning of seed sales volume, anticipated profits, pricing, etc. in 15-20 years (including the duration of selection 10-12 years with registration 2-5 years) is hardly possible. Availability of prototypes from other crops (for example, IMI- herbicides tolerance of sunflower) may be helpful for development of innovation

Seed life cycles of corn, sunflower, and sugar beet were comparatively short in Ukraine (9, 10 and 11 years). They last longer in Russia (11, 11 and 14 years correspondingly), and were the longest in Kazakhstan (20, 10, 19 years) (Figure 2). Genotype role is less important in Kazakhstan, then weather and climate conditions, with higher input on crops yield volatility.

Sunflower seed market is niche one in Belorussia, and therefore, seed life cycle is quite long there (19 years) with limited interest from breeders there. Cereals are losing their attractiveness for farmers in competition with higher margin crops sunflower, corn, sugar beet, rape seed etc.)

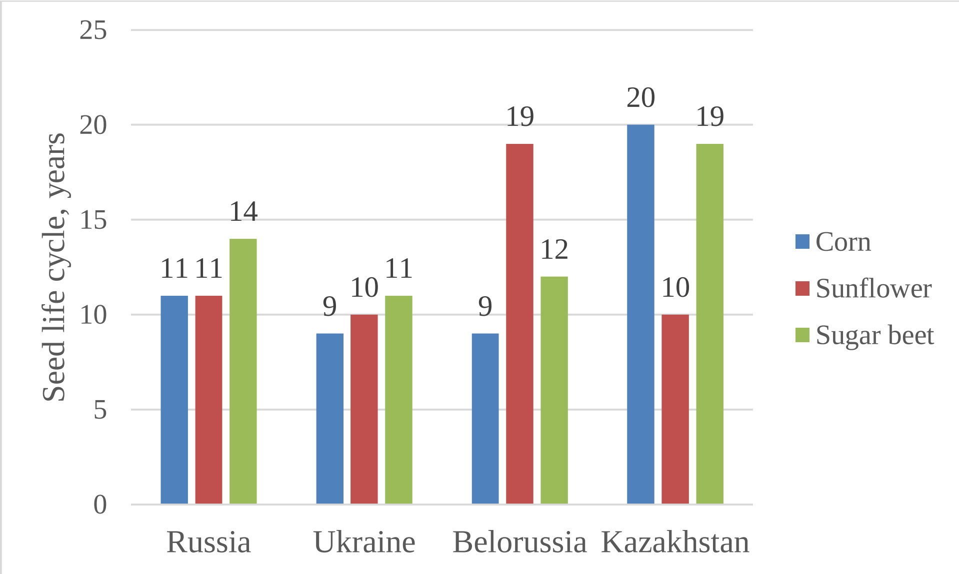

Figure 2. Seed life cycle duration in Commonwealth of Independent States countries, years

Seed companies prefer to multiply the new variety in advance to offer seeds to the market simultaneously with its registration decision, and be ready to conclude licensing contracts as well. Return of investment in breeding may be improved by harmonization of royalty collection for the sold certified seeds, and also for the farm-saved seeds.

The market introduction of the new variety is normally aligned with risks of the failure, costs of breeding, and registration fees. Seed companies invest in promotion, i.a., on the farmer awareness about the new products through demo-fields, co-promotion by potential partners in multiplication, advertising, branding, etc. Volumes of seeds are slow growing, as the new variety competes with the already available in the market. Different strategies are applied to the certain stages of seed life cycles for return of investment improvement (Table 1).

Table 1. Stage management of seed life cycle

Characteristics	Stages of seed life cycle			
	Introduction	Growth	Maturity	Decline
Seed sales	low	rising	Peak	decline
Profit	negative	rising	High	decline
Market objectives	product awareness	maximize market share	maximize profit	reduce expenditures
Customers	innovator	early adoptor	Magority	lagard
Product (variety)	market offer	services, quaranties, solutions	brand diversification	stop seed production
Price	premium	to win market	competitive varities	reduced

Distribution	selective	Intensive	support of intensive distribution	common
Seed sales promotion	seed strategy	partners choise	brand development	reduced
Advertising goals	variety awareness	mass interest	underline brand	minimized

Conclusions

Range of strategies targeting return of investment, are recommended for every stage of the seed life cycle.

Corn seed life cycle lasts from 9 years in Ukraine and Belorussia till 20 ones in Kazakhstan; sunflower one - from 10 years in Ukraine and Kazakhstan till 19 ones in Belorussia; sugar beet one - from 11 years in Ukraine till 14 ones in Kazakhstan.

The higher input in crop production (and, the better yields, and the bigger margin), the shorter seed life cycle is in CIS countries.

Abstract

The aim of this study was to investigate the effects of application of Ca - containing metallurgical slag on chemical composition (macro and trace elements) of chard (Beta vulgaris var. cicla) aerial parts. The study was performed in semi-controlled glasshouse conditions, and the effects of metallurgical slag was compared to those of other lime materials (ground limestone and hydrated lime) in combination without and with standard mineral and organic (liquid fish) fertilizers. P was determined by spectrophotometer, K - by flame emission photometry and N, C, S - using elemental CNS analyzer Vario EL III. In the determination of Fe, Zn, Cu and Cd, atomic absorption spectrometry was used. The results of the paper indicate that all Ca-materials studied, including metallurgical slag, along with the studied fertilizers, showed positive effects on the content of main and beneficial biogenic macroelements in aerial biomass of the tested vegetable. There is a noticeably and statistically significant tendency of an increase in the content of P, K and S in tested plant in the treatment with liquid fish fertilizer in relation to other treatments. Regarding the concentration of trace metals in tested vegetable, there was not found higher accumulation of Fe in tested plants in the treatments where metallurgical slag was applied in spite of its significant content in this liming material. As for Cd, its concentrations were within the safety limits and allowed concentrations in all the treatments, which is a highly desirable outcome.

Keywords: *Metallurgical slag, lime materials, mineral and liquid fish fertilizer, acid soil, chemical composition, chard.*

Introduction

Liming an acid soils, such as stagnosols, is the first step in creating favorable soil conditions for productive plant growth. Crops vary in their ability to tolerate an acidic (low pH) soil. In general, chard (*Beta vulgaris* var. *cicla*), belongs to those vegetables that grows well in a soil of pH around 6.5-6.8 and acidic conditions will stunt its growth. Thus, a necessary lime should be applied. Acid soils require liming and constant mineral and organic fertilization when used in agricultural production. The application of traditional alkaline liming materials such as limestone, dolomite and burnt lime to acid soils for the amelioration of acidity consequently improving crop production is a common practice (Barber, 1984; Troeh and Thompson, 2005). However, the alkaline nature and the need for sustainable and environmentally acceptable disposal options for metallurgical slag (Lopez *et al.*, 1995) have prompted its use as a liming material on acid agricultural soils.
The liming materials in metallurgical slag comprise water-soluble and less water-soluble Ca and Mg compounds. Free Ca in slag reacts rapidly with water to form $Ca(OH)_2$. The $Ca(OH)_2$

will react rapidly with soil acidity. In addition to the liming materials, metallurgical slag contains various concentrations of plant nutrients, such P, S, Mn, Fe, and Mo.

As early as the 1930s, metallurgical slag was being used as an agricultural amendment in Alabama, Illinois, Indiana, Kentucky, Maryland, New York, Ohio, Pennsylvania and West Virginia. White *et al.* (1937) reported on field trials in Pennsylvania that crop yields of corn, wheat, oats, buckwheat and soybeans with metallurgical slag applications were as good or better than an equivalent amount of limestone.

Some slags may contain elevated concentrations of trace metals such as iron, cadmium, chromium, copper, lead, molybdenum, nickel, and zinc. Concentrations of these metals vary in slags from different sources. All of these metals occur naturally in soil, and many are essential plant nutrients. If concentrations in the slag are similar to soil concentrations, they present no problem. If they are present at substantially higher concentrations in the slag than in the soil, repeated application of the slag could significantly increase soil concentrations of the metal in soil. This possibly could lead to plant toxicity, increased plant uptake and transfer of metals to animals or humans, or to other environmental problems. Although metallurgical slags contain varying concentrations of trace elements (e.g., trivalent Cr (III) and Zn), the bioavailability of these metals is very low (National Slag Association, 2001).

As a co-product of an industrial process, metallurgical slag offers considerable cost advantages over commercial limestone. In that manner, along with other lime materials (ground slag stone, saturated slag etc.) present in Serbia, metallurgical slag from Steel factory - Smederevo (Serbia) can be of great importance.

In addition, the aquaculture industry in recent years had to develop various management strategies to reduce the environmental impacts of aquaculture manure waste. In this regard, to evaluate the potential of aquaculture solid waste for use as a fertilizer, the aquaculture industry and regulatory agencies require analytical data regarding the concentrations of various plant nutrients found in the waste (Naylor *et al.*, 1999).

Regarding the aforementioned comments, the aim of this research was to investigate the effect of calcium containing metallurgical slag, a by-product from Steel factory from Smederevo, Republic of Serbia, on chemical composition of the aerial parts of chard. The effects of metallurgical slag was compared to those of other lime materials (ground limestone and hydrated lime) in combination without and with standard mineral and organic (liquid fish) fertilizers.

Material and Methods

Greenhouse experiment. The study was carried out in pot experiments under semi-controlled conditions in the glasshouse of the Institute of Soil Science (Belgrade in Serbia), from the fourth decade of March to the fourth decade of July, in 2015. In the experiments the comparison of the effect of metallurgical slag (MS) with other lime materials (ground limestone and hydrated lime) in combination with and without mineral NPK [composite NPK (15:15:15)] and organic (liquid fish - LF) fertilizers were studied. The ground limestone (calcium carbonate or calcite, $CaCO_3$) contains 60% of carbonate. Hydrated lime (slaked lime, $Ca(OH)_2$) reacts very rapidly and has a TNV (Total Neutralizing Value) of 135, thus 740 kg of hydrated lime is equivalent to one ton of ground limestone i.e. the TNV = 135 (Culleton *et al.*, 1999).

The experiment was undertaken with 1.4 kg per pot of Stagnosol (WRB, 2014), a type of marginal soil from Western Serbia region that has very low pH and poor physical and biological properties. The following nine designed variants were carried out in three replications: control (untreated soil) - V1; NPK mineral fertilizer - V2; $CaCO_3$ - V3; $Ca(OH)_2$ - V4; MS - V5; LF fertilizer - V6; NPK mineral fertilizer + $CaCO_3$ - V7; NPK mineral fertilizer + $Ca(OH)_2$ - V8; NPK mineral fertilizer + MS - V9.

Before sewing the chard, the amount of fertilizers and slag was measured according to the experimental design and mixed with soil (calculated as for 1 ha): NPK fertilizer (15:15:15) = 500 kg ha^{-1}; LF fertilizer = 170 kg ha^{-1}; $CaCO_3$ = 4 t ha^{-1}; $Ca(OH)_2$ = 2,8 t ha^{-1}; MS = 4 t ha^{-1} (same as the amount of $CaCO_3$, in spite of lower amount of slag). All three Ca-materials with granulation of 0.2 mm were applied in the experiment.

Chemical properties of the studied soil. Chemical characteristics and elemental composition of plowed layer of the Stagnosol used in this study were analyzed and determined in our previous studies (Pivić *et al.*, 2011; 2013). Accordingly, in relation to the reference values suggested by Šestić *et al.* (1969), the soil is characterized by very acid soil reaction, with pH in KCl 4.12, then, potential acidity (Y) and significantly low saturation of CEC, low content of soluble phosphorus and it is well supplied with available potassium.
Certain types of soil, including stagnosols, require the periodic application of soil conditioners such as commercial liming materials to provide aeration, increase moisture retention, and promote root permeation and growth. In several experiments in European countries it was determined the ability of metallurgical slag to raise the pH of acid soils (Rodriguez *et al.*, 1994; National Slag Association, 2011).

Chemical properties of MS. Chemical composition of MS used (Table 1) was determined in our previous study (Pivić *et al.*, 2011).

Table 1. Chemical composition of MS (Pivić *et al.*, 2011).

Parameter	Average value
pH in H_2O	12.48
Total Ca (%)	26.20
Total CaO (%)	36.60
Total $CaCO_3$ (%)	65.80
Available Ca (%)	17.18
Total Mg (%)	0.41
Available Mg (%)	0.07
Total P_2O_5 (%)	0.61
Total Fe (%)	15.34
Available Fe (mg kg^{-1})	3.38
Total Mn (%)	1.80
Available Mn (mg kg^{-1})	3.12
Total Zn (%)	14.60
Total Cu (%)	228.8

Accordingly, this material has very alkaline reaction (pH = 12.50), with the content of calcium in oxide forms (CaO) from 33-45%, of which about 50% is easily soluble in 1 M ammonium acetate; content of the total magnesium is about 0.40% and it was mainly in forms of MgO (0.70%); total phosphorous contained in the material is about 0.60%, where nearly all the amount is in available forms for plants; content of the total iron is high (about 15%), with noticeable lower amounts of its soluble forms; manganese is present in total amount of about 1.8% , but with noticeable low amounts of soluble forms; zinc is contained in lower amounts (10-20 mg kg^{-1}), while the content of copper is a little higher (about 200 mg kg^{-1}).

Origin and chemical analysis of LF fertilizer. The settleable faecal fish waste, used as liquid fertilizer in this study, was obtained from the farm growing rainbow trout (*Oncorhynchus mykiss*) in village Krupac, municipality of Pirot. Chemical composition of LF fertilzer included the following analysis: total nitrogen (N), carbon (C) and sulphur (S) were determined on elemental CNS analyzer Vario EL III (Nelson and Sommers, 1996); available phosphorus (P_2O_5) was determined by spectrophotometer and potassium (K_2O) by flame emission photometry, according to Egner-Riehm (Riehm, 1958), after they were heated to boiling with the mixture of concentrated sulfuric and perchloric acids.

Plant preparation and analysis. The aerial parts of chard plants were taken and after drying at 105°C the plant biomass was weighed. For all the plant samples from all the treatments the chemical composition of the aerial parts was analyzed. The content of nitrogen (N) was determined on elemental CNS analyzer Vario EL III (Nelson and Sommers, 1996). Phosphorus (P) and potassium (K) concentrations were determined by so called “wet” combustion, i.e. they were heated to boiling with the mixture of concentrated sulfuric and perchloric acids. In the obtained solution, P was determined by spectrophotometer with molybdate, and K – by flame emission photometry (Riehm, 1958). In the determination of investigated trace biogenic elements - iron (Fe), zinc (Zn) and copper (Cu), as well as cadmium (Cd) as the toxic heavy metal, plant material was converted to a solution by the so-called "dry" combustion, i.e., first by heating at 550ºC (for several hours) and then by treating the obtained ash with hydrochloric acid. These elements were determined by atomic absorption spectrometry - AAS (Wright and Stuczynski, 1996).

Data analysis. The effects of V1-V9 treatments on the studied chemical parameters of the plants were evaluated using the analysis of variance (SPSS 20.0, Chicago, USA), followed by Duncan's Multiple Range Test (DMRT). Significant differences between means were tested by the LSD test at P = 0.05.

Results and Discussion

Chemical composition of LF fertilizer. By screening the content of the main chemical parameters of faecal fish waste in this study, it was determined its moderate to high quality for use as an organic fertilizer (Table 2).

Table 2. Chemical composition of LF fertilizer.

Parameter	Average value
Total N (%)	3.33
Total C (%)	36.5
Total S (%)	0.36
Available P_2O_5 (mg 100 g^{-1})	10.2
Available K_2O (mg 100 g^{-1})	0.12

According to the certain previous studies (Olson, 1992; Westerman *et al.*, 1993) fish fertilizers tend to be highly variable in their chemical content, which is also the case with other manures. The various data demonstrate a wide variability in the general chemical composition of fish manure, although its macronutrients composition is of primary interest, given the end use of the manure as an agricultural fertilizer. As stated by Olson (1992), fish manure contains moderate amounts of essential plant nutrients in dry matter (2.83% N; 2.54% P; 0.10% K; 6.99% Ca; 0.53% Mg), which is similar to the results of the current study. Nevertheless, as suggested by Naylor *et al.* (1999), it is difficult to compare the values from the present study with those from others because of the differences in conditions under which the solids were produced, separated, stored, and collected.

Chemical composition of chard. The optimum pH range in soil for growth of most crops in soil is between 5.5 and 7.0, within which most plant nutritives are available (Prasad and Power, 1997). Some trace elements may pose a toxicity threat if present at elevated levels as their availability and mobility increases under acidic conditions (Pawlowski, 1997).

Data on the content of main and beneficial biogenic macroelements in aerial parts of the tested vegetable (Table 4) show the statistically significant differences between the treatments at P<0.05, that are due to increased crop yield (their dissolution in plants, especially for some elements: N, K), and due to higher accumulation of some elements and their mobilization from natural soil reserves primarily, as influenced by the additional lime materials in combination with mineral and LF fertilizer. There is a noticeably and statistically significant tendency of an increase in the content of P, K and S tested plant material in the treatment with LF fertilizer in relation to other treatments.

The nature of applied treatments and their combinations have an impact on trace metals accumulation, their mobility and storing capacity in plant tissues (Riesen and Feller, 2005). The concentration of trace metals in chard aerial parts shows that there are statistically significant differences between different treatments at P<0.05 (Table 5). It should be noted that there was not found higher accumulation of Fe in tested plant in the treatments where metallurgical slag was applied in spite of its significant content in this liming material. According to the reference values of Kloke *et al.* (1984), the concentrations of Cd were within the safety limits and allowed concentrations in all the treatments, which is a highly desirable outcome (Table 5).

Conclusions

The results of the paper indicate that all Ca-materials studied, including metallurgical slag, along with the studied fertilizers, showed positive effects on the content of main and beneficial biogenic macroelements in aerial biomass of the tested vegetable. There is a noticeably and statistically significant tendency of an increase in the content of P, K and S in tested plant in the treatment with liquid fish fertilizer in relation to other treatments. Also, there was not found higher accumulation of Fe in tested plant material in the treatments where metallurgical slag was applied in spite of its significant content in this liming material. As for Cd, its concentrations were within the safety limits and allowed concentrations in all the treatments, which is a highly desirable outcome. Generally, it was estimated that the studied metallurgical slag of the standardized chemical composition can be added to the acid soils toward amelioration the fertility without adverse effects.

Abstract

It is known that brassinosteroid phytohormones can influence the redistribution of mass in the plant, ie. the so-called. source-sink relationships that represent main determinante of yield of crops. These processes has long been investigated, the various methods, for different levels of material of plants (the subcellular biochemical processes, the cell and culture of plant cells, tissues and organs of plants, whole plants, plant communities-phytocoenoses and agrophytocoenoses), but even today, many details of these processes are unexplained. We have considered here the problems in the corn plants (Z. mays L; hyb. ZP704), aged 1-2 months during the experiments, grown in vessels of different volumes (V = 5 or 11 l, S and L plants), wherein the part of the plant transplanted from vessels less than vessels having a larger volume (RP plants), thus, we manipulate the status of the root. At the beginning of the test plants were treated with 10^{-8} mol of 24-epibrasinolide (24-EBL) or with 10^{-6} mol propiconazole (PZR), an inhibitor of the biosynthesis of brassinosteroids. During the treatment, we have taken samples for morphometric analysis of plant growth, and we measured Chla fluorescence parameters as indicators of photosynthesis. We note that the manipulation of roots in plants grown in S wessel greatly restricts growth of maize plants stems, roots and leaves, where it is visible to this plant for 2 months fail to enter the generative phase of development, which does not apply to RP and L plant. 24-EBL phytohormones and PZR biosynthesis inhibitor of brassinosteroid synthesis generally act slightly stimulating effect on the growth of plants, wherein it is somewhat more pronounced effect of the PZR. Plants growing in small vessels also has lower values of photosynthesis parameters then in L and RP plants, but treatment of a 24-EBL works more on stimulating photosynthesis, then treatment of PZR.

Introduction

Interrelationships between factors that affect crop growth are complex. The redistribution of assimilates from different plant organs is a key factor in the crop yielding and it depends on the plant hormonal status (particularly brassinosteroids: BRs; Clouse and Sasse, 1998) and the stress and other factor presence (Larcher, 2003). From that point, we investigated maize (ZP704) growth and photosynthesis influenced by root manipulation (Poorter and Nagel, 2000; Farrar and Gunn, 1998) and 24-epibrasinolide (24-EBL) phytohormone and propiconazole (PZR; an inhibitor of the brassinosteroids synthesis; Hartwig et al., 2012) during period of optimal temperature (~20-25 °C) for the maize growth, with the goal of finding new opportunities for increasing corn yield.

Materials and methods

Maize plants (ZP704) were grown in half-shade (PARmax≈500μmol photon cm^{-2} s^{-1}) one month in the summer of 2016 close to the our Institute (Belgrade, Serbia) in the pots of V=5 l (2/3 so called "S plants") and V=11 l (1/3 so called "L plants"), when ½ of 5 l plants grown were replanted in V=11 l pots (so called "RP plants"). Then samples for analysis of different morphometric parameters (Lambers et al., 1998) were taken, while the remaining plants were transferred to full daylight (PARmax1500 mmol photon cm^{-2} s^{-1}). After 7 days of light acclimation, 1/3 of plants were treated with 24-EBL (≈10^{-8} mol) solution, other 1/3 with PZR (≈10^{-6} mol) solution and 1/3 were control (K) plants. Treatment was repeated after 7 days. Then parameters of Chla fluorescence (Maxwell and Johnson, 2000; Lichtenthaler and Miehe, 1997) were measured and calculated. After 2 weeks experiment was finished, with the final Chla fluorescence measurements, together with the final analysis of different morphometric parameters (Lambers et al., 1998).

Results and disscusions

We note that the manipulation of roots in plants grown in S wessel greatly restricts growth of maize plants stems, roots and leaves, where it is visible to this plant for 2 months fail to enter the generative phase of development, which does not apply to RP and L plant (Table 1).

Chla: chloprophyll a; Abrreviations of parameters of Chla fluorescence and photosynthesis described in references: Maxwell and Johnson (2000) and Lichtenthaler and Miehe (1997)

According our previous results (Nikolić et al., 2014; Waisi et al., 2017) and the observed changes in plant mass allocation and photosynthesis (Table 1 nad 2), induced by root manipulation procedures and influence of changes in plant content of brassinosteroid type phytohormones, we hypotetized that these changes are mediated by their impact on plant energetics (see changes of parameters ETR and R_{FD730}). As we know that the plant roots is place of synthesis of phytohormones of cytokinine type with with a strong effect on photosynthesis processes (Nešković et al., 2003), we next hypotetized that on the redistribution of mass, plant growth and photosynthesis are mostly influenced by the interaction of the phytohormones of the cytokinine and brasinosteroid types, which opens up new possibilities for manipulating the yield of corn plants.

Abstract

The objective of this research was to compare the effects of different irrigation treatments on soybean [*Glycine max* (L.) Merr.] productivity and water use efficiency on experimental fields of the Maize Research Institute of Zemun Polje(Serbia), in 2007 and 2008. Four irrigation levels were investigated: full irrigation (I_{100}), 65% and 40% of I_{100} (I_{65} and I_{40}) and a rain-fed (I_0) system. The crop water use efficiency (CWUE, also known as crop water productivity –CWP), irrigation water use efficiency (IWUE) and evapotranspiration water use efficiency (ETWUE) were used to assess the water productivity of each studied treatment. The efficiency of the same treatment differed between the years as it depended on seasonal water availability, weather conditions and their impact on seed yields. Maximum and minimum yields were obtained in the I_{65} and I_0 treatments, averaging 3.41 t ha^{-1} and 2.26 t ha^{-1}, respectively. Water use efficiency values were influenced by the irrigation levels. In general, CWUE values increased with the increased level of irrigation. In both growing seasons, IWUE and ETWUE decreased with increasing the seasonal water consumption and irrigation depth. On average, treatments I_{40} and I_{65} resulted in similar or higher CWUE and ETWUE than I_{100}, in both growing seasons. I_{65} resulted in the highest IWUE, averaged over the two seasons, while I_{100} had the lowest IWUE. I_{65} could be proper for the soybean irrigated in Vojvodina when there is no water shortage and I_{45} could be used as a good basis for reduced sprinkler irrigation strategy development under water shortage.

Keywords: *Limited irrigation, Crop water productivity, Crop water use efficiency*

Introduction

Drought stress affects soya bean growth and productivity in Serbia as it does in many parts of the world. In Vojvodina, northern part of the Republic of Serbia, agriculture depends mainly on rain. However, the amounts and distribution of rainfall vary from year to year and during growing seasons. In the variable climatic conditions of Vojvodina, in which summers are semi-arid to semi-humid (Bošnjak, 2001), high and stable yields of soybean can be obtained only by irrigation.

In this region, as in many similar regions around the world, the availability of freshwater resources for agricultural use has been decreasing due to climate change and increasing consumption. Therefore improving CWUE is vital for meeting the increasing food and fiber demand. Water deficits often inhibit crop growth and the production potential of agroecosystems, given that most crops are sensitive to a short supply of water in different critical stages of growth. On the other hand, excessive soil moisture tends to increase farming costs and pollute the environment (as fertilizers and other agrochemicals are carried away). As such, improving water productivity (WP), also referred to as water use efficiency (WUE), is very important in agriculture. The widespread opinion is that increasing water productivity in agriculture is key for mitigating water scarcity and addressing environmental challenges.

Numerous experiments (Garcia y Garcia *et al.*, 2010; Kirnak *et al.*, 2010; Candogan *et al.*, 2013) have been conducted at different locations to determine soybean responses under different water management conditions. These studies suggest that limited irrigation during the whole growing season or during a specific growth stage can significantly increase WUE and soybean yields, and that the magnitude of the response to irrigation depends upon climate, rainfall during growing season, soil properties, cultivar genetic, soil and crop management practices, experimental procedures, and other factors. Given that water use efficiency of the same crop differs between regions, a local database of water productivity indices (CWUE, IWUE and ETWUE) needs to be developed (Djaman and Irmak, 2012). Information is lacking on the impact of different irrigation levels on soybean yield and water use efficiency in the Vojvodina region. Therefore, the objective of the present research was to determine and compare water productivity indices of soybean under full and deficit sprinkler irrigation and rainfed conditions in a temperate environment of Vojvodina. The results of this study can help better estimate crop yield response to the amount of water added by irrigation in local farming conditions.

Material and Methods

Site description

The study carried out in Maize Research Institute of Zemun Polje (Serbia) for two growing seasons (2007, 2008). The soil is classified as a calcaric, silty clay Chernozem and exceeded 1.2 m-depth. The averaged soil water content of the top 0.6 m soil, measured by a pressure plate extractor, is 35% by volume at –0.033 MPa (field capacity – FC), and 15% at –1.5 MPa (permanent wilting point – PWP) (Kresović *et al.*, 2016). The climate is moderate continental influenced by the Mediterranean (Kresović *et al.*, 2016).. Figure 1 shows average monthly temperatures and precipitation levels in 2007 and 2008 growing seasons for the period April-September.

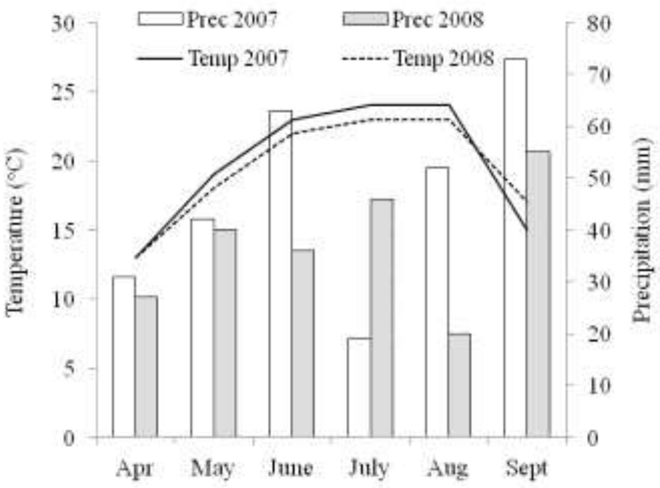

Figure 1. Average monthly temperatures and precipitation during study growing periods.

Experiment plan

Comparisons were made between four irrigation regimes: full irrigation (I_{100}), 65% and 40% of I_{100} (I_{65} and I_{40}) and no irrigation – rainfed (I_0). The setup was of a randomized complete block design, and each treatment was replicated four times. Each experimental plot was designed 7.14 m long and 8.0 m wide (57.12 m^2). Irrigation amount and time were determined based on the soil water content in the effective zone of the root system (0–60 cm deep). The amount of water then given to the full I_{100} treatments was calculated to refill the root zone close to the field capacity. The total water amount applied was 50, 80 and 135 mm in 2007 season, and 95, 160 and 235 mm in 2008 season for I_{40}, I_{65} and I_{100}, respectively. Irrigation was applied using hand-move sprinkler irrigation systems with sprinkler heads on a 12 m × 12 m square grid. Sprinkler heads (Model RINKA), with two nozzles (4 mm × 3.2 mm), were mounted on 2.8 m higher risers, and the operating mean pressure was 350 kPa with a flow rate of 1.47 $m^3\ h^{-1}$.

Soybean cv. Nena (MG II) of Maize Research Institute "Zemun Polje" company was sown on 24 April 2007 and 6 May 2008 with a four-row planter with 0.5 m row and the seeding rate was 4.45 seed m^{-2}. Seed yield was measured by harvesting an area of 5.0 m^2 per plot. Hand-harvest took place on 18, and 15 October, respectively for the two seasons. Seed yield was normalized for 13% seed water content.

Water use efficiency indices

CWUE, IWUE and ETWUE were used to assess the efficiency and productivity of soybean in different irrigation treatments. CWUE (kg m^{-3}) was calculated using the following equation (Boss, 1985):

$$\mathrm{CWU} = Y/ETa \tag{1}$$

where Y - seed yield (kg m^{-2}), ETa - crop water demand, expressed as seasonal actual evapotranspiration under varying irrigation regimes (mm).

ETa was calculated with the soil water balance equation:

$$ETa = P + I \pm \Delta SW \tag{2}$$

where P - precipitation (mm), I - amount of irrigation water applied (mm), ΔSW - variation in water content (mm) of the soil profile.

To help account for the irrigation component on CWP, Boss (1985) suggested two new indices – irrigation water use efficiency (IWUE) and evapotranspiration water use efficiency (ETWUE):

$$\mathrm{IWUE} = (Y_i - Y_r)/I \tag{3}$$

$$\mathrm{ETWUE} = (Y_i - Y_\mathrm{r})/(ET_i - ET_r) \tag{4}$$

where IWUE and ETWUE are expressed in kg m^{-3}, Y - yield by treatment (kg m^{-2}), ETa and I are the seasonal actual evapotranspiration and the amount of water added by irrigation per treatment (mm), and subscripts i and r denote the level of irrigation (or lack thereof).

The ANOVA was performed at $p \leq 0.05$ level of significance to determine whether differences existed among treatments means. Regression analysis was used to evaluate water seed yield–irrigation water and water productivity indices–seed yield and irrigation depth. All the analyses were done using a statistical software package (SPSS windows version).

Results and Discussion

Treatment effects on seed yield

There was a highly significant increase in yields as the irrigation level increased from I_0 to I_{65}, but dropped at full irrigation in both years (Fig. 2). In this research, adding irrigation water for maintaining soil moisture at 65% of full irrigation (I_{100}) was enough for soybean water needs, since the further increment of water completed with yield reduction by 2.8% (2007) and 16.2% (2008) as compared to I_{65}. Therefore, in normal climatic year 80 mm of irrigation application amount is enough to compensate the shortage of rainfall in growing season. Although I_{65} received about 69% and 47% less irrigation water applied to the I_{100} plots, seed yield was increased by an average of 2.9% and 19.3%, respectively. In 2007 growing season, there was no statistical difference between I_{65} and full irrigated treatment at a significance level of 0.05 (data not shown), which supports the finding that limited irrigation can be effectively used to conserve water with minimal to no effect on seed yield. However, I_{40}, I_{65} and I_{100} were statistically different from rainfed conditions, with mean differences of 0.96, 1.15 and 0.84 t ha^{-1}, respectively.

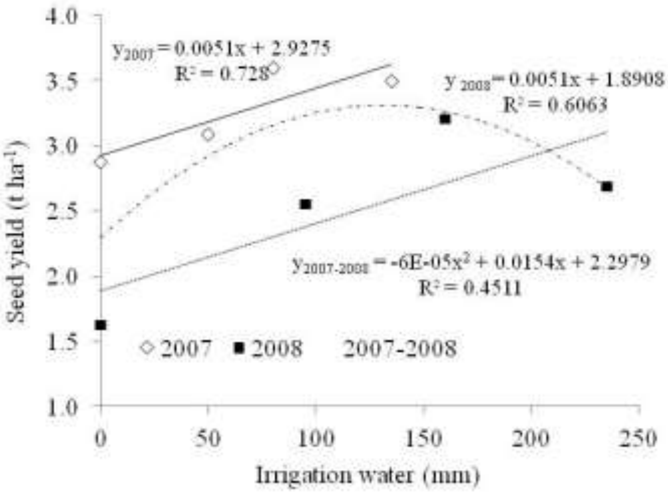

Figure 2. The relationship between soybean seed yield and seasonal irrigation.

Kranz and Benham (2004) reported that irrigation and/or high amounts of rainfall during vegetative growth of soybean are not normally beneficial except during periods when soil water contents are extremely low. Excessive water during the vegetative stage stimulates vegetative growth and increases the potential for water logging and fungal diseases with essentially no increase in seed yield. In some cases, excessive early season precipitation and/or irrigation can lead to seed yield reduction.

A similar effect of water deficit and drought-stress on soybean seed yields was also observed by other researchers (Sincik *et al*., 2008; Kirnak *et al*., 2010; Candogan *et al*., 2013). To determine the effect of irrigation water on soybean yield, regression analysis was utilized and test results indicated statistically significant good linear relationship between seed yield and irrigation treatments with R^2 = 0.73 and R^2 = 0.61 for 2007 and 2008, respectively (Fig. 2). Similar to our results, Dogan *et al*. (2007) reported linear relationship between seed yield and seasonal irrigation water for soybean grown under semi-arid climatic conditions, Quadratic relationships between soybean seed yield and seasonal irrigation water also were observed Gercek *et al*. (2009) in semi-arid climate (Sanliurfa, Turkey).

Treatment effects on CWUE

In 2007 growing season, CWUE was higher than in 2008 (28%, 20%, 17%, and 37 % for I_0, I_{40}, I_{65}, and I_{100}, respectively) due to better climatic conditions that were favourable to carbon assimilation and photosynthesis (Fig. 3). The large variations in CWUE and seed yield between growing seasons can be attributed to seasonal differences in air temperature and the distribution of rain during the grain-filling period. In both growing seasons CWUE increased with irrigation depth, reached maximum values in treatment I_{65} and then gradually declined as the amount of water added by irrigation increased. CWUE values of I_{65} were higher than the other treatments with the percentage of 4.6–19.4% and 8.4–40.1% for the same years, respectively. In the relatively wet season (2007) no significant difference was found between treatment I_0 and I_{40}.

Comparable to our results, Sincik *et al*. (2008) and Demirtas *et al*. (2010) reported significantly lower WUE values of deficit irrigated soybean in a sub-humid environmental conditions of Turkey, which ranged from 0.46 to 0.58 kg m^{-3} and from 0.41 to 0.64 kg m^{-3}, respectively. Our results are in agreement with those of Katerji and Mastrorilli (2009), who reported WUE values for soybean of 0.73 (clay soil) and 0.81 kg m^{-3} (loam soil).

The regression analysis in Fig. 4 shows a linear CWUE increase with seed yield (R^2 = 0.06) in 2008 growing season, while the CWUE decreased linearly with seed yield in 2007 (R^2 = 0.03) and irrigation in both study seasons (R^2 = 0.40 and R^2 = 0.17, respectively). The relationship between CWUE and seed yield and seasonal irrigation was poor in both growing seasons. Payero *et al*. (2005) also reported poor the relationship between CWP and seasonal irrigation of deficit irrigated soybean grown in the semi-arid environment of west-central Nebraska. Howell (2001) reported that irrigation can be an effective resource to improve WUE through increasing crop yield especially in arid and semi-arid environments. Even in humid and sub-humid environments, irrigation is particularly effective in overcoming short-duration droughts. However, irrigation by itself may not always produce the highest WUE possible.

Treatment effects on IWUE

Results obtained in this experiment indicate that irrigation regimes significantly ($p < 0.05$) affected IWUE in both growing seasons (Fig. 3). Lower IWUE values observed in 2008 (drier season) than in the 2007. Large variation in IWUE values was found as a result of significant differences in applied irrigation water across growing seasons. IWUE is affected not only by the irrigation depth, but also by the amount of rainfall during the growing season. However, IWUE can be inconsistent because of potential out-of-purpose use of irrigation water (e.g. soil water retention, deep percolation, excessive soil water evapotranspiration, runoff, etc.) (Howell *et al*., 1990). In deficit irrigated treatments, greater IWUE values were obtained as it was determined by different researchers (Sincik *et al*., 2008; Gercek *et al*., 2009). Treatment I_{65} resulted in the highest IWUE values in both growing seasons. Due to more severe climatic conditions in 2008 growing season, the soybean responded more favorably to irrigation water, resulting in higher IWUE values for I_{40} and I_{65} than for the fully irrigated treatment. In a relatively dry 2008 no significant difference was found between treatment I_{40} and the rainfed. Treatment I_{65} is the most efficient in IWUE with the value of 0.90 and 0.98 kg m^{-3} for 2007 and 2008 growing season, respectively. IWUE values of I_{65} were higher than the other treatments with the percentage of 1–18% (in 2007) and 16–30% (in 2008) for the same growing seasons, respectively.

In general, the IWUE values from this research were higher than many of the values reported in the literature (Evett *et al*., 2000; Sinick *et al*., 2008; Demirtas *et al*., 2010). Higher values for IWUE in this study were because we applied less irrigation water during growing seasons (50–235 mm), whereas Evett *et al*. (2000) applied 371–671 mm of water for different irrigation regimes, Sincik *et al*. (2008) applied 160–464 mm for a deficit irrigated treatments and Demirtas *et al*. (2010) applied 428–453 mm for well-watered soybean grown in sub-humid environment (western Turkey) under a drip irrigation system. Our findings are between values for IWUE ranging from 0.07 to 1.04 kg m^{-3} (average 0.56 kg m^{-3}) for a soybean estimated from results obtained by Pejić *et al*. (2012), where the soil and climate conditions are similar location as our research.

Figure 4 shows a linear increase in IWUE with seed yield, while the IWUE decreased linearly with irrigation in both growing seasons. There was good linear relationship between IWUE and seed yield for 2007, but not for 2008 (Fig. 4). In addition, good linear relationship was observed between IWUE and irrigation water for 2008, but not for 2007 (Fig. 4).

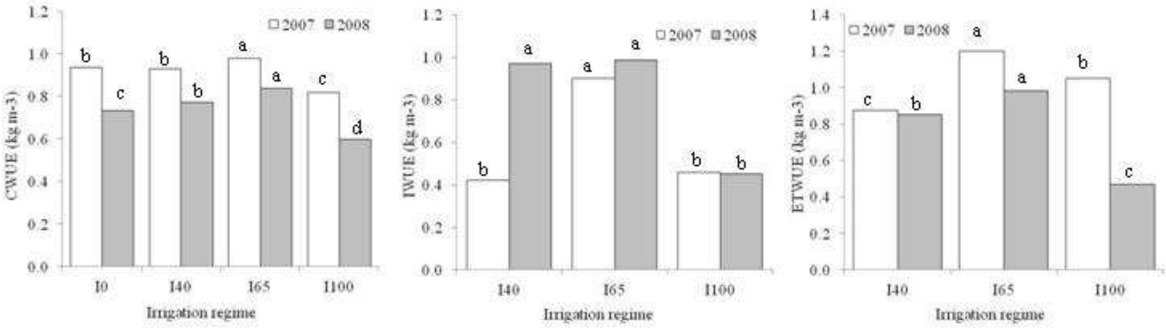

Figure 3. CWUE, IWUE and ETWUE indices of soybean in different irrigation treatments. Histograms with the different letters denote the significant differences between treatments according to LSD test ($p < 0.05$).

Treatment effects on ETWUE

Observed soybean crop cumulative *ETa* values ranged from 308 to 427 mm in 2007, and from 227 to 450 mm in 2008 season (data not shown). The I_{100} treatment resulted in the highest seasonal *I* and crop *ETa*, while the lowest values were obtained for the I_0 treatments for both the years. The irrigation water and crop *ET*a values of all deficit irrigated treatments were clearly less than that of the full irrigated (I_{100}) treatment for both years.

In these research, ETWUE of soybean varied from 0.88 kg m^{-3} at I_{40} to 1.05 kg m^{-3} at I_{100} in 2007 (Fig. 3). The highest ETWUE values, averaging 1.20 and 0.98 kg m^{-3}, was obtained for treatment I_{65} in both years; while the lowest value was found for treatment I_{40} (0.88 kg m^{-3}) in 2007 and 0.47 kg m^{-3} in full irrigated treatment in 2008 season. The results of this research are similar to those of Pejić *et al.* (2012).

There was good linear relationship between ETWUE and seed yield for 2007 ($R^2 = 0.92$), but not for 2008 ($R^2 = 0.29$) (Fig. 4). The relationship between ETWUE and irrigation water was not consistent across the two seasons. Figure 4 shows a linear increase in ETWUE with seed yield in both growing seasons and irrigation ($R^2 = 0.15$) in 2007, while the ETWUE decreased linearly with irrigation water ($R^2 = 0.56$) in 2008 growing seasons. Differences in CWUE, IWUE and ETWUE across growing seasons are partially due to weather differences.

Conclusions

This study indicated that irrigation is necessary for soybean cultivation because rainfall is insufficient to meet the crop water needs. In general, CWUE, IWUE and WUE of the deficit irrigated treatments (I_{40} and I_{65}) were higher than those of the fully irrigated treatments (I_{100}). In terms of crop response to irrigation levels, the I_{65} treatment is viable practice in increasing yield and WUE of soybean with sprinkler irrigation under the conditions experimentation took place. The results show that under limited water situation, I_{40} is an acceptable irrigation strategy to increase seed yield and WUE. In brief, the overall results indicated that the irrigation water was used effectively in deficit irrigated treatments in comparison to the full irrigated treatment (I_{100}).

Abstract

The aim of the experiment was to analyze forage yield, seed yield and seed yield components of the cultivars of birdsfoot trefoil (*Lotus corniculatus* L.) grown in combined production for forage and seed on acid soil. The field trial was established in 2012 in Čačak city area (Serbia) in a randomized block design with three replications on the loessivized vertisol with acid reaction (pH in H_2O 4,8). Trefoil cultivars (K-37 and Rocco) were seeded in a 20 cm row distance with 10 kg ha^{-1} of seed. In the year of planting, due to an expressed dry period, there was no yield, and the analyses were done in the second and the third year of cultivation. Forage yield of birdsfoot trefoil in the first cut in the second year of production was low, which was also the result of the long dry period in the previous year. However, the relatively high seed yield in the second growth in the second year of the cultivation and high forage yield in the third year of the cultivation indicated that the trefoil was largely tolerant to condition of acid soils. The cultivars did not differ among themselves significantly in terms of forage yield. Significant differences between the cultivars were recorded in terms of dry matter content in the time of the cutting. The cultivars also differed among themselves in terms of the seed yield, which was the consequence of the differences in the number of stems per unit area and the number of seeds per pod.

Introduction

Birdsfoot trefoil (*Lotus corniculatus* L.) is a perennial forage legume which is widespread in the world. In Serbia, there are no reliable statistics about the surface where it is grown and yields, but it is considered that among perennial forage legumes it takes the third place according to prevalence, after alfalfa and red clover. It is particularly important plant in the hilly and mountainous regions of Serbia (Petrović et al., 2011), given that is used for establishing of grassland in the conditions bad for alfalfa (Dimitrova, 2010). According to Vučković (2004) the average forage yields of birdsfoot trefoil ranging from 35 to 40 t ha^{-1}, and hay 8-10 t ha^{-1}. Mijatović (1975) points out that on the basis of the four-year results, production potential of birdsfoot trefoil on eroded land in the hilly area is higher by 25.5 % in comparison to alfalfa.

Soil acidity is one of the factors that limit the cultivation of many cultivated plants. According to Vučković et al. (2005) birdsfoot trefoil is tolerant towards the alkaline reaction, up to pH 9 as well as towards the acid reaction, up to pH 4, but according to Hall (2004) it gives the best yields on the soils which pH is around 7. Đukić et al. (2009) point out that nitrogen fixation and adoption of phosphorus at birdsfoot trefoil plants is highest when the pH value is between 4.8 and 7.4. Stevanović et al. (1995) reported that from 4 700 000 ha of cultivated area in Central Serbia and Kosovo, over 2 800 000 ha are acid soils, which is more than 60%, of which around 30% are extremely acid soils. The aim of the work was to analyze the forage yield, hay yield and seed yield of birdsfoot trefoil cultivars in the crop grown on the acid soil for combined production of fodder and seed.

Materials and methods

The experiment was established in Čačak (43°54'39.06" N, 20°19'10.21" E, 246m a.s.l.) in 2012, on the loessivized vertisol type of soil, with the acid reaction (pH in H_2O 4.8), which contains 3.18% of organic matter, 0% $CaCO_3$, 22.08 mg P_2O_5, 30.0 mg K_2O 100 g^{-1} of soil, 12 mg kg^{-1} Al and 1,111 mg kg^{-1} Mn. The main tillage of soil was carried out to a depth of 30 cm. Together with the main tillage and after everyone of the vegetations 300 kg ha^{-1} of $N_{15}P_{15}K_{15}$ were incorporated into the soil. Two cultivars of birdsfoot trefoil were used: K-37 (Institut for forage crop Kruševac) and Rocco (Italian variety). The field experiment was set up using a randomized block design with three replications with plot size of $5m^2$ (5x1m). Sowing was done at a distance of 20 cm of interrow spacing, with the seeds amount of 10 kg ha^{-1}. Weed control was done mechanically on two occasions. The crop was grown without irrigation. Mean annual air temperature and the amount of annual precipitation in the period of performing the experiments are shown in the Table 1.

Table 1. Precipitation and mean monthly temperatures during period of 2012-2014.

	Month	1	2	3	4	5	6	7	8	9	10	11	12	$\bar{x}$ i $\sum$
2012	t (°C)	1.8	-2.5	6.8	12.2	17.3	24.1	26.6	25.4	20.9	13.8	9.5	1.4	13.12
	P (L m^{-2})	60.0	70.0	10.0	47.0	68.0	38.0	22.0	0	7.2	30.0	23.7	87.6	463.5
2013	t (°C)	3.5	3.8	6.6	13.2	18.2	20.6	23.3	24.1	17.2	14.5	8.9	2.0	12.99
	P (L m^{-2})	51.0	68.0	65.7	37.0	78.5	61.5	10.0	62.5	87.0	17.0	40.5	4.0	582.7
2014	t (°C)	4.0	6.6	10.2	12.8	16.1	21.1	22.7	22.1	20.1	15.1	8.9	3.1	13.6
	P (L m^{-2})	21.5	6.0	52.5	105	125	103	163	56.0	101	50	19	90	892

In the year of planting, due to expressed dry period, there were no yield, and the analyzes were done in the second and the third year of cultivation. The first growth in the second year and everyone of the three growth in the third year of cultivation were cut in the optimal stage for forage production. Forage yield was determined by measuring the total mass from the plot immediately after cutting and converted to forage yield in t ha^{-1}. After drying the sample at the room temperature, hay yield (t ha^{-1}) and dry matter content in the forage (the share of hay in the total forage yield) (%) was recalculated.

The second increase in the second year of growing was used for the seed production. Following yield components were determined: stems number m^{-2} and inflorescences number m^{-2} (by counting on the area of 0.2 m^2 per elementary plot), inflorescences number per stem and the pods number per inflorescence (counting on the ten randomly selected stems from elementary plot). In the laboratory were determined: flowers number per inflorescence and seeds number per pod (in the sample of ten inflorescences per elementary plot), as well as the thousand seeds weight (based on the mass of 5x100 seeds). The potential seed yield was determined on the basis of components of yield (inflorescences number m^{-2}, pods number per inflorescence, seeds number per pod, thousand seed weight) and recalculated on the seed yield in kg ha^{-1}.

The obtained results were processed with the analysis of variance of one-factorial experiment using SPSS software (1995).

Results and discussion

Cultivars of birdsfoot trefoil did not significantly differ among themselves in terms of forage and hay yield in the first cut in the second year of cultivation, although the variety Rocco had a significantly higher content of dry matter in the forage (Tab. 2). Forage yield and hay yield in the first cut in the second year of cultivation were low (forage yield was 12.5 t ha^{-1} in the variety K-37 and 13.85 t ha^{-1} in the variety Rocco, and hay yield 2.47 t ha^{-1} in the variety K-37 and 3.06 t ha^{-1} in the variety Rocco). The low yield is the result of a long and expressed dry period in the previous year.

Table 2. Forage yield, hay yield and dry mater content in forage of birdsfoot trefoil cultivars in the first cut in second year of cultivation.

		Forage yield (t ha^{-1})	Hay yield (t ha^{-1})	Dry mater content (%)
Cultivar	K-37	12,5	2,47	19,87b
	Rocco	13,85	3,06	22,16a

The values denoted with different small letters within columns are significantly different ($P \leq 0.05$) in accordance with the LSD test

In the third year of cultivation in all of the cuts, there were no significant differences reported between the cultivars in terms of yield of forage and hay (Tab. 4). A significantly higher content of dry matter in the forage was reported in the first and second cut in the variety Rocco. In contrast to the relatively low yield of forage and hay in the second year of cultivation, in the third year was reported a satisfactory yield of forage and hay, due to the favorable weather conditions. The highest yield of forage and hay was reported in the first cut, slightly lower in the third and the lowest in the second cut. The total forage yield in the third year of cultivation was 54.06 t ha^{-1} in the variety K-37 and 57.06 t ha^{-1} in the cultivar Rocco, respectively hay yield was 10.62 t ha^{-1} in the variety K-37 and 12.38 t ha^{-1} in the variety Rocco. Similar results also had Radović et al. (2007), who reported the average yield of cultivars of birdsfoot trefoil of 53.85 t ha^{-1} in the third year of production on the degraded alluvium. According to Đukić et al. (2007), cultivar K-37 can give the forage yield of 69.4 t ha^{-1} and 13.2 t ha^{-1} of hay per year.

The total yield of the hay in the third year of production in our experiment was 10.62 t ha^{-1} in the variety K-37 and 12.38 t ha^{-1} in the variety Rocco. Balan et al. (2002) reported that average yields of dry mater of the examined genotypes of birdsfoot trefoil ranged from 5.4 to 5.8 t ha^{-1}. Higher yield of forage and hay in our experiment was the consequence of good supply of nutrients and water in soil, regardless of the acid reaction, as well as favorable weather conditions with sufficient rainfall in 2014.

Table 3. Seed yield and yield components of birdsfoot trefoil cultivars in the second growth in the second year of cultivation

		SNM	INS	INM	FNI	PNI	SNP	TSW	SY
Cultivar	K-37	823	1,77	1427	2,64	2,51	15,04	1,22	655b
	Rocco	949	1,78	1695	3,27	2,59	17,82	1,25	990a

SNM - stem number m^{-2}, INS - inflorescence number per stem, INM - inflorescence number m^{-2}, FNI - flower number per inflorescence, PNI - pod number per inflorescence, SNP - seed number per pod, TSW - thousand seed weight (g), SY- seed yield (kg ha^{-1}). The values denoted with different small letters within columns are significantly different at ($P \leq 0.05$) in accordance with the LSD test.

Birdsfoot trefoil cultivars did not significantly differ among themselves in terms of the seed yield components in the second cut in the second year of cultivation (Tab. 3). Potential seed yield (calculated on the basis of yield components) was 655 kg ha^{-1} in variety K-37 and 990 kg ha^{-1} in the variety Rocco. Differences in seed yield were primarily due to differences in the number of stems per unit area and the seeds number per pod. In full maturity pods easily shatter an seeds effuse. Shattering problem significantly limits the successful production of seeds (Fairey, 1994). According to Winch et al. (1985) losses in harvesting birdsfoot trefoil seeds are large, ranging up to 85 % of potential yield. In this paper, the birdsfoot trefoil seed yield is presented, recalculated on the basis of yield components, without taking into account the losses at harvest. According to Turkington and Franco (1980) and Gullien (2007) potential seed yield of birdsfoot trefoil is estimated at 1200 kg ha^{-1}, while the average harvested yields on the global level are below 200 kg ha^{-1}. According to McGraw et al. (1986), the average yield of birdsfoot trefoil seed varies from 50-175 kg ha^{-1}, or in average it is about 100 kg ha^{-1} of seed. Seaney and Henson (1970) state that seed yields of birdsfoot trefoil range from 50-560 kg ha^{-1}. Seed yields of birdsfoot trefoil in USA range from 50 to 170 kg ha^{-1} (Fairey and Smith, 1999), in Uruguay between 120 and 150 kg ha^{-1} (Garcia et al., 1991; Artola, 2004) and in Argentina between 25 and 150 kg ha^{-1} (Mazzanti et al., 1988). According to Vojin et al. (2001), in agro-ecological conditions of Serbian Republic in the area of Banja Luka, there was a birdsfoot trefoil seed yield of 272 kg ha^{-1}. In Republic of Serbia, seed yield ranges from 100-280 kg ha^{-1} (Vučković et al., 1997). According to Miladinović (1967), with full agrotechniques, seed yields of birdsfoot trefoil in the Republic of Serbia could reach even more than 350 kg ha^{-1}.

Table 4. Forage yield (FY) (t ha^{-1}), hay yield (HY) (t ha^{-1}) and dry mater content in forage (DM) (%) cultivars of birdsfoot trefoil in the third year of cultivation.

		The first cut			The second cut			The third cut		
		FY (t ha^{-1})	HY (t ha^{-1})	DM (%)	FY (t ha^{-1})	HY (t ha^{-1})	DM (%)	FY (t ha^{-1})	HY (t ha^{-1})	DM (%)
Cultivar	K-37	21,2	4,21	19,87b	12,95	2,68	20,69b	19,91	3,73	18,79
	Rocco	23,3	5,16	22,15a	15,58	3,55	22,79a	18,18	3,67	20,22

The values denoted with different small letters within columns are significantly different ($P \leq 0.05$) in accordance with the LSD test

Conclusion

In the second and the third year of cultivation between the cultivars of birdsfoot trefoil there were no significant differences in terms of forage and hay yield. Significant differences between the cultivars were recorded in terms of the content of dry matter at the time of cuting. The cultivars also differed among themselves in terms of the seed yield, which is the consequence of differences in the number of stems per unit area and number of seeds per pod. Forage and hay yield of birdsfoot trefoil cultivars in the first cut in the second year of cultivation was low. Low yield is the consequence of long and expressed dry period in the previous year. In the third year of growing, due to a favorable weather conditions, the satisfactory forage and hay yield of birdsfoot trefoil was recorded. Relatively high seed yield in the second growth in the second year of cultivation and high forage yield in the third year of cultivation indicate that birdsfoot trefoil is largely tolerant to conditions of acidic soils.

NS PEPPER VARIETIES IN A MULTIVARIATE FRUIT ANALYSIS

Dario DANOJEVIĆ*, Slađana MEDIĆ-PAP, Janko ČERVENSKI

Institute of Field and Vegetable Crops, Novi Sad, Serbia
*Corresponding author: dario.danojevic@ifvcns.ns.ac.rs

Abstract

Peppers (*Capsicum annuum* L.) have a very diverse use in Balkan cuisines and Serbia is no exception. Different ways of consumption has come as a result of various types, colours and sizes of peppers. The aim of this study was the phenotypic evaluation of 16 pepper varieties. Ten pepper varieties were selected at the Institute of Field and Vegetable Crops in Novi Sad (IFVCNS), and 6 were domesticated pepper varieties from the IFVCNS assortment. The trial was conducted in field conditions on chernozem soil in 2016. The experiment was established in a randomized block design with three replications. Five fruits per replicate were used for a phenotypic evaluation. The varieties were characterized for 7 quantitative and 5 qualitative fruit traits. The principal component analysis (PCA) was used to identify the most significant traits and to show distances between the varieties in a biplot. The cluster analysis was applied to show similarities between the varieties and to create common groups. In the PCA biplot all pepper varieties were grouped into five groups, but in the cluster analysis they made six groups. The biggest group in both analyses consisted of bell peppers. Those multivariate analyses are suitable to represent differences and similarities among pepper varieties visually.

Key words: *Capsicum annuum, Cluster, Fruit evaluation, PCA, Serbia.*

Introduction

In most cultivated species, the loss of genetic variability began with the process of domestication (Tang et al. 2010). In contrast, thousands of years of human selection in different conditions and growing methods bring to the development of new mutations and gene combinations that are of agricultural importance, with low probability to occur under the pressure of natural selection. Pepper (*C. annuum* L.) is one of the major vegetable species in Serbia. Pepper comparing to other vegetable crops (excluding potato) has the first rank in Serbia with 16,977 ha in 2016 (Statistical Office of the Republic of Serbia, 2017). In different regions of Serbia people consume pepper fruits with various shapes, sizes and colors (Danojevic *et al.*, 2016). Fruit characterization is the first step in the description and classification of pepper germplasm for breeding purpose. The application of appropriate statistical methods is a useful tool for the description and genotype classification, since it enables plant breeders to identify and select valuable genetic resources in a breeding programs (Jankulovska *et al.*, 2014). Smith and Basavaraja (2005) and Bharadwaj *et al.*, (2007) found that during selection of peppers a very important traits are: fruit weight, fruit length and fruit diameter because they directly affecting the yield. Significant positive correlation between the morphological traits and AFLP markers indicated that the difference in AFLP distances tend to reflect the morphological differences. Therefore, the genotypes can easily be distinguished using only phenotypic traits (Geleta *et al.*, 2005). Hierarchical cluster analysis is a useful tool for partitioning variability of collections for managing them effectively and provides ground for curators and breeders to enhance the usefulness of their collections (Peeters and Martinelli, 1989). Many scientists around the world have studied variability in pepper germplasm and have clustered them into genetically related groups in order to select superior genotypes for use in future breeding programs (Cvikić, 2009; Occhiuto *et al*., 2014, Silva *et al*., 2015). The aim of this research was to characterize pepper varieties for main fruit traits visually and to found relationship between traits and varieties.

Materials and Methods

Sixteen pepper genotypes from the Institute of Field and Vegetable Crops assortment were sown in the last week of March in 2016 in a plastic house. The field trial was conducted at the experimental field of the Institute of Field and Vegetable Crops (Rimski Šančevi), Novi Sad (Serbia). Genotypes were transplanted in tree replicates (rows) with 20 plants in each row at last decade of May. Density of plants was 70 x 25 cm. Regular cultural practices were applied throughout the growing season (inter-row cultivation, irrigation). Five fruits per replicates were harvested in October at the physiological maturity. The following quantitative traits were analyzed: fruit weight, fruit length, fruit diameter, fruit index, locule number, number of apexes, and pericarp thickness. Also fruit color before maturity, fruit color at maturity, fruit shape in longitudinal section, fruit attitude and presence of capsaicin in placenta were noted according to UPOV Test Guidelines (2006). Software package Statistica for Windows ver. 12, (StatSoft. Inc. 2013) were used for Principal Component Analysis (PCA) and Cluster Analysis (CA) to evaluate the level of diversity for pepper varieties and to rank the contribution of the variables. Mean values per genotype were standardized (Mean=0, SD=1) and used for analysis. For the construction of dendrogram Complete Linkage with squared Euclidean dinstances was used. Principal components have been extracted until the Eigen value > 1.

Results and Discussion

PCA indicated that the first three components explained 84.81% of the total variance (Table 1). Since the first three principal components (PC) were over Eigenvalue 1, only those were intepreted.

Table 1. Eigenvalues and total variance of the first three principal components (PC) in pepper varieties.

PC	Eigenvalue	% Total variance	Cumulative Eigenvalue	Cumulative variance %
1	6.205197	51.70998	6.20520	51.7100
2	2.834814	23.62345	9.04001	75.3334
3	1.138196	9.48497	10.17821	84.8184

The most important positive traits in first PC were: fruit index, fruit shape in longitudinal section, and capsaicin in placenta, while the negative were: fruit diameter, fruit weight, pericarp thickness and number of apexes (Table 2).

Table 2. Correlation between original variables and the first three principal components (PC) in pepper varieties.

Variable	PC 1	PC 2	PC 3
Fruit Length	0.103355	**-0.938267**	-0.076459
Fruit Diameter	**-0.953260**	-0.203104	0.144728
Fruit Index	**0.948926**	0.134171	-0.120185
Fruit Weight	**-0.848412**	-0.240125	0.161494
Number of Apexes	**-0.810313**	0.502003	-0.134416
Locule Number	-0.567144	0.531240	-0.381190
Pericarp Thickness	**-0.936573**	-0.175492	0.076035
Fruit Color before Maturity	0.324726	0.257422	**0.877431**
Fruit Color at Maturity	-0.642038	-0.440472	-0.020056
Fruit Shape in Longitudinal Section	**0.772349**	-0.535953	0.102178
Fruit Attitude	0.021784	**-0.823186**	-0.213464
Capsaicin in Placenta	**0.833944**	0.217655	-0.274644

Ilić *et al*., (2013), found that beside the fruit yield per plant, fruit weight and pericarp thickness were the most important variables in the first PC. In the second PC the most important traits were: fruit length and fruit attitude. Bozokalfa *et al*., (2009) found that in the first two PC, the greatest variation was described with following fruit traits: fruit diameter, fruit weight, fruit volume, fruit wall thickness, pedicel length and fruit length. Based on PCA analysis, pepper varieties have been grouped according to the fruit characteristics (Figure 1).

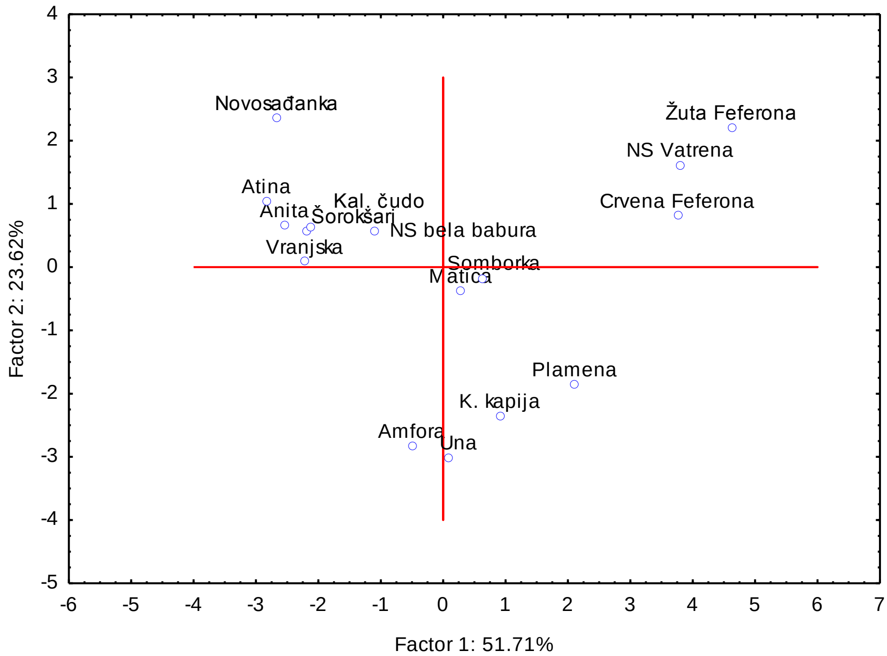

Figure 1. Biplot of the two principal components for the NS pepper varieties based on fruit traits

In the first quadrant were varieties: Crvena feferona, Žuta feferona and the new NS Vatrena. All varieties belonged to small hot peperoni type with erect fruit, while the largest differences were at color maturity. Bell peppers and Novosađanka (tomato shaped pepper) were represented in the second quadrant. In the lower part of biplot were kapia type varieties (Amfora, Una, and Kurtovska kapia), as well as shipka type (Plamena). Varieties with upright fruit position and conical shape (Matica and Somborka) were located in the center of biplot. Although that relatively small number of varieties were included in this analysis, they showed high variability. Because of high diversity for morphological fruit traits in Capsicum, this genus is highly applicable for genetics and breeding in practical classes with students (Prohens *et al.*, 2010). All our varieties could be also presented through a picture of one or two fruits per genotype and grouped according to PCA analysis. That type of visual fruits presentation will be good for students to learn better fruit similarity and divergence between pepper genotypes. A great relationship were established with PCA analysis between the major fruit characteristics: fruit weight, pericarp thickness and fruit diameter (Figure 2). Fruit attitude is in the great dependence on the fruit length (shorter fruits are usually upright). The number of apexes is highly dependent on the locule number, and the pungency is related to the fruit index.

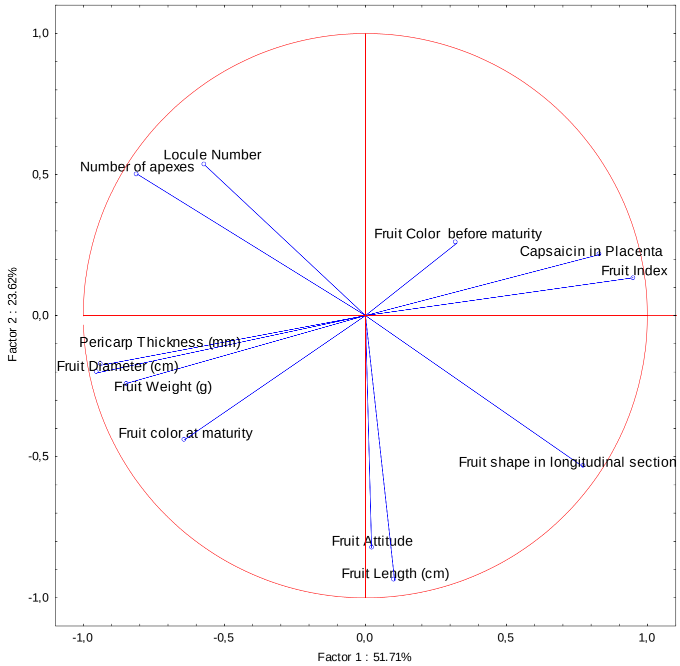

Figure 2. The two principal components for the NS pepper varieties based on fruit traits

Zečević (2001) noted that the fruit diameter, fruit length, pericarp thickness, number of fruits and fruit weight are in a strong correlation. Positive correlation was found between fruit weight and fruit length, fruit diameter, pericarp thickness, and locule number (Danojević *et al.*, 2016). According to Cvikić (2009) the cluster analysis based on the quantitative traits gave results that are much more applicable than grouping of genotypes with morphological markers. Reason of this phenomenon is because the fruit weight has greater variability than any other quantitative trait, and it has the highest contribution in multivariate analysis. Although researchers usually evaluate the germplasm variability separately for quantitative and qualitative traits, a small number of them combines these two trait types in a one multivariate analysis. Based on cluster analysis, varieties included in this research have been grouped into 6 groups (A-F) (Figure 3). In group A (bell pepper type), were the most number of varieties: Vranjska, Anita, Šorokšari (Soroksari), Atina, Kalifornijsko čudo (Cal. Wonder) and Novosadska bela babura. Variety Vranjska is set aside in a separate subgroup primarily due to the hanging fruit position, while other varieties have upright position. Novosađanka is allocated in a second group (B) as the only tomato variety in that group. Varieties with conical fruit shape and the upright position (Matica and Somborka) were in the group C. The varieties with kapia fruit type (Kurtovska kapija, Amfora, Una) and shipka type (Plamena) have been classified into group D and E. Žuta Feferona, Crvena Feferona and NS Vatrena (small hot peperoni type) were clustered in the group F.

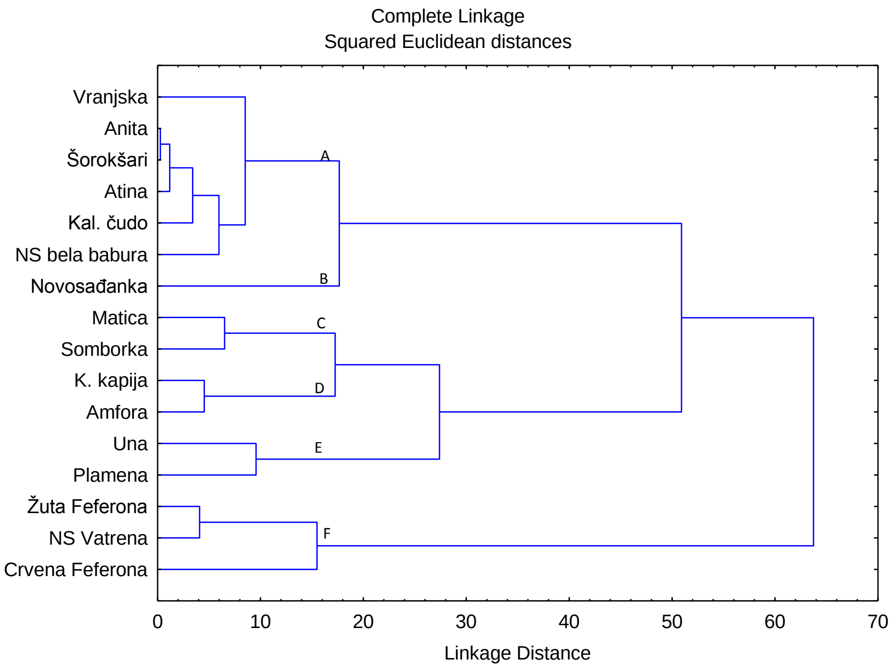

Figure 3. Dendrogram of NS pepper varieties based on evaluated fruit traits

Conclusions

Evaluated varieties showed significant differences from the Institute of Field and Vegetable Crops assortment. The largest group of varieties consisted of bell peppers but they showed very similar characteristics. Choosing of some important fruit traits and use of Principal Component Analysis and Cluster Analysis is appropriate method for good visual presentation of different pepper varieties. There is still a need for increasing the number of new pepper varieties, because customers want pepper fruits with different sizes, colors, shapes and pungency levels.

Abstract

Humus is a very important soil component, which is a source of nutrients and is a factor in fertility preservation. An analysis of 4.346 soil samples from 743 farms at the location of Aleksinac municipality, whose total area is 1.747,57 ha, has found that 0.2% of the samples belong to the class of very poorly humified soil, containing organic matter up to 1%. It has also been found that 43.3% of the samples belong to the class of poorly humified soil, with the organic matter content ranging from 1% to 3%. Furthermore, 55.2% of the analyzed soil samples belong to the class of well-humified soil, with the humus content ranging from 3% to 5%. The lowest value was found in one of the samples from the village of Rsovac, and it was 0.08%, while 4 out of 5 samples with the highest humus values were found in the village of Aleksinacki Bujmir (9.98% was the highest value that was found). Chemical analysis were performed in 2015, in the Agricultural Advisory and Professional Service - Nis, where the humus content was determined by using the Tyurin method. Soil samples were taken from a depth of 0-30 cm in field crops and vegetable cultures, or 0-60cm in orchards. The results obtained are consequence of insufficient application of organic fertilizers, excessive use of mineral fertilizers, inadequate agricultural technology, irrational removal of crop residues and their burning. The organic matter content in the analyzed plots of Aleksinac municipality, as well as throughout Serbia, is under a strong anthropogenic influence. In accordance with this, the removal of crop residues without prior analysis and determination of organic matter in soil is not recommended and, in particular, the burning of crop residues should be avoided.

Keywords: *humus, organic matter, soil.*

Introduction

The research of the humus content in agricultural soil was performed in the municipality of Aleksinac, which was 26% of the total surface area of the region of Nis, with a surface area of 707 km² (1.3% of the territory of Serbia). Arable land is 65% of the total area of the municipality of Aleksinac, and the remaining 35% are hills and mountains. Irrational and intensive land use has resulted in loss of soil fertility (the quality decreases). Humus is a source of nutrients and a factor in soil fertility preservation. Humus is a very important soil matter, due to its ability to bind large amounts of water and nutrients, which are easily available for plants. The humus content decreases in deeper soil. Production of food, especially healthy food, is a global problem, because conventional agriculture creates a great number of negative effects (Pejanović, 2015). In order to preserve the natural fertility of soil, it is necessary to create a minimum of 3-3.5 t/ha of humic substances out of manure or other organic matter microbiologically.

One of the ways of losing humus is removal of or burning biomass of field plants. In this way, not only is organic matter lost, but also biogenic elements, which are fully or partially lost during the burning process (Kastori *et al.*, 2012). In order to stop further land degradation, organic farming is discussed more frequently. Fertilizers are not applied in organic production and, for this reason, long-term maintenance of soil fertility is important. The application of organic fertilizers introduces microorganisms to the soil, and the entered organic matter is partially mineralized, then high-molecular organic compounds, humic substances, are formed from the degradation product (FAO, 2011). Soils with a higher content of total nitrogen contain more humus, so they are more fertile (Ubavić *et al*.,1990). Organic substances and mineral fertilizers in the soil contribute to an increase in the mass of roots (Jaćimović *et al*., 2014). Straw incorporation (SI) by plowing shows similar results to those achieved by the incorporation of fertilizers; it improves soil properties and grain yields. The fertilization of nitrogen (N) fertilizers also increases the quantity of crop residues, which is reflected in an increase in the humus content and the retention of carbon in the soil by the incorporation of crop residues into the soil (Halvorson *et al*., 1999). Soils rich in humus show a lower volumetric density, from 1.0 - 1.6 g/cm^3, due to a lower particle density and a higher porosity, which is created between and within structural aggregates under the influence of humus. How to prevent a further humus reduction in the soil? The solution is sought in bacteria, by using bacterial fertilizers. During one year, bacteria leave about 10 tons of organic mass, which comes from their dead bodies, and most of this mass is humified into mature humus (European Commission DG ENV, 2010). A humus decline in the soil is caused by the fact that the quantity of nutrients that leave the soil through the yield is greater than the quantity of nutrients that are returned to the soil. To prevent any further decline of humus in the soil, plowing of crop remains is recommended as one of the measures. In addition to this measure, fertilizing with manure and plant cultivation (mainly legumes) in order to increase the organic matter in the soil are also recommended.There are several methods for humus determination, and a treatment in which strong oxidants affect the organic matter, wherein the oxidation of carbon (C) from humus occurs, is common to all the methods. Carbon is essential for life and the reproduction of microorganisms that favorably affect the biological properties of soil. The most common humus forms are mild (mature) humus and acidic humus. Crops grow better in mild (mature) humus, where the C:N ratio is very similar; mild humus is found in the best soils. Acidic humus is found in poorer soils. Legumes have the greatest effect on the preservation of a stable structure and good-quality humus in the soil (Stošić, 2005). Soil fertility control is a legal obligation of the owner or user of agricultural land under the Agricultural Land Law (Official Gazette of the Republic of Serbia, 2009. No. 62/06, 65/08, 41/09).

Material and Methods

An analysis of 4.346 soil samples from 743 farms (total area is 1.747,57 ha) of Aleksinac municipalit. Humus analyses (Tyurin method) were performed in 2015, in the Agricultural Advisory and Professional Service – Nis in Serbia.
Soil samples were taken from a depth of 0-30 cm (field crops and vegetables), and 0-60 cm (orchards).

Figure 1. A map of Aleksinac municipality with the number of samples taken in the villages (Dragan Grcak, 2017)

An individual sample consisted of 20 to 25 individual samples (in lots up to 5 ha) from a depth of 0-30 cm) in plots under field or vegetable crops or in plots where field or vegetable crops were planned to be grown, and from a depth of 0-60 cm, in plots under orchards or vineyards or in plots where orchards and vineyards were planned to be located.

Research data processing was performed by using a mathematical-statistical method in the computer program SPSS (Statistical Package for the Social Sciences).

Results and discussion

The analysis included 59 out of total 71 villages in the municipality of Aleksinac (Figure 1). Figure 1 shows the number of sample plots in the villages. The lowest number of samples (one per village) was taken in the villages Čukurovac, Krušje and Ljupten, and the largest number of samples was taken from the village of Mozgovo (495 plots sampled).In the course of soil fertility control, the content of organic substance, i.e. humus, was analyzed as one of the parameters. Based on the processing of 4.346 data on the farms of Aleksinac municipality, it was found that a large percentage of 43.3% of the samples analyzed belonged to the class of soils with poor humus content, i.e. below 3%. 55.2% of the agricultural lands analyzed belonged to the class of soils with good humus content, from 3 to 5%. Only 1.3% of the samples analyzed belonged to the class of highly humified soils with the humus content higher than 5%.The variability indicator was calculated through standard deviation using the computer, and the standard deviation was ± 0.77, which indicated that there were no major differences among the values of humus. Humus increases the water holding capacity in sandy soils, and it causes looseness in clayey soils. The rate of humus disintegration depends on the intensity of land treatment and irrigation (PSSS, 2011). Calcification, as an agro-technical measure, abruptly changes the biological properties of soil, changing the balance of formation and decomposition of humus in the direction of more intense mineralization. This process depletes soil and a drop in productivity occurs. This adverse effect can be reduced by applying organic fertilization (manure). Fertilizing with manure is recommended after calcification for 3-4 weeks (Milanović and Memić). In the past decades, a decline of humus content, 0.38% on average, has been found in the soils of Vojvodina. This situation is due to a number of factors: an increased use of artificial (inorganic) fertilizers, a reduced use or nonuse of manure (organic fertilizer), burning of the by-products of cultivated plants, etc. (Bogdanović *et al.*, 1993). Livestock capacities have significantly decreased, thus the production of manure is negligible. The number of livestock units per hectare of arable land is 0.33 (Macroeconomics, 2016). One conditional head of livestock is necessary to increase the nutrient content in the soil. In this way, the water-air, thermal, nutritional and microbiological properties of the soil would be improved. Fertilization with organic and mineral fertilizers helps the increase in humus content in the soil (Manojlović, 2008). The results of the humus content in the paper Milivojević *et al.*, 2012, on field crops on the arable land in the town of Kragujevac, show that 59.54% of the samples (average humus content 3.29%) belong to the class of soils with good humus content, while 35.77% of the samples (humus content ranging from 1.01 to 3.00%) belong to the class of soils with poor humus content. In the examination of the humus content in the course of soil fertility control in Central Serbia in 2015, 70.723 samples were analyzed. The mean value of the analyzed samples is 3.73%, which belongs to the class of humified soils (3-5% of humus). The analyzed samples indicate that the soils under orchards, meadows and pastures belong to the class of humified soils (3-5% of humus), while the arable land and vineyards belong to the class of poorly humified soils (1-3% of humus) (Ministry of Agriculture and Environment Serbia, 2017). Based on a detailed classification (Figure 2), the samples with the organic matter content ranging from 2% to 3% are dominant in the class of poorly humified soil, whereas the soils with the humus content ranging from 3% to 4% are dominant in the class of humified soil. In Serbia and in other parts of the world, experiments that have been carried out show that plowing harvest residues increases the yield and its quality, and it also increases the content of total nitrogen (N) and carbon (C) (Powlson et al., 1987).

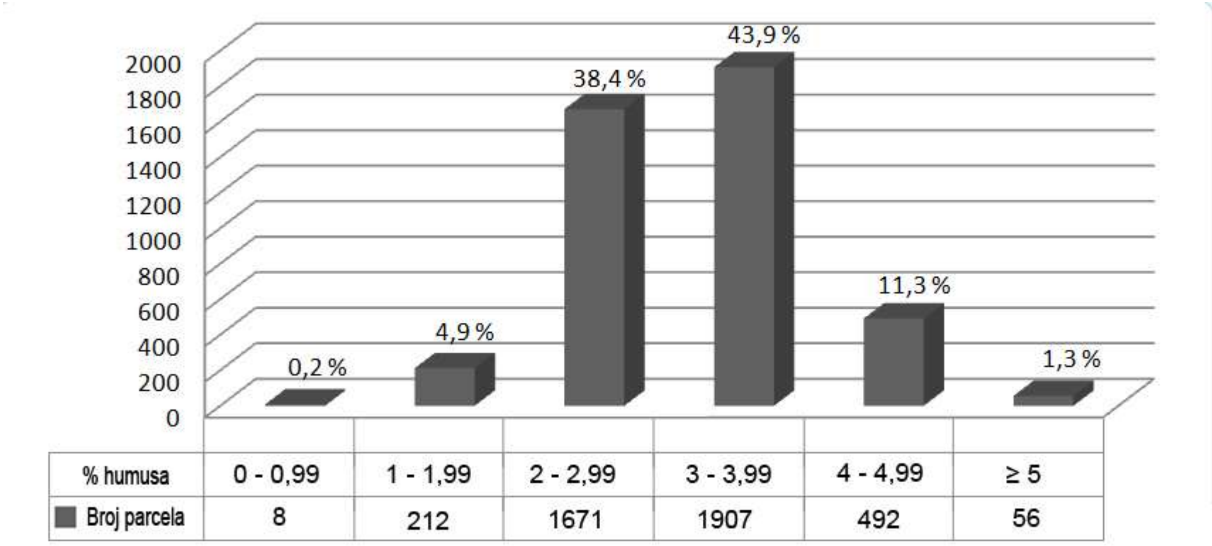

Figure 2. The proportion of samples that belong to certain classes of humus content (%) in the municipality of Aleksinac (number of samples 4.346).

Conclusions

Based on the results of the analyses of soil samples from the municipality of Aleksinac (Serbia), it can be concluded that the humus content in the soil is different, as a result of different soil types and different use of agricultural areas. It was found that:
Less than 1% of the samples belonged to the class of very poorly humified soil
Little less than a half of the samples belonged to the class of poorly humified soil
Little over a half of the analyzed soil samples belonged to the class of well-humified soil
The humus content above 3% was dominant, but it should be maintained and increased by plowing harvest residues and by organic fertilization.
Based on the results of the examination, it can be concluded that organic fertilizers should be used more in the future.
The humus content analysis shows that the majority of the soil analyzed belongs to the class of humified soil and poorly humified soil.
The decrease in the content of humus in the soil is worrisome, especially in the soils where its level is lower than 1%. This tells us that, by cultivating and using land, we have reduced the organic matter, i.e. an imbalance between the entry and exit of the organic matter in the soil has occurred. Dehumification is present in almost all agricultural soils in Serbia. The results obtained are consequence of excessive use of mineral fertilizers, inadequate agricultural technology, insufficient application of organic fertilizers, irrational removal of crop residues and their burning.
The soil analysis serves as a recommendation of the use of a certain quantity and composition of fertilizers in accordance with the demands of different crops and expected yield.

Abstract

Phenological traits, yield, and fruit characteristics of seven plum cultivars of medium early maturation time were studied in the region of Belgrade (Serbia) in the four-year period (2013-2016). Control cultivar for comparison was 'Čačanska lepotica'. The average time of flowering of tested cultivars was in the first half of April, and the average duration of flowering varied from 7.8 to 11.3 days. The average time of maturation ranged from July, 17 ('Valerija') to July, 31 ('Hanita'). The average yield per tree was the lowest in the cultivar 'Venera' (8.6 kg) and the highest in the cultivar 'Valerija' (28.6 kg). Compared to control, significantly higher yield was achieved in the cultivar 'Valerija', while the lower yield was found in cultivars 'Venera', 'Excalibur', 'Kišinjevska rana' and 'Čaradejka'. The lowest vigor was recorded in the cultivar 'Valerija', and the highest in the cultivar 'Reeves'. The average fruit weight ranged from 36.1 g in the cultivar 'Hanita' to 71.1 g in the cultivar 'Reeves'. Compared to control, fruit weight was significantly higher in cultivars 'Reeves', 'Excalibur' and 'Valerija'. High soluble solids content (above 18%) was found in cultivars 'Venera' and 'Kišinjevska rana'. Based on the obtained results, for growing in Belgrade region, cultivars 'Valerija' and 'Hanita' can be recommended.

Key words: *Prunus domestica, flowering, maturation, yield, fruit characteristics*

Introduction

Plum (*Prunus domestica* L.) is the most important fruit species in Serbia with the average production of 420.000 t per year in the period of 2011-2016 (Statistical Office of the Republic of Serbia, 2017). However, the average yield is low, only 5,4 t/ha. This is because the production is mostly extensive and cultural practices are often at a low level. The largest amount of produced fruits is processed into brandy (more than 60%), while much smaller amounts are dried, frozen, and processed into other product. Fresh consumption of plums is quite small. In recent years, there is a tendency to increase export of fresh fruits, mostly in Russia (Milatović, 2013).

A lot of work has been done on creation of new plum cultivars with improved characteristics, such as better adaptation to different ecological conditions, increased disease resistance, self-fertility, higher yield and better fruit quality. In the last 20 years more than 170 new plum cultivars were released in Europe (Butac et al., 2013). The introduction of new foreign cultivars and their study in Serbian climatic and soil conditions allow better choice of cultivars, and may improve the production of plums.

Plum breeding has been developed at the Fruit Research Institute in Čačak since 1946. The result of this programme are 15 released cultivars (Glišić et al., 2015). Most grown Serbian cultivars in new orchards are: 'Čačanska rodna', 'Čačanska lepotica' and 'Čačanska rana'.

The aim of this study was to evaluate phenological traits, yield and fruit characteristics of seven plum cultivars of medium early maturation time. The best performing cultivars will be recommended for growing in the region of Belgrade, as well as in other regions with similar environmental conditions.

Material and Methods

The study was conducted in the plum collection orchard at the Experimental Station "Radmilovac" of the Faculty of Agriculture in Belgrade during the period of four years (2013–2016). The orchard was planted in 2009. The rootstock is Myrobalan (*Prunus cerasifera* Ehrh.) seedling, training system is central leader, and planting distance is 4.5 x 3 m. All cultivars are represented by five trees. The study included seven plum cultivars: 'Čaradejka' (Belarus), 'Excalibur' (England), 'Hanita' (Germany), 'Kišinjevska rana' (Moldavia), 'Reeves' (Canada), 'Valerija' (Serbia), and 'Venera' (Belarus). Control cultivar for comparison was 'Čačanska lepotica'.

Flowering was recorded by recommendations of the International Working Group for pollination: start of flowering – 10% open flowers, full bloom – 80% open flowers, end of flowering – 90% of the petal fall (Wertheim, 1996). Trunk cross-sectional area (TCSA) was calculated on the basis of trunk circumference measured at the height of 30 cm above the ground level. Cumulative yield efficiency was calculated by dividing the cumulative yield over four years by TCSA in the last year (2016). Fruit characteristics were measured on a sample of 25 fruits per cultivar. Fruit shape index was calculated using the formula: length × length / width × thickness. Soluble solids were determined by refractometer and total acids (expressed as malic acid) by titration with 0.1 N NaOH. Sensory characteristics of the fruit (appearance and taste) were evaluated by a five-member jury, scoring the cultivars using the scale from 1 to 5 points.

The obtained data were statistically analyzed using analysis of variance. The significance of differences between mean values was determined using Duncan's multiple range test at 0.05 level of probability.

Results and Discussion

Average time of flowering of tested cultivars was in the first half of April (Table 1). The earliest flowering was recorded in the cultivar 'Valerija', and the latest in the cultivar 'Čaradejka'. The average difference between cultivars with earliest and latest flowering was 4 days.

Table 1. Phenological characteristics of plum cultivars (average, 2013–2016).

Cultivar	Flowering dates			Duration of flowering (days)	Abundance of flowering (0-5 scale)	Harvest date
	Start	Full	End			
Č. lepotica (control)	4 April	7 April	14 April	9.5	4.7	22 July
Čaradejka	6 April	9 April	16 April	10.0	4.1	18 July
Excalibur	5 April	7 April	14 April	9.0	3.7	30 July
Hanita	4 April	6 April	14 April	10.3	3.8	31 July
Kišinjevska rana	6 April	8 April	14 April	7.8	3.5	22 July
Reeves	6 April	8 April	15 April	8.8	3.5	24 July
Valerija	2 April	5 April	14 April	11.3	4.7	17 July
Venera	5 April	7 April	15 April	10.5	2.7	20 July

Among years, the earliest flowering was in 2014, when the average date of the flowering onset for all cultivars was March, 24. The latest flowering was in 2013 when the average date of the flowering onset was April, 17. The difference between years with earliest and latest flowering was 24 days and it was much bigger than the difference between cultivars.

The average duration of flowering ranged from 7.8 days (‘Kišinjevska rana’) to 11.3 days (‘Valerija’). Among years, the average duration of flowering for all cultivars ranged from 7.8 days in 2015 to 11.5 days in 2016. The most abundant flowering was recorded in cultivar ‘Valerija’ (the same as in control cultivar, ‘Čačanska lepotica’). The lowest flowering intensity was recorded in cultivar ‘Venera’.

The range of fruit maturity was from July 17 (‘Valerija’) to July 31 (‘Hanita’). For most cultivars the earliest fruit maturation was in 2016, and the latest in 2014. Difference between years with earliest and latest fruit maturation varied from 7 to 15 days.

Flowering and maturation time of plum cultivars in the region of Belgrade was earlier comparing to Czech Republic (Blažek and Pišteková, 2009), Central Bulgaria (Dragoyski et al., 2010), and Northern Montenegro (Božović and Jaćimović, 2012). These differences can be explained by different environmental conditions between the study regions.

The average yield per tree was the lowest in the cultivar ‘Venera’ (8.6 kg) and the highest in the cultivar ‘Valerija’ (28.6 kg) (Table 2). Compared to control, significantly higher yield was achieved in the cultivar ‘Valerija’, while the lower yield was found in cultivars ‘Venera’, ‘Excalibur’, ‘Kišinjevska rana’ and ‘Čaradejka’.

Table 2. Yield, trunk cross-sectional area, and yield efficiency of plum cultivars.

Cultivar	Yield (kg per tree)					Trunk cross-sectional area (cm^2)	Cumulative yield efficiency (kg/cm^2)
	2013	2014	2015	2016	Average		
Č. lepotica (control)	10.3	36.7	5.5	30.5	20.8 b	79.8 cd	1.04
Čaradejka	6.1	3.7	23.2	15.4	12.1 cd	113.0 bc	0.43
Excalibur	6.3	25.4	5.1	6.2	10.7 d	151.4 b	0.28
Hanita	7.9	22.4	6.9	39.5	19.2 bc	97.5 cd	0.79
Kišinjevska rana	8.3	23.5	9.1	5.6	11.6 d	89.9 cd	0.52
Reeves	3.1	36.7	23.4	0.3	15.9 bcd	209.1 a	0.30
Valerija	13.3	32.4	12.1	56.4	28.6 a	68.5 d	1.67
Venera	2.5	5.4	3.0	23.6	8.6 d	109.0 c	0.32

Mean values followed by the same letter within a column do not differ significantly according to Duncan’s multiple range test at $P \leq 0.05$.

Among studied cultivars, the lowest vigor was found in the cultivar ‘Valerija’, and the highest in the cultivar ‘Reeves’. Our results of high vigor of cultivars ‘Reeves’ and ‘Excalibur’ confirm previous findings of Meland (2010).

Cumulative yield efficiency ranged from 0.28 to 1.67 kg/cm^2. The cultivar ‘Valerija’ stands out for high cumulative yield efficiency. On the other side, cultivars ‘Excalibur’, ‘Reeves’ and ‘Venera’ are characterized by low yield efficiency.

All studied cultivars are characterized by large fruit (more than 30 g). Fruit weight ranged from 36.1 g in the cultivar ‘Hanita’ to 71.1 g in the cultivar ‘Reeves’ (Table 3). Compared to control, fruit weight was significantly higher in cultivars ‘Reeves’, ‘Excalibur’ and ‘Valerija’.

Table 3. Fruit characteristics of plum cultivars (average, 2013–2016).

Cultivar	Fruit weight (g)	Stone weight (g)	Stone share (%)	Fruit dimensions (mm)			Shape index	Stalk length (mm)
				Length	Width	Thickness		
Č. lepotica (control)	39.4 cd	1.6 d	4.0	43.7 b	37.9 bc	36.8 cd	1.36	14.4 bc
Čaradejka	42.2 bcd	1.9 c	4.5	44.4 ab	38.0 bc	38.7 cd	1.34	17.0 b
Excalibur	64.0 a	2.3 b	3.5	48.1 a	45.8 a	45.2 ab	1.12	21.7 a
Hanita	36.1 d	2.0 c	5.5	46.0 ab	35.5 c	36.4 d	1.64	16.3 b
Kišinjevska rana	42.9 bcd	1.5 d	3.4	43.6 b	38.4 bc	39.8 bcd	1.24	10.9 c
Reeves	71.1 a	2.8 a	4.0	47.8 a	47.7 a	51.1 a	0.94	15.5 b
Valerija	49.6 b	1.9 c	3.9	43.5 b	42.6 ab	42.8 bc	1.04	16.0 b
Venera	46.1 bc	2.3 b	5.0	44.9 ab	39.6 ab	39.8 bcd	1.28	17.3 ab

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

Stone weight ranged from 1.5 g ('Kišinjevska rana') to 2.8 g ('Reeves'), and its share in the fruit weight ranged from 3.4% ('Kišinjevska rana') to 5.5% ('Hanita').
Fruit length was highest in the cultivar 'Excalibur', whereas width and thickness were highest in the cultivar 'Reeves'. Significant differences were found between cultivars for fruit dimensions. Based on the fruit dimensions the shape index was calculated, whose values ranged from 0.94 in 'Reeves' (flat round shape) to 1.34 in 'Čaradejka' (ovate shape). Stalk length was the shortest in 'Kišinjevska rana' (10.9 mm), and the longest in 'Excalibur' (21.7 mm).
Results of fruit characteristics are in accordance with the previous findings for some cultivars (Hartmann, 1998; Dragoyski et al., 2010; Milatović et al., 2011; Ionica et al., 2013).
Cultivars 'Kišinjevska rana' and 'Venera' are characterized by high soluble solids content (18.2-18.7%), significantly higher than in the control (Table 4). Cultivars 'Excalibur' and 'Kišinjevska rana' are characterized by low acid content.

Table 4. Indices of fruit quality of plum cultivars (average, 2013–2016).

Cultivar	Soluble solids (%)	Total acids (%)	Soluble solids /Total acids	Sensory evaluation (1-5)	
				Appearance	Taste
Č. lepotica (control)	15.3 bc	1.26 ab	12.1	4.2	4.1
Čaradejka	16.9 ab	1.04 bc	16.2	2.9	3.3
Excalibur	16.3 abc	0.70 d	23.3	3.8	4.1
Hanita	16.3 abc	1.38 a	11.9	4.0	4.1
Kišinjevska rana	18.2 a	0.79 cd	23.0	3.9	4.1
Reeves	15.1 bc	0.92 cd	16.4	4.0	3.4
Valerija	13.8 c	0.99 bcd	13.9	4.2	3.5
Venera	18.7 a	0.94 cd	19.8	4.1	3.9

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

It is a well-known fact that the ratio between the soluble solids content and total acids (SSC/TA), rather than the very content of soluble solids, represents a reliable indicator of a cultivar's suitability for acceptance by consumers (Crisosto et al., 2004). Cultivars 'Excalibur' and 'Kišinjevska rana' are characterized by high SSC/TA ratio (above 20).

The data on the chemical composition of fruits are in good agreement with most of the previous findings (Hartmann, 1998; Vangdal et al., 2007; Bohačenko et al., 2010; Dragoyski et al., 2010; Milatović et al., 2011; Ionica et al., 2013).
The highest scores for fruit appearance obtained the cultivar ‘Valerija’, and for taste cultivars ‘Hanita’, ‘Excalibur’ and ‘Kišinjevska rana’. Our results for taste for cultivars ‘Excalibur’ and ‘Reeves’ are in accordance with those of Vangdal et al. (2007) and for cultivar ‘Hanita’ with those of Hartmann (1998).

Conclusion

Based on the four-year evaluation of seven plum cultivars of medium early maturation time, for growing in Belgrade area can be recommended cultivars ‘Valerija’ and ‘Hanita’. Both of them are suitable for fresh fruit consumption. Besides, the cultivar ‘Hanita’ is also suitable for fruit processing.

Abstract

This paper presents an analysis of the impact of different natural red clover seeds purity on the quantity of seeds obtained in the processing center of the Institute for forage crops in Kruševac. The purity of eight different natural lots of red clover seeds ranged from to the lowest 75% to the highest 85%. The content of inert materials and weeds was different in different seed lots. The content of inert materials was from smallest 7.2% to the highest 21%. The highest weed content in natural red clover seeds was 12%. The purity of the red clover seeds after the processing ranged from at lowest 97% in the case of seed lot II to highest 99.7% in the seed of lot IV. Red clover (*Trifolium pratense* L.) per share in the production of fodder in Serbia is in second place, immediately after the alfalfa. Agrotechnical significance of red clover is very high. Red clover improving the physical characteristics of the soil, significantly increases the nitrogen content and the organic matter in the soil. For the establishment and use of red clover seeds for sowing must be clean, have high germination and genetic values. In the processing the quantities of red clover processed seeds directly depends on the content of impurities of organic and inorganic origin. It also depends on the quantity and type of weed seeds that are being processing. The aim of the study was to identify relevant parameters of red clover seed processing depending on the equipment. The relevant parameters for processing seeds of red clover are: content of pure seeds (%), weed seeds and the seeds of other cultures (%), the inert matter (%), the quantity of processed seeds (kg), the losses of seeds (%) and the processing output (%). Based on the obtained results, it is possible to make an optimal adjustment, and selection of the appropriate equipment for processing seeds of red clover, depending on the amount and type of impurities in natural seeds of red clover in the processing.

Keywords: *Seeds, processing, red clover, weed species, impurities.*

Introduction

Red clover (*Trifolium pratense* L.) is one of the most important perennial legumes in our agroecological conditions. Among the fodder legumes in the Republic of Serbia, red clover occupies the second place, immediately after the alfalfa. It is distinguished by high biomass yield, feed quality, and rapid regeneration after cutting. Leaves are particularly rich in proteins, the content of which is about 25% in the phase of butonization (Vasiljević *et al.*, 2011). In animal feed, red clover can be used as green fodder or processed in the form of hay, shaded, silage, and dehydrated in the form of flour (Vučković, 1999). According to the content of vitamins and minerals, red clover is one of the best and most important forage species. It contains large amounts of pro-vitamin A, vitamin C, D, E, K, B1, B2, B3 and microelements - molybdenum, cobalt, boron, copper and manganese. The hay collected at the beginning of the butonization is rich in proteins (18 - 24%), phosphorus and calcium (Marković *et al*., 2007). In the Republic of Serbia in 2015 year the red clover was grown on average to 76.625 ha, whereby 222.596 t of dry matter was obtained with an average yield of 2.9 t ha^{-1} (http://pod2.stat.gov.rs/ObjavljenePublikacije/G2016 /pdf/G20162019.pdf.). Red clover can successfully replace alfalfa on soil with increased acidity in plain and mountainous areas. Land for cultivation is medium heavy, wet, medium fertility of the type of plantain, alluvial and smonitza (Lugić *et al*., 2000; Lakić and Vojin, 2010). Serbia's climate is judged to be moderately favorable for the production of seed legumes. The average yield of alfalfa and red clover seeds is about 250 kg ha^{-1} (Karagić *et al.*, 2010). The seeds of red clover separates the pure grain of the basic culture to ensure good sowing, germination and sprouting, as well as storage until the time of sowing (Đokić et al., 2012; 2016). Seed processing is based on the physical characteristics of the seed and therefore it is necessary to carefully analyze all the quantities of seeds and to do the appropriate adjustment of the processing equipment (Babić and Babić, 1998; Black *et al*., 2006; Copeland *et al*., 2004; Đokić, 2010; Đokić and Stanisavljević, 2012). In the seed crop of red clover, the most damaging quarantine weeds are dodder (*Cuscuta* spp.) and curly dock (*Rumex* sp.). The dodder belongs to the most dangerous and economically most damaging weeds and can cause enormous damage especially if no suppression is done (Čuturilo and Nikolić, 1986; Đukić *at al*., 2004). Curly dock can increase the losses during the seed processing. It is very difficult to separate this seeds from the seed of the basic culture due to its shape and size. (Karagić *at al*., 2007). The Law on Seeds of the Republic of Serbia defines the conditions and manner of production, processing, use, trade, import and testing of the quality of seeds of agricultural plants (Official Gazette of the Republic of Serbia, 45, 2005). The Rulebook on the Quality of Seeds of Agricultural Plants (Official Gazette of the SFRY, 47/1987), which is harmonized with international seed regulations (ISTA, 1999) defined the quality standard for the quality of seeds of red clover. According to this Rule, the quality of seeds of red clover (*Trifolium pratense* L.) must have a minimum seed purity of 95%, with 2% of seeds of other species, weeds not more than 0,5% (including dodder and curly dock), and up to 2,5% inert materials. The aim of the study was to compare the relevant seed quality parameters in the seed processing and determine which initial seed purity yielded optimum results in processing.

Material and Methods

The experiment was carried out at the processing center of the Institute for Forage Crops in Kruševac-Serbia where (in three replications) the natural red clover seed of eight lots of different purity was processed. The processing equipment (Danish manufactures of Kongskilde and Damas) consisted of the following machines and devices: intake pit with belt conveyor, belt conveyors, bucket elevators, fine cleaning machine type Alfa-4, and magnetic separator type 4 of the German manufacturer Emceka Gompper. In the upper shaker shoe are six screens with round openings of diameter: 2.75 mm; 2.5 mm; 2.25 mm; 2.0 mm; 2.0 mm and 1.9 mm. In the lower shaker shoe there are screens with longitudinal - cut openings of width: 1.4 mm; 1.3 mm; 1.2 mm; 0.6 mm; 0.5 mm and 0.5 mm. In order to analyze the content of foreign matter in the seed, a laboratory lamp with light and precision electronic scale was used. Samples for analysis were weighing 5 g and 50 g. Measurement of the mass of the processed seed was carried out using electronic weighing range of up to 300 kg. In each of the repetitions by laboratory analysis, the following parameters were measured: quantity of pure seed (%), seed of other species (%), inert matter (%), weed (%), and amount of processed seed (kg). Processing output (%) and seed losses on processing equipment (%) were determined by calculation. The obtained results were analyzed by variance analysis (ANOVA), and the significance of the mean difference was tested with the Tukey test. The statistical program Minitab 16.1.0 (statistics software package) was used for data processing.

Results and Discussion

The purity of the natural seed of the red clover of all eight seed lots is shown in Table 1. The purity values ranged from the lowest 75% for seeds from seed lot II to 85% for seed lots of I, III and VIII. The purity of seeds of lots IV, V and VII was 80%. The VI seeds were clean 78%. In the seed of red clover were found of the other species, 0.8% (III lot) of alfalfa seeds, 1% (lot VI) and 0.5% (lot VIII). Inert materials consisted of cereal residues, blossoms, empty seed and broken seeds, and their part ranged from the lowest values of 7.2% in natural seed of lot III, to 21% for seeds of lot VI. In the seeds of lot I inert matter were 11.6%, in seed lot II inert matter amounted to 11.5%. In seed of lot IV, inert matter was 16.5%. Seed lot V and VII accounted for 20% of the inert matter in the form of harvest residues, while for seeds of lot VIII they amounted to 14.5%. In the seed of seed lot III, 7% of the weeds were. From weed seed sample of 5 g, 6 seeds of dodder (*Cuscuta* spp.) and 6 seeds of curly docks (*Rumex* sp.) were found. The other weeds were pigweed (*Amaranthus retroflexus*), bindweed (*Convulvus arvensis*), white goosefoot (*Chenopodium album*), and lowgrass (*Polygonum aviculare*). Seeds of lot II had the highest number of weeds (12%) in the form of plantains (*Plantago* L.) and chamomile (*Matricaria chamomilla*). In a sample of 5 g analysis, 6 seeds of dodder were found. In the seeds of lot I 3.4% of weeds were found, and in the seed sample of 5 g were found 20 of dodder and 5 seeds of curly dock. The natural seed of the lot IV, had 3.5% weeds, and in the 5 g sample there were 20 seeds of dodder, as well as seeds of plantains and chamomile. In the seed of the lot V there was the seed of the plantains. The seed of the lot VI had 25 seeds of the dodder and 2 seeds of curly dock in the sample of 5 g. In the seed of VII and VIII lots, no significant quantities of weeds were found in the samples.

Table 1. The average purity of red clover seed

Lot	I	II	III	IV	V	VI	VII	VIII	*F test*
Seed structure	%	%	%	%	%	%	%	%

Tukey test statistical significance levels: p≤ 0.05, differences in row marked in small letters a, b, c...

The purity of the red clover seeds after the processing is shown in Table 2. The red clover seeds had higher purity than legally prescribed (>95%). The purity ranged from at least 97% in the case of seed lot II seeds to 99.7% in the seed of lot IV.

Table 2. The average purity of processed red clover seed

Lot	I	II	III	IV	V	VI	VII	VIII	*F test*

Total	100	100	100	100	100	100	100	100	-

F test, statistical significance levels: $*p\leq 0.05$, $**p\leq 0.01$, $***p\leq 0.001$, ns – not significant ($p \geq 0.05$)
Tukey test statistical significance levels: $p\leq 0.05$, differences in row marked in small letters a, b, c...

In the purity of the processed seed, no statistically significant difference was found between the lots ($p\geq 0.05$). All other lots of processed seeds had the content of quarantine weeds and impurities within legally prescribed limits. Seed of quarantine weeds of the dodder and curly dock was not found in seed samples for analysis. At the end of the seed processing the amount of processed seed was measured. The quantities of natural seed of the red clover of all eight lots at the beginning of the seed processing and the amount of processed seeds at the end of the seed processing are shown in Table 3.

Table 3. Amounts of proceseed red clover seed on processing machines

Seed structure	Lot (kg)								*F test*
	I	II	III	IV	V	VI	VII	VIII

F test, statistical significance levels: $*p\leq 0.05$, $**p\leq 0.01$, $***p\leq 0.001$, ns – not significant ($p \geq 0.05$)
Tukey test statistical significance levels: $p\leq 0.05$, differences in row marked in small letters a, b, c...

This table also shows the calculated values for the processing output and the losses on the processing equipment expressed in percentages. The highest percentage processing output of seeds ranged from 74.91%, 74.72% and 74.43% in seeds of I, III and VIII lot, respectively. The smallest percentage of the use of red clover seeds was for seeds of seed lot VI and amounted to 53%. In this seed, the largest loss of seeds on the processing machines was 32%. The smallest seed losses ranged from 11.26%, 11.86% and 12.1% to seeds of II, I and III lot, respectively. Highly significant influence of seed lot on natural seed, processed seed, processing output, and seed losses ($p\leq 0.01$ or $p\leq 0.001$) was determined.

Conclusion

Based on the obtained results of the research it can be concluded that in the seed processing of the red clover seed with a different content of inert materials and weeds, all relevant parameters of the treatment depend on the initial purity, and the content of quarantine weeds. The purity of natural red clover seeds ranged from 75% to 85%. The content of inert materials and weeds was different in different seed lots. The content of inert materials was from 7.2% to 21%. The largest weed content in natural seed was 12%. The biggest problem in the processing of red clover seeds is quarantine weeds, above all the dodder (*Cuscuta* spp.) and curly dock (*Rumex* sp.). Their removal makes processing more difficult and more expensive to, and therefore increases the costs. In the production of red clover seed it is best preventive use pure seed without weeds. During the seed processing all failures in the technological process can lead to large losses of seeds, which at the same time presents great economic losses.

Abstract

The paper deals with results of the effects of different crop rotation on the weediness of maize. The trial was carried out on the experimental estate of the Faculty of Agriculture - Zemun "Radmilovac" near Belgrade in Serbia. The trial was established in 1992 and has been lasting ever since. The following cropping patterns were included in investigations: continuous cropping, two-field crop rotation (winter wheat-maize) and three-field crop rotation (winter wheat-maize-soya bean) and six-field crop rotation (sunflower-winter wheat-maize-soya bean, spring barley+red clover, red clover). The goal of a crop rotation is to create an unstable environment that discourages weeds from becoming established in the field. The following effects of different crop rotation were studied: floristic composition in weed sinuzia of maize, number of individuals and biomass. Cropping pattern which included many various crops (two-field crop rotation, three-field crop rotation, six-field crop rotation) have better effect in weed control, especially perennial, than continuous cropping of maize. On the basis of our investigations, it has been concluded that the cropping systems had the important application in maize production and protective role in weed control. By rotating crops with different planting dates and growth periods, contrasting competitive characteristics and dissimilar management practices, the regeneration niche of different weed species could be disrupted and particular weed species prevented.

Keywords: *Crop rotation, Continuous cropping, Weeds, Maize.*

Introduction

On the basis of many researches for future of agriculture development in XXI century, as alternatives of conventional obtrude sustainable agriculture. It is considered that future in agriculture will be on the flexible cultural practice, developing of biotechnology and appreciation of basic ecological principles in soil usage. Cultural practices enable maximum utilization of genetic potential for grain yield under the specific agro-ecologic conditions. Today we have important changes will appear in application some cultural practices first of all: soil tillage, fertilization, weed control, crop rotation etc. (Kovacevic, 2008). Agriculture is increasingly based on market laws of supply and demand, that is, conjuncture and this is where economic interests dominate, which are often not in accordance with the agro-biological reasons, at least when it comes to crop rotation (Kovacevic, 2012b). The main crop in sowing structure in Serbia is maize. Apart from continuous maize cropping that is still evident and is still only possible due to the absolute domination of maize on arable land in sowing structure of Serbia, there is still two-field crop rotation (winter wheat - maize) and an increasing number of three-field crop rotation, which includes soya bean, which is very positive (Dolijanović et al., 2009). Dynamics of weed populations in arable fields are influenced by environmental and soil characteristics and also by cropping system and management practices. Manipulation of cropping systems to improve weed management requires a better understanding of the spatial and temporal dynamics of weeds, seed losses and seed production (Koocheki et.al. 2009). Crop rotation is the most general and most comprehensive cultural practice, which more or less links all others in a mutually dependent system, designed for the successful achievement of certain objectives. The application of crop rotations can significantly increase yield, and one of more important reasons for the yield increase is the reduction of weed infestation, especially of the number of plants per perennial weed species. Two, three and four crop rotations are exceptionally important for the reduction of weed infestation of the most important field crops: maize, wheat and soya bean (Kovacevic and Lazic Branka, 2012a,). All stated studies emphasise the reduction of the number of weed plants per species, the number of perennial weeds, and therefore the reduction of weed biomass per area unit. A situation is largely reverse, when winter wheat is cultivated in continuous cropping, especially in long-term continuous cropping. The effect of the crop rotation on weediness of crops is long lasting: as effects of continuous cropping cannot be explained in a short period, equally, the effects of crop rotations, particularly multi species crop rotations, can be explained only after long-term cultivation of a certain crop in such cultivation systems (Liebman et al, 2001; Dolijanovic et al., 2014). The aim of present study was to evaluate the effects of continuous cropping and different crop rotation on weed community in a twenty three-year period.

Material and Methods

The effect of multi-year continuous cropping and different cropping rotations on weediness in maize were examined on luvic chernozem soil type in the experimental estate of the Faculty of Agriculture - Zemun "Radmilovac" near Belgrade (Serbia), in 1992 and has been conducted ever since (Picture 1).

Picture 1 Experimental field with different rotation marked with arows and circle (Google map)

The following cropping pattern has been observed:

continuous cropping of maize and different crop rotations: two-crop rotation (winter wheat-maize), three-crop rotation (winter wheat-maize-soya bean) and six-crop rotation (winter wheat-maize-soya bean-spring barley+ red clover-red clover-sunflower).

The plot size under one crop that is one rotation was 12 areas.

The common conventional cropping practices specific for each individual crop were applied in systems, continuous cropping and crop rotations. Long-term effects of various cultivation systems on weed infestation were observed on weed samples drawn on May 27, 2015 by the one square meter area method.

The floristic composition, number of weed plants per species and fresh biomass were determined in the field and then air dry biomass of weeds was measured.

All parameters of weed infestation were statistically processed by the method of a single factor analysis of variance (STATISTICA 5.0 for Windows), while the least significant difference (LSD) test was used for individual comparison of differences between means.

Results and Discussion

Tables 1 present long-lasting effects of continuous cropping of maize and a various crop rotations on weed floristic composition in maize.

The differences between continuous cropping of maize and other crop rotation systems in weediness were obviously, mainly a result of different weather conditions, especially precipitation sums, and distribution during the growing season of maize in investigated period. Not only do crop rotations affect the reduction of weed infestation, but they also result in greater efficiency of other cropping practices in weed control, first chemical and mechanical crop cultivation measures (Kovacevic et al., 2008). According to data presented in Tables 1, the weed community of maize in all rotation systems was composed of 15 weed species during investigation period, respectively. *Solanum nigrum* L., *Chenopodium album* L., *Amaranthus retroflexus* L., and *Datura stramonium* L. prevailed among annual broadleaf weed species, while *Convolvulus arvensis* L., *Sorghum halepense* (L.) Pers., *Agropyrum repens* (L.) Beauv. *Cynodon dactylon* (L.), Pers., and were dominant perennial weed species. The highest number of weed plants and weed plants per species, with a significant number of annual broadleaf weed plants per species, was registered in maize continuous cropping in investigation period. Perennial weed species, *Convolvulus arvensis* L., *Sorghum halepense* (L.) Pers., Agropyrum *repens* (L.) Beauv., *Cynodon dactylon* (L.) and prevailed and their number was significantly higher with longer continuous cropping compared with tree crop rotation. Not only was a great number of weed plants per species detected in continuous cropping, but also the greatest fresh and air-dry weed biomass was recorded. Again, perennial weed plants per species were more troublesome and they could not be easily eliminated by the application of herbicides. Several-year continuous cropping resulted in qualitative changes in the composition of anthropogenic weed community, due to the application of selective herbicides, which successfully suppressed weed species, and a vacant ground was inhabited by resistant and perennial weed species (Drazic Danica, 1999).

Crop rotations, even a two-crop rotation, as a crop rotation with the lowest number of rotations, have a positive effect on the reduction of weed infestation (Kovacevic, 1989). Kovacevic (2004) pointed out that the crop rotation was not just the most important measure, but also the only measure that could properly facilitate crop protection against weeds, diseases and pests.

Table 1: The effect of different rotations on weed floristic composition in maize (2015.)

No	Weed species	Continuous cropping of maize	Crop rotation		
			two-crop rotation	three-crop rotation	6 - crop rotation
1.	*Agropyrum repens* (L.) Beauv.	3.20

Number annual broadleaf weed individuals		28.83	11.22	8.76	16.79
Number perennial weed individuals		30.03	5.08	11.87	9.96
Fresh Biomass g m^{-2}		284.13	144.51	156.10	168.11
Air Dry Biomass g m^{-2}		61.10	31.02	34.41	50.60

LSD	Total number individuals of weeds	Total number of weed species	Number annual broadleaf weed individuals	Number perennial weed individuals	Fresh Biomass	Air Dry Biomass
0.05	1.98	0.51	2.02	2.02	8.81	2.11
0.01	3.13	0.92	3.01	3.01	12.14	3.44

Due to a greater number of plant species entering the six-crop rotation, possibilities for weed infestation are also greater. According to our studies and studies conducted by Kovacevic et al. (2008), the six-crop rotation expressed greater efficiency in the reduction of weed infestation only in relation to winter wheat continuous cropping. Liebman and Davis (2000) have stated that by the rotation of crops with different sowing dates (summer, spring, autumn) and growth periods, contrasting competitive characteristics and dissimilar management practices, regeneration niches of different weed species could be disrupted and increases in specific weed species prevented. The increased number of weed plants per species per area units means enhanced competition for principal factors of the growth and development, hence the crop density is lower, and without the optimum density, there are no optimum yields. Our study show that the greatest number of weed plants per species was detected in continuous cropping of maize, then in six crop rotations and the lowest number was established in the two crop rotation. A statistically significant dependence between continuous cropping and crop rotations, as well as, among crop rotations, was estimated by the statistical analysis of data obtained during the year s of investigation. The differences between two and three crop rotation, as well as, between two and six crop rotation were statistically significant. The increase of weed fresh biomass per area unit is mainly a result of a greater presence of perennial or annual broadleaf weeds, which are generally more competitive. The lowest values of weed fresh biomass per area unit were obtained in the three crop rotation. The differences in weed fresh biomass among cultivation systems were mainly statistically very significant, with the exception of the difference between the two crop rotation and remaining studied rotations.

Conclusion

According to the obtained results during investigations of effect multi-year different cropping rotations (crop rotation and continuous cropping) on the weediness of maize in the experimental agricultural farm of Radmilovac (Serbia) the following conclusions can be made:

The weed community in maize was composed of 15 weed species, with dominancy of terophytes.

The annual species *Solanum nigrum* L., *Chenopodium album* L., *Amaranthus retroflexus* L., and *Datura stramonium* L. prevailed among annual broadleaf weed species, while *Convolvulus arvensis* L., *Sorghum halepense* (L.) Pers., *Agropyrum repens* (L.) Beauv., *Cynodon dactylon* (L.), Pers., prevailed from perennials in the weed community in maize.

Obtained results indicate that the highest number of weed plants, weed plants per species, fresh and air-dry biomass were recorded in maize continuous cropping of maize.

The statistically lowest values of the number of weed plants per species and fresh biomass, as the most important parameters of weedines, were recorded in the three crop rotation (winter wheat-maize-soya bean).

Crop rotations, especially three and two crop rotations, were more efficient in the reduction of weed infestation than the six crop rotation and especially continuous cropping of maize.

Abstract

The aim of this paper is to present soil as a growing medium used in germination tests of seeds of some insecticide-treated maize inbred lines that have been carried out at the seed testing laboratory of the Maize Research Institute, Zemun Polje in Belgrade. Although soil is not recommended as a primary growing medium for seed germination because it is not included into standard methods, it is the most natural and the best growing medium for seed germination testing under laboratory conditions. Soil is recommended when seedlings show phytotoxic symptoms or when results of the standard germination test are uncertain. The standard method B(etween) P(aper) with 4x100 seeds and filter paper + soil method with 4x50 seeds were applied in the study in 2015 and 2016. Seeds were treated with the fungicide Maxim Xl and the insecticide Sonido. Soil used in the study was degraded chernozem taken from a maize field and prepared for the medium according to the standard procedure. Seeds were germinated in the germination room at the temperature of 20<=>30^{o}C and 16:8 of light : dark photoperiod. The first count and total germination were recorded on the 4th and the 7th day, respectively, in both methods. Obtained results indicate that total germination for all maize inbred lines was greater in both years of investigation when filter paper + soil method was applied.

Key words: *Seed germination, Maize inbreds, Soil*

Introduction

Seed germination is the most important parameter of seed quality and its laboratory testing provides information on the maximum potential of germination under optimum conditions. The maximum seed germination potential is often directly opposed to seed germination under environmental conditions, due to which there are differences between laboratory and field germination.

Beside standard methods in seed germination testing, non-standard methods that provide natural conditions for seed germination, are often applied, and they usually give better results of testing. Non-standard methods have to be verified to be applicable. A cold test is a non-standard method applied in seed vigour testing, where soil, sand or their mixture are used as a substrate. Nijënstein and Kruse (2000) established that the least variation of the results was obtained when sand was used as a substrate in the cold test.

The seed germination testing in the soil as a substrate is non-standard method and it is not recommended as a primary method for germination tests, but as an alternative to organic substrates, when results of standard germination tests are doubtful and when a germination expresses phytotoxic symptoms. When the soil is used as a substrate in the seed germination tests, it is necessary that soil meets criteria given in the paragraph 5.4.2 of the ISTA Rules, ISTA Rules (2017), according to which there should be a sufficient amount of air and moisture to provide the growth of the root system; pH has to be within the range of 6.0-7.5

and the substrate has to be microbiologically pure and non-toxic. Each new soil supply for seed germination tests is subject to quality control of these parameters, with the recommendation that the germination substrate is used only once. The two-year research of seed germination in soil in the Missouri laboratory showed that the soil was the best substrate for the growth of all kinds of seeds, Fuhr (1933). Comparing germination substrates and their effects on germination, the seedling development was the most advanced only in the soil, ISTA Handbook of Seedling Evaluation (2013). Although the soil is the most natural substrate for seed germination, it is difficult to standardise this method to be applicable in the laboratory, because each laboratory uses soil from its surroundings, and due to it test results are inconsistent. More consistent results may be gained by using the same soil in the inter-laboratory test comparisons. Radić et al. (2004) established that the seed testing methods should be developed and that their standardisation should be performed in the future, so that they would meet current quality standards and market requirements. A greater application of soil as a seed germination substrate has begun by insecticide treatments of seeds due to phytotoxicity and uncertainty of the results obtained by the standard method. It has been observed in laboratories that seed germination in the soil had yielded the best results of total germination, especially in seeds of inbred lines treated with insecticides, which otherwise had slower and lower germination than hybrids.

Material and methods

During 2015 and 2016, 10 seed lots of inbred lines, produced in various locations and different years, were tested at the Seed Testing Laboratory of the Maize Research Institute, Zemun Polje. The seed was processed and treated with fungicide Maxim XL 035FS and insecticide Sonido. According to Ferguson (1993), seed lots with similar values of seed germination, may differ in physiological maturity, and therefore in seed vigour. The following two test methods were applied: BP (between filter paper method) with 4x100 seeds (standard method) and the filter paper + soil method with 4x100 seeds (non-standard method). The soil was degraded chernozem taken from the maize field, sieved to obtain a smaller and more uniform fraction. In 2015, 20 bags with soil were taken from the field (pH=7.5, moisture=17.9%, and moisture capacity=48%). Seeds of the species *Festuca rubra*, susceptible to toxicity, were germinated to establish non-toxicity of the collected soil. The soil was sieved through the 5-mm sieve and 67.6% soil passed through the sieve. In 2016, 60 bags with soil were taken from the field. Seeds of the species *Festuca rubra* were germinated to establish non-toxicity of the collected soil, and at that time it was established that the soil did not contain toxic matters and that it was microbiologically pure (pH=7.5, moisture=14.4%, and moisture capacity=46%). Furthermore, the soil was sieved through the 5-mm sieve and 93.24% soil passed through the sieve with this mesh size, ISTA Handbook of Seedling Evaluation (2013). When the standard method was applied, the seed was placed on water saturated filter paper, which was covered by another filter paper, then it was rolled and placed into the germination cabinet at the alternating temperatures 20<=>30^{o}C and the light regime 16 h : 8 h (light : dark). When the non-standard method was applied, the seed was placed on previously water saturated filter paper, to which soil was added, then it was rolled and placed into the germination cabinet under the same test conditions (alternating temperatures 20<=>30^{o}C and the light regime 16 h : 8 h (light : dark)). The first count, in both methods, was made on fourth day, while the total germination was determined on the seventh day, ISTA Rules (2017). The obtained values were expressed as the percentage of normal seedlings.

Gained results were statistically processed by the computer program MSTAT. The two factorial analysis of variance and the least significant difference (LSD) test were applied, Hadživuković (1991).

Results and Discussion

The analysis of variance shows statistically significant differences in total germination over tested seed lots, as well as over the applied germination methods. The seed germination method, year of seed germination testing and the analysed lots of inbred lines affected seed germination. Interactions among observed factors were also very significant (Table 1).
The year of investigation did not affect tested seed germination. There were no statistically significant differences between replications and between the interactions of the factor B.

Table 1. Statistical significance of effects of observed factors on total germination of seeds

Factor	Degree of freedom (DF)	Mean squares (MS)	F value
Replication	1	2.450	0.261^{ns}
Method (A)	1	4681.800	500.8646^{**}
Year (B)	1	31.250	3.3432^{ns}
AB	9	352.800	37.7430^{**}
Lot (C)	9	356.856	38.1768^{**}
AC	9	145.439	15.5592^{**}
BC	9	182.944	19.5716^{**}
ABC	9	76.439	8.1775^{**}
Error	39	9.347	

ns – not significant; ** - significant at the level of 0.01%; df – degree of freedom

The highest seed germination percentage in both years was recorded when the filter paper + soil method was applied. Lower values were obtained by the standard seed germination method.
In 2015, average total germination over methods was higher by 19% when the filter paper + soil method was applied. Moreover, in 2016, total germination was greater by 11% in the variant when the filter paper + soil method was applied The lowest total seed germination was recorded in the lots 1, 2 and 4 (80.00%, 74.88 and 67.75%, respectively), while the highest value was established in the lots 6, 8 and 10 (87.00%, 88.75% and 87.38%, respectively).
The analysis of results by the LSD test for the interaction between two methods and lots shows that the lowest value of total germination was in the lot 4 (F), which is a statistically significant difference, while differences obtained in lots 8, 10, 6 and 7 (A) were not statistically significant.
The gained results on seed germination (Table 2) indicate that the filter paper + soil method is suitable for testing seeds treated with insecticides. The comparison of results obtained by the standard and non-standard method shows that seed germination was significantly lower when the standard method was applied including all 10 lots and both years of investigation.

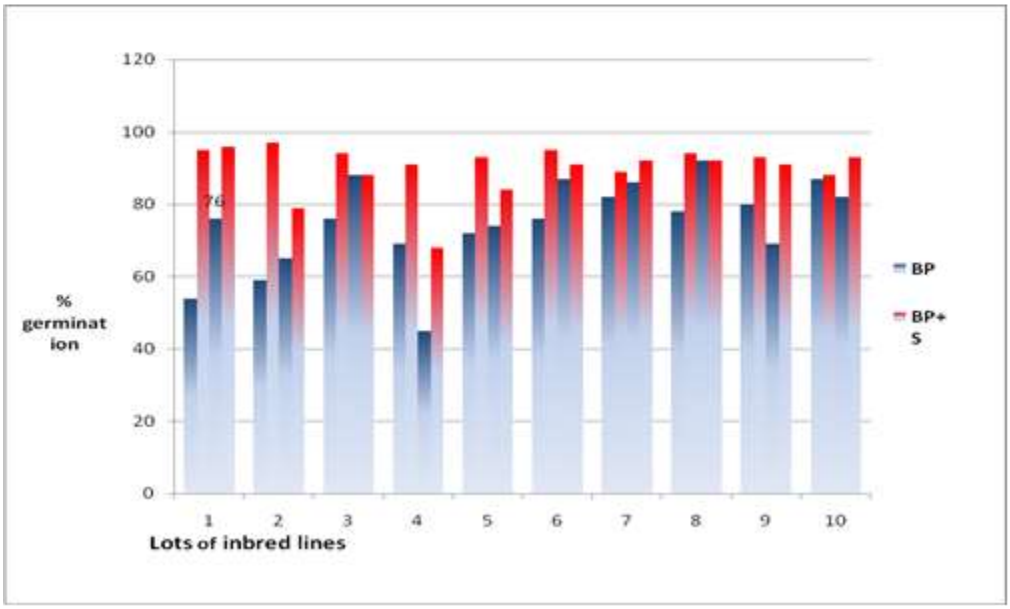
FP+S-filter paper + soil, BP – between filter papers

Figure 1. Total seed germination (%) over methods



BP – between filter papers, FP+S-filter paper + soil

Conclusion

Based on achieved results it can be concluded that soil as a substrate for seed germination tests is suitable for seeds treated with insecticides. It was also confirmed that soil as a substrate in seed germination tests is more natural environment for seed, hence the results of germination tests were higher than the results gained by the standard method. Despite the defined properties that the soil has to have in order to be used as a substrate for seed germination tests, it is difficult to standardised soil as a method due to its inconsistency in chemical, microbiological and physical traits. The soil method should always be an alternative to the standard seed germination method when there is a doubt in test results. Results of germination tests obtained by the filter paper + soil method were higher in both years than those obtained by the standard BP method. The Seed Testing Laboratory has been using soil as the substrate for seed germination tests. Although this method is very demanding, as it is necessary to collect soil, sieve and check it, certainty of results is the reason why we have decided to use this method.

Abstract

The aim of this research was to determine differences in physico-chemical properties of strawberry in four harvest time (T1: 05.05.; T2: 13.05.; T3: 22.05.; T4: 29.05.). The research was conducted in an experimental planting of strawberry cultivar 'Joly'at the Fruit Research Institute, Čačak (Serbia). Strawberries were planted in August 2015 in double rows on beds covered with black polyethylene foil. Physico-chemical properties such as fruit mass, size, (length and width), shape index, firmness, total soluble solids and antioxidant capacity were investigated. Results showed that major changes in fruit were developmentally regulated. Significant decreases in mass and size coupled with significantly decline in antioxidant capacity were determined at T3 and T4 time. Shape index was higher in fruits gathered at T3 compared to another harvest times. On the other hand, significantly higher total soluble solids and firmness were observed in the fruits collected at T3 and T4 time. The obtained results underline the important role of harvest time on quality characteristics of strawberry 'Joly'. Fruit harvested in the first half of harvesting season showed a good physical properties and antioxidant capacity, which could positively influence the fruit marketing. The best performance in terms of fruit firmness indicates better shelf life of fruits harvested in the second half of the harvesting season.

Keywords: *strawberry, harvest time, physico-chemical properties*

Introduction

An important factor in the intensification of strawberry production is cultivar innovation, which aims to ensure that the market is supplied with high quality fruits as evenly as possible. In strawberries plantations of Republic of Serbia, apart from 'Clery', as a predominant cultivar, an intense expansion of the cultivar 'Joly' can be observed in recent years. When defining the value for cultivation and use of introduced cultivars, a lot of importance is given to ripeness, maturity, irrigation, and fertilisation, in addition to the effect of genotype. Strawberry is a non-climacteric fruit and it must be harvested at full maturity to achieve maximum quality. The main changes in fruit composition, which are usually associated with ripening, take place when the fruit is still attached to the mother plant. Consequently, strawberries should be harvested ready for consumption. This means there is very short period of fruit at its best quality (Manning, 1996; Cordenunsi et al., 2003; Voća et al., 2006). Pincemail et al. (2012) point out that the harvest (in the phase of the full maturity of fruit) is a highly significant factor of fruit quality. Harvesting at the proper stage of maturity is essential for optimum quality and often for the maintenance of this quality after harvest (Strum et al. 2003).

The aim of this study is to establish the harvests, which will secure the best quality of strawberries 'Joly'.

Materials and Methods

The strawberry samples intended for the analysis of the fruit quality were harvested in the plantation of ‘Joly’ cultivar located in central Čačak, in the Western Morava valley, the west area of Serbia (43º 53' N, 20º 20' E, 225 m altitude). The layout of the experiment was a completely randomized design, with the effect of one factor, harvest time, analyzed. Sixty plants (3 replications, 20 plant each) were planted in August 2015, applying the standard cultural practices, including a drip-irrigation system. The plants were planted on the slopes, covered with a black PE foil, in a two-row planting system, and the density of 30×30cm. In March, the plantation was covered with a plastic tunnel. The samples for the analysis were gathered in the four harvest time during of May 2016(T1: 05.05.; T2: 13.05.; T3: 22.05.; T4: 29.05.) in phase completely ripe when exhibited an intense red colour all over the fruits. Physical properties of fruit (weight (g), length (mm), width (mm), shape index and firmness) are determined by standard morphometric methods on the sample of 60 fruit per a harvest (3 replications, 20 fruits each). Fruit weight is determined by measuring on analytical scale Mettler, with accuracy of ± 0.01 g. Height and width are determined by a digital caliper (Carl Roth, Germany) accuracy of ± 0.05 mm. (mm). The value of fruit shape index is obtained by calculation, establishing relationship between fruit length and width. Fruit firmness is determined by using a penetrometer, and results were expressed in N. The soluble solids content (SSC) was determined by digital refractometer (ATC, Belgium)at 21°C.A drop of homogenized and filtrated sample was placed on the lens and the reading was taken in % of soluble solids content in the fruit. The antioxidant capacity was determined by a ABTS method, spectrophotometry in ethanol extract of the sample (Re et al., 1999). The results were expressed in mg equivalents of Trolox per 100 g of fresh weight (mg Troloxeq 100 g^{-1}fw). The data obtained in the research was processed applying the Fisher model of variance analysis (ANOVA, F test) and the statistics software package STATISTICA version 8.0 (StatSoft, Inc., Tulsa, OK, USA). The analyses were performed in three replications and the obtained values were expressed as the mean value. Testing the significance of differences between the means of the treatments and their interaction effects was performed using the LSD test and the significance level of 0.05.

Results and Discussion

Physical properties of fruits represent an important indicator of quality, and fruit mass is one of the most important pomological properties of the highly productive cultivars of strawberry. In evaluating new strawberry cultivars, large fruits are especially favoured, which is significant from the point of increasing the efficiency of hand-picking and marketing. The results obtained in this research revealed a significantly higher fruit mass in the first harvest (40.1 g), compared to other harvests under consideration (Table 1). In accordance with the greatest fruit mass, the highest values of fruit dimensions were also recorded (52.2 and 46.7 mm) in T1. Milivojević et al. (2015) emphasize that despite approximate yields of cultivar ‘Joly’ per plant as in cultivar ‘Clery’, the average fruit mass of the cultivar ‘Joly’ were higher for the 4.1 g. The variation in the shape of fruit was also evident between the two mentioned cultivars, whereas ‘Joly’ was characterized by an elongated conical shape (value of the shape index of 1.11), and the fruit shape in ‘Clery’, predominantly roundly tapered (value of the shape index 0.99) In our study too, the cultivar ‘Joly’ was characterized by an elongated conical shape of the fruit throughout the harvesting season, with a significantly higher value in T3 (value of the shape index 1.3), compared to other investigated harvests. In addition to the mass, dimension and shape index, the firmness is a trait that directly affects the quality of the strawberries. According to the results obtained in our research, a significantly higher firmness was observed in T3 and T4 (13.08 and 13.90 N, respectively), compared to other two harvests under consideration. Shape, size, density, specified gravity, colour, firmness, pH value, and titratable acids are some of the major physical and physicochemical characteristics that are critical in the design of harvesting and processing equipment (Liang et al. 1991; Xie & Zhao, 2003).

Table1. Influence of harvest time on fruit physical properties

Harvest time	Mass (g)	Length (mm)	Width (mm)	Shape index	Firmness (N)
T1	40.1 ± 079 a	52.2 ± 1.49 a	46.7 ± 1.82 a	1.1 ± 1.82 b	8.50 ± 0.05 b
T2	26.6 ± 1.57 b	42.5 ± 0.84 b	38.7 ± 1.41 b	1.1 ± 1.41 b	10.27 ± 0.03 b
T3	12.0 ± 0.68 c	38.4 ± 1.62 c	29.5 ± 0.73 c	1.3 ± 0.73 a	13.08 ± 0.02 a
T4	8.3 ± 0.26 d	25.8± 0.32 d	25.8 ± 0.42 c	1.0 ± 0.42 b	13.90 ± 0.03 a

The different lower-case letters in the columns indicate statistically significant differences among the mean values at P≤ 0.05 level (LSD test).

Our research shows that there has been a considerably growing dissatisfaction with non-uniform quality of strawberry fruit (Voća et al., 2007). Consumer acceptance of strawberries depends to a large extent, on the taste of the fruit, which is closely related to the content of soluble solids matter (Tulipani et al., 2008). Figure 1 shows the impact made by the harvest time on SSC in strawberry fruits.

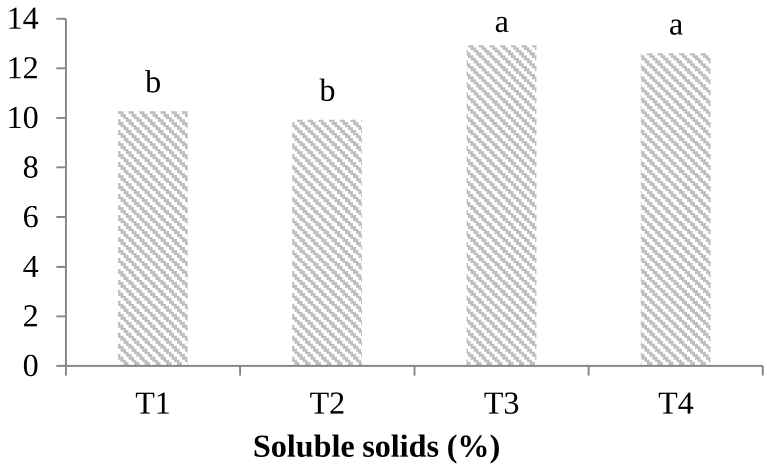

Figure 1. Effect of harvest time on the soluble solids content in strawberries ‘Joly’; the different letters indicate statistically significant differences at P ≤ 0.05 level (LSD test).

Significantly higher SSC was observed in later harvests (T3–12,93% and T4–12,60%) compared to earlier harvests (T1–10,27% and T2–9,93%). The results obtained in this work correspond to earlier investigations carried out by Strum et al. (2003) who, in the course of studying the content of total soluble solids in strawberry fruits of 13 different cultivars and maturity stage, established a strong increase in SSC during the last stage of ripening in cultivars ‘Miss’, ‘Eros’ and ‘Simphony’. On the other hand, Capocasa et al. (2008) found a negative correlation between fruit size and most of the nutritional quality parameters. The same authors pointed out that strawberry fruit size negatively correlated with the commercial quality (TA and SSC) and nutritional parameters (TPH, TEAC and FRAP). The stated results are in accordance with the results of our investigations, having in mind that fruits of the second half of harvesting season are characterized by significantly lower mass and dimension, and a substantially higher content of SSC in relation to the fruits picked in the first two harvest times. However, based on the data shown in Figure 2, a consistently high antioxidant capacity in all harvests could be observed, except in T4 with the lowest value of antioxidant capacity recorded (2.64 mmol Trolx eq·100 g fw^{-1}). Results by Tomić et al. (2015) indicate that a newly strawberry cultivar 'Joly' containing high antioxidantive capacity was superior to a major cultivar 'Clery' that has been broadly cultivated in Republic of Serbia. The stated results are important particularly having in mind that demand and availability of strawberries (Fragaria × ananassaDuch.) have increased substantially during recent years, driven in part, by the highly desired taste of the fruit, along with its known health-promoting properties (Wang et al. 2005; Bordonaba& Terry, 2010). The greatest part of biological effects of polyphenols can be contributed to their antioxidant activity. However, it is important to emphasize that the chemical composition of fruit berries is conditioned by a number of factors, among which most important are genotype, climatic conditions, agricultural practices, degree of fruit ripeness and others. Previously conducted research (Battino & Mezzetti, 2006; Tulipani et al., 2008) point to the crucial role of genotype in the content of antioxidants in strawberries.

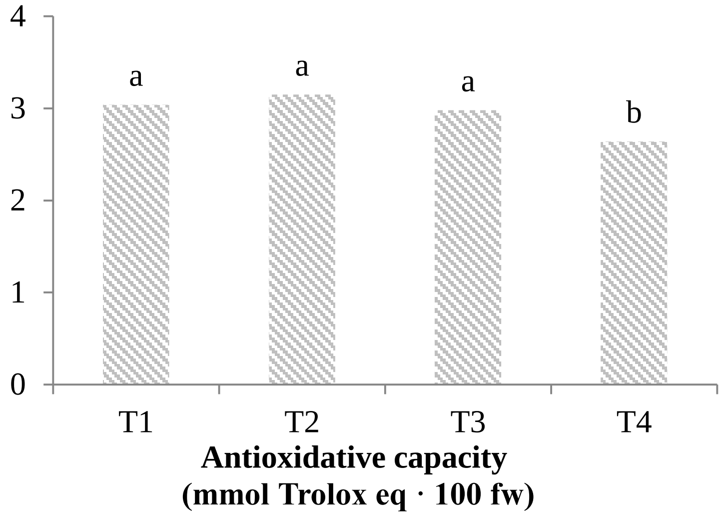

Figure 2. Effect of harvest time on the antioxidant capacity in strawberries 'Joly'; the different letters indicate statistically significant differences at $P \leq 0.05$ level (LSD test).

Conclusion

The best result concerning the external appearance and the beneficial health effect of fruits strawberry cultivar 'Joly' can be achieved in earlier harvests, which could positively influence the fruit marketing. The best performance in terms of fruit firmness and soluble solids content indicates better shelf life of fruits harvested in the second half of the harvesting season. We suggest that the fruit quality of strawberry cultivar 'Joly', in future investigations, should be coupled with subjective evaluations by a taste panel to yield complete information about the edible quality of fresh fruit.

Acknowledgements

This study is the part of the project No. 31093 financed by Ministry of education, science and technological development of the Republic of Serbia. We hereby express our sincere gratitude for the support. ‘Content of bioactive components in small and stone fruits as affected by cultivar specificities and growing conditions, and obtaining biologically valuable products by improved and newly developed technologies’.

Abstract

In this study, 11 winter wheat cultivars (KG-56S, Toplica, Perfekta, Takovčaka, Aleksandra, Vizija, Planeta, Kruna, Harmonija, Rujna and Premija) were investigated. The research was conducted in experimental field of the Centre for Small Grains Kragujevac (Serbia) during two growing seasons (2012/13, 2013/14). Variability of bread-making quality properties (sedimentation value and wet gluten content) was investigated. Quality components depended significantly upon genotype and environment factors. For a two-year average, sedimentation value varied from 23.33 ml (Premija) to 33.33 ml (Aleksandra, Planeta and Harmonija). The analyses of variance showed highly significant differences in sedimentation values between genotypes (F=244.273**), investigated years (F=717.176**), as well as their interaction (F=50.767**). The highest wet gluten content on average was established at KG-56S cultivar (39.63 %) and the lowest at Kruna (27.92 %). There were highly significant differences in the wet gluten content among genotypes (F=81.622**), investigated years (F=816.569**), as well as their interaction (F=25.974**). The analysis of phenotypic variance indicated that the highest impact of variance for sedimentation value belonged to genotype, while the highest impact of variance for wet gluten content belonged to year.

Key words: *wheat, cultivar, quality, sedimentation value, gluten content.*

Introduction

Grain quality is a complex character that depends on a number of traits, and the individual contribution of each trait varies depending on the specific reaction to environmental conditions (Mladenov *et al.*, 2001).

It is known that the quality of wheat depends, to a large extent, on the quantity and quality of gluten. Gluten proteins, consisting of gliadins and glutenins, play an important role in bread-making quality of wheat flour as gliadins mainly contribute to dough viscosity and extensibility, while glutenins affect dough strength and elasticity (Wieser, 2007). The composition of the stored proteins is a genotype characteristic and is independent of the conditions of the external environment. In recent years, a large number of papers have been published in which the emphasis of the positive effect of some gluten subunits on the technological quality of wheat (Li *et al.*, 2009; Kaya and Akcura, 2014; Mohan and Gupta, 2015).

However, the quantity of proteins depends to a great extent on the environmental factors. Thus, in a favorable regime of a mineral nutrition, soil moisture and air temperature, wheat genotypes achieve greater efficiency in pouring grains, accumulation of nitrogenous substances in the grain, and therefore increased protein content in grains. On the other hand, high temperatures in the filling phase, as well as prolonged harvest caused by abundant precipitation, lead to changes in the quality of wheat and protein content (Đurić *et al*., 2010; Hurkman and Wood, 2011).

Knowledge of the relative contributions of genotype and environment, as well as genotype and environment interaction effects on wheat quality, leads to more effective selection in breeding programs and segregation of more uniform parcels of grain better suited to the needs of customers (Williams *et al*., 2008). It is desirable that wheat varieties maintain a good and stable grain quality in different environmental conditions. Stability of wheat quality characteristics over locations and years is important to the milling and baking industry, whose processing technology requires consistent raw materials in order to produce a quality end product (Grausgruber *et al*., 2000).

The goal of this research is investigation of influence of the year, genotypes and their interactions on some wheat quality traits.

Materials and Methods

In this study, 11 winter wheat cultivars (KG-56S, Toplica, Perfekta, Takovčaka, Aleksandra, Vizija, Planeta, Kruna, Harmonija, Rujna and Premija) were investigated. The research was conducted in the experimental field of the Centre for Small Grains Kragujevac (Serbia) during two growing seasons (2012/2013 and 2013/2014). Experiment was carried out by the standard technology of scientific farming production of wheat. The period of the experiment is characterized by different meteorological conditions. During the growing period of wheat 2012/2013., 611.1 mm of precipitation felt in the area of Kragujevac. The average air temperature for the same period was 9.83°C. In the range from October 2013. to June 2014., 629.6 mm of precipitation felt in Kragujevac, while the average air temperature for the same period was 10.42°C (Republic Hydrometeorological Service of Serbia). The stem elongation period of wheat, during the month of April, started in similar temperature conditions in both vegetation seasons, with an amount of precipitation significantly higher in 2013/14. (129.1 mm compared to 41.2 in 2012/13.). During a May, when heading take a place and the process of grain filling starts, 2013/14 is characterized by extreme rainfall (227 mm) and slightly lower air temperature (15.4°C). However, in June, the air temperature was similar in both vegetation seasons but the amount of rainfall was higher in 2012/13. (85.4 mm compared with 66.9 mm in 2013/14.).

Variability of bread-making quality properties (sedimentation value and wet gluten content) was investigated. Grain samples were milled using a Brabender Quadrumat Junior laboratory mill. The quality analysis of Zeleny sedimentation test was carried out by ICC standard method No. 116/1 (1994), and wet gluten content was done by ICC standard method No. 106/2 (1984).

The results of the research were studied by Analysis of Variance (ANOVA) according to completely randomized block design with two main factors (genotype and year) and using MSTAT-C statistical program. Evaluation of importance of the difference between average values of studied characteristics was tested by separate LSD test. Components of variance (genetic, interaction and environment) were calculated by Falconer (1981).

Results and Discussion

The genetically determined composition of gluten is the main determinant of genotypic differences in baking quality (Payne *et al*. 1987). Sedimentation value and wet gluten content are important quality components due to their positive correlation with other parameters of technological quality of wheat (Zečević *et al*., 2004; Vázquez *et al*., 2012; Laidig *et al*., 2017). These quality parameters are both an indicator of the quality and quantity of proteins.

In these studies, it was found that sedimentation value in analyzed wheat cultivars varied, and on average it ranged from 23.33 ml (Premija) to 33.33 ml (Aleksandra, Planeta and Harmonija). In the first year of the research, the highest average value of the sedimentation had the cultivar Planeta (32.67 ml), and in the second year the cultivar Harmonija (38 ml). On average, the sedimentation value was higher in 2014 (31.76 ml) compared to 2013 year (28.03 ml), Table 1.

Analysis of variance showed highly significant differences among investigated genotypes (F=244.273**), years (F=717.176**) and their interactions (F=50.767**). Components of variance for sedimentation volume have shown that the most variability belonged to genotype (46.07%), while the influence of the year (28.82%) and interactions genotype x year (23.68%) was lower (Table 2). This suggests that sedimentation depends predominantly on genetic factors, but the impact of environmental factors and their interaction (genotype x environment), that play a major role in the expressing of this property, should not be ignored (Zečević *et al*., 2007; Kaya and Akcura, 2014; Abdipour *et al*., 2016).

Table 1. Mean values for sedimentation volume of winter wheat cultivars

Genotype	Sedimentation volume (ml)

The quality of wheat products depends on the quantity and quality of gluten. It is known that the quality of gluten is one of the most important factors in breeding to improve the quality of grain wheat, which plays a decisive role in the quality of dough and bread.

The highest wet gluten content was established in average at Kg-56 s cultivar (39.63%), and the lowest at Kruna (27.92%). Looking at the years of research, in the first year the highest wet gluten content was established at Kruna cultivar (45.20 %), and in the second year at Planeta (35.25 %). On average, the wet gluten content was higher in 2013 (36.89%) compared to 2014 year (30.75%). All of the analyzed cultivars had wet gluten content above 30%, except at Kruna, what indicated good technological quality of flour and dough (Table 3).

Table 3. Mean values for wet gluten content of winter wheat cultivars

Genotype	Wet gluten content (%)		
	Year		Average
	2012/13	2013/14	
Kg-56S	45.20a	34.06fg	39.63a

These results were different from the results published by Zečević *et al*. (2007), who established that the largest impact of variances in the total variance for gluten content belongs to the genotype. Mladenov *et al*. (2001), on the other hand, found that the largest contribution of variance for wet gluten content belongs to the interaction cultivar x environment. These authors carried out research on a number of sites, which affected high components of the variance for the interaction cultivar x environment. The same authors pointed out that relatively high value of genotype x environment interaction for quality traits require multiple years and site testing to accurately assess the genetic potential of varieties.
Improvement of end-use quality in bread wheat depends on a complete understanding of current wheat quality and the influences of genotype, environment, and genotype x environment interactions on quality traits (Zhang *et al*., 2004).

Conclusion

The investigation of wheat quality characteristics has shown that there are differences between wheat varieties indicating the specificity of the genotype. Different values of tested wheat properties in different cultivation years have also been established, which indicates the existence of different environmental factors in the years of research. On average, the highest sedimentation value was established at Premija cultivar. Components of variance for sedimentation volume were shown that the most variability belonged to genotype, while influence of the year and interactions genotype x year was approximately the same.
Cultivar KG-56S had the highest average value of wet gluten content. On average, the wet gluten content was higher in 2013 compared to 2014 year. Analysis of variance showed highly significant differences among investigated genotypes, years and their interactions for both analyzed traits of wheat quality.

Abstract

This research was conducted in order to examine the influence of zeolite and hydrogel, on the growth of *Tagetes patula* var. Disco Marietta and *Salvia splendens* var. Fuego transplants. Both, zeolite and hydrogel have ability to improve physical and mechanical properties of the soil, they increase its ability to retain water and nutrients. The experiment was set in a split-plot design with a total of 100 plants for each species. Four different media were studied: plants potted in commercial substrate, plants potted in the combination of commercial substrate and zeolite (90:10),plants dipped in the solution of hydrogel and water (2gr/dm^3) and then potted in commercial substrate, plants dipped in solution of hydrogel and water (2gr/dm^3) and then potted in the combination of commercial substrate and zeolite (90:10).Depending of species, different parameters were observed. For *Tagetes patula* in this research the measured parameters were: the height of plants, number of formed leaves, length of formed leaves and the number of formed flowers. To examine the influence of zeolite and hydrogel on the growth of *Salvia splendens* transplants following parameters were measured: height of the plants, number of formed leaves, height of the flowering stem, number of formed flowers. The results of this research showed that the use of the combination of zeolite and hydrogel, or separately is recommended for production of these plants. The best results, for *Tagetes* were given by the transplants that were treated with the combination of zeolite and hydrogel, while the measured parameters of *Salvia* were highest if the transplants were treated with zeolite only.

Keywords: *Tagetes, Salvia, zeolite, hydrogel, flowers*

Introduction

French marigold (*Tagetes patula* L.) and scarlet sage (*Salvia splendens* L.) are very popular decorative flowering species in urban green areas due to its beautiful colored flowers and resistance on different types of stress. These annual decorative flowering plants are mostly used in urban green areas and home gardens; they are most decorative during the summer while they are flowering. *Salvia splendens* var. „Fuego“, used for the purpose of this research is one of the most popular varieties of this species because it produces a continuous display of bright red bushy spikes during the summer, also *Tagetes patula* var.„Disco Marietta“ is becoming more popular due its highly decorative double-colored long-lasting flowers. According to Zeljković et al., (2010),growth and survival of plants in open field strongly depends on flower transplants quality, therefore it is important to examine the influence of different soil materials in order to produce quality transplants and minimize the stress during open field planting. According to Orikiriza et al., (2009)water is the most important soil physical factor that affects plant growth and quantification of such growth is relevant for the understanding of the plant-water relationship. With the use of different soil amendments, it is possible to minimize the effect of drought and to conserve and enhance soil fertility. Soil amendment is any organic or inorganic material that could be added to a soil to improve its physical properties with a goal to provide a better environment for roots growth and development (Owais et al., 2009). Zeolite is one of the natural soil amendments often used in developing new substrates for seedlings production and potted plants growing because of its positive effects on improving drainage and aeration, reducing leaching of pesticides and fertilizers from the substrate, and saving water during irrigation. It has strong sorption properties, high cation exchange capacity (CEC) and high content of micro- and macronutrients (Noori et al., 2006). The aim of this research was to determine the influence of zeolite as a natural, and hydrogel as a synthetic soil amendments on growth of French marigold (*Tagete spatula* var. „Disco Marietta") and scarlet sage (*Salvia splendens* var.„Fuego") transplants.

Material and methods

This research was conducted during 2016 in greenhouse of the Faculty of Agriculture in Novi Sad, Vojvodina, Serbia.The town of Novi Sad has long tradition in landscape architecture, in production and usage of different decorative flowers in order to improve the complete look of its streets and parks. The experiment was designed by split plot method in 4 repetitions using 10 plants in control group, and 30 plants in each examined media. Seeds of *Tagetes patula* var. „Disco Marietta" and *Salvia spendens* var. „Fuego" were used as plant material. All seeds were sown in containers filled with Klasmann-Deilmann substrate. A substrate was the mixture of white and black peat, with pH 5.5-6.5. After reaching growth of two true leaves development plants were transplanted in PVC pots with 8 cm diameter filled with different substrates. Total number of 100 plants of each species was used, divided into 4 different groups, depending on the substrate. For each species, 10 plants in control groups (C) were potted in commercial Klasmman-Delimann substrate „Florabella" which is a mixture of white and black peat, with pH 5.5-6.5. Number of 30 plants for each species were planted in mixture (Z) of commercial substrate „Floribunda" and commercial zeolite (klinoptilolit) originated from Serbian mines ina ratio 90:10. Third media, used during this research (H) was created by dipping the plants in the solution of commercial hydrogel produced by german company Evonik Stockhausen Gmbh and water (2gr/dm^3). After the treatment plants were potted in the commercial substrate „Floribunda". The last examined media (ZH) was created as a combination of commercial substrate „Floribunda", zeolite and hydrogel. First step was to create a media, mixture of zeolite and commercial substrate (90:10) as for group Z. Plants were treated with solution of water and hydrogel, as for group H, and then potted in the media. Depending of species, different parameters were observed. For *Tagetes patula* var. „Disco Marietta" in this research measured parameters were: the height of plants, number of formed leaves, length of formed leaves and the number of formed flowers. To examine the influence of zeolite and hydrogel on the growth of *Salvia splendens* var. „Fuego" transplants following parameters were measured: height of the plants, number of formed leaves, height of the flowering stem, number of formed flowers.

Results and discussion

There is numerous research on positive impact of different soil amendments including zeolite as natural and hydrogel as synthetic amendment, on various plants species growth. This research was conducted in order to examine the influence of different media amendments and its combinations on vegetative growth and number of formed flowers on two popular flowering species: *Tagetes patula* var. „Disco Marietta“ and *Salvia splendens* var. „Fuego“. The results of measured parameters were observed 45 days after the treatment of transplants. Presented values are referred to average number of examined properties per plant. According to previous research on influence of zeolite on growth of French marigold (Farzad et al., 2007) zeolite decreased leaching of nitrogen, potassium, phosphorus, calcium, and magnesium due to increase in cation exchange capacity (CEC) of soil mixture. Considering that, zeolite has positive effects on vegetative growth of French marigold and ability to form flowers, which the results of this research confirm. The results shown on Graph1. indicate that in this period of time highest measured parameters were observed in the group of plants that are treated with hydrogel and then potted in mixture of commercial substrate and zeolite (Z). Average height per plant in this group was (33,4 cm) for 7,4 cm higher than the average height of plants in control group (26 cm). Average height per plant in groups treated with zeolite (30cm) and hydrogel (32,1 cm) is higher than in control group for 15,3 % and 23,4 % respectively. The average number of formed leaves per plant and its length was the lowest in control group 15,2 leaves per plant and 10,7 cm respectively, while in the group of plants treated with mix of hydrogel and zeolite the average value of number of formed leaves was 39,4per plant and its length 14,6 cm. Higher results of these parameters were observed in the other two groups in comparison with control group; plants treated with zeolite were higher for 4 cm in average per plant in comparison to a control group, and developed 19,8 more leaves in average per plant. Plants treated with hydrogel were in average higher for 6,1 cm per plant, and developed 23,4 more leaves in average per plant in comparison to control group. During the research it was observed that flowering started on all plants that were treated with these soil amendments. In this period of time none of the plants in control group formed flowers. Highest number of formed flowers were observed in the group of plants treated with combination of hydrogel and zeolite (7,5 per plant), and lowest values were observed in group of plants treated with hydrogel (6,3 per plant) and zeolite (5,4 flowers per plant).

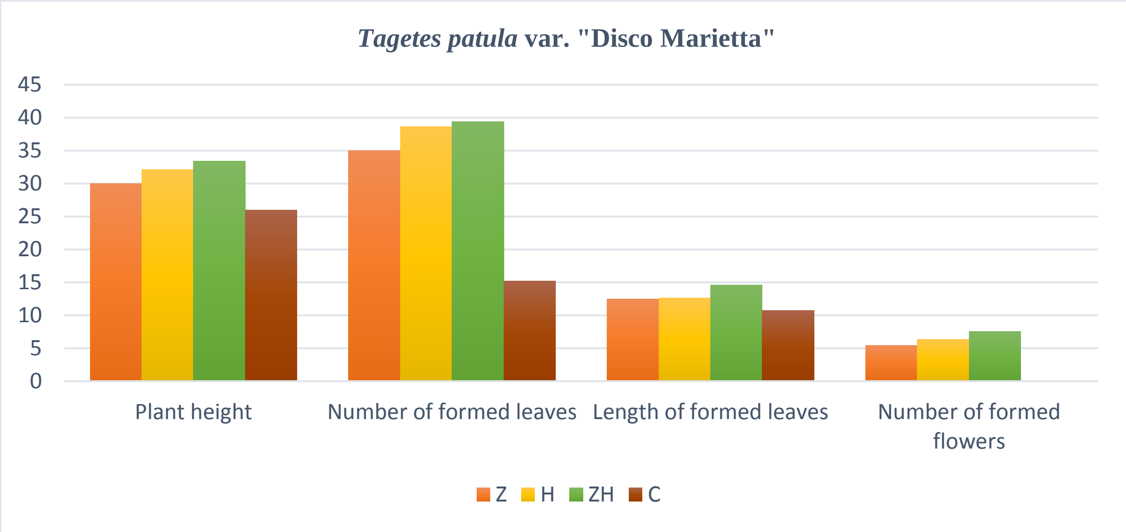

Chart 1. Results of measured parameters on *Tagetes patula* var. „Disco Marietta“

Data shown on Chart 1. represents the results of the final measurement which was conducted 45 days after the treatment of *Tagetes patula* var. "Disco Marietta" transplants. Different colors represent measured parameters: height of the plants (cm), number of formed leaves on the plants, length of formed leaves (cm) and the number of formed flowers on plants planted in different media. Orange color represents results of plants that were planted in mixture of commercial substrate and zeolite (Z), yellow color represents values of plants that were treated with hydrogel (H), green color stands for values of measured parameters of plants that were treated with hydrogel and then potted in mixture of commercial soil and zeolite (HZ), and red colors represents control (C), untreated group of plants that were potted in commercial substrate.

Hydrogel as a synthetic material used as a soil amendment, according to Akhter et al., 2004. has enormous capacity to absorb water, and make it available to plants over time, also increase in water holding capacity due to hydrogel significantly reduced the irrigation requirement of many plants. According to previous research (Ljubojević et al., 2017) hydrogel has positive growth effects on different *Salvia* species; amended hydrogel provided sufficient amount of available water and ions, also mitigated the negative influence of higher salt concentrations, thereby decreased leaf damage, defoliation and petal loss, while also improved vitality. Zeolite is being used as a soil amendment during the production of different ornamental plants, also, based on previous research zeolite used as a soil amendment has positive effect on growth of *Petunia hybrid* Juss. transplants (Zeljković et al., 2017). During this research, highest values of measured parameters on Scarlet sage transplants are recorded in the group of plants treated with zeolite. Compared to control group, average height per plant in this group (32cm) was for 8 cm higher than the average height per plant in control group (26 cm). Plants from other two treated groups also developed greatest height than plants in control group. Average height per plant in group treated with hydrogel (28 cm) was for 4 cm higher than in control group, and average height per plant in group of plants treated with zeolite and hydrogel (30 cm) was for 6 cm higher than in control group. The number of formed leaves per plant in control group was 7 which is lower than the other treated groups of plants. Groups of plants treated with zeolite, combination of hydrogel and zeolite and hydrogel formed 16,10 and 16 leaves in average per plant, respectively. Parameters which included observing flowers in this research were the highest on the plants that were treated with zeolite. Plants in this group formed 66 flowers on flower stem in average per plant, with the height of flower stem of 22 cm per plant. Number of formed flowers on flower stem in control group was for 11,86 % lower with average number of 59 formed flowers per plant. Average length of flower stem per plant formed in control group (15cm) was lower than in group of plants treated with hydrogel (17 cm) and group of plants treated with combination of zeolite and hydrogel (18 cm). Average number of formed flowers on flower stem per plant in groups that were treated with combination of hydrogel and zeolite and hydrogel was higher than the number of formed flowers on flower stem in control group, but lower for 6,4 % and 4,7% in comparison to the number of formed flowers on flower stem in the group of plants treated with zeolite.

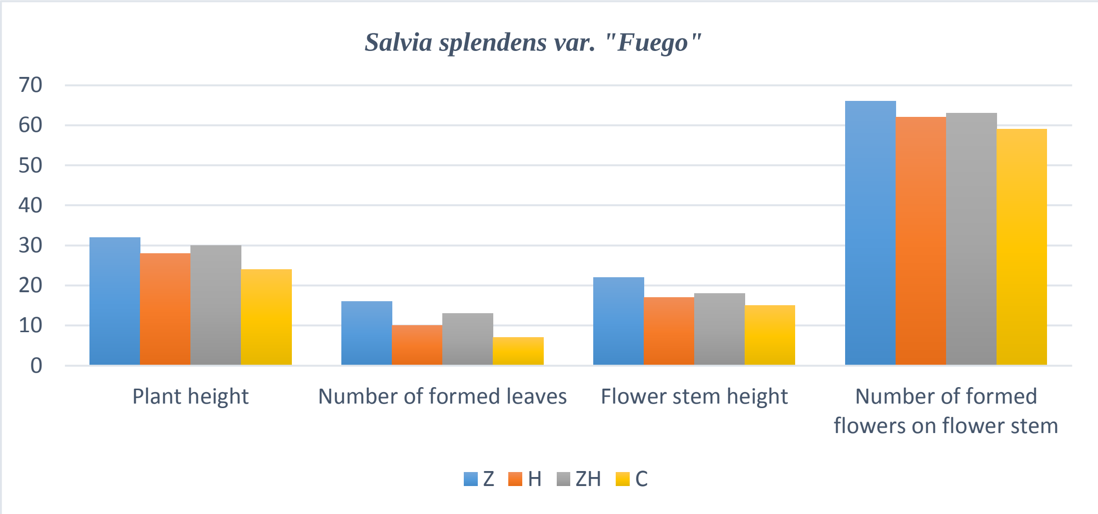

Chart 2. Results of measured parameters on *Salvia splendens* var. „Fuego“

Data shown on Chart 2. represents the results of the final measurement which was conducted 45 days after the treatment of *Salvia splendens* var. “Fuego” transplants. Different colors represent measured parameters: height of the plants (cm), number of formed leaves on the plants, length of formed flower stems (cm) and the number of formed flowers on plants planted in different media. Blue color represents results of plants that were planted in mixture of commercial substrate and zeolite (Z), orange color represents values of plants that were treated with hydrogel (H), grey color stands for values of measured parameters of plants that were treated with hydrogel and then potted in mixture of commercial soil and zeolite (ZH), and yellow colors represents control (C), untreated group of plants that were potted in commercial substrate.

Conclusions

Measured data, collected during this research show evidence for a positive impact of both hydrogel and zeolite, as well as the combination of these two soil amendments have on vegetative growth and forming of flowers on *Tagetes patula* var. „Disco Marietta“ and *Salvia splendens* var. „Fuego“. During this research, all of observed parameters on both species were higher in comparison to non treated plants in control group. The results show that vegetative growth of French marigold, its height, number and length of formed leaves were the highest on plants that were potted in media which was a mixture of these two soil amendments and commercial substrate. Also, this group of plants had highest number of formed flowers. Highest vegetative measured parameters, its height and number of formed leaves observed on Scarlet sage were in the group of plants which were treated with zeolite. Scarlet sage plants treated with zeolite also formed the highest number of flowers and highest flowers stem. It was concluded that both, zeolite and hydrogel had a pronounced effect on vegetative growth, flower and physiological characteristics of African marigold and Scarlet sage. It may be recommended that zeolite and hydrogel being used, as an amendment to soil of ornamental plants such as African marigold and Scarlet sage to improve vegetative growth and flowering.

Abstract

The production of potatoes, as a highly labor-intensive and profitable vegetable and field crop, requires fertilization, especially the use of nitrate fertilizers, as a major cultural operation. To determine the most favorable nitrogen application rate that would ensure high yields along with optimum nitrate accumulation in potato tubers, a field trial was established using different types (urea and CAN) and rates (50, 100 and 200 kgN/ha) of nitrogen fertilizers in two potato cultivars ('Lizeta' and 'Kondor'). The experiment was conducted on a leached soil under the agroenvironmental conditions of Mountain Radočelo (slopes of Mountain Golija) in Serbia. Results showed that, in both cultivars, average potato yields were higher under CAN treatment ('Lizeta' 32.511 kg/ha; 'Kondor' 32.952 kg/ha) than under urea treatment ('Lizeta' 31.877 kg/ha; 'Kondor' 29.142 kg/ha). Increasing rates of nitrogen and treatments with urea and CAN led to an increase in soil nitrate nitrogen after plant uptake, but its content was lower in all treatments than before trial establishment. Nitrate nitrogen levels in the soil were higher after urea fertilization (12.2 mg/kg) than after CAN treatment (7.6 mg/kg). Average nitrate accumulation was higher in potato tubers fertilized with CAN, particularly in 'Lizeta' ('Lizeta' 236.2 mg/kg; 'Kondor' 198.3 mg/kg), whereas the use of urea gave an average nitrate content of 208.4 mg/kg in 'Lizeta' and 174.7 mg/kg in 'Kondor'.

Keywords: *Potato, Nitrogen fertilizers, Yield, Nitrate content*

Introduction

Nitrogen (N) is one of the nutrients that exert the greatest influence on plant growth and development under diverse environments (Cao and Tibbitts, 1993). It is for this reason that the use of nitrogen fertilizers has been intensified in agricultural production. Crops can utilize different N forms, the main ones being nitrate (NO_3^-) and ammonium (NH_4^+) ions (Coraspe-Léon et al., 2009). Also, urea is an important N source, but experimental results have indicated that uptake capability and use of different N forms (NO_3^-, NH_4^+ or urea) vary depending on the plant species, developmental stage, soil pH, temperature, light intensity and root carbohydrate content (Cao and Tibbitts, 1993; Tan et al., 2000; Lea and Azevedo, 2007). Moreover, as different forms of nitrogen cause an uneven uptake and accumulation of harmful nitrates by crops, it is essential to properly determine the amount of nitrogen required to achieve high yields of good quality crops, particularly in view of the increasing importance given to nitrate content as a quality parameter of vegetables. Given that vegetable consumption accounts for the highest daily dietary intake of nitrates (about 72-94%, European Commission), and considering the important role of potatoes in the amount of vegetables consumed, some European Union countries have recommended limits for nitrate levels in tubers used in the human diet. In Germany, the maximum allowable nitrate concentration in tubers should not exceed 200 mg/kg; in Poland, nitrate limits are set at 183 mg/kg (Cieslik and Sikora, 1998).

Previous research on the effect of different forms and rates of nitrogen on crop yield and nitrate uptake in different plant species has shown that nitrate accumulation in edible organs is directly dependent on the type of nitrogen fertilizer applied (Gunes et al., 1995; Pavlou et al., 2007). The lowest nitrate accumulation was found under treatment with urea, followed by ammoniacal nitrogen, and the highest under nitrate nitrogen (Inal and Tarakcioglu, 2001; Abu-Rayyan et al., 2004; Silva et al., 2013). Nitrate content in potato tubers was about four times lower under ammoniacal nitrogen than after treatment with the nitrate form of nitrogen (Seria et al., 2004). Potato yield was highest after urea treatment, which gave a tuber nitrate content of 207.8 mg/kg (Drápal et al., 2013). Given the economic importance and nutritional value of potatoes and their high proportion in the human diet, this study focused on examining the effect of different nitrogen forms and rates, and cultivars on yield and nitrate accumulation in edible parts.

Material and methods

The effect of different types and rates of nitrogen fertilizers (CAN and urea) on tuber yield and nitrate accumulation in tubers of two potatoes cultivars (‘Liseta’ and ‘Kondor’) was examined in 2015. The experiment was laid out in a randomized block design with three replications at the village of Bzovik, Municipality of Kraljevo (Latitude 43^0 25' 33" N, Longitude 20^0 25' 53" E; 1107 m altitude), on a luvisol of the Mountain Radočelo massif.
Fertilization treatments included: T1 – (unfertilized) control; T2 –50 kgN/ha using CAN; T3–100 kgN/ha using CAN; T4–200 kgN/ha using CAN; T5–50 kgN/ha using urea; T6–100 kgN/ha using urea; T7–200 kgN/ha using urea. Potatoes were planted on 30 April 2015 at a spacing of 70 x 25 cm, and harvested on 28 September 2015.
Before trial establishment, soil samples were collected from a depth of 30 cm for the following analyses: soil pH was measured at a 1:2.5 ratio of soil to distilled water and 1M KCl; humus content was determined by oxidation with $KMnO_4$ solution (according to Kotzman); total nitrogen was estimated by Kjeldahl analysis (Gerhardt Vapodest); nitrate nitrogen content in the saline extract; available phosphorus and potassium were evaluated by extraction with 0.1M NH_4-lactate and 0.4M CH_3COOH, according to Egner-Riehm (P was analyzed spectrophotometrically by the phospho-vanadate colorimetric method and K was determined by flame photometry); available Al was measured by Sokolov’s method.
After harvest, potato tubers were sampled and analyzed for nitrate content by Kjeldahl’s micromethod.
All data in the present study were subjected to analysis of variance (ANOVA), and means were separated by LSD test at $P \leq 0.05$ using the MSTAT-C statistical computer package (Michigan State University, East Lansing, MI, USA).

Results and discussion

Soil along with its physical and chemical properties is an important prerequisite for crop production. The results of agrochemical testing (Table 1) showed an acid reaction of the soil, indicating the necessity for soil amendment practices such as liming and humification in further potato production as the coefficient of nutrient use efficiency in such soils is lower than in less acidic soils richer in organic matter (Bošković-Rakočević and Bokan, 2003). Regardless of the strongly acid reaction of this soil, mobile aluminum content (3.38 mg/100 g soil) was within the limits tolerable to plants (Jakovljević et al., 1991). This was of high importance, given the particularly deleterious effect of excess mobile aluminum in the arable layer, as evidenced by the decrease in root penetration depth and, hence, reduction in the uptake of nutrients and water from the soil (Foy, 1974). Total nitrogen, available phosphorus and available potassium levels were high, whereas the concentration of nitrate nitrogen was optimal, suggesting the suitability of this soil for potato production.

Table 1. Agrochemical characteristics of the soil

Depth (cm)	pH/H_2O	pH/KCl	Humus (%)	N (%)	NO_3-N (mg/kg)	Al	P_2O_5	K_2O
						mg/100 g

After the experiment and upon potato harvest, soil analyses revealed significant changes in nitrate nitrogen content (Table 2), which was lower in all treatments than before trial establishment (19.8 mg/kg). As indicated by its low levels in the soil, the nitrate nitrogen applied through fertilization was uptaken by plants, and the amount of nitrate nitrogen remaining in the soil after CAN treatment was significantly lower than after urea treatment. This was an expected finding considering the long period of time taken for urea as an amide fertilizer to transform in the soil. Increasing rates of both fertilizers led to an increase in the level of nitrate nitrogen remaining in the soil after plant uptake, but all values were below the maximum level tolerable by vegetable crops (<50 mg/kg). Similar conclusions in a study on lettuce were drawn by Bošković-Rakočević et al. (2009). Cultivars showed no significant differences in soil nitrate nitrogen content.

Table 2. Nitrate content in the soil and potato tubers (mg/kg)

Treatment	NO_3-N in the soil		NO_3-N in potato tubers

Soil nitrogen content is the most important external factor affecting nitrogen accumulation in plants. As the soil in this study had optimal nitrate levels, nitrate concentration in potato tubers, particularly at the highest nitrogen application rate, was above the average for this crop (below 200 mg/kg) (Corré and Breimer, 1979). The lowest nitrate content in potato tubers was recorded in the control treatment, in both cultivars ('Liseta'-52.0 mg/kg; 'Kondor' 58.0 mg/kg), and the highest at an application rate of 200 kgN/ha, using both nitrogen fertilizers. As shown by the results given in Table 2, the increasing nitrogen rates led to an increase in the nitrate content of potato tubers, and nitrogen rates up to 100 kg/ha posed no risk of increased nitrate accumulation in edible parts of potatoes, which was consistent with the findings of Đurovka et al. (1992). After urea treatment, potato tubers accumulated significantly lower levels of nitrate than after

CAN treatment, which complied with the results of Inal and Tarakcioglu (2001) and Silva et al. (2013), who also determined the lowest nitrate accumulation after urea treatment.

The analysis of the effect of cultivar on the nitrate content of potato tubers showed that 'Liseta' accumulated significantly higher amounts of nitrate after both urea and CAN treatments, compared to 'Kondor', as previously reported by Bošković-Rakočević and Pavlović (2009). The average nitrate content after CAN treatment was 236.2 mg/kg in 'Liseta' tubers and 198.3 mg/kg in 'Kondor' potatoes. A similar tendency was observed after urea treatment ('Liseta' 208.4 mg/kg, 'Kondor' 174.7 mg/kg). These results indicate that 'Kondor' has better genetic tolerance to nitrate accumulation, as previously found by Joern et al. (1995), who studied genotypic differences in potato nitrogen requirements and highlighted the importance of nitrogen fertilizer optimization as the main factor in improving potato tuber yield and quality.

In addition to the proper choice of cultivar, proper mineral nutrition adapted to soil fertility conditions is an important parameter in obtaining high yields. As the soil in this study had a good supply of nutrients and as the tested factors included different potato cultivars and nitrogen forms and rates, the different yields produced were due to the interactive effects of these factors (Table 3).

Table 3. Yield of potato cultivars 'Liseta' and 'Kondor'(kg/ha)

Treatment	'Liseta'		'Kondor'	
	Yield	Index	Yield	Index
Control	26,857	100	21,428	100
50 kgN/ha KAN	31,428	117.0	31,428	146.7
100 kgN/ha KAN	30,285	112.8	29,714	138.7
200 kgN/ha KAN	36,000	134.0	37,715	176.0
Average	*32,571*		*32,952*	
50 kgN/ha Urea	29,864	111.2	26,285	122.7
100 kgN/ha Urea	31,482	117.2	29,142	136.0
200 kgN/ha Urea	34,286	127.7	32,000	149.3
Average	*31,877*		*29,142*	

The lowest average potato yield in both cultivars was obtained in the control ('Liseta' 26,857 kg/ha, 'Kondor' 21,428 kg/ha). Increasing nitrogen rates for both types of nitrogen fertilizer resulted in an increase in potato yield, particularly in 'Kondor'. Specifically, the nitrogen rate of 200 kgN/ha applied through CAN increased potato yield in 'Kondor' by 76.0%, as opposed to the 34.0% increase in 'Liseta'. Similarly, under urea treatment, at the highest nitrogen application rate, potato yield increased by 49.3% in 'Kondor', and by 27.7% in 'Liseta'. The average potato yields, as dependent on the nitrogen application rate, indicated that yield was substantially affected by mineral nutrition (Drápal et al., 2013; Silva et al., 2013). Table 4 shows the effect of cultivar, fertilization and the cultivar x fertilization interaction on potato yield, nitrate content in the soil and nitrate content in potato tubers. The results of ANOVA indicated very significant effects of cultivar, fertilization and the cultivar x fertilization interaction on all tested parameters, except the effect of cultivar on soil nitrate content.

Table 4 - Analysis of variance of the tested parameters (ANOVA)

NO_3-N in potato tubers	12644	2107	16.29**	0.000000

Conclusions

The study on different potato cultivars fertilized by different forms and rates of nitrogen suggested the following:

Increasing rates of nitrogen and treatments with urea and CAN led to an increase in soil nitrate nitrogen after plant uptake, but its content was lower in all treatments than before trial establishment.

The lowest nitrate content in potato tubers was recorded in the control treatment, in both cultivars, and the highest at an application rate of 200 kgN/ha, using both nitrogen fertilizers. After urea treatment, potato tubers accumulated significantly lower levels of nitrate than after CAN treatment, with ‘Liseta’ accumulating significantly higher amounts of nitrate compared to ‘Kondor’. Nitrogen fertilization rates up to 100 kg/ha posed no risk of increased nitrate accumulation in potato tubers, whereas the rate of 200 kgN/ha resulted in the nitrate content of tubers higher than the average for this crop.

The average potato yields showed that mineral nutrition had a significant effect on yield.

Abstract

The entire quantity of microorganisms and some of their ecophysiological groups represent the most significant factor of soil fertility under the sown growing plants.
In this research, we have determined the number of *Azotobacter* sp., the group of free azotofixators depending on the soil type, the manner of the soil cultivation and the quantity of the applied N fertilizer. Sowing of the soil samples from which *Azotobacter* sp. was isolated, had been done on the selective fertile Fjodor ground. We estimated the influence of two soil types, "cernozem" and "gajnjaca", on the quantity of *Azotobacter* sp. The microfield observation of the "cernozem" soil type was set on the location of Zemun Polje (Serbia) while the microfield observation of the soil type "gajnjaca" was set on the location of Rača Kragujevačka. The quantity was estimated on "ugar" and under the sown corn. We studied the growing quantities of azote fertilizers, N_{30}, N_{60}, N_{120}, N_{180} kg ha^{-1}, on the quantity of *Azotobacter* sp. The control was with no fertilizer. The quantity of *Azotobacter* sp. showed the depending result on the soil type, the manner of the soil cultivation and the applied fertilizer quantity. The high quantity of the applied azote fertilizer had an inhibitory influence on the number of this group of microorganisms.

Keywords: *microorganisms*, *Azotobacter*, *soil*, *azote*, *corn*.

Introduction

Soil is a very dynamic environment and a basic substratum for growing plants. Microorganisms are a living part of soil and a biological azotofixation is one of the most important processes that they take part in (Govedarica et al., 1997). Although symbiotic azotofixation has a special place in a fixation of atmospheric nitrogen, free azotofixators are also significant for agroecosystems. Free azotofixators make a high proportion in soil (Najdenovska, 2001). They obtain different organic compounds out of the root secretions of plants which they use as energetic source for their metabolism. As a result, their concentration in rhizosphere is higher. *Azotobacter* sp. is usually found in surface soil layers and it is mainly proportioned in rhizosphere of plants. The number and activity of free azotofixators depend on great number of factors (Kiss et al., 1978). The entire number of bacteria as well as free azotofixators varies, depending on a soil type and profile depth. The greatest number in all soil types is in their surface Ah horizon, in 0-10 centimeters, while their number decreases with the depth growing (Cvijanović, 2002). *Azotobacter* was found in all subtypes of "cernozem". "Gajnjaca" can be very abundant or reduced in *Azotobacter*, which is caused by heterogenity that appears in the processes of genesis (Vojinović, 1956). The important factor that affects the entire number of microorganisms and their ecophysiological groups is the applied fetilizer. High quantities of the applied NPK fertilizer decreases the contents of organic substance in soil (Asmus, 1980; Popović, 2010; Tabaković, et al., 2015).

There is a concerned dependance of the influence of the applied mineral fertilizers on the number and activity of soil microorganisms (Đorđević, 1998). High quantities of the applied mineral fertilizers have an inhibitory influence on both, the entire number of microorganisms and azotobacters as well as on general soil biogenesis (Glamočlija et al., 2016). In this work, the number of *Azotobacter* sp. is determined depending on soil type and the quantity of applied nitrogen fertilizer under "ugar" and sown maize.

Material and methods

The research of the influence of the soil type and quantity of nitrogen on the number of *Azotobacter* sp. is carried out in two areas: Eastern Srem (The Institute for maize "Zemun Polje") and Central Šumadija (Rača Kragujevačka) in Serbia during 2013. year. Microfield testings are done by method of split plots in four repetitions. The research included the three following factors:

1. Soil type (A)
   - A_1 – "cernozem" (Zemun Polje)
   - A_2 – "gajnjaca" (Rača Kragujevačka)
2. Quantity of nitrogen (B)
   - B_1 – Control (without fertilizer)
   - B_2 – $P_{\mathbf{90}}$ $K_{\mathbf{60}}$ $N_{\mathbf{30}}$ kg ha^{-1} (basis, phon)
   - B_3 – P_{90} K_{60} $N_{\mathbf{60}}$ kg ha^{-1}
   - B_4 – P_{90} K_{60} $N_{\mathbf{120}}$ kg ha^{-1}
   - B_5 – P_{90} K_{60} $N_{\mathbf{180}}$ kg ha^{-1}
3. The manner of using soil (C)
   - C_1 – "ugar"
   - C_2 – under crop

The applied agrotechnique during the observations was standard, as the same as for regular maize production. During the realization of this project, the following methods are used:
- method of field observation,
- analysis of meteorological conditions during the observational period,
- laboratory analysis of the chemical features of soil.

The variation of the income of grown plants and the number of soil microorganisms can be observed in great measure as a consequence of weather conditions. For undisturbed growth and development of maize, as well as for proliferation of microorganisms, there is a requirement for convenient meteorological conditions, above all, average air temperatures and good regime of rainfall during the time of researching.

Eastern Srem is settled in the area of medium continental climate, between two big rivers, the Danube and the Sava with which it borders in the north, east and south. This area is specified by average annual temperature of 11.9^{0}C and the quantity of rainfall is to be 638.3 mm. Winters are with approximate temperatures of 1.6^{0}C and rainfall of 113.4 mm. Springs can be slightly colder (12.1^{0}C) than autumns (12.4^{0}C), but with a higher quantity of rainfall (159.0 mm in relation to 152.1 mm). Average summer temperatures are 21.4^{0}C and rainfall of 213.8 mm. A microfield testing station was set in Zemun Polje, on 88 meters altitude.

The area of Rača Kragujevačka encloses the basin of the samenamed river which lies between the basin of the Jasenica in the north and the basin of Lepenica in the south and it belongs to Šumadija lowlands (Milojević, 1954). The climate of Rača is medium continental. The average annual temperature, according to the meteorological station recordings in Kragujevac, is 11.2^{0}C and the average annual rainfall is 617 mm. The period with temperatures above 10^{0}C lasts for 206 days (4. IV- 27. X), and the average sum of effective temperatures is about 1.451^{0}C. (Živković and Kostoski, 2000). In geomorphological respect, Rača Kragujevačka represents the integral part of Šumadija lowlands relief. Field microtesting is conducted on 193 meters altitude. The number of *Azotobacter* sp. depending on mentioned factors, is examined on different soil types; "cernozem" (subtype carbon cernozem) and "gajnjaca" (entric cambisol). Chemical features of "cernozem" are dependant on its abundance in humus and mineral clay as well as in lime and absorbed calcium (Ca^{++}). The quantity of humus in "cernozem" can vary considerably, and its quantity in our "cernozem" is 2.5 to 6%.

Table 1. Chemical features of carbon "cernozem" (Zemun Polje)

Depth (cm)	pH H_2O	pH n/1KCl	Humus (%)	Nitrogen (%)	C/N	$CaCO_3$ (%)	mg /100 g P_2O_5	mg /100 g K_2O
0 - 30	7.71	7.34	2.86	0.19	8.6:1	4.40	25.40	22.20
30 - 60	7.81	7.48	2.47	0.17	8.6:1	11.60	17.10	18.40
60 - 90	7.87	7.66	1.11	0.08	8.4:1	24.10	2.70	7.00

On the basis of the chemical analysis results (table 1), which are performed in the agrochemical laboratory of The Faculty of Agriculture in Zemun, it can be said that the reaction of the soil mixture was mild alcal. There is medium humus and nitrogen concentration present in this type of soil and easily accessible phosphore and kalium are highly proportioned. The proportion of carbonates rises as a depth of a profile grows.
As a climately adjust soil, "gajnjaca" is created in all elements of relief, so it is formed in plains, loess plateaus, river basins as well as on hilly relief of Šumadija. Biological activity of "gajnjaca" is significant. It influences fast humus decomposing in field soil. Chemical features of soil on a tested field are shown in table 2.

Table 2. Chemical features of "gajnjaca" (Rača, Miraševac)

Depth (cm)	pH H_2O	pH n/1KCl	Humus (%)	Nitrogen (%)	C/N	$CaCO_3$ (%)	mg/100 g P_2O_5	mg/100 g K_2O
0 - 30	6.40	5.58	2.73	0.16	9.8:1	0.00	4.30	18.90
30 - 60	6.51	5.71	2.00	0.12	9.6:1	0.00	0.60	17.80
60 - 90	6.53	5.74	1.56	0.10	9.0:1	0.00	0.70	20.00

According to the results of the chemical analysis (table 2), conducted in the agrochemical laboratory of the Faculty of Agriculture in Zemun, it can be said that the reaction of soil mixture was acidly mild. The proportion of humus and nitrogen concentration was medium. On the basis of easily accessible phosphore contents, which is obtained by Al- method, its supply was low, while easily accessible kalium, taken by the same method, had a medium proportion. The presence of carbonates in a layer from 0 to 90 centimeters wasn't confirmed. The soil samples for microbiological analysis are taken on the depth from 0 to 30 centimeters. The number of microorganisms is determined by a standard indirect method of sowing diluted samples on selective nutritious substrata, which were afterwards incubated on the temperature of 28^0C. The number of *Azotobacter* sp. in the soil is determined by the method of fertile drops on nutritious substratum of Fjodorov (10^2g^{-1}).

Table 3. Chemical composition of nutritional substratum of Fjodorov

K_2HPO_4	0.3 g
$CaHPO_4$	0.2 g
$MgSO_4$	0.3 g
K_2SO_4	0.2 g
NaCl	0.5 g
FeCl	0.1 g
$CaCO_3$	5.0 g
Mixture of microelements	1.0 ml
Saccharose	20.0 g

Agar	16.0 g
Distilled water	1000 ml

The number is expressed in grammes of completely dry soil. The results of the research were analysed by descriptive statistics method.

Results and discussion

Azotobacter sp. belongs to a group of free azotofixators, the group of microorganisms that adopt elementary nitrogen and changes into amoniac form and then turn into organic one. The number of *Azotobacte*r sp. is in significant and very significant correlative connection with the entire number of microorganisms (Šarčević, Ljubica, 2010). The number of *Azotobacter* sp. in "cernozem" was from 100.4 – 182.7x10^{2}g^{-1} and its number in "gajnjaca" was 45.7 - 119.2x10^{2}g^{-1}. The variable analysis confirmed the influence of all examined factors and their interactions on the number of *Azotobacter* sp. (table 4).

Table 4. The influence of soil type, quantity of nitrogen and the manner of using soil on the number of *Azotobacter* sp. (10^{2}g^{-1})

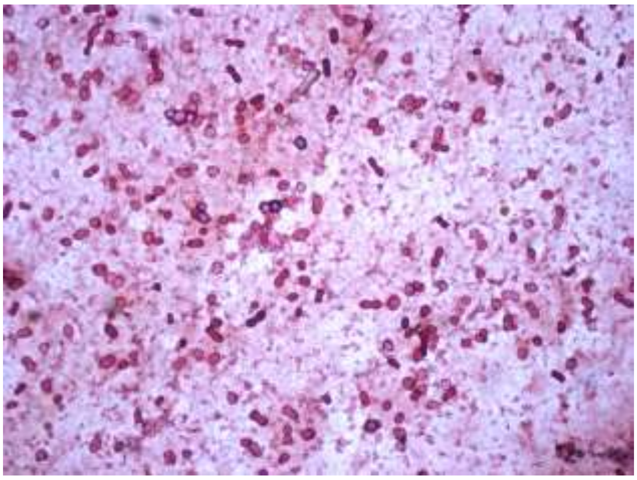
L S D	A	B	C	AB	AC	BC	ABC
0.05	16.54	18.91	29.05	33.21	42.87	44.98	59.28
0.01	19.39	24.32	35.12	50.31	57.01	56.30	69.13

The soil type influenced in great measure the number of *Azotobacter* sp. There was a higher number of *Azotobacter* sp. in "cernozem" than in "gajnjaca". This phenomenon can be explained by the fact that "cernozem" is a type of soil with significant biogenesis, weak alcal reaction of soil mixture, easily accessible phosphore and very rich in kalium which has been proved by the results of chemical analyses (table 1).
The applied quantity of nitrogen had remarkably good impact on the number of *Azotobacter* sp. All of the applied quantities of nitrogen caused a significant and very significant decrease of the number of *Azotobacter* sp. in relation to the control.



Picture 1. *Azotobacter* sp. isolated from the samples of "cernozem" on nutritious substratum of Fjodorov

The process of nitrogen reduction consists of a series of biochemical reactions, which are catalized by the ensime of nitrogenase and it is highly sensitive on molecular nitrogen. Molecular nitrogen is a powerful recepient of hydrogen and it suppresses the creation of reduced nitrogen products (Đukić and Jemcev, 2000). The majority of researches (Epanchinov, 1975; Đorđević, 1998; Hajnal-Jafari, 2010; Šarčević, Ljubica, 2010) showed that the number of *Azotobacter* sp. increases only after the applying of N_{30} and N_{60} kg ha^{-1}, whereas high quantities of the applied nitrogen (N_{90} and N_{120} kg ha^{-1}) decreases very significantly the number of *Azotobacter* sp. in relation to the control in soil under sown maize. These researches confirmed this noticed pattern.
The variable analysis confirmed that the way of using soil ("ugar" or "under crop") had a significant effect on the number of *Azotobacter* sp. The number of *Azotobacter* sp. under "ugar" was higher than under sown maize. Considering the fact that "ugar" is soil without herbal tillage, the noticed pattern can be explained by the absence of competitive connections of *Azotobacter* sp. with herbal roots.

Conclusion

The number of *Azotobacter* sp. in "cernozem" was between 100.4 – 182.7x$10^2$$g^{-1}$, and in "gajnjaca" 45.7 – 119.2x$10^2$$g^{-1}$. The variable analysis confirmed a significant influence of all examined factors and their interractions on the number of *Azotobacter* sp.
The number of *Azotobacte*r sp. in "cernozem" was considerably higher than in "gajnjaca".
All the applied quantities of nitrogen caused a significant and a very significant decrease of the number of *Azotobacter* sp. in relation to the control.
The number of *Azotobacter* sp. under "ugar" was higher than under sown maize.

The more expressive number of free azotofixators in "cernozem", which correlates with a general biogenesis, apart from the abundance in humus and mineral substances, proves itself as a notable factor which provides soil fertility.

Abstract

Radicchio, *Chicorium* spp. var. *rossa di treviso*, grows well in soils with a pH of 5.5 - 6.8, especially in well drainaged loose fertile soils which are rich in nutrients. Thus, if the cultivation of this plant is planned on the soils with high soil acidity such as Stagnosol, a necessary lime should be applied along with regular fertilization. The aim of this study was to investigate the influence of calcium containing metallurgical slag (MS), a by-product from a steel factory, as a potential liming agent on macroelement content in radicchio leaves. The effect of applied bacteria was also tested, knowing that some of the fluorescent *Pseudomonas* species are plant growth promoting rhizobacteria (PGPR) capable to colonize the plants roots, stimulate the growth and have antagonism towards phytopathogenic microorganisms. The study was performed through vegetative experiments in semi-controlled greenhouse conditions. Along with the slag, the effect of two indigenous PGPR strains from *Pseudomonas* genera, Q4 and B25, was tested through the following variants: V1: Control; V2: Strain Q4; V3: B25 strain; V4: Metallurgical slag; V5: MS+ strain Q4 and V6: MS + strain B25. P was determined by spectrophotometer, K - by flame emission photometry and total N and C by using elemental CNS analyzer Vario EL III, while Ca and Mg were determined by AAS. All treatments showed positive effects on plant and root yield as well as on elemental chemical composition of radicchio leaves, whereby the effect of variant with MS and Q4 strain was the most pronounced. In addition, this effect on N, K, Ca and Mg contents was statistically significant in relation to the control.

Keywords: *Pseudomonas strains, metallurgical slag, stagnosol, macroelements, radicchio.*

Introduction

Radicchio "Rossa di Treviso" is the classic red tall Italian radicchio. It belongs to the genus *Cichorium* and family Asteraceae. Radicchio plant is resistant to cold, as it is an early variety which can be harvested from the end of the summer and during the winter. Radicchio is suitable for growing in containers or pots. Due to nutritional features of radicchio leaf, the consuming in a form of fresh vegetable was intensified, which lead to increasing commercial interest during the last years (Filippini et al., 2011). Radicchio has many useful substances with antioxidant properties, including carotenoids, vitamins A, B_6, K, as well as macro- and micro- elements, such as phosphorus, potassium, zinc, copper, iron, etc. (Ćustić et al., 2003; Mulabagal et al., 2009). The plant has a certain kind of bitterness since it has high content of sesquiterpene lactones, such as lactucin, 8-desoxylactuctin and lactucopicrin (Ferioli et al., 2015).
Regarding the soil, it grows well in soils with a pH of 5.5 - 6.8, but loose fertile soils that have plenty of nutrients and good drainage are ideal. Thus, if the cultivation of this plant is planned on the soils with high soil acidity such as Stagnosol, a necessary lime should be applied along

with regular fertilization. The use of traditional alkaline liming materials in amelioration of soil acidity consequently improves crop production and it is a common practice (Bolan et al., 2003; Troeh and Thompson, 2005). During the last few years, metallurgical slag has prompted its use as a liming material on acid agricultural soils (Lopez et al., 1995). In recent years, interest in soil microorganisms able to promote plant growth or help prevent the attack of soil-borne plant pathogens has increased. These beneficial bacteria are usually referred to as plant growth-promoting rhizobacteria or PGPR (Lucas García et al., 2004). Their use as biofertilizers in plant production plays an important role as a supplement for improving the growth and yield of several agricultural, horticultural and medicinal plants (Lugtenberg and Kamilova, 2009). Growth promotion and disease control by these bacteria are complex interrelated processes, involving direct and indirect mechanisms that include synthesis of some metabolites (auxin, cytokinin and gibberellins), production of siderophore, antibiotics, hydrogen cyanide (HCN), and volatile compounds, while the others include mineral solubilization (e.g., phosphorus), competition, and induced systemic resistance (Adesemoye et al., 2008). Some of the fluorescent *Pseudomonas* species have already been considered as potentially powerful PGP agents (Souza et al., 2015). The aim of the study was to investigate the influence of calcium containing metallurgical slag, a by-product from the steel factory, as a potential liming agent, along with two indigenous plant growth promoting rhizobacterial *Pseudomonas* spp. strains Q4 and B25, on macroelement content in the leaves of radicchio grown on acid Stagnosol type of soil.

Material and Methods

The bacterial strains *Pseudomonas* spp. Q4 and B25, isolated from rhizosphere of maize and clover, respectively, were characterized in our previous studies using biochemical and 16S rDNA analyses (Jošić et al., 2012; Jošić et al., 2015). The bacteria were grown in liquid King's B medium (KB) for 24 h at 120 rpm. All experiments were conducted using bacterial culture in concentration of 10^6 CFUml^{-1}. The experiment was conducted using homogenized soil - Stagnosol (WRB, 2014). The soil samples were air-dried, crushed and passed through a sieve (≤ 2 mm). Before setting up the trial, preliminary soil physical and chemical properties were studied. Soil granulometric composition and chemical soil properties were determined (Maksimovic et al., 2008). The same soil type was used in our previous investigation of radicchio without MS amedment (unpublished data). The soil properties are shown in Table 1.

Table 1. Physical and chemical properties of Stagnosol (means ± standard deviation value).

Granulometric composition (fraction, %)		Chemical properties	
Bulky sand (2-0.2 mm)	5.0±0.59	pH in 1M KCl	4.45±0.01
Miniature sand (0.2-0.02 mm)	25.9±1.33	Humus (%)	2.26±0.47
Dust (0.02-0.002 mm)	45.1±1.22	Available P_2O_5 (mg 100g^{-1})	3.73±0.28
Clay (< 0.002 mm)	24.0±0.21	Available K_2O (mg 100g^{-1})	19.80±1.54
Total sand (> 0.02 mm)	30.9±1.05	Available Ca (mg 100g^{-1})	240.00±19
Dust + clay (< 0.02 mm)	69.1±1.05	Available Mg (mg 100g^{-1})	35.00±3.89

Chemical composition of metallurgical slag (MS) used in this experiment (Table 2) was determined in our previous study (Pivić et al., 2011). This material has very alkaline reaction (pH = 12.50), with the content of calcium in oxide forms (CaO) from 33-45%, of which about 50% is easily soluble in 1 M ammonium acetate; content of the total magnesium is about 0.40% and it was mainly in forms of MgO (0.70%); total phosphorous contained in the material is about 0.60%, where nearly all the amount is in available forms for plants; content of the total iron is high (about 15%), with noticeable lower amounts of its soluble forms; manganese is present in total amount of about 1.8% , but with noticeable low amounts of soluble forms; zinc is contained in lower amounts (10-20 mg kg^{-1}), while the content of copper is a little higher (about 200 mg kg^{-1}).

Table 2. Chemical composition of metallurgical slag (Pivić et al., 2011).

Parameter	Average value	Parameter	Average value
pH in H_2O	12.48	Total P_2O_5 (%)	0.61
Total Ca (%)	26.20	Total Fe (%)	15.34
Total CaO (%)	36.60	Available Fe (mg kg^{-1})	3.38
Total $CaCO_3$ (%)	65.80	Total Mn (%)	1.80
Available Ca (%)	17.18	Available Mn (mg kg^{-1})	3.12
Total Mg (%)	0.41	Total Zn (%)	14.60
Available Mg (%)	0.07	Total Cu (%)	228.8

The pot experiment was conducted during the fourth week of July until the second week of November in 2013, in plastic pots with 4 kg of homogenized soil. The effect of PGP *Pseudomonas* spp. and MS amendment were studied on radicchio (*Cichorium* spp.) variety *rossa di treviso*, in pot experiment (five plants per pot) under semi-controlled conditions in the glasshouse. Six experimental variants were set up in 3 replications, as follows: Control (V1); strain Q4 (V2); strain B25 (V3); Metallurgical slag (V4); strain Q4 + MS (V5); strain B25 + MS (V6). Before sewing the radicchio, MS with granulation of 0.2 mm and in the amount of 1.33 g kg^{-1} was mixed with soil in appropriate experimental plastic pots (V4-V6). The inoculation of the soil and radicchio plants in appropriate pots (V2-V3, V5-V6) was carried out with the solution containing 150 ml of distilled water and 50 ml of Q4 or B25 liquid culture. Control (V1) was treated with solely 200 ml of distilled water. Radicchio plants were grown for 16 weeks according to the standard growing methods. Leaf and root samples were dried at 105^{o}C for a period of 2 hours and their biomass was weighed. The following macroelements were analyzed in the leaf samples: nitrogen (N) and carbon (C) were analyzed on elemental CNS analyzer Vario EL III (Nelson and Sommers, 1996); phosphorus (P) and potassium (K) contents were determined by method named as “wet” combustion, i.e. they were heated to boiling with the mixture of concentrated sulfuric and perchloric acids. In the obtained solution, P was determined by spectrophotometer with molybdate, and K - by flame emission photometry (Jakovljević et al., 1985); calcium (Ca) and magnesium (Mg) were determined by Atomic Absorption Spectrometry (AAS) (Wright and Stuczynski, 1996), where the plant material was converted to a solution by method named as "dry" combustion, i.e., first by heating at 550ºC (for several hours) and then by treating the obtained ash with hydrochloric acid (Miller, 1998). The obtained data on soil properties represent the arithmetic means of three replicates and standard deviation values. The effects of V1-V6 treatments on the studied chemical parameters of the plants were evaluated using the analysis of variance (SPSS 20.0, Chicago, USA), followed by Duncan's Multiple Range Test (DMRT). Significant differences between means were tested by the LSD test at P = 0.05.

Results and Discussion

The results of physical and chemical properties of plowed layer of the studied Stagnosol, shown in Table 1, indicated that it is a clay loam according to the soil textural class determined on the basis of particle size distribution. According to the reference values (Šestić et al., 1969), it has very acid reaction and medium humus content, with a very low content of available phosphorus and medium provided with available potassium. It is medium provided with calcium and with high content of magnesium. All tested variants gave higher yield in comparison with the control sample (Table 3). Application of MS in combination with B25 strain (V6) had the best activity on yield of plant mass, while the combination of MS and Q4 strain (V5) showed slightly weaker activity. These two variants also gave the highest root mass yields. Results of merely application of MS (V4), Q4 (V2) and B25 strain (V3) were similar, with values of plant and root yield not significantly higher than the control sample (V1).

Table 3. Yield of plant and root mass for each variant

Variant	Yield of plant mas (g/pot) *	Root mass yield (g/pot) *
V1 (Control)	7.06±0.03^{b}	0.46±0.02^{b}
V2 (Q4)	13.14±0.20^{b}	0.76±0.09^{b}
V3 (B25)	11.82±0.82^{b}	0.94±0.36^{b}
V4 (MS)	10.86±5.70^{b}	0.63±0.36^{b}
V5 (Q4+MS)	20.03±5.15^{a}	1.51±0.04^{a}
V6 (B25+MS)	21.48±0.92^{a}	1.43±0.13^{a}
P value	***	***
LSD (0.05)	5.65	0.39

*means ± standard deviation; LSD - least significant difference; values followed by the same letter in a column is not significantly different at P< 0.05 based on Duncan's Multiple Range Test

Pseudomonas spp. has also proven to increase tomato plant yield for 46%, due to its ability to colonise the plant's root, produce variety of antimicrobial compounds, and induce plant's defence mechanisms (Arseneault et al., 2015). Increase in root yield for 179% has been recorded for apple plants, 42% for wheat and maize, and up to 200% for potato, when treating plants with different *Pseudomonas* strains (Gupta et al., 2013). These data are in consistence with results obtained in our study, where V5 and V6 induced plant and root mass yield increase for over 280%.

The data on main chemical growth parameters in radicchio leaves influenced by the treatments applied is shown in Table 4. The positive effects N, P, K, C, Ca and Mg content in the samples of leaves in relation to the control was observed for all studied treatments. The maximal values for all tested available macroelements were achieved by apllying the combination of MS and Q4 strain (V5). This influence was statistically significant at P<0.05 regarding the content of N, K, Ca and Mg, with the highest statistical significance for K, while for the content of P and C there were no statistically different between the treatments.

Table 4. Effect of applied treatments on the content of macroelements in radicchio leaves.

Variants	Macroelements (% of dry biomass)*					
	N	P	K	C	Ca	Mg
V1 (Control)	3.39±0.03^{b}	0.65±0.04	2.11±0.09^{c}	38.09±0.58	1.32±0.08	0.31±0.01^{b}

Limitations in crops growth on acid soils are well known. However, the optimum pH range of soil for the growth of most crops is between 5.5 and 7.0, within which most plant nutritive are available (Goulding et al., 2016). Regarding the effects of slag amendments to acid soil, Besga et al. (1996) reported increase in the soil pH linearly, which has allowed the plant absorption of phosphorus, due to a changing of insoluble forms to soluble ones, as well as increase in the Ca and Mg contents. Other authors have also proved that PGP *Pseudomonas* strains can induce increase in N, P and K levels in different plants (Vikram et al., 2007; Ordookhani et al. 2011).

Conclusions

Application of MS in combination with B25 strain (V6), as well as its combination with Q4 strain (V5) had the best activity on yield of plant and root mass. The data on studied macroelements in radicchio leaves showed that all studied treatments exhibited positive effects on the content of N, P, K, C, Ca and Mg in relation to the control. The most pronounced effect was registered in the variant with metallurgical slag and *Pseudomonas* sp. Q4 strain. This influence was statistically significant regarding the content of N, Ca, Mg and especially K, which presents a very important element for nutrient quality of vegetables.

Abstract

Darwin's barberry is a decorative, medicinal, edible and low demanding evergreen shrub, grown as an ornamental plant in Western Europe. This species should be used in green spaces in Serbia more often. *B. darwinii* can be propagated by seed, but it has endogenous seed dormancy. For this reason, we decided to investigate which chilling treatment will be effective in breaking its dormancy. The seeds used in our experminets were collected in Hyde Park in London, and after maceration they were cold stratified in perlite or in bags without a substrate for 3, 4 and 5 months. The parameters of seed germination were determined according to the ISTA rules. The best results were achieved with the seeds cold stratified in perlite for 4 and 5 months, whose germination rate was 73.5% and 73.0% respectively. However, seeds stratified for 5 months in perlite had a higher germination energy (69.0%) compared with seeds stratified for 4 months (37.0%). There are indications that germination rate can be improved with combination of warm and cold stratification, so additional research should be conducted.

Keywords: *Darwin's barberry, seed dormancy, cold stratification, generative propagation.*

Introduction

Darwin's barberry (*Berberis darwinii* Hook) is a thorny, dense branched, evergreen shrub growing up to 3 m (4 m). The leaves are dark glossy green, broadly oblong, with a spiny margin. It flowers from April to May, and the flowers are gold to orange, produced in dense, drooping racemes, followed by blue-black berries ripening in summer (Tenenbaum, 2003; Weber, 2017). Darwin's barberry is native in South America, growing in moist open woodlands of the alpine regions of Chile, Argentina and Patagonia (Weber, 2017). It is a decorative, low demanding plant suitable for slopes and cottage or informal gardens. It is a good hedging plant, that can be pruned. *B. darwinii* prefers warm, moist loamy soil, but it also tolerates thin, dry and shallow soil as well as heavy clay soil. It grows well in full sun or light shade, in zones 7 to 9 (Huxley *et al.*, 1999; Tenenbaum, 2003). This is a melliferous, edible and medicinal species (Fern, 2000; Janick and Paull, 2006). Outside its native range, Darwin's barberry is grown as an ornamental plant in Western Europe and North America. In New Zealand and Australia it is considered an invasive species and a serious threat to indigenous biodiversity (Weber, 2017). However, according to the DAISIE, a database of alien and invasive species in Europe (http://www.europe-aliens.org/), Darwin's barberry is not an invasive species in Europe. Furthermore, the Royal Horticultural Society recommends its use as a low maintenance and decorative species (https://www.rhs.org.uk). Taking into account all these characteristics, *B. darwinii* should be recommended for use in green spaces in Serbia.

B. darwinii can be propagated from seeds or cuttings. Vegetatively, Darwin's barberry can be propagated from semi-hardwood cuttings (Hartmann *et al.*, 2010). Its seeds have dormancy mechanisms in order to prevent seed germination during an inappropriate season. For this reason, in natural conditions, seeds germinate in the spring following dispersal (Figueroa, 2003), therefore seed dormancy is often broken during a certain period of low temperature. This can be achieved artificially by storing imbibed seeds at low temperatures, a treatment known as a cold stratification (Baskin, Baskin 1998, Grbić, 2003). *B. darwinii* has endogenous seed dormancy and its seeds require cold stratification, for 2 to 3 months at 4°C or can be sown in fall in a cold frame when it should germinate in early spring (Dirr and Heuser, 1987; Bonner and Karrfalt, 2008; Hartmann *et al.*, 2010). It is important to remove all pulp from the seeds, because the seeds are susceptible to fungal infections (Piotto and Noi, 2003). However, there are no data available about the exact stratification time and expected germination rate. For this reason, we decided to investigate the effect of different seed pretreatments on the dormancy breaking and germination of this species.

Material and Methods

Seeds were collected from the mother plant growing in Hyde Park in London, near the Diana Princess of Wales Memorial, on 17th of June, 2008. After collection, all pulp from seeds was removed and they were thoroughly washed with distilled water, surface dried and stored at room temperature before testing. Six pre-sowing chilling treatments were made. The seeds were stratified at 3-5°C for for 3, 4 or 5 months. There were two groups of treatments. The first one was chilling in plastic, transparent bags which were opened each week and moisture was controlled (naked stratification). The second gruop of seeds was put in the chilling in perlite. The seeds in control treatment were tested without chilling pretreatments. After stratification, the seeds were treated with Previcur N fungicide (0.3 % v/v) and placed on the top of two layers of filter paper in petri dishes. Humidity was controlled daily by adding distilled water if necessary. Temperature during germination was 20°C. Germination was carried out in long day conditions (light/dark period 16/8h). The germination was tested according to ISTA (1985) rules for the genus *Berberis.* The first count was the 7th day (germination energy) and the last count was the 21th day after placing the seeds. In this period, the number of germinated seeds was recorded daily. Besides germination rate and germination energy, real germination rate was also calculated as a percentage of sound (viable) seeds that germinate (Grbić *et al.*, 2010). Each treatment consisted of four replicates with 50 seeds per repetition. The obtained data were statistically analyzed using the program Statgraphics Plus, Ver 2.1.

Results and Discussion

In the control treatment there were no germinated seeds. The same result was obtained after a 3-month stratification period, with seeds that did not germinate in both treatments (chilling in plastic bags and chilling in perlite). After 4 months of chilling in perlite, seeds started to germinate during stratification, and 26% seeds germinated before testing. The seeds continued to germinate and germination energy was 37.0%, germination rate was 73.5%. Contrary to that, the seeds from naked stratification did not germinate during a 4-month stratification period, and after testing, germination rate was noticeably lower - only 4.5%, and germination energy was 0% During 5 months of stratification in perlite, the seeds also started to germinate, and after stratification there were 67.5% germinated seeds. After testing on the filter paper in petri dishes, germination rate reached 73.0%. In naked stratification treatment, during the 5 months of stratification, only one seed germinated. After testing, germination energy was low - 1.5% and germination rate was only 7% (table 1).

Table 1. Germination of collected seeds

Treatment	Germination rate	Germination energy	Real germination rate
Control	0.0c	0.0c	0.0c
3 months stratification in perlite	0.0c	0.0c	0.0c
3 months naked stratification	0.0c	0.0c	0.0c
4 months stratification in perlite	73.5a	37.0b	73.8a
4 months naked stratification	4.5bc	0.0c	4.8bc
5 months stratification in perlite	73.0a	69.0a	75.1a
5 months naked stratification	7.0b	1.5c	7.1b

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Compared to results obtained with other barberry species, germination rate recorded in our research is lower than germination percentage of *B. aristata* (84%) after 2 months of stratificaton at -5°C (Thakur *et al.*, 2005). Belwal *et al.* (2015) had applied different pretreatments including soaking the seeds in different solutions, different temperatures and storage conditions and they got germination rate 92% for *B. aristata*, but only 50.6% for *B. jaeschkeana.* Results obtained in our research showed that stratification in substrate as well as duration of stratification strongly influenced germination response (Table 1). Germination rate was almost the same after 4 or 5 months for seeds stratified in perlite (73-73.5%), but germination energy was considerably higher after 5 months of stratification than after 4 months. An investigation of the germination of *B. manipurana* indicated that light conditions can also affect germination (Deb *et al.*, 2017). The highest germination rate (seeds stratified at 4°C for 75 days) was 82.5% in 50% shade, 65% in 75% shade and 52.5% in normal light conditions. However, Deb *et al.* (2017) stated that *B. manipurana* is a species that grows in shady moist habitats, so better germination in light shade than in full sun conditions could be expected. Contrary to this, Maliwichi-Nyirenda *et al.* (2011) showed that light conditions did not affect the germination of *B. holstii,* but seeds stored at 5°C germinated faster than the seeds kept at room temperature, although *B. holstii* is the African species that does not require cold stratification for germination. Thakur *et al.* (2006) found that seeds of *B. aristata* are facultatively photoblastic with a maximum germination of 77-83% after 3 months of stratification. Bonner and Karrfalt (2008) stated that simple cold stratification of *Berberis* spp. is not always successful and that there is a possibility of presence of some immature embryos in some barberry seeds, so a period of warm stratification followed by cold stratification can increase germination rate.

Conclusion

B. darwinii satisfactory germination rates (73%) can be obtained after 5 months of stratification in perlite at temperatures from 3 to 5°C. However, taking into account the results obtained with other barberry species, there is a possibility of improving the germination of *B. darwinii* by testing the effects of other factors (e.g. light, stratification at other temperatures, soaking the seeds in different solutions).

Abstract

Propagation of blue-eyed grass (*Sisyrinchium angustifolium* Mill.) is difficult due to its embryo dormancy. The aim of this research is to establish a suitable method of breaking seed dormancy of this species. The seeds used in this experiment were collected in a private garden in Belgrade, and the effect of different treatments on seed germination was evaluated. These treatments included the application of different concentrations (10^{-3} M, 10^{-4} M, 10^{-5} M) of GA_3 (gibberellic acid), application of 0.2% KNO_3 (potassium nitrate), cold stratification (1 or 2 months at 3-5^{o}C) and combinations of these treatments. The obtained results showed that *S. angustifolium* requires cold pretreatment for germination, but germination percentage can be considerably improved by treating the seeds with KNO_3 or GA_3. Data were statistically analysed and the best results were achieved with the seeds treated with 10^{-3} M or 10^{-4} M GA_3 and cold stratified for 2 months (79% and 70% germination rate, respectively).

Keywords: *Blue-eyed grass* (*Sisyrinchium angustifolium* MILL.), *cold stratification, GA_3, KNO_3,*

Introduction

Blue-eyed grass *(Sisyrinchium angustifolium* Mill.) is a clump-forming perennial species, usually 25-30 cm tall, with a tuft of basal, simple, long, narrow grass-like or linear sword-like leaves. Blue-eyed grass blooms from late spring to mid-summer and flowers are formed in clusters (1 -3 flowers), about 2 cm across, violet-blue with yellow centers. Each flower is short lived, but they bloom successionally and flowering can last several weeks (Chapman, 2008; Steiner, 2005). The flowers are open only in the sun, when bees are likely to visit (Cullina, 2000). After flowering, the seed capsules (4-6 mm in diameter) ripen from greenish yellow to dark brown, then split open in 3 sections releasing black, spherical seeds (about 1-1.4 mm in diameter). The seeds should be harvested when the capsules are dark colored and the seeds can be easily taken out (Cullina, 2000; Gardner, 2010). It is native to North America, where it grows on moist fields and meadows, prairies, in open woods, slopes and along stream banks (zones 4 - 9). Blue-eyed grass is grown as an ornamental plant, especially suitable for informal gardens (cottage gardens, woodland gardens, wild gardens), usually used at the front of mixed borders, as an edger for paths or walkways or in rock gardens (Cullina, 2000; Chapman, 2008; Steiner, 2005). *S. angustifolium* is a highly adaptable plant that can survive summer drought but it prefers moderately moist soils that do not dry out with good drainage. It grows in full sun, but tolerates part shade (Cullina, 2000). According to DAISIE (Delivering Alien Invasive Species Inventories for Europe), *S. angustifolium* is escaped from cultivation in some parts of Europe, but it is not considered as an invasive or potentially invasive species (http://www.europe-aliens.org). Also, plantings can be cut back after bloom to avoid any unwanted self-seeding (Steiner, 2005).

Blue-eyed grass can be propagated by seeds or by division of clumps in early spring or fall (Cullina, 2000; Samuels, 2005). According to Cullina (2000) seeds germinate at 21°C after 90 days of moist cold stratification at 4-5°C, but Gardner (2010) states that this presowing treatment is not effective, giving only 15% germination. Similary, Kuzovkina et al. (2016) state that germination of *S. angustifolium* can be difficult or slow. For species with endogenous dormancy various chemical treatments (gibberellic acid, potassium nitrate) can result in breaking dormancy and increasing the seed germination (Grbić, 2003). Gibberellins promote growth by increasing plasticity of the cell wall followed by the hydrolysis of starch to simple sugars. These sugars reduce cell osmotic potential which results in absorption of high amount of water, thus resulting in cell elongation and growth (Arteca, 1996).

The aim of our research was to find suitable presowing treatment to improve germination of *S. angustifolium*.

Material and Methods

The ripe fruits were collected in private garden in Belgrade, in September, 2013. Experminet was conducted in the Laboratory for seed testing in Faculty of Forestry, Belgrade. The weight of fruits was measured as well as weight of seeds. This data were used for calculation of extraction factor (the weight of cleaned seeds per given weight of ripe fruits, expressed in percent), number of seeds in 1 kg and absolute weight of seeds (weight of 1000 seeds). Absolute weight of seeds was calculated as a mean weight of 4 samples of 100 seeds multiplied by 10. Collected seeds were used for the next experiment - evaluation of influence of different seed pretreatments on germination. The seeds are treated with solution of GA_3 (gibberellic acid) in concentrations of 10^{-3}M, 10^{-4}M, 10^{-5}M for 24h or with 0.2%, solution of KNO_3 (potassium nitrate) for 24h, or they were soaked in the distilled water also for 24h (control). The imbibition is conducted using a water pumps and silicone hoses that enabled a constant flow of oxygen, at the temperature of 20°C. After imbibition, the seeds are put on stratification at the temperature of 3-5°C during 1 or 2 months. The part of seeeds are tested without stratification. Total 15 treatments including the control were made (Table 1).

Table 1. Seed pretreatments

Abbreviation	Treatment
C	control
KNO_3	0.2% solution KNO_3
GA_3^{-3}	solution 10^{-3}M GA_3
GA_3^{-4}	solution 10^{-4}M GA_3
GA_3^{-5}	solution 10^{-5}M GA_3
1K	1 month stratification
$1KNO_3$	0.2% solution KNO_3 + 1 month stratification
$1GA_3^{-3}$	solution 10^{-3}M GA_3 + 1 month stratification
$1GA_3^{-4}$	solution 10^{-4}M GA_3 + 1 month stratification
$1GA_3^{-5}$	solution 10^{-5}M GA_3 + 1 month stratification
2K	2 month stratification

$2KNO_3$	0.2% solution KNO_3 + 2 month stratification
$2GA_3^{-3}$	solution 10^{-3}M GA_3 + 2 month stratification
$2GA_3^{-4}$	solution 10^{-4}M GA_3 + 2 month stratification
$2GA_3^{-5}$	solution 10^{-5}M GA_3 + 2 month stratification

Each experiment consisted of four replicates with 25 seeds each. Before testing, seeds were treated with 0.6% solution of commercial preparation Previcur (fungicide). The seeds were placed on the top of two layers of filter paper in the petri dishes, humidity was controlled daily by adding the distilled water if necessary. Temperature during germination was 20°C. Germination was carried out in long day conditions (light/dark period 16/8h). The first count was the 7th day (germination energy) and the last was the 21th day after placing the seeds into germination. Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1.

Results and Discussion

Weight of fruits was 118.12 g, weight of seeds was only 10.86 g, so the extraction factor was low - 9.19. Absolute weight of seeds was 0.63 g, and number of seeds in 1 kg was 1587301. According to Kuzovkina et al. (2016) the number of seeds of *S. angustifolium* in 1 kg is slightly higher - 757000/lb (approximately 1682222/kg).

Table 2. Germination of *S. angustifolium* seeds

Treatment	Germination rate (%)	Germination energy (%)
Control	3^{f}	0^{f}
0.2% KNO_3	16^{ef}	0^{f}
10^{-3}M GA_3	7^{f}	1^{f}
10^{-4}M GA_3	21^{e}	0^{f}
10^{-5}M GA_3	8^{ef}	0^{f}
1 month stratification	42^{d}	35e
0.2% KNO_3 + 1 month stratification	61^{bc}	61^{b}
10^{-3}M GA_3 + 1 month stratification	67^{ab}	67^{ab}
10^{-4}M GA_3 + 1 month stratification	47^{d}	44^{de}
10^{-5}M GA_3 + 1 month stratification	67^{ab}	60^{bc}
2 month stratification	37^{d}	34^{e}
0.2% KNO_3 + 2 month stratification	61^{bc}	57^{bc}
10^{-3}M GA_3 + 2 month stratification	79^{a}	79^{a}
10^{-4}M GA_3 + 2 month stratification	70^{ab}	68^{ab}
10^{-5}M GA_3 + 2 month stratification	48^{cd}	48^{cd}

In control treatment, only 3% of seeds germinated, and in other treatments without cold stratification (0.2% KNO_3, 10^{-3}M GA_3, 10^{-4}M GA_3, 10^{-5}M GA_3) germination percentage was also low, ranging from 7% to 21% (Table 2), indicating that *S. angustifolium* seeds have endogenous dormancy that requires cold pretreatment.

Potassium nitrate (KNO_3) is widely used chemical in the presowing treatments for promoting germination (Copeland and McDonald, 2013). Its use is recommended by ISTA as a standard presowing treatment for germination test of many species (ISTA, 1985). In our research, pretreatments with solution of potassium nitrate influenced germination percentage. After 1 month and 2 months stratification, seeds treated with 0.2% KNO_3 solution germinated better (61%) then seeds stratified without it (42% for 1 month stratification, 37% for 2 month stratification) (Table 2). In treatments without cold stratification, germination percentage was also higher for seeds treated with KNO_3 (16%) compared to control (3%), but there were no significant statistical differences among these values.

Gardner (2010) emphasizes that *S. angustifolium* may requires light pretreatments for germination, and that KNO_3 pretreatment can influence germination of species sensitive to light (Copeland and McDonald, 2013). Deno (1993) states that 40% of *S. angustifolium* seeds germinated after treatment with light, without stratification, at the temperature of 21°C and that there were no germinated seeds in the dark. However, influence of KNO_3 pretreatment on germination is different depending on species, in some cases KNO_3 can be substitute for light, in some cases the light sensitivity of seeds is only increased, but in some cases KNO_3 pretreatment can counteract light inhibition of seed germination. For this reason, additional research of influence of light on *S. angustifolium* seed germination should be conducted.

For stratified seeds, treatments with GA_3 solutions influenced germination percentage strongly, increasing also the germination energy (Table 2). Response of seed on different concentrations of GA_3 differed depending on length of stratification. The best results were achieved with seeds treated with 10^{-3}M GA_3 followed by 2 month stratification - 79% germinated seeds. This value was the same as germination energy, which means that all 79% of the seeds germinated after first count, on 7th days from placing seeds on germination.

Copeland and McDonald (2013) indicate that GA_3 pretreatment can be effective for freshly harvested seeds, reducing the time to germination and improving the rate of germination; but also dry seeds that have been after-ripened by natural storage are not as responsive to addition of GA_3. Deno (1993) states that GA_3 pretreatment did not stimulate germination of *S. angustifolium*, but his experiment was conducted without stratification, and seeds germinated at 21°C, which is in accourdance to our results, where percentage of germinated seeds treated with GA_3 without stratification was also low (Table 2).

Conclusion

S. angustifolium can be easily propagated by seeds. The best results are obtained with seeds treated with 10^{-3} M GA_3 followed by cold stratification for 2 months at the temperature of 3-5^{o}C. Obtained germination rate was 79%. However, there is possibility to improve germination rate and additional research should be conducted in order to investigate the effect of light on germination of *S. angustifolium*.

Abstract

Acid soils have unfavorable physic-chemical properties. The aim of this study was investigate the impact of mineral, lime and organic fertilizers on grain yield of triticale on pseudogley. Investigations were carried out in the vicinity of Kraljevo (Serbia) during the 2011/2013. In the trial two varieties oftriticale and 10 fertilization variants (V1-N_{35} P_{60} K_{60}, V2-N_{60} P_{100} K_{100}, V3- $N_{35}P_{60}K_{60}$ + 2.5 t/ha $CaCO_3$, V4- $N_{60}P_{100}$ K_{100} + 2.5 t/ha $CaCO_3$, V5- $N_{35}P_{60}K_{60}$ + 5 t/ha $CaCO_3$ and V6- $N_{60}P_{100}K_{100}$ + 5 t/ha $CaCO_3$, V7- $N_{35}P_{60}K_{60}$ + 2.5 t/ha $CaCO_3$ + 20 t ha^{-1} manure, V8- $N_{60}P_{100}K_{100}$ + 2.5 t/ha $CaCO_3$ + 20 t ha^{-1} manure, V9- $N_{35}P_{60}K_{60}$ + 5 t/ha $CaCO_3$ + 20 t ha^{-1} manure i V10- $N_{60}P_{100}K_{100}$ + 5 t/ha $CaCO_3$ + 20 t ha^{-1} manure) were included. The resulting data were analyzed using the analysis of variance. The application of all the variants of fertilization has led to a significant increase of grain yield compared to the control. The highest average yield of 4750 kg ha^{-1} was achieved at the variant with the highest dose applied mineral, lime and organic fertilizers. The average yield achieved using only triticale fertilizers was 2809 kg ha^{-1}. Average yield triticale achieved by using a combination of mineral and lime fertilizers was 3726 kg ha^{-1}. Combination of mineral, lime and organic fertilizers achieved average yields grain of triticale of 4463 kg ha^{-1}. The use of lime and organic fertilizers in combination with the mineral, the acid soils can achieve a satisfactory yield of triticale.

Key words: *mineral fertilization, organic fertilization, pseudogley, yield, triticale.*

Introduction

Villegas *et al.* (2010) point out that triticale is the first artificially created crop due to crossbreeding of wheat and rye. It aimed at combining the desirable characteristics of the parents. Triticale appeared as an interesting crop, suitable for less favorable agroecological conditions and conditions when the production of wheat or rye is limited (Estrada-Campuzano *et al.*, 2008 and Lalević *et al.*, 2012). Estrada-Campuzano *et al.* (2012) they point out that new varieties of triticalea are more fertile and well-adapted to the conditions of the soil and the environment in relation to wheat. Samner and Noble (2003) they emphasize that soil acidity is one of the limiting factors of successful plant production and that there are around 4 billion hectares of acidic land in the world, which represents about 30% of the area. Acidity of soil often affects agricultural production, slows down growth, absorbs water and nutrients, which leads to a decrease in the yield of cultivated plants (Sumner *et al.*, 1986). Beckie and Ukrainetz (1996) point out that the weak growth of plants on acid soils can be the result of the presence of phytotoxic substances in a solution such as Al and Mn that cause defects of P, Ca and Mg and reduce the intake of nutrients. The application of N, P and K on acidic soils is of great importance for increasing yields, although they are poorly exploited on these soils (Rashid *et al.*, 2007). Prado *et al.* (2007) and Alvarez *et al.* (2009) note that the lime has long been known as the main material for improving the productivity of mushroom soil and shows

a positive reaction to crops due to the alleviation of poor production characteristics of acidic soils. The use of organic fertilizers, such as green manure and harvest residues, significantly influences the improvement of the soil structure, the increase in productivity of the soil, the reduction of erosion, and the like (Janusiene, 2000).
The aim of our research was to determine the yield of triticale grown on acid soil, depending on the fertilization with mineral, lime and organic fertilizers.

Materials and Methods

The research was conducted in the vicinity of Kraljevo (Serbia) during the 2011/2013. The trial, in addition to two varieties of triticale (KG-20 and Odisej), control (V0) and ten variants of different combinations (V1-V10) of NPK, liming with $CaCO_3$ and farmyard manure (FYM) were applied (Table 1).
So there were two variants of only mineral fertilizers (V1- V2), four variants of both mineral and lime fertilizers (V3- V6), and finally four variants consisted of mineral, lime and manure fertilizers, together (V7- V10). Mineral fertilizers were represented with NPK fertilizer, lime with $CaCO_3$ and organic with manure.
The trial was set according to a block system in three repetitions. Before the basic land cultivation, mineral, lime and manure fertilizers were distributed on the soil surface, and then ploughed in. Other half of nitrogen fertilizer was used in top dressing in a form of ammoniacal nitrogen. Basic land cultivation was carried out in a classic way, on 25 cm depth. Sowing was carried out in October. Harvest was carried out in the phase of dead ripe, and yield was corrected on 14% of moisture. Results were presented as an average of two years experiment and anlysed with ANOVA.

Soil and climatic conditions
Soil at Kraljevo location belongs to the pseudogley soil type. This soil has very bad physical properties (compacted, having high content of silt and clay particles, with slow water percolation) and extremely acid pH value (pH<4.5). Its total humus content is relatively fair, but microbiological activity is low, because of its poor physical properties. That causes low mineralization of organic nitrogen, and so nitrogen fertilizers show a great effect on such soils. It is characterized by low content of available phosphorus (6.70-6.90 mg/100g of soil) and potassium (7.80-9.80 mg/100g of soil). In table 1 are shown chemical properties of the soil.

Table 2. Chemical properties of the soil

Depth (cm)	pH		Humus	Available (mg/100g of soil)	
	H_2O	nKCl	(%)	P_2O_5	K_2O
0-20	5.24	4.34	3.90	6.70	7.80
20-40	5.55	4.48	3.13	6.90	9.80

Average monthly temperature of air, u 2011-12 were slightly lower, especially in January and February, compared with 2012-13. However, in both years, temperatures ranged as optimal and did not have a negative impact on yield. Higher precipitation and their better distribution were noted in the 2012/13 year, especially in October, November and December, which contributed to a better application and the decomposition of fertilizers applied and thus and higher yields. Average temperature and total precipitation was at the level of long-term averages, with the exception of 2011/2012 year where total precipitation was slightly less (table 3.).

Results and Discussion

The goal of each production is to achieve high yields. The yield of triticale grains depends on several factors, such as variety, agro-climatic conditions, agro-technology. Fertilization is a very important agrotechnical operation, especially on lands of poor chemical and physical properties. The following table (table 4.) gives an overview of the yield of triticalea depending on the fertilization of acidic soils and variety.

Higher quantities of precipitation and better distribution in 2012/2013 caused higher yields of triticale in that year. The varieties did not differ significantly from the average yield of grain. Varieties of fertilizers did not significantly affect the differences in grain yield between varieties. Only, at the highest doses and combinations of mineral, lime and organic fertilizers, the Odyssey variety had a yield that was higher on the border of statistical significance than KG-20. Thus, the Odyssey variety had the highest yield of 5010 kg ha^{-1} on variant 10, where the highest dose of mineral, lime and organic fertilizers was applied. It is evident that the Odyssey variety responded positively to the yield on larger doses of fertilizers.

All varieties of fertilization showed a significant increase in grain yield relative to control. The average yield for both varieties grew with increasing dosage and type of fertilizer. Thus, the highest average yield of 4750 kg ha^{-1} was achieved in variant 10 where the highest dose of mineral, lime and organic fertilizers was applied, and the smallest in variant 1 where a lower dose of mineral fertilizers was applied.

By combining mineral and lime fertilizers, the average yield was significantly higher than the yield achieved using only mineral fertilizers. Also, by using a combination of mineral, lime and organic fertilizers, the yield was significantly higher than the yield obtained using the combination of mineral and lime fertilizers, ie very significantly higher than the yield obtained using only mineral fertilizers.

The average yield of triticale was achieved using only mineral fertilizers was 2809 kg ha^{-1}, using a combination of mineral and lime fertilizers 3726 kg ha^{-1} and using a combination of mineral, lime and organic fertilizers 4463 kg ha^{-1} (Figure 1).

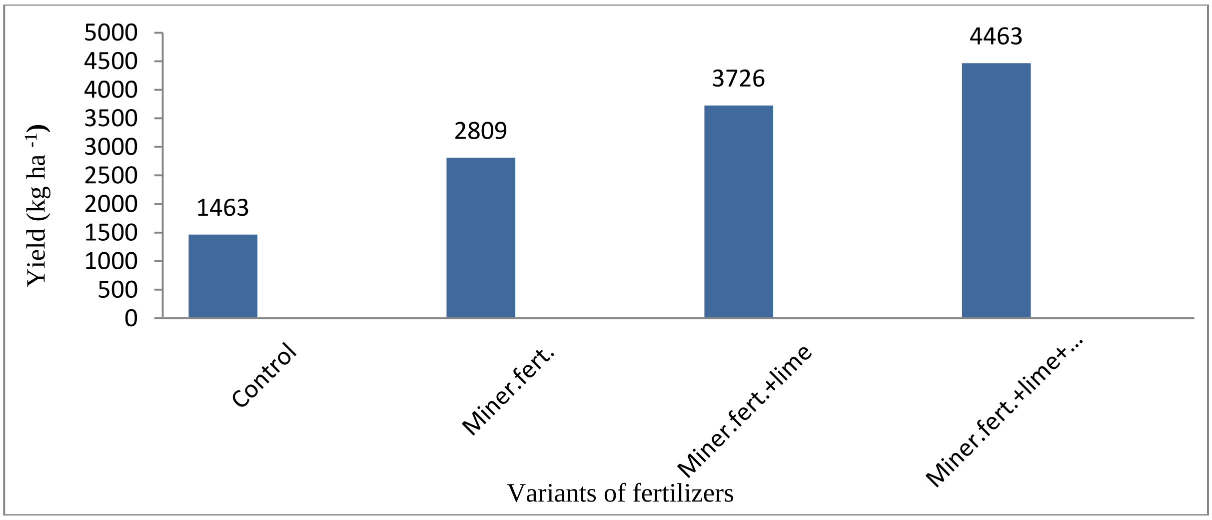

Figure 1. Triticale yield (kg ha^{-1}) depending on the mineral fertilizer, lime and organic fertilizers

These differences in yield are statistically significant.

The results of numerous authors in the country and abroad (Scott *et al.*, 2001; Kaitibie *et al.*, 2002; Kovačević *et al.*, 2006; Jelić *et al.*, 2013: Biberdžić *et al.*, 2013, 2015) show that the application of lime fertilizers in combination with the organic and mineral, the most efficient way to repair acidic soils and increase the yield of cultivated plants, with which our results are in agreement.

Conclusion

Based on the results of the research, the following can be concluded:

There were no significant differences in grain yield between varieties.

The application of all varieties of fertilization has led to a significant increase in yield of grain in relation to control.

The highest average yield of triticale grains achieved in the variant where the highest dosage of mineral, lime and organic fertilizers was applied.

The average yield of triticale with only mineral fertilizers was 2809 kg ha^{-1}.

The average yield of triticale was achieved using a combination of mineral and lime fertilizers amounted to 3726 kg ha^{-1}

Using the combination of mineral, lime and organic fertilizers, average yield of triticale of 4463 kg ha^{-1} was achieved.

Using lime and organic fertilizers in combination with mineral, acidic soils, satisfactory yields of triticale grains can be achieved.

Abstract

Cropping systems are basically defined by crop rotation. Two crop rotations with winter wheat or three crop rotations with legume crops are the more efficient for maize productivity. When grown in a crop rotation system, maize produces higher biomass, larger leaf area and larger height. Grain yields are also higher and one can also notice other positive effects on agro-ecosystem, including soil and pests. The objective of the study was to evaluate the effects of the cropping systems, namely continuous cropping, two and three crop rotations of maize, on plant height and grain yields and to analyse relations between those two parameters. The study was conducted in an experimental field of the Maize Research Institute Zemun Polje, in Serbia, during 2009-2012. The following factors were evaluated: 1. cropping system of maize - continuous cropping, maize-winter wheat, maize-soybean-winter wheat and maize-winter wheat-soybean rotation; 2. type of hybrid - ZP677 as an older hybrid and ZP606 as a newer, modern hybrid with higher yield potential. The standard technology of maize production was applied. Every year, in the anthesis stage when plants are completely developed, plant height was measured from ten plants per elementary plot while grain yields of maize were determined from two inside rows at the end of the growing season. The data were processed by ANOVA. The grain yield of both maize hybrids was higher when maize was grown in two and three crop rotations in comparison to maize continuous cropping. Newly developed hybrid ZP606 had, on average, a higher yield than ZP677, especially in maize - w. wheat - soybean rotation (8.02 and 10.14 t ha^{-1}). The correlation analysis showed high and positive interdependence between plant height and grain yield of maize in all the investigated cropping systems.

Key words: *Crop rotation, Maize hybrid, Plant height, Yield.*

Introduction

The cropping systems are basically defined by crop rotation. Two crop rotations with winter wheat or three crop rotations with winter wheat and legume crops are more efficient for maize productivity. Due to specialisation in agricultural production in Serbia, manure has become less available and mineralised organic matter has to be compensated from other sources. Modifications in cropping systems that increase frequency of legume crops are the most rational method. The presence of plants from the family Fabaceae family significantly contributes to the efficiency of the crop rotation trough the reduction of mineral nitrogen fertilizers by 50%, maize yield increase and soil preservation and improvement (Videnović et al., 2007; Jovanović et al., 2004). The advantages of crop diversification lie in less frequent tillage and thereby energy saving, lower amount of applied fertilizers and herbicides and agroecosystem preservation (Spasojević, 2014; Simić et al., 2016). Results from previous investigations showed that crop rotations, especially three crop rotations, reduces number of

individuals and biomass of weeds in maize field more than continuous cropping or six crop rotation (Dolijanović et al., 2011).
When grown in a crop rotation system, maize produces higher biomass, larger leaf area and larger height (Verhulst et al., 2011). Grain yields are also higher and one can also notice other positive effects on agro-ecosystem, including soil and pests. Three crop rotations with legume crop are very effective in maize height and grain yield production (Boomsma et al., 2010). Crop rotation and soil tillage systems influences physical and chemical properties of soil in the root zone which is positively reflecting on maize growth (Martinez et al., 2008).
The objective of the study was to evaluate the effects of the cropping system, namely continuous cropping, two and three crop rotations of maize, on plant height and grain yields and to analyse relations between those two parameters.

Material and Methods

The study was initiated in MRI Zemun Polje, in Serbia, during 2009-2012, with the aim to evaluate the effects of different production systems on maize growth and grain yield. The soil type at the experimental field was slightly calcareous chernozem with 53% sand, 30% silt, 17% clay; with good fertility and 3.3% of organic matter content and moderate drainage. The pH is 6.9 and soil structure is silty clay loam.
The following factors were evaluated: 1. cropping system of maize - continuous cropping (MC), maize-winter wheat (MW), maize-soybean-winter wheat (MSW) and maize-winter wheat-soybean (MWS) rotation; 2. type of hybrid - ZP677 as an older hybrid and ZP606 as a newer, modern hybrid with higher yield potential. The standard technology of maize production was applied. In the autumn of 2008, farmyard manure was applied in all production systems and in MC and MSW every third year, in MW each second year while in MWS rotation farmyard manure was not applied. Additionally, mineral fertilizers were applied in the autumn and during early phases of maize development in the spring. The amounts of mineral fertilizers were determined by the soil analysis. For weed control, herbicide mixture for complete weed control of broadleaf and grass weed species were applied at the recommended doses.
Every year, at the end of the pollination period when plants are completely developed, plant height was measured from ten plants per elementary plot while grain yields of maize were analysed at the end of the growing season. The maize grain yield was measured from two inner rows of each subplot and calculated to 14 % of moisture. The experimental data were statistically processed by analysis of the variance (ANOVA) and analysed by the LSD-test (5%).
Meteorological conditions
Meteorological conditions during investigated period were different, (Figure 1). Year 2012 was characterised by the highest average temperature in July and August (27.1 °C and 26.6 °C, respectively). Moreover, the lowest precipitation amount, of only 4 mm was also obtained in August. Present conditions could affect grain filling, reflecting on relative low values of grain yield.
The sum of precipitation was higher in 2009, 2010 and 2014 than in 2008, 2011 and 2012. The 2012 was extremely dry (June - 30.7 mm; August - 5.8 mm and September - 26.0 mm) and unfavourable for maize production. A dry spell during June-September period in 2012 year was especially important since it coincided with maize pollination and yield formation (Figure 1).

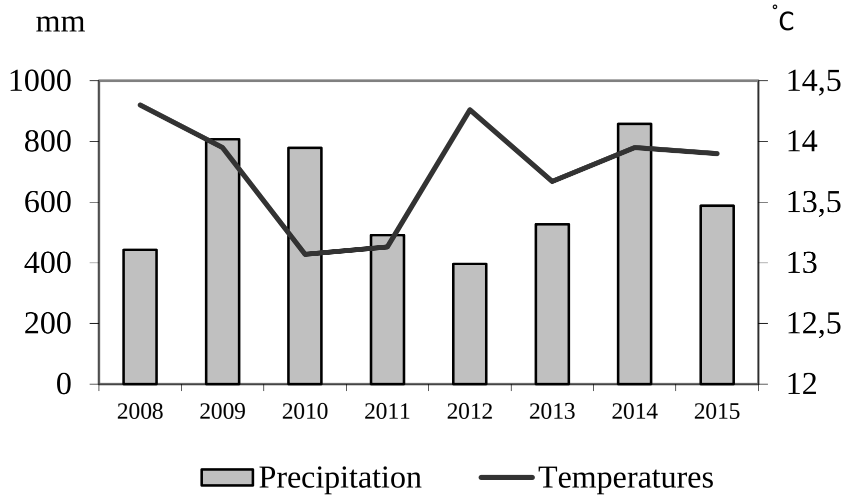

Figure 1. Meteorological conditions 2008-2015

Results and discussion

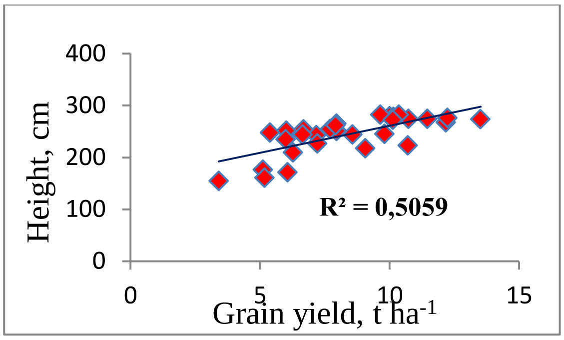
Cropping system influenced maize plant height and grain yield after only one rotation, Table 1. In 2011, when maize was sown on the same field after winter wheat, plant height (269.8 and 260.5 cm) was higher for both hybrids than in continuous cropping (247.0 and 253.2). Grain yield was also higher in MW system (9.1 and 10.6 t ha^{-1}) than in MC (7.9 and 8.6 t ha^{-1}), especially for hybrid ZP606.

Table 1. The effects of crop rotation on plant height and grain yield of two maize hybrids

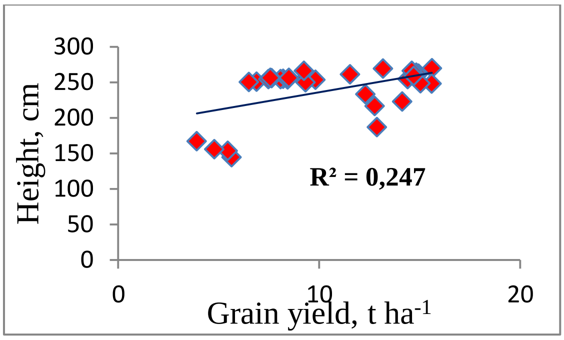
	Plant height (cm)	Grain yield (t ha^{-1})	Plant height (cm)	Grain yield (t ha^{-1})
Crop rotations	Hybrid ZP677		Hybrid ZP606	
		2011.		
MC	247.0	7.9	253.2	8.6
MW	269.8	9.1	260.5	10.6
		2012.		
MC	182.9	4.9	180.9	4.8
MSW	201.9	5.2	197.5	7.0
MWS	180.3	5.6	175.8	5.9

In three crop rotations, after one cycle, MSW have shown positive influence on maize height (201.9 and 197.5 cm) in comparison to MC (182.9 and 180.9 cm) while MWS did not (180.3 and 175.8 cm). The similar was with grain yield where both rotations influenced maize yield positively by increasing of yield values in case of hybrid ZP677 while only MSW rotation was suitable for hybrid ZP606.

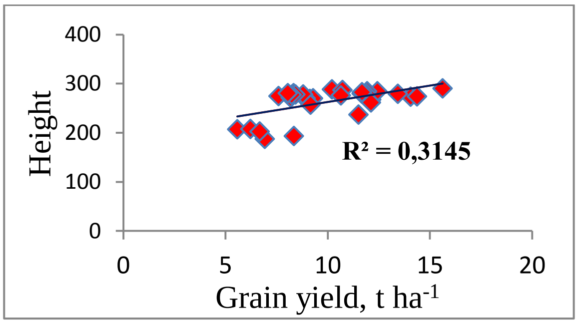
Relations between plant height and maize yield were positive and significant in both cropping systems-MC and MW for both hybrids (Figure 2). Results from monoculture and three cropping system were even better. The maize plant height and grain yield were highly and positively correlated in MC, MSW and MWS for both maize hybrids (Figure 3). This shows that for investigated hybrids grain yield is influenced by plant height and probably by ear position on the stem. The highest R^2 value - 0.9168 was obtained in MSW rotation for hybrid ZP606.



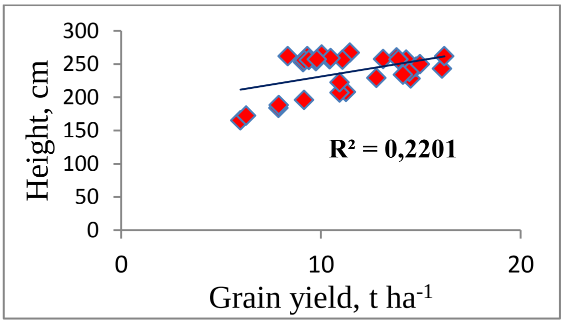
Hybrid ZP677 in MC



Hybrid ZP 606 in MC



Hybrid ZP677 in MW



Hybrid ZP 606 in MW

Figure 2. Interactions between plant height and grain yield of maize in continious cropping ant two crop rotation

The period when development of upper and ear leaves of maize plants is completed is very important. The significant relation is obtained between level of development of some morphological parameters of plants and maize grain yield (Raun et al., 2005; Teal et al., 2006). When the maize inbreed lines and hybrids were studied, results showed that stem diameter, plant height, ear position on the stem, and dry matter of all plant are significantly related to grain yield (Sadak et al., 2006 cit. Valizadeh and Bahrampour, 2013). In all cropping systems the positive and significant interaction between maize plant height and grain yield were obtained which is in accordance with results of previous studies (Golam et al., 2011). Authors conclude that, beside ear position, the height of whole maize plant significantly correlated with grain yield. Liu and Wiatrac (2011) also noticed significant influence of maize plant height at the stage when upper leaves are developed on grain yield. Regarding to results of previous experiments (Martin and Russell, 1984), maize plant height and ear position are in strong and positive relations with grain yield. Ashofteh Birgi et al. (2010) proved the similar relations between maize grain yield and plant height, ear position and number of rows on the cob. Alaei (2012) received positive and significant correlations between maize plant height and grain yield on the P>0.05 level while on the P>0.01 level, the relations were not significant.

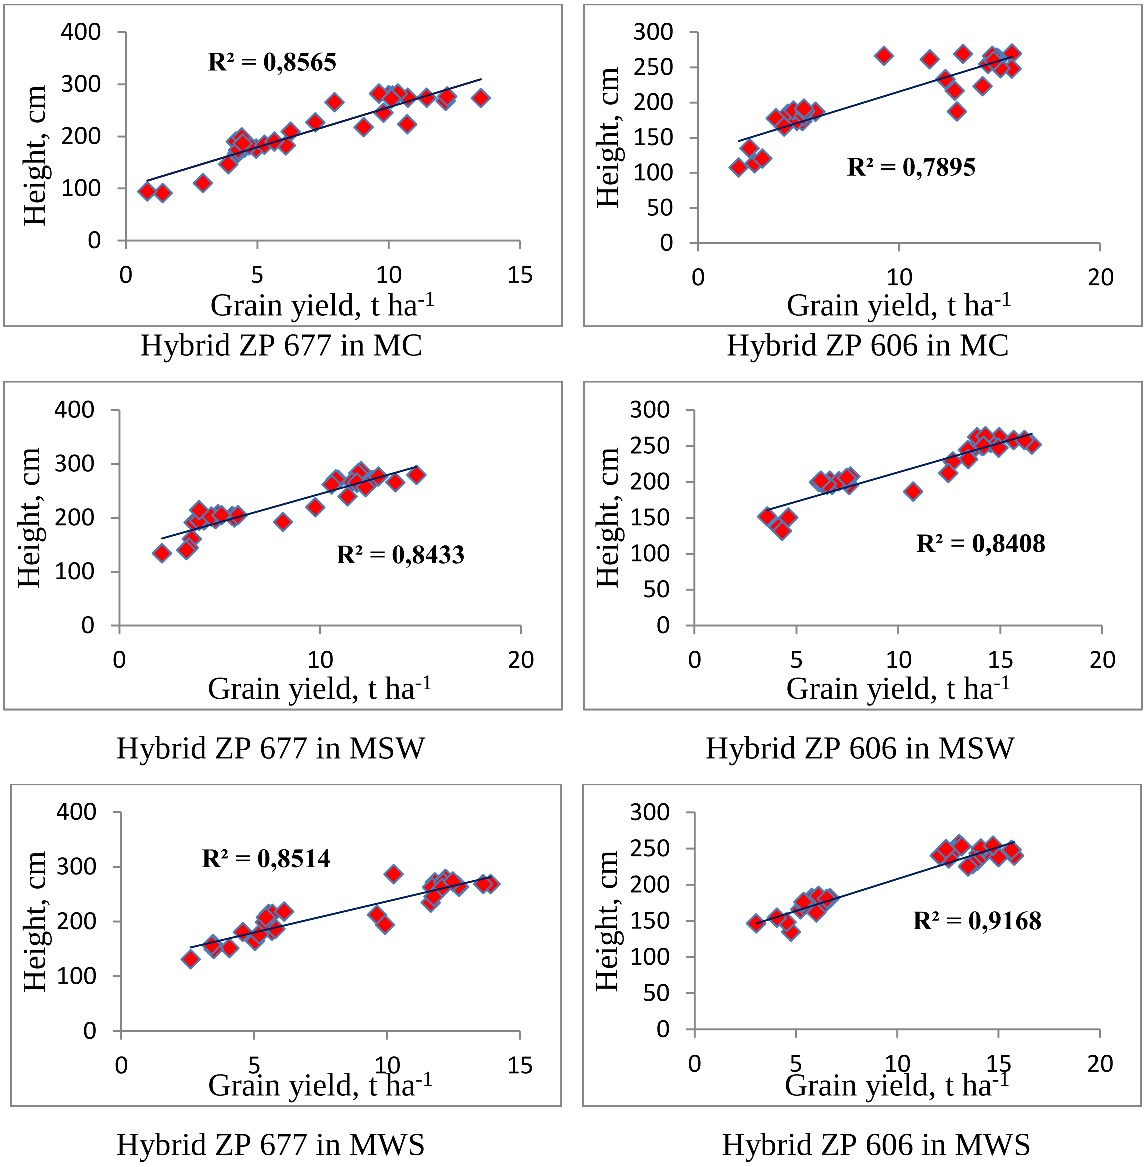


Figure 3. Interaction between plant height and grain yield of maize in continious cropping ant three crop rotations

Conclusion

The maize plant height and grain yield were highly and positively correlated in maize continuous cropping, maize-soybean-winter wheat and maize-winter wheat-soybean rotation for both maize hybrids, ZP 677 and ZP 606. This shows that for investigated hybrids, plant height and probably by ear position on the stem have influenced grain yield. The values of all measured parameters were the highest in MW rotation which shows that old and the most present cropping system, based on old type of farm ownership and organisation, has advantage in maize production. But, in present time, with new system of farming land organization, crop rotation with legumes as nitrogen source, could be a good substituent and certainly takes advantage over maize continuous cropping.

Abstract

According to the total number of trees and average annual production, the plum has had the leading position among fruit crops in the Republic of Serbia for many years. According to the data on the period from 2005 to 2014, the Republic of Serbia was the second in the world in the production of these fruit crops, right after China. Extremely favorable natural conditions for plum cultivation, among other things, have certainly contributed to the abundance of plums in the Republic of Serbia. However, one can notice that the productive area under this crop has not increased in the past couple of years, which is worrisome. This paper presents an analysis of plum production in the Republic of Serbia, using the index comparison method, i.e. using the statistical data on previous years, comparing them with the data on 2016. The data available on the website of the FAOSTAT statistical database and the Statistical Office of the Republic of Serbia (RZS) were used for the comparison and analysis. The analysis of the available data on the period from 2005 to 2015 showed that the total yield of plums in this period varied, as well as the yield per hectare in tons, ranging from 2.8 to 7.3, depending on the year. However, in 2016, one can notice a slight increase in the total plum production in comparison to 2014 and 2015, while 2013 is still a record year when it comes to yield. The data from these sources differed for certain years, but these deviations of the total yield can be attributed to variations conditioned by the very manner of yield counting, import and export.

Keywords: *plum, production, analysis, yield*

Introduction

If one focuses on the period from 2005 to 2014, based on the FAOSTAT data, one can see that Asia is the world leader in the production of plums with 63.4%. Europe is the second largest producer with 24.9%, followed by North and South America that produce a total of 8.6% of plums in the world market. Africa has a share of 2.9% in the production, while Oceania is at the bottom with only 0.2%. The reason for this dominance of the Asian continent is China, whichhas a share of 5,538,620 t out of 6,755,726 t, the total weight of plums produced in Asia. These figures are, as already mentioned, an average value in the period from 2005 to 2014. As for the old continent, the plum production in this period has an average of 2,650,880 t. The Republic of Serbia has a share of 20.05%, i.e. 531,405 t and, as such, ranks second in plum production in the world, right after China. A visual presentation of these data is shown in figures 1 and 2. Since the reign of Milos Obrenovic, plums have had great economic significance for Serbia (Michael R. Palairet, 1997). From 1968 to 1977, Yugoslavia had a share of about 18% of the total world production of plums. Today, Serbia is one of the largest producers of plums in the world (Blagojević and Božić, 2012). Serbian climate and soil conditions are extremely favorable for the cultivation of this fruit, so this data has a solid basis (Nikolić *at al.,* 2012). However, what concerns us, and what will directly affect the production of plums in Serbia, is the fact that the production of this type of fruit has beendecreasing for years, and currently there are no indications for a comprehensive solution to this problem. The objective of this paper is an analysis of the plum production in the Republic of Serbia, which is shown in numbers that represent plum production in recent years, as well as a comparison with the most recent data on the plum production in Serbia.

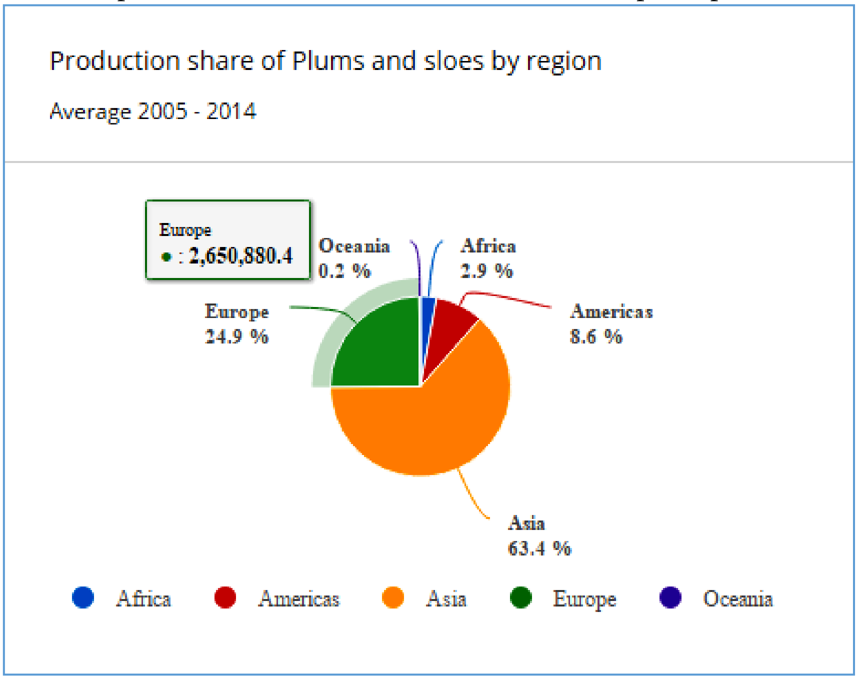

Figure 1. A graphical display of the share in plum production of specific regions in the period from 2005 to 2014, which is available on the FAOSTAT statistical database website.

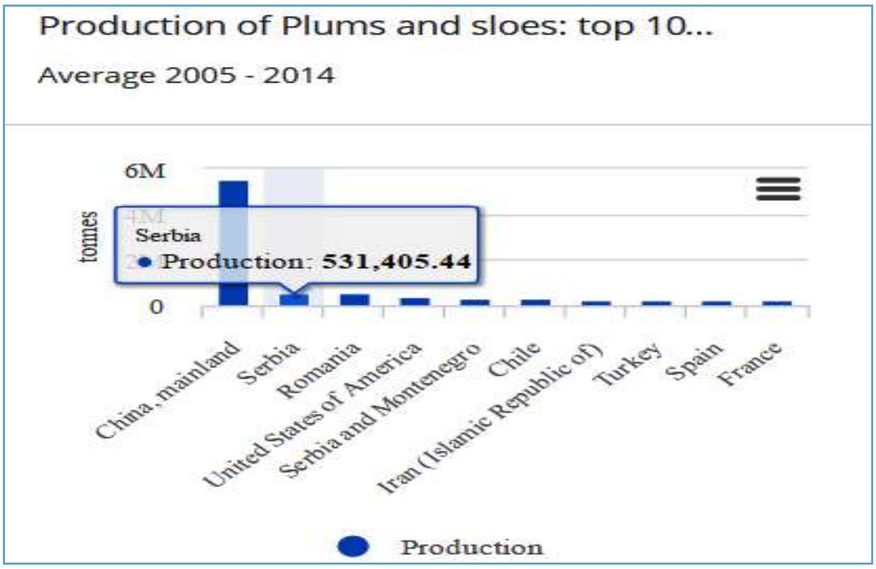

Figure 2. A graphic display of the largest producers of plums in the world in the period from 2005 to 2014, which is available on the FAOSTAT statistical database website.

Material and methods

According to the data of the Bureau of Statistics of the Republic of Serbia (Table 1), a total plum yield of 463,115 t was found in a productive area of 77,949 ha, while the average yield per hectare was 5.9 t. Out of this, 13.85% of plums wereproduced in the territory of Serbia - North (Belgrade and Vojvodina region), while 86.15% of plums were produced in the territory of Serbia - South (region of Sumadija, Western, Southern and Eastern Serbia;no data for the autonomous region of Kosovo and Metohija). The data available on the website of the Republic Statistical Office (RZS), as well as the statistical base FAOSTAT, were used for comparison of plum production in recent years with the most recent yield.

Table 1. Plum production in the Republic of Serbia in 2016

2016.	Area harvested (ha)	Production (t)	Yield (t/ha)
Republic of Serbia	77949	463115	5.9
SERBIA - NORTH	5482	64149	11.7
Belgrade region	2507	19908	7.9
Vojvodina region	2975	44241	14.9
SERBIA - SOUTH	72467	398966	5.5
Šumadija and western Serbia	53306	259707	4.9
Southern and eastern Serbia	19161	139259	7.3

Results and Discussion

An index comparison of the total yield of plums in the Republic of Serbia in recent years (in the interval from 2005 to 2015), which is available on the website of the Republic Statistical Office (RZS), with the last recorded yield from the database of the same website (on 22 February 2017), is presented in Figure 3.

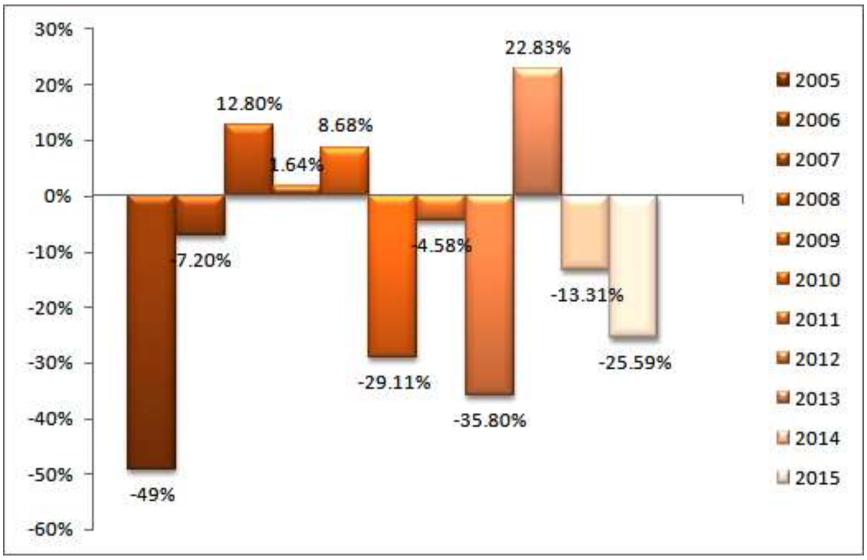

Figure 3. Index display of the total yield of plums in recent years with the current status, which is available on the website of the Republic Institute for Statistics.

Table 2. The data on areas, production and average yieldsrefer to intensive and extensive orchards together. The data are available on the RZS website.

Republic of Serbia (years)	Plum			Population
	Area harvested, ha	Production, t	Yield, t/ha Yield per tree (kg)	
2005	83.560	235.431	2,8 (7)	7.440.769
2006	81.930	429.822	5,2 (13)	7.411.569
2007	81.545	522.366	6,4 (14)	7.381.579
2008	82.407	470.713	5,7 (14)	7.350.222
2009	80.151	503.321	6,3 (15)	7.320.807
2010	80.306	328.285	4,1 (12)	7.291.436
2011	78.663	441.885	5,6 (14)	7.258.753
2012	77.949	297.446	3,8 (11)	7.199.077
2013	77.949	568.840	7,3 (16)	7.164.132.
2014	77.949	401.452	5,2 (13)	7.131.787.
2015	77.949	344.612	4,4 (12)	7.095.383.
2016	77.949	463.115	5,9	**7.076.372**

Using the index comparison of the total yield of plums in the Republic of Serbia in the period from 2005 to 2015 with the current status, it can be noted that the fluctuations in the results in the given period of observation are relatively large. However, what one can also recognize is some increase in yield in 2016 compared to the two previous years, namely: an increase in the total yield of 25.59% compared to the yield in 2015 and an increase in the yield of 13.31% compared to 2014. In addition to what is stated in Figure 3, the highest total yield was registered in 2013, 22.83% higher compared to the most recent data, while the lowest total yield was registered in 2005, 49% lower compared to the results found in 2016. One can also note from these figures that, compared to 2016, better results regarding the total yield were achieved in the period from 2007 to 2009, as well as in 2013.

From Table 2, one can conclude that the reduction of the productive area under the fruit species was not of crucial importance for the plum yield, although the productive area in 2016 was smaller by 6.7% compared to 2005. In the last 5 years, there have been no changes in this field, but it is a fact that the productive area under plums was steadily decreased in the period from 2005 to 2012, with smaller deviations in 2008 and 2010. According to the data of the Republic Hydrometeorological Service of Serbia on 2015/2016 production year, due to the extremely hot summer and autumn, which was much warmer compared to average conditions, and due to heavy rainfall, conditions for the development of fungal and bacterial diseases were met. In July, a massive hatching of larvae of the second and third generations of the plum moth was registered, but despite all this, the results for 2016 were very favorable, for which timely protection was responsible.

If one looks at Figure 4, which presents information about the total production of plums and sloes in the Republic of Serbia, one can note that there are certain differences in total production between the Statistical Office data and the statistical base FAOSTAT data. The sloe is a fruit species that is grown in small areas in Serbia, so we believe that the data on the FAOSTAT website refer primarily to the plum.

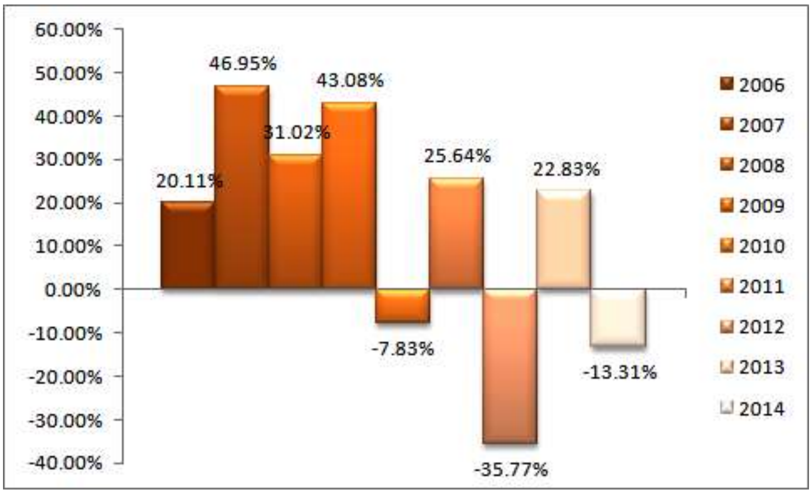

Figure 4. Index display of the total yield of plums for the period from 2006 to 2014, which is available on the FAOSTAT website, with the current status that is available on RZS.

Although the FAOSTAT database currently (22 February 2017) does not possess any data on the production of plums in Serbia before 2006 nor any data after 2014, what one can note is that the FAOSTAT data on the period from 2006 to 2011 are quite different, while the data for the period after 2011 are approximately equal to the data from the Republic Institute for Statistics database. The data on 2014 and 2013 correspond to the data from the RZS database, while the data on the yield in 2012 differ by only 0.03% compared to the data from the RZS database. By observing this index display, one can identify different minimum and maximum values. Unlike the RZS data, based on Figure 4, there is a situation that the maximum total yield was by 46.95% higher in 2007 than the yield registered in 2016.The lowest yield was achieved in 2012, and it was lower by 35.77% compared to the yield in 2016. In Figure 5, the value in tons regarding the yield of plums is presented and the productive area is expressed in hectares. The biggest difference between the FAOSTAT data and the RZS data is for the year 2009, when the yield, according to the FAOSTAT database, was 34.4% higher compared to the RZS data on the same year.

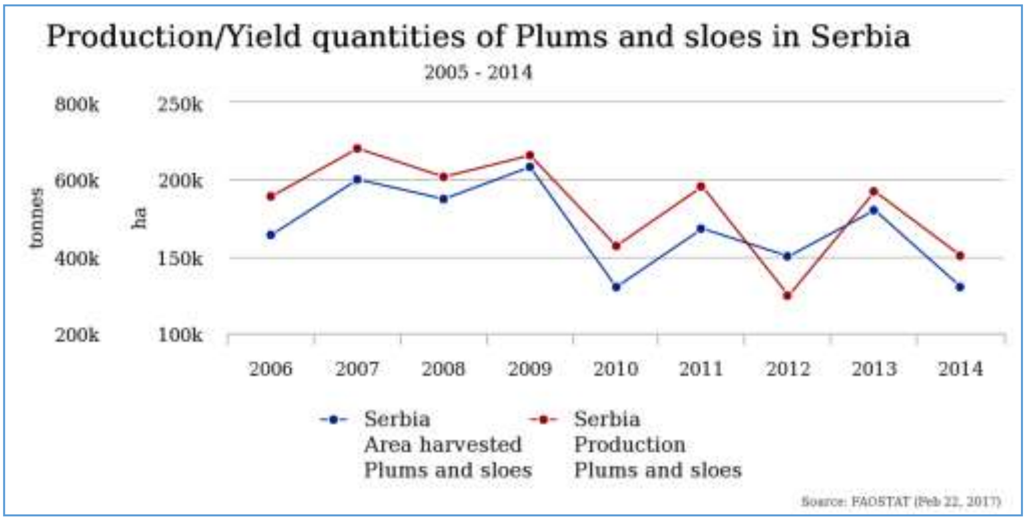

Figure 5. A graphical display of produced plums and sloes, as well as the productive area in the Republic of Serbia for the period from 2006 to 2014, which is available on the FAOSTAT website.

Conclusion

By an index comparison of the total yield of plums in the Republic of Serbia from 2005 to 2014, including the latest yield in 2016, one can notice a slight increase in production compared to the previous two years. A yield of 463,115 t was foundin a productive area of 77,949 ha. Although it was not the highest plum yield in Serbia in this crop area,the yield of 2013 was 568,840 t, which showed that the yield was on the rise compared to the previous two years. Certain deviations from the total yield, which can be noted between the different sources in previous years, can be attributed to variations conditioned by the manner of data collection regarding the yield, import and export. In recent years, there has been compliance of the data from these two sources (FAOSTAT and RZS), which isa positive development in this regard.

Abstract

The aim of this paper is to examine the impact of climate change on potato yield and propose adaptation measures for three different climatic areas in Bosnia and Herzegovina (B&H). Aquacrop model V4.0 was used for yield estimation. Input bias corrected data for future climatic parameters were obtained from EBU-POM for IPCC/SRES scenarios A1B and A2, for three time lags early future (2010–2039), mid (2040–2069), and end of century (2070–2099), for three distinct areas Banja Luka, Mostar and Bijeljina. Model calibration was based on available scientific papers. Shorter growing cycle of potatoes on the observed areas is expected in future climatic conditions due to an increase in temperature of air. Slightly shortening of growing cycle till the end of the century can be expected in the Mostar area, and it may even increase on the other ones. Sowing date will be moved towards the winter months. Shorter growing cycle could enable the unrestircted growth of potatoes at all sites, because growth would terminate before the on set of the dry season. Obtained data indicate an increase in the yield of potatoes in relation to the reference period, slight in the area of Banja Luka and Bijeljina, but significant in the Mostar to 13.8% in the near future, 28.7% in mid-century and up to 33% by the end of the century. The largest water shortage might occur in Bijeljina (35%), slightly less in the area of Banja Luka, while irrigation is not primarily in the Mostar area, but timely soil drainage instead.

Key words: *climate change, Aquacrop, potato, yield, irrigation.*

Introduction

Enhanced temporal and spatial climate variability was manifested in the last 10 years in Bosnia and Herzegovina (B&H), causing severe droughts (2007, 2011 and 2012) or flooding (2009, 2010 and 2014) and consequently significant material damage in crop production. Many researches has estimated further climate instability in the Southeast Europe throughout the 21st century (Senevirante et al., 2006; IPCC, 2014; Jacob et al., 2014) emphasizing that agricultural production would be the most vulnerable (Trbić et al., 2014; Mihailovic et al., 2015). In such changeable weather condition unconstrained crop production depends mainly on water resources management but also on the preparedness of a timely application of adaptation and mitigation measures. Proper preparedness should be based on lesson learned through the historical period, reliable risk approach, and use of crop growth modeling for yield and water management estimation and optimization. Impact of climate change on yield and water requirement of staple food crop has not been widely studied in B&H, only few researches have been done on maize (Stojaković et al., 2015), due to the reasonable restrictions. Namely, for the application of crop growth modeling many reliable input data from experimental researches is needed. Such data are hard to find due to the war. Researches in surrounding countries confirmed possible impact on climate change on main field crops such as maize, soybean, wheat or sugar beet (Vučetić, 2011, Lalić et al., 2013; Stričević et al., 2014). Since potato is one of the main staple crop with shallow root system, which yield might be affected either by heat, drought or water logging, the aim of this research is to examine the impact of climate change on potato yield and propose adaptation measures for three different climatic areas in Bosnia and Herzegovina (B&H).

Materials and methods

In this research AquaCrop v4.0 model was used for the yield, sowing date and water requirement estimation. This model is water driven, based on water productivity, which means that yield mainly depends on water availability, taking into account temperature and soil fertility stress as limiting factor that might affect the final yield. The model was described in details by Steduto et al., (2009) and Raes et al., (2009). Input climatic data for the three distinct area Banja Luka, Mostar and Bijeljina on a monthly bases for the AquaCrop model was grouped into five section: reference period (1961-1990), current weather condition (2004-2013) (Hydro-meteorological services in Banja Luka; Federal hydrometeorological Service B&H) and the bias corrected data for future climatic parameters were obtained from the regional climate model EBU-POM (Eta Belgrade University - Princeton Ocean Model) (Djurdjević and Rajković, 2008; Gualdi et al., 2008). Initial and boundary conditions were taken from the global model ECHAM5, and the domain of integration covered the Euro-Mediterranean area with the Mediterranean Sea (without the Black Sea). The spatial resolution of atmospheric part of the model was 0.25 ° (about 30 km) and for ocean 0.2 °. Two climate scenarios IPCC SRES A1B and A2 for time slices in the future, centered on the 2020s (2010-2039), the 2050s (2040-2069) and the 2080s (2070-2099) were considered.
AquaCrop model calibration was based on available scientific researches and studies (Ćota and Šilj, 2012; Govedarica et al., 2016; Biancalani et al., 2004; Group of authors, 2014). As the technology of cultivation during the reference period (1961-1990.) differed significantly from contemporary ones, the yield simulation was performed for the period 2004 - 2013. Comparison of the obtained results is given as a relative ratio, for example, the possible yield of the climatic conditions during the reference period and the yield of expected future climate conditions during a given scenario, on the same soil and the agronomical practices. The yields (tha^{-1}) could not be compared, because in one experimental field in the course of one year, very different yields were achieved due to the variety, crop density, planting date, growing technology, and so on (Žurovec and Čadro, 2011; Ćota and Šilj, 2012). Such approach was used by other researchers (Bird et al., 2016; Linker et al., 2016).

Results and discussion

Potato growth simulations were run for the sowing optimal time taken from the recorded data (Phenological yearbook, 2004-2014, Hydrometeorological Services for each studied area) which coincide when T_{min} fixed at 7 °C for 7 successive days. The obtained sowing dates were in the last decade of 22th March in Banja Luka, mid March in Bijeljina and mid to late February in Mostar area, which is in agreement with the current field management practices. Shorter growing cycle of potatoes on the observed areas is expected in future climatic conditions due to an increase in air temperature (Table 1). Current growing season is already shorter for 10 days in the Mostar and Bijeljina and 20 days in the Banja Luka area (2004-2013.) in comparison with reference one. Slight shortening of growing cycle might be expected in the Mostar area until the end of the century, and may even increase on the other areas in regard to actual ones. It shuld be exphasize that the sowing dates would be significantly moved towards the winter months (Table 2), due to the expected air temperature increament. An average daily temperature above 7 °C, as favorable conditions for potato planting is expected to be from the end of January to mid-February. Earlier sowing dates and shorter growing cycle will enable the smooth growth of potatoes at all areas and will senesence and mature before the onset of the dry season. The similar results of growth shortening due to temperature increase was obtained in European part of Russia (Novikova et al., 2017), suggesting the same adaptation measures.

Obtained results indicate even an increase in the yield of potatoes in comparison with the reference period (Table 4). Slight increment is expected in the area of Banja Luka (0 - 9.5%) and Bijeljina (from 2.3 - 6.9%), by the 2080s, but significantly in the Mostar area up to 13.8% in the near future, and then up to 28.7% by the 2050s and up to 33% by the 2080s. The only prerequisite in the Mostar area is ensuring a good drainage that can enable soil warming and early planting of potatoes. Obtained results are in accordance with finding of Peltonen-Sainio et al., (2010) styding the long term historical data set on potato yield accross the Europe. They emphasize that potato is very prone to react in yield reduction due to any weather anomaly, but also if well supplied by water with favourable temperature could increase yield. Lizana et al., (2017) studied impact of increased temperatures on potato yield. They obtained significant increment of the potato yield when occurred during beginning and mid tuber bulking period and no changes if occurred later. They also emphasized that yield sensitivity was highly dependent on genotype, as it was obtained in B&H (Ćota and Šilj, 2012).

Irrigation of potato should be planned, too. It would enable achievement of genetically potential yield on researched areas. Beside ensuring readily available water to the potato, irrigation affect favourable micro climatic condition. In last few years, irrigation is used not only to provide water to the root system, but also to cool the top soil up to desirable level to assure desirable quality.

The highest increment of water shortage (Table 4) will occur in the Bijeljina region (up to 35%), slightly less in Banja Luka area, whereas in the Mostar, drainage will be primordial measure, not irrigation (Table 5). The area prone to water logging nowadays will continue to under threat of water excess such as Mostar and Herzegovina in general. Whole this region will have favourable climate for potato, but only if drainage channels would be well maintained. These results are somehow expected, due to early sowing dates and avoiding drought period by shorter growing cycle of potato. On another side, the biggest worries for farmers will be the frost that can harm or kill the plants or even snow occurence, as it was on spring of 2016 or this year. Irrigation system could be designed also to be used as anti-frost mitigation measure, but threat from snow will be farmer's crucial concerns.

Conclusion

Impact of climate change without adaptation measures would be definitely harmful on potato production in all study region in B&H. Applying relatively simple adaptation measure such as earlier sowing date, potato production could stay on present level, or even slightly increase in Banja Luka and Bijeljina area and much more in Mostar. However some prerequisite should be fulfilled such as drainage canals maintenance. For the stable and high yielding production of potato irrigation should be envisaged, especially in the Bijeljina region, and Banja Luka, on shallow and light sandy or sandy-loam soils.

THE ROLE OF AGRICULTURAL SERVICE IN PRODUCTION OF HEALTH PLANTING MATERIAL IN RASINA DISTRICT, SERBIA

Sandra MILETAKOVIC*, Radomir JOVANOVIC, Dragoljub MILOSAVLJEVIC, Branka ANTIC

Agricultural Service Krusevac, Krusevac, Serbia
*Corresponding author: sandramiletakovic@gmail.com

Abstract

Rasina district has tradition in production of planting material for the production of nursery plants of fruits and grapevines in the Republic of Serbia. Production of certified planting material is a complex and demanding job that requires good organization, the necessary legislation, trained people, properly equipped competent institutions, a good knowledge of the epidemiology of pathogens and constantly adopting new scientific knowledge, strict implementation of scientific know-how in production process, in order to guarantee the varietalaccuracy, defined health status and quality of planting material.According to the current international and national legislation, propagation material can be placed on the market only if it is produced in registered nurseries underofficial control of phytosanitary service if officially confirmed that they belong to one of the categories listed in the scheme of regulation and certification. Agricultural Service Krusevac, as competent institution for phytosanitary control with professional capacities for the implementation of health control has decades of experience in the control of pathogens of fruit trees and vines in parent plantations and seedling.Phytosanitary control hasparticular socio-economic importance for farmersproviding them with guaranteed quality, safe product placement and incomeon the domestic and international markets. The production of healthy planting material is also important for farmers, because it allows the fulfillment of international obligations and raisingof reputation of the country, compliance with international conventions, and enabling farmers realization of safe financial income of the export of planting material, as well as large quantities of high-quality fruit and grapes and their products.

Keywords: *Nursery plants, healthy planting material, Rasina district, Serbia.*

Introduction

The quality planting material is one of the basic conditions of successful fruit growing. The production of planting material in Serbia is regulated by a great number of Rulebooks (Official Gazette of Republic of Serbia, 66/99 and 13/2002; Official Gazette No.10/2003 and 13/2013 and Official Gazette No.39/2016, 59/2016, 115/2016, 119/2017 and 107/2018). The continental species of fruit trees and grapevine are the hosts of a large number of infectious pathogens: viruses, viroids and phytoplasma, systemic infections, as well as deseases of sensitive species of hosts. Depending on specific interaction of species of host plants / degree of the sensitivity of a variety / base and species / kind of pathogens, in appropriate agroecological conditions, the negative effects of infections are being manifested, that can significantly influence the growth and development of the plants, and even the quality of the fruit. Direct economic damages in fruit and vine growing caused by the above mentioned pathogens are well known and documented, as well as the expenses of carrying out the measures of eradication or controlling the diseases.

Infected and grown wild plants present the source of systemic pathogens and by vegetative reproduction it is being transmitted and spread. Legal, not enough controlled, and illegal turnover and exchange of infectious reproductive material for planting is the most important and the most dangerous primary way of spreading the pathogens, at the long distances from the place of growing the main plants to the place of planting material production and nursery plant establishment. Secondary, locally in the nursery plants and between them, certain infectious pathogens are being spread by different vectors. Because of the inability for healing once plants are infected and their long life, infected plants present the permanent source of infection in the wild, with the possibility of being infected by another pathogen or pathogen present in the environment, which together can lead to even more damage. Successful strategies for suppressing systemic pathogens and their elimination, or minimizing economic damage, are based on the integral application of a set of mainly preventive measures: quarantine control of taking in and spreading of harmful pathogens by international trade and the exchange of plant material with a potential pathogen, production and use for planting true-to-typeand healthy planting material, phytosanitary control of the health of risky categories of plants for the purpose of early detection and elimination of the sources of infection, the suppression of natural transmitters, the creation and cultivation of commercially acceptable, resistant and tolerant varieties and bases.

In many countries, programs have been functioning for years and include defined procedures for creation, maintenance and production of non-viral or virus tested plants under official phytosanitary control, in recent decades in regulations known as "certification schemes". Most widespread programs of certification are just for different types of fruit trees and vines, developed and recommended in Europe by European and Mediterranean Plant Protection Organization (EPPO) within the phytosanitary measures and standards for the production of healthy plants for planting. The adopted EU directives define the requirements that must be fulfilled regarding the quality and health correctness so that the plant material could be acceptable for the EU market, as well as to prevent taking in and spreading of harmful organisms (Directive 2008/09/EC referringto bringing into the market reproductive planting material and seedlings intended for the production of fruit; Directive 68/193/EEC referring to bringing into the market material for vegetative reproduction of grapevine; Directive 2014/98/EU referring to the implementation of Directive 2008/90/EC for specific requirements of certain kinds and species of fruit trees; Directive 2000/29/EC referring to the protectionmeasures regarding the taking in and spreading into EU of organisms harmful for plants and herbal products). National phytosanitary regulation:Law on planting material of the fruit trees, grapevine and hops and Law on plant health (2009) and appropriate Rulebooks are generally compliant with the regulations of EU. According to the valid, international and national legislation, reproductive and planting material can be put on sale only if it is produced in registered nurseries under official phytosanitary control and if it is officially certified that it belongs to one of the categories stated in the regulation and certification schemes: pre-basic, basic and certified, CAC material, standard and standard S-A material. The knowledge of presence and widespread of pathogens, their biology and epidemiology and existence of reliable methods of detection and identification are necessary precondition and base for each certification scheme implementation.

Material and Methods

The work is based on control system of the existance of the pathogens in main nursery plant, seed plots, grapevine cutting nursery, nursery bedsimplementationin the Rasina District area in the Republic of Serbia. The survey was published by Agricultural Service Krusevac, and as authorised institution with a professional capacity it is included into a national phytosanitary system for implementation of the system of control of prevention of taking in and out of systemic fruit tree pathogens and grapevines into the country and out of it. It also controls the existance of pathogens in main nursery plants and nursery beds. The aim of health control, implemented by Agricultural Service Krusevac,is risk control of the presence of the virus in the reproductive and planting material of pome and stone fruit and grapevine, and this is what this work will be based on. Health examinations include visual examinations for the presence of plant diseases and pests of the fruit trees and grapevine. Health examinations are done according to the correctly determined rules and above mentioned regulations and rulebooks referring tonursery plants, nursery beds and nursery areas. Health examination and sampling of stone fruit (plums, cherry plum, peach, nectarine, appricot, almond, cherry, magrives, sour cherry) in the planting material production refer to the control of plum pox virus, Prune dwarf virus (PDV), as well as Prunus necrotic ring spot virus (PNRS). Health examinations are done by visual examination and sampling. During the control, there are two obligatory visual examinations. The first visual examination: performing a visual examination for the presence of pox virus symptoms of all the plants in main nursery plants and nursery beds in the nursery garden during the phase of active vegetative plant growing, in the period of the end of May-June and beginning of July. The visual examination for the presence of host plants of pox virus and eventually the presence of the symptoms on these plants is obligatory in the spatial isolation zone (buffer protection zone) as well, around the queen cell (1km in radius) and around the nursery beds in the nursery plant (in radius of 500 m). The burgeon of the bases of stone kinds of fruit trees in the queen cells of the nursery plant could have a very significant role in spreading the virusinfecting by leaves lice. During the visual examination of the queen cells and nursery plants we state the presence of the burgeons as well and give suggestionsfor their removal. The existing situation and the result of visual examination is noted. The second visual examination for the presence of the pox symptoms on the plants in the queen cells, nursery beds and spatial isolation zone is performed for the second time in the period of September-October.

The appropriate sampling is the key step for successful determining of the viruses in the plant material, and for this kind of examination thesampling data are used, which was done in the period from 2008-2016. In the main nursery plant, samples of leaves from each individual main tree of all categories of reproduction material were taken during the period of the first visual examination. Where there were symptoms which eventually can indicate the presence of the virus, leaves with the symptoms were sampled. Where sympoms weren't noticed, the sampling is done in the following way: completely developed leaves from the basic part of burgeon from all sides of the treetop were sampled, but also from the inside of the treetop, 3-4 leaves from each branch (from 4 branches 3-4 leaves are sampled or from 5 branches 2-3 leaves are sampled for example; 12-16 leaves in total). The samples are packed with adequate marking and official order of the authorized service - Agricultural Service Krusevac- should be sent to diagnostic laboratory of first degree, according to the procedure decsribed in Standard operating procedure for phytopathological diagnostic laboratories.Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia (SOP) for plum pox virus (MPŠVRS and IVČ, 2008).

In the Nursery rootstock and planting material, leaves with the symptoms which can indicate the presence of pox virus from each seedling in the period of first visual examination were sampled. Leaves from individual host plant with manifested symptoms which can indicate the presence of pox virus within the phytosanitary regulations regulated isolation space were sampled. The samples are packed, marked with official order of authorized service- Agricultural Service Krusevac- and forwarded to authorized diagnostic laboratory of first degree, according to the procedure described in SOP for plum pox virus (MPŠVRS and IVČ, 2008). During the second sampling, which spans September and the beginning of October, collective samples of leaves are randomly taken from four consecutive seedlings in a row, including the second visual check of nursery beds of the planting material which didn't show any presence of the Sharka virus and where hosting plants failed to show the presence of the virus in the puffer zone. The samples are taken to be tested in a diagnostic laboratory of the first degree. The nursery beds intended for export are especially tested by taking of random collective samples. In case of the detection of the Sharka virus hosting plants in the puffer zone during the first visual check and the confirmation of the virus by means of a serial test, during the second sampling it is obligatory for samples to be taken from 1% of the plants in nursery beds. The collective samples of leaves from four consecutive seedlings in a row are taken to be tested by ELISA serial test or collective samples from ten seedlings are taken to be tested by IC-RT-PCR/RT-PCR test. Sampling for the presence of PDV and PNRSV is conducted within original nursery blocks of grafts and seeds; 10% of an area is sampled depending on the type not the variety. Four shoots, in the length of 10-15 cm, including leaves, are taken as samples from 10% of the trees; one shoot is taken on each of the four main points of the compass (north, south, east, and west) and put in a bag to make a single sample comprising four shoots. If there are trees with changes detected on them, a targeted sampling is conducted. The samples are packed, labeled and sent in accordance with the warrant issued by the designated institution, Agricultural Service Krusevac, to a diagnostic laboratory of the first degree, following the procedure laid out in the rulebook for sanitary check of crops and objects for production of planting material (MPŠVRS, 2008). The pome fruit (apple, pear, medlar, quince and sorbus) is checked in its original nursery blocks and nursery beds for the presence of *Erwinia amylovora* – two visual checks are conducted (the period between the checks is the same as with the stone fruit). The checks were conducted in the original nursery blocks and nursery beds and in the isolated perimeter ranging 500 meters in radius. In the nursery blocks where the presence of *Erwinia amylovora* was not confirmed, 10% of the main trees and bushes were checked for the presence of Apple chlorotic leafspot trihovirus (ACLSV). Leaves were sampled from the bottom part of the tree tops of the original trees on each of the four main points of the compass (north, south, east, and west). One sample contains 24 leaves. The samples are packed, labeled and sent in accordance with the warrant issued by thedesignated institution,Agricultural Service Krusevac, to a diagnostic laboratory of the first degree, following the procedure laid out in the rulebook for sanitary check of crops and objects for production of planting material (MPŠVRS, 2008).

As far as the grapevine is concerned, two sanitary checks were conducted during one year on original plants (vines) and the production of grapevine grafts (grapevine graft nurseries). The first sanitary check is due in the period that spans July, August and the first half of September and the second in October. The samples are checked for the presence of Grapevine Fanleaf Virus (GFLV) and Grapevine Leafroll Virus (GLRV); the check was particularly conducted on original seedlings of grapevine buds and cuttings. Each of the espaliered original seedlings of grapevine for production of cuttings and buds was visually checked according to the rulebook; 10% of the vine samples formed 1% of the collective samples. The samples are packed, labeled and sent in accordance with the warrant issued by the designated institution, Agricultural Service Krusevac, to a diagnostic laboratory of the first degree, following the procedure laid out in the rulebook for sanitary check of crops and objects for production of planting material (MPŠVRS, 2008).

Results and Discussion

Testing of the nursery blocks to above-mentioned viruses in the period between 2008 and 2016 proved that the main nursery blocks situated in an enclosed spaceshowed no sign of PDV, PNRSV and ACLSV viruses in that particular period. However, the viruses were detected on a small number of original trees situated in an open space during the same period. Due to that fact, our recommendation was that the open-space production should be eradicated while the enclosed-space production should be increased. Our recommendation was accepted by those who produce planting material; the result is that complete growing of main plants in the Rasina District is conducted within enclosed spaces. Enclosed spaces are specially modified areas that should be enclosed from above by a PVC foil which is resistant to radiation and tearing and by a double net with small openings on each side to protect it from insects as the main virus spreading factor as far as the enclosed spaces are concerned. On the front side, it should be protected by a double door with two layers of net. Such an area used for production of the reproductive material (scions) is isolated from the surroundings and completely protected from insects. That particular type of material which is used for production of fruit seedlings and produced in an enclosed space is healthy and free of viruses thus limiting drastically the possibility for their appearance, the PPV especially. The priority of modern growing is choosing the most adequate area where growing shall take place. The choice of the most adequate place for production is a priority of the modern production of seedlings and stone fruit rooted stems. This choice is important since it affects the enclosed perimeter where plants are situated during the two-year growing process and the check for the plants which are the carriers of viruses is obligatory. The prevalence of blackthorn or sloe in the areas where stone fruit is grown happens to be the reason why in the Rasina District exists a great possibility for it to be found near the main nursery blocks and nursery beds, cherry plums and some home-grown varieties of plum; it is not uncommon for blackthorn to appear even within the enclosed perimeter. The role which blackthorn has to play in the spreading of Sharka virus has been examined by means of testing 557 samples gathered in the Rasina District spanning the municipalities of Trstenik, Krusevac, Varvarin and Cicevac. The examination showed that there were no samples of blackthorn which showed any symptoms of a PPV infection; there were no plants stricken with a latent infection. PPV has been detected in only 5 (0.9%) out of 557 samples – the samples have shown signs of chlorotic rings and linear discolouration which couldn't be distinguished from the symptoms detected on a plum infected with the Sharka virus; the remaining 15 plants were infected with the Prune Dwarf Virus (PDV). Prunus Necrotic Ring Spot Virus (PNRS) has been detected in only 3 samples (0.5%). Despite not being the source of latent PPV infection, blackthorn can be the source of a latent PDV infection (117 - 96.7%- out of 121 samples have shown the symptoms of latent PDV infection). It is more than interesting that not one plant infected with the virus of Sharka was detected in 121 sample taken from the blackthorn found in the surroundings of the nursery blocks on peach plantations; on the other hand, those samples proved to be 100% infected with the PPV. It is possible that leaf lice proved resistant to the natural infection with the PPV-M variety of the virus. It is indicative that the PPV infection has been detected only in those samples of blackthorn which showed visible signs of it. Many grown and weed annual plants could get infected during an experiment with Sharka virus, but it is still not proven that PPA could be transmitted by natural means from herbaceous plants to Prunus varieties. It is possible for leaf lice to transmit the virus locally from infected to healthy plants in and between nursery blocks in a non-persistent manner. Leaf lice pick up the virus very quickly and are capable to transmit it only within a few minutes after they had fed on an infected plant; after that period they become less viral. During intervals in spring and autumn, number of leaf lice reaches it peak; the spring interval spans May, June and the beginning of July and the autumn interval spans the second half of August and the first half of September. The spring intervals are statistically more prominent than the autumn ones, but certainly there are ways for the virus of Sharka to be transmitted during the autumn interval too. The recommendation is for the treatment with mineral oils to be conducted during both intervals thus reducing the possibility of the virus to spread. According to certain studies, transmission via leaf lice is most frequent among those trees that are nearest to the source of infection; it doesn't necessarily happen only among trees in direct neighbouring surroundings but also among the plants as far as 12 meters and farther from the source. Literature sources for the monitoring of the transmission by molecular method show that in 90% of the cases the transmission reaches the distance between 120 (Conti, 1986) and 200 meters , however, transmissions to the distances longer than a few hundred meters have also been recorded. Transmission via leaf lice to a distance longer than 1 kilometer hasn't been confirmed yet, so it is probably as far as the virus can reach in this way.

Conclusions

Sanitary control is of great importance both socially and economically to the growers to whom guarantees quality, safe distribution and income both on domestic and international market. It provides fruit and vine growers with healthy planting material to enable them to take the first and financially most difficult step towards establishing multi-annual nurseries; it also enables them to keep those uninfected if there are no natural factors and the nurseries are situated on locations safe for production which are isolated enough or far from the source of infection. Sanitary control thus actually enables fruit and vine growers to delay or to slow the factors of infection with the economically harmful pathogens in conditions of their endemic presence which ensures yield and its quality. The production of good planting material is of great importance to the fruit-growing countries that need to raise and preserve the reputation of their country by abiding to the international contracts and respecting the conventions and rules of the organizations of which they are members; it enables them to achieve a secure income via unhinged export of planting materials, large quantities of fruit and grapes, and various products derived from them. The Agricultural Service of Krusevac has- by introducing an enclosed production of original plants, constant monitoring and sanitary check of the isolated perimeter - reduced the number of seedlings of stone fruit and pome fruit which are infected by viruses to the lowest possible degree.

EFFECT OF DIRECT SELECTION ON PRODUCTIVE TRAITS OF VALERIAN (*Valeriana officinalis* L.)

Slobodan B. DRAŽIĆ*

Serbian Assotiation of Plant Breeders & Seed Producers, Zemun-Belgrade, Serbia
*Corresponding author: s.drazic47@gmail.com

Abstract

Effect of direct selection on root yields and on the essential oil content, are analyzed in the paper. As a source of variability we used selection material which consisted of the heterogeneous population of cultivated valerian. Using the method of direct selection (by vegetative multiplication), we created eight promising clones. Following traits were observed at the selected offspring: plant height (cm), yield of roots per plant (g) and essential oil content (%). During a two-year period of research, clones marked with numbers 97 and 156 have achieved reliably higher root yields. The values for essential oil content were different (0.457-0.825%). Values of variance and coefficients of variations for yield of roots, point out the existence of variability, which is an essential condition for the beginning of selection. The application of direct selection resulted in a high selection grain for yield of roots per plant and very low for essential oil content. The selection grain was greater at the selection intensity of 5% than of 10%.

Introduction

There are 200 species belonging to the genus *Valeriana* distributed in the regions of the Old world, South America and Africa. Besides *Valeriana officinalis*, the following species of this genus are the most important: *V. vallichii* (India), *V. edulis* (North America), *V. latifolia* (Asia) (Dajić and Rančić, 2001). *Valeriana officinalis* L. (2n=14) is the most distributed species in Europe.Variability of valerian is expressed through polyploidy, hence there are tetraploid and octoploid types. Valerian from central Europe is mainly tetraploid, while species in England belong to the octoploid type (Schratz,1961).The increase of the number of chromosomes from 2n to 3n, 4n and more, results in the increase of cells and organs. The number of chromosomes and the amount of DNA doubled or quadrupled, which did not happen simultaneously with remaining organoids in the cytoplasm, because the actual cytokinesis was omitted. The increase of the whole set of whole set of chromosomes has a positive effect only to a certain extent, thus too many chromosomes may have a depressive effect. As the frequency of polyploidy incidence in nature is small, its occurrence in valerian provides the possibility to select, cross various genotypes and to develop new cultivars. In addition to the occurrence of polyploidy, the studies have shown the presence of variations in yields and essential oil contents, as well as in its ingredients within the species *Valeriana officinalis*, which may be a source of germplams for the development of improved cultivars (Bos et al., 1998,Dražić, 1990,Nemeth,2005, Prodanović et al. 2015).

In valerian breeding the programs of direct and indirect selection can be applied, where by it can be used generative and vegetative way of reproduction.Vegetative propagation in the process of breeding is a suitable tool for the observation of effects of genotypes and environmental factors on the development of quantitative and qualitative traits (Dražić and Stepanović, 2001, Dražić,2014). Breeding goal was to create an impowd and homogenus genotype, wich will contribute to the stability increased production of valerian traits.

Material and methods

Using the method of direct selection (by vegetative multiplication), we created eight promising clones. They were homogeneous and had a higher mean values for important traits, so they were additionaly studied in comparative experiments.Selected clones were observed in the experimental field in the course of two year. Three traits (height, root yield and essential oil content) were analysed in genotypes that represent selected clone progenies of valerian and were designated. The four-replication trail was set up according to the randomised complete-block design on the marchy black soiltype. The elementary plot size amounted to 4 m^2.The planting distance was 50 x 20cm (100,000 plants ha^{-1}). The genotypes were grown as the annual crop. The common cropping practices were applied during the growing season. Planting was done in October, while roots were harvested in October of the subsequent year. The best quality of valerian roots was determined in October, while the essential oil quality decreased during winter. The roots harvested in spring provided drug of poor quality (Bos et al., 1998). Roots were dried in the warm air dryer.Following main biometric parameters have been calculated: mean value, variance and coefficient of variation. The results were processed by variance analysis application, and significance by LSD test. The effects of selection of superior clones for the height, yield and the essential oil were evaluated. The gain of the selection was expressed in absolute and relative values, as a difference between mean values obtained from selected clones and mean values gained from the entire population of clones.

Results and discussion

Root yield. The mean values for the plant height obtained from selected clones were different. Variation width was high, as well as variance and coefficient of variance. Additionally, yields of a dry root varied in a wide range, too. They amounted from 13.1 g (clon 220) to 33.0 g (clon 97) per plant. The average value of root yield per plant was 18 g in a grown population, respectively 17,6 g in selected clones. However, the clones 97 and 156 achieved reliably higher root yields compared to the standard.There are statistically significant differences among these two clones. In comparison to the standard, clone 97 had yield increase of 16g or 84%, while in clone 156 yield was increased for 6 g or 34 %. Both, variance and yield variance had high values, and this indicates on presence of the variability, which is the main precondition for starting the selection process. Variation width was very low for the essential oil content and this reflected on lower values for variance and coefficient of variance. The average content of essential oil in cultivated population was 0.520 %, and 0.582% in selected clones. Clones marked with numbers 97 and 156 had the highest essential oil content - 0.737%, respectively 0.825%. However, this difference in the amount of essential oil content have no statistical significance (Table 1 and Table 2).

Table 1. Mean values of traits to select clones

Traits	Clones No.										LSD	
	28	49	97	98	101	148	156	220	Mean	Standard	5%	1%
Height (cm)	36	57	85	53	55	32	77	60	57	64	9.5	13.0
Root yield (g)	14.3	13.8	33.0	13.5	16.0	13.2	24.0	13.1	17.6	18.0	5.5	7.0
Essential oil content (%)	0.49	0.51	0.74	0.62	0.43	0.62	0.83	0.46	0.58	0.52	-	-

Table 2**.** Parameters of variability code to eight selected clones

Trait	Mean	Min.	Max.	Variance	CV
Height (cm)	57	32	85	284.93	30
Yield of dry roots per plant (g)	17.6	13.1	33.0	45.375	37
Essential oil content (%)	0.582	0.434	0.825	0.0165	22

Selection gain. The gain of the selection is expressed in absolute and relative values, as a difference between mean values obtained from selected clones and a mean values obtained from the entire population of clones. Realized selection gain varied depending on the traits and years.For the root yield it varied in the range from 62% to 72%, when the intensity of the selection was 10%, i.e. 5%, Table 3. Unlike root yield, values of the selection gain for essential oil content varied from 0.53% to 0.62% at the selection intensity from 10%, i.e. 5%. In quantitative terms, these acquired values are very small.According to results from previous and these researches, it is concluded that the root yield can have bigger impact on essential oil yield per unit area than its percentage content (Dražić et al. 2006). The analysis of dependence of the yield and the amount of essential oil on the growing conditions, pointed out that the essential oil quantity was a more stable trait, i.e. its variability was under greater control of genetic factors (Dražić and Šurlan, 1991). Recent studies on effects of phenological phases, especially of flowering, pointed out to significantly negative correlations with the essential oil content (Pop, 2010).

Table 3**.** Selection gain

Selection intensity	Selection for a trait			
	Roots yield (g)		Essential oil content (%)	
	Absolute	Relative	Absolute	Relative
10%	16	62	0.0031	0.53
5%	19	72	0.0036	0.62

Conclusion

Using the method of direct selection (by vegetative multiplication), we created 8 promising clones. Clones marked with numbers 97 and 156 have achieved reliably higher root yields of 84% and 34% compared to standard. Values of variance and coefficients of variations for yield of roots, point out to the existenceof variability, which is an essential condition for the beginning of selection. The values for essential oil content were different (0.457-0.825%). However these differences did not show statistical significance.The application of direct selection (with the use of vegetative multiplication) resulted in a high selection grain for yield of roots per plant and very low for essential oil content. The selection grain was greater at the selection intensity of 5% than of 10%.

Abstract

Tall fescue (*Festuca arundinacea* Scherb.) is a perennial grass species, with high yield potential and good biomass quality. It is one of the most productive forage grasses under optimum conditions. This species is often dominant in pastures. Also it has been used for intensive production of hay meadows, in pure sown or in mixtures with legumes. When used for forage production it is not usually mixed with other grasses. Variability of initial material (autochthonous populations, breeding populations or cultivars) is basic requirement for successful breeding of this, as well as other species. The investigated collection included eight autochthonous populations and five cultivars. The study was conducted in an experimental field of the Institute for Forage Crops, on degraded alluvium soil type. The trial was set up in a space plant nursery with plant to plant distance 60x60cm as a randomized block design with 30 plants per genotype in two years. The aim was to determine values and variability for the most important phenological (heading date), morphological traits (plant height, length of leaf, width of leaf, the leaf number, panicle length and the number of tillers per plant), dry matter yield per plant and dry matter yield quality. The highest dry matter yield per plant was measured in cultivars K-20, K-19, Belfine and Elfina. Investigated material has demonstrated significant variability within the genotypes for all studied parameters. Also, among populations variability was very statistically significant for all investigated traits. Genotypes used in this study can be a source of genes for improved productivity and quality in further breeding programme.

Keywords: *tall fescue, variability, autochthonous populations, cultivars.*

Introduction

Tall fescue is forage and turf grass species in temperate regions of the world. Tall fescue is hexaploid (2n = 6x = 42), with high level of self-incompatibility (Xu et al., 1991). It is one of the most productive forage perennial grasses, especially in extreme environmental conditions, like summer drought or winter hardiness. Also, regrowth production (second and third cut) is higher than other forage grasses Niemelainen et al. (2000). Increased interest for tall fescue in Europe coming from increased frequency of dry periods during summer. New cultivar of tall fescue have higher digestibility than wild ecotypes which dominate in permanent grasslands that have lower digestibility than other forage grasses. Tall fescue has been usually used for intensive production of hay meadows. Also, it is very tolerant to grazing therefore pastures where it dominates are long lasting. It can be grown as a pure crop or in mixtures with legumes.

Initial step in grass breeding process is identifying of genetic variability of breeding material, which existence ensures success of a plant breeding program. Autochthonous populations have natural variation and very often have satisfactory yielding performance in comparison with introduced cultivars (Babić et al., 2014), which referred them for direct phenotypic selection for cultivars release (Posselt and Willner, 2007). Most of created cultivars contain autochthonous populations and represent great and important resource of genetic variability.

The genetic variability of all traits important for breeding process represents a basic prerequisite for successful selection. The primary aim in tall fescue forage breeding is obtaining cultivars with a high yield and improved quality for livestock feed. The aim of this investigation was to determine genetic variability of eight autochthonous populations and five cultivars. The most important breeding criteria in tall fescue breeding programs, as well as other forage grasses, were increasing of forage yield and digestibility, disease resistance and drought and frost tolerance. Since is tall fescue use as a component of grass-legume mixtures in Serbia, dry matter yield and quality, persistency and rust resistance is most important breeding criteria of this species.

Material and methods

A collection consisting of eight autochthonous populations and five cultivars of tall fescue was investigated during a two years period. Autochthonous populations have collected in hilly-mountainous areas of Serbia, while cultivars originating from commercial production.

Investigation was conducted in an experimental field of the Institute for Forage Crops, on degraded alluvium soil type. The trial was set up in a space plant nursery with plant to plant distance 60x60cm as a randomized block design with 30 plants per population in three replications. Heading date (HD) and morphological traits plant height (PH) (cm), leaf length (LL) (cm), leaf width (LW) (cm), the number of leaves per tiller (NLT), panicle length (PL) (cm), the number of tillers per plant (NTP) and dry matter yield (DMY) (g per plant) were investigated in 2 years; results are shown as two-year mean values. Heading date is presented as number of days from April the first. All morphological traits and dry matter yield per plant were measured at the full heading stage in first cut. Dry matter yield quality (crude protein, crude fibre, ADF and NDF) was determined by the Weende system, in two cuts and the results were presented as two-year average values.

All data were analysed by ANOVA. Differences between accessions were tested by the LSD test. Broad sense heritability (h_b^2) was calculated for all traits according to the formula

$$h_b^2 = \frac{\delta_g^2}{\delta_f^2} \cdot 100$$

(δ_g^2-genetic variance; δ_f^2 - phenotypic variance)

Results and discussion

Analyses of maturity, morphological traits which influence dry mater yield and quality, as well as biomass production and dry matter quality traits of tall fescue populations and cultivars, showed high within population variability (Table 1 and 2). Also, significant differences between tall fescue autochthonous populations and cultivars were determined for all studied traits (LSD values in Table 1 and 2). For all studied traits determined high values for broad sense heritability, especially for quality traits (Table 3). Leaf length and width and number of leaves per plant influence the forage quality by increasing the crude protein content and improving the dry matter quality. From the point of tall fescue breeding, except increasing of forage yield, soft and smooth leaves were favorable traits, in order to have better dry matter quality.

The most important indicator of the biomass quality is content of crude protein, which mainly depends on the growth stage at the time of cutting. In this study the accessions with highest crude protein content and lowest crude fibre content were K-19, Kora, Belfine, Elfine and M. Polje 2, accessions with the best ratio leaf length, width and number per plant (Table 2), which gives them characteristics to be used as sources for improved dry matter quality breeding.

Average crude protein content of collection in the first cut was 123.4 gkg^{-1} which is significantly lower compared to the results reported by Niemelainen et al. (2000), where the crude protein content ranged from 151 to 161 gkg^{-1}. In the second cut crude protein content (136.3 gkg^{-1}) was similar with Niemelainen et al. (2000).

Heading date is a very important trait, because accessions differing in this trait would enable creating of cultivars with diverse maturing time. In general, the latter accessions of grasses have better biomass quality than earlier. In this study, earlier accessions have higher quality values compared to latter, which is substantially similar to results published by Jafari and Rezaeifard (2010). Autochthonous populations included in investigation have latter maturity than cultivars, which provides the ability to create the cultivars differing in maturity, which is of interest for the composition of mixtures for various terms and duration of utilization (Sokolović et al., 2010).

In grasses, number of tillers per plant in the first cut is the trait which has the highest influence on dry matter yield, but number of tillers per plant also affects other important traits like seed production. The highest number of tillers per plant were found in populations Zlatibor Kremna (260.92) and cultivars Belfine (225.26) and Elfina (218.19).

Table 3. Heritability, genetic and phenotypic coefficient of variation

		h_b^2 %	CV_G %	CV_F %
Heading date		65,47	12,19	15,06
Plant height		57,66	8,31	10,91
Leaf length		59,12	11,59	15,08
Leaf width		69,81	9,67	11,57

Panicle length		34,58	4,48	7,63
Number of tiller per plant		53,67	22,09	30,15
Dry matter yield per plant		85,45	19,65	21,26
Crude protein	1 cut	95,23	12,23	14,68
	2 cut	97,26	13,36	15,83
Crude fibre	1 cut	96,26	7,86	9,61
	2 cut	95,46	7,64	9,42
ADF	1 cut	95,26	8,43	9,98
	2 cut	94,68	9,12	10,03
NDF	1 cut	95,58	5,14	6,94
	2 cut	97,45	4,89	6,78

Dry matter yield per plant is one of the most important traits in the breeding process. The main aim is to increase the yield of dry matter, or maintain the yield through improving of other traits. The yield is very variable trait, influenced with high number of genes, and largely depends on the agroecological conditions. Highest dry matter yield per plant were scored for cultivars included in research, K-20 (392.49 g per plant), K-19 (387.25 g per plant), Belfine (385.09 g per plant) Elfina (384.83 g per plant) and Kora (356.93 g per plant). Autochthonous population Zlatibor Kremna is in range with cultivars by dry matter yield with 319.78 g per plant. Variability within genotypes studied (CV %) for pheno-morphological traits (Table 1 and 2) was not high, but differences between some genotypes (LSD) were statistically highly significant (Table 1 and 2.). The highest coefficients of variation were for number of tillers per plant (36.68%) and dry matter yield (28.06%), while heading date showed the lowest within population variability (15.08%). Within population variability for quality traits, such as other, was not high, ranged from 12.12 to 15.02%, which is in agreement with results Babić et al. (2012). Genetic and phenotypic coefficients of variation are relative indicators of variability. They are used to compare the level of variability of traits expressed different units of measure. The most variable traits, as expected, are number of tillers per plant and dry matter yield per plant (Table 3). Broad sense heritability (Table 3) was high for all studied traits, except for panicle length (34.58%). The highest broad sense heritability determined for dry matter yield (85.45%). Broad sense heritability was high for all quality traits, where the lowest heritability was determined for crude protein content in the first cut (95.23%). High values of broad sense heritability for most traits indicate that an improvement of these traits could be possible and predictable in these collections.

Conclusion

According to results of this study, significant differences within and between tall fescue autochthonous populations and cultivars were found for most studied traits. For the most important productivity traits like number of tillers per plant and dry matter yield, the highest values were determined for cultivars included in study and for populations Zlatibor Kremna. Also, important tall fescue criteria breeding are to improve biomass quality. Cultivars K-19, Kora and Belfine and populations M. Polje 2 have favourable ratio of leaf length and width and number of leaves per plant, which influenced that these accessions have the highest crude protein content. The average values, coefficients of variation and broad sense heritability for the most important traits, especially for number of tillers per plant, dry matter yield, leaf length and width and number of leaves per plant indicate a high breeding potential of investigated autochthonous populations and cultivars of tall fescue for these most important traits in tall fescue breeding process.

Abstract

One of the most powerful natural fat-soluble antioxidants are tocopherols or better known as vitamin E. Compared with other staple foods, maize grains contain high level of tocopherols. This research was performed to estimate differences in tocopherols (*α-, β + γ-, δ)* content in 69 maize inbred lines by using high-performance liquid chromatography (HPLC). Among the inbred lines, significant variation was observed in the traits of interest: average γ -tocopherol content was higher in the sweet corn inbred lines (7.10 µg/g) but the average α-tocopherol content was lower (12.99 µg/g) than in the inbred lines with standard kernel type (40.14 µg/g and 13.5 µg/g), respectively. The content of *α*-tocopherol ranged from 2.35 to 38.14 µg/g in inbreds and from 7.66 to 17.79 µg/g in sweet corn inbreds and γ tocopherol content from 12.10 to 105.2 µg/g in inbreds and from 50.09 to 101.32 µg/g in sweet corn inbreds. The lowest level of all tocopherols have inbred K1263. The inbred lines with the highest content of α-tocopherol are TVA 973 and H, and with the highest γ -tocopherol content inbred Yum 1-3 and sweet corn line Esteem-F1-6. Those inbred lines could be used in future breeding programs for improving the tocopherol content of commercial inbred lines.

Keywords: *genetic variability, inbred lines, maize, tocopherols*

Introduction

Vitamin E is the common name that describes eight naturally occurring compounds that are lipid-soluble antioxidants with two distinct groups, tocopherols and tocotrienols. The two groups differ in the saturation of the side chain and vary in the number and location of methyl groups (Rocheford, 2002). They are classified according to the location of the methyl group as α-tocopherol, β-tocopherol, δ-tocopherol, γ-tocopherol, α-tocotrienol, β-tocotrienol, δ-tocotrienol and γ-tocotrienol (Moss, 1981). Vitamin E plays an important role in plants development and can protect cell membranes from oxidation, prevent oxidation of polyunsaturated fatty acid, prevent several diseases in humans and other animals, such as cardiovascular disease, Alzheimer's disease, neurological disorders, cancer, cataracts, inflammatory diseasesand age-related macular degeneration (Herrera, *et al*. 2001). Vitamin E antioxidant activity order is as follow: α-tocopherol > β-tocopherol > γ-tocopherol > δ-tocopherol. α-tocopherol is the major vitamin E in nearly all green plants, as well as in seeds and fruits γ-tocopherol is preferentially found (Matea *et al*., 2008). Tocopherols are essential micronutrients for humans and animals, with several beneficial effects in plants. Among cereals, only maize grains contain high concentrations of tocopherols. Tocopherol levels in maize kernels vary widely, however, the two predominant isomers are γ-tocopherol and α-tocopherol (Rocheford, 2002). Grams *et al*. (1970) study the concentration of tocopherols in the germ, endosperm and pericarp of the kernal of four maize hybrids. They found that the germ fraction contained 70-86% and the endosperm fraction 27-11% of the tocopherols extracted from the whole grain. In the four hybrids analyzed, the germ fraction contained 94-

96% of the α-tocopherol as well as 93-96% of the γ-tocopherol extracted from the whole grain. Maize kernels have low α-tocopherol content, the compound with the highest vitamin E activity, thus, raising the risk of vitamin E deficiency in human populations relying on maize as their primary vitamin E source. Several studies have shown significant differences among maize inbreds for tocopherol levels (Egesel, 2001, Drinic *et al*., 2014, Anđelković *et al.*, 2016). The aim of this study was comparison tocopherol content of 69 maize inbred lines with differnt kernal type.

Material and Methods

Sixty nine maize inbred lines, 19 sweet corn (L1-L19) and 50 maize inbred line with standard kernal type (L20-L69) were study for tochopherol content. Maize seed were milled (Perten 120, Sweden) into flour (particle size < 500 μm), in order to obtain greater surface contact and stored at -20˚C prior to analysis. Tocopherols (α-, γ+, *β*- and δ) were extracted by method proposed by Gliszczyńska-Świgło *et al* (2007) with minor modification. Approximately 0.2 g of sample was mixed with 2-propanol (4 mL) and homogenised for 30 min at room temperature. The extracts were then centrifuged at 3000 rpm for 5 min, filtered through a 0.45 μm membrane filter and a aliquot of clear supernatant was directly injected into the Dionex UltiMate 3000 liquid chromatography system (Thermo Scientific, Germany) equipped with fluorescence detector (FLD–3100). Chromatographic separation of tocopherols was accomplished on analytical column, Acclaim Polar Advantage II, C18 (150 × 4.6 mm, 3 μm) operated at 30ºC. Mixture of acetonitrile and methanol (1:1, v/v) was used as a mobile phase at flow rate of 1 mL/min. Injection volume was 5μL, while the wavelengths for excitation and emission were maintained at 290 nm and 325 nm, respectively. Tocopherols were identified and quantified comparing characteristic retention time of corresponding standards. The tocopherols content is expressed as micrograms per gram dry matter.

Results and Disscussion

Maize displays considerable natural variation for tocopherols content. Presence of tocopherols can vary by genotype, but the majority of the tocopherols in the maize kernel are found in the germ along with most of the stored oil which contains 70% to 86%, while the endosperm contains 11% to 27% (Rocheford *et al.*, 2002). Maize grains have been evaluated for tocopherol levels and substantial natural variation of α, γ, and δ-tocopherols has been observed, with levels of γ-tocopherol predominant in the total tocopherols pool (Weber, 1987; Egesel *et al*., 2003).

Average content of α tocopherol was higher in inbred lines with standard kernal type (13,50 μg/g) than in sweet corn inbred lines (12,99 μg/g) but sweet corn inbred lines have higher content of γ tocopherol (70,10 μg/g) than standard inbred lines (40,14 μg/g). Content of α tocopherol varied from 7,66 to 17,79 μg/g for sweet corn and from 2,35 μg/g to 38,14 μg/g in inbred lines with standard kernal types. The highest level of α tocopherol have inbred line TVA973 (38,14 μg/g) folowed by inbred line H (24,04 μg/g) and lowest one 2,35 μg/g inbred line Va 93. γ tocopherol content range from 50,09 μg/g to 101,32 μg/g for sweet corn and from 12,10 μg/g to 105,02 μg/g for inbred lines with normal kernal type (Table 1). The γ tocopherol content was highest in Yum1-3 (105,02 μg/g), followed by the sweet corn inbred line Esteem-F1-6 (101,32 μg/g), and was lowest in K1263 (12,10 μg/g). The highest level of δ tocopherol 4,66 μg/g have sweet corn inbred line RBN9024-9 and lowest one 0,48 μg/g inbred line Yum1-3, average 2,81 μg/g in sweet corn inbred lines and 1,47 μg/g in inbred lines with standard kernal types. The lowest level of all three (α, γ, δ) tocopherols have inbred K1263

(7,84 μg/g, 12,10 μg/g, 0,96 μg/g, respectively). The distribution of different tocopherols in the inbred lines also varied. In TVA973-1, the content of γT (41,24 μg/g) was almost same as that of αT (38,14 μg/g), where as γT content in Oc117A3T (14,17μg/g) was nearly twice as that of αT (7,40μg/g), even in sweet corn inbred lines LSh2 γT content (77,11μg/g) was more than ten times as that of αT (7,66 μg/g).

Several studies have shown significant differences among maize inbreds for tocopherol levels. Forgey (1974) evaluated 20 inbreds and found α tocopherol ranged from 9.1 to 64.6μg/g and γ tocopherol from 13.6 to128.7μg/g. Kurilich and Juvik (1999) found that total tocopherol content averaged 30.1 μg/g dry weight among 44 maize varieties, with γ-tocopherol most predominant at two-thirds of total tocopherol, α-tocopherol making up 27%, and δ-tocopherol only 4%. Ibrahim and Juvik (2009) study 41 sweet corn genotypes and found that the most abundant form of tocopherols were gamma-tocopherol. α/γ ratio was highest in inbred line H (0,954), followed by L317 (0,938) and TVA973-1 (0,925) and was lowest in Va 93 (0,085) (Table 2).

Table 2. α/γ ratio in sweet corn (1 – 19) and normal inbred lines (50 – 69)

14	0,227	28	0,093	42	0,218	56	0,393		

Besides having a characteristically sweet taste, sweet corn varieties have unique carotenoid and tocopherol profiles relative to common maize, γ-tocopherol is the primary tocopherol. The high variability among sweet corn genomes regulating the synthesis of tocopherols suggests that they are feasible targets for biofortification efforts focused on enhancing antioxidant levels (Nuss and Tanumihardjo, 2010).

Conclusions

Tocopherols are compounds present in maize that provide health and economic benefits, which potentially could be captured by both producers and consumers to add value to the grain. So, increased levels of tocopherols in maize grain, because of their antioxidant activity, should increase the nutritive value of corn. Compared with sweet corn inbred lines, the normal inbred lines contained broader genetic variations for tocopherols, though the number of sweet corn lines (19) was far smaller than that of normal lines (50). Sweet corn inbred lines have more γ-tocopherol. An effective increase in vitamin E concentration could be achieved by increasing total tocopherols or by increasing the α/total tocopherol ratio.

Abstract

The second half of 20th century was with growing awareness of importance of landraces conservation for the future. A total of 2217 maize landraces collected in the former Yugoslavia, are stored at Maize Research Institute (MRIZP) gene bank. Out of them, 222 accessions were from the Republic of Macedonia. During 2014, new collecting missions were organised in the eastern and western part of Macedonia. According to collecting site, kernel type and colour, 12 samples from Macedonian (MK) gene bank were chosen for the comparison and identification of possible duplicates with the 16 accessions from the same area and kernel characteristics within MRIZP gene bank. Duplicate accessions are not valuable for widening diversity and required increased financial and storage capacity. In the last few decades, application of molecular markers for polymorphism investigation at the DNA level has been very successful in genetic diversity studies. Based on molecular analysis by 12 Simple Sequence Repeats (SSR), ten genotypes (five from MRIZP and five from MK gene bank) clustered together, with obtained similarity from 0.687 to 0.844. The pair (ZP 1172 and FZNH010040058), had the highest similarity and could be treated as duplicate for MRIZP gene bank. Application of DNA markers, unaffected by environment, successfully discriminate closely related genotypes and possible duplicate accessions. Since identification of absolute genetically identical samples is possible only by comparison of complete genome, that is not necessary for samples considered as duplicates in gene bank management.

Key words: *accessions, duplicates, landrace, maize, SSR.*

Introduction

Maize genetic resources are of high importance for agriculture, but breeding of modern hybrids in the second half of the 20th century, contributed to rapid replacement of traditional landraces in Europe. The need for preventing the loss of maize genetic diversity led to organised collecting missions. Since landraces are a valuable source of potentially useful traits, there is necessity to properly conserve and characterise them, prevent from disappearing, and to keep for utilization in breeding. Many maize gene banks were established in different countries, and characterisation of genetic diversity was carried out (Rebourg *et al.*, 2001). However, the usefulness of applied morphological characterisation of gene bank accessions became limited, since they are strongly affected by environment. In the last few decades, application of molecular markers for polymorphism investigation at the DNA level has been very successful in genetic diversity studies (Ignjatović Micić *et al.*, 2008; Barcaccia *et al.*, 2016). Efficient management in gene banks, through seed multiplication and regeneration in *ex situ* collections, is affected by possible loss of genetic integrity and existence of duplicate accessions. The term duplicate accession distinguished historical and genetic or biological duplicates in genebanks. Passport data, together with geographical origin and/or historical data were used in duplicate identification in many gene banks, but could be uncertain (Hintum and Knüpffer, 1995; Lund *et al*., 2003). Duplicate accessions are burden to gene bank since they are not valuable for widening diversity and their maintenance and multiplication increase costs. These are important facts for necessity of duplicates identification and elimination of redundant accessions (Treuren *et al*., 2001). For genetic resources conservation, it is important to know whether phenotypically similar genotypes share similarity in gene combinations. Microsatellite markers are appropriate for the assessment of genetic diversity given their informativeness, co-dominance, high polymorphism, repeatability, and simplicity (Bourguiba *et al*., 2010). In numerous diversity studies, application of SSRs was appropriate for grouping accessions according to their geographical origin, e.g. in bean (Sharma *et al*., 2013), tomato, (Mercati *et al*., 2015), maize (Cömertpay *et al*., 2012).Replacement of local maize landraces with hybrid maize in the second half of the 20th century occurred in former Yugoslavia (western Balkan region, Andjelkovic and Ignjatovic-Micic, 2012). Collection, characterization, and natural classification in coming decades resulted in more than 2000 local maize landraces, stored at MRIZP gene bank. Out of them, 222 landraces were collected in the Republic of Macedonia (Andjelkovic and Ignjatovic-Micic, 2012).In the present paper, diversity between maize landraces collected in the Republic of Macedonia in the second part of 20th century, and in 2014. were studied. Applied SSR analysis will contribute to the more efficient *ex situ* conservation, and rationalisation of gene bank collection, e.g. elimination of potential duplicate accessions.

Material and Methods

Field Trails

Maize accessions from MRIZP genebank were collected in different years (1974, 1975, 1978, 1980, 1983, 1984 and 1989), and 12 samples from MK gene bank were collected in 2014 (Ivanovska and Jankulovska, 2016) from several locations in R. Macedonia (Table 1). Samples from both genebanks were grouped based on the same/similar collection sites, kernel colour and texture. The landraces were evaluated in 2015 in Zemun Polje, Serbia, and Kumanovo, R. Macedonia with two replications, with the usual cultivation practice. Plants were sown in single row plots with 15 hills per row and spaced 0.75 m apart with intra-row spacing of 0.4 cm between hills. Plots were overplanted and thinned to two plants per hill after seedling establishment.

DNA Extraction and SSR Analysis

DNA samples from each of the 28 accessions were isolated using leaf material from 15 individuals in a population. Harvested leaves were kept frozen at -30°C and powdered in liquid nitrogen. Total genomic DNA was extracted and purified from 0.1 g of the powder by a CTAB method (Saghai-Maroof *et al*., 1984). The DNA was quantified and assessed for purity spectrophotometrically, and diluted to a working concentration of 50 ng/μl. A final set of 12 SSR primers were applied in the analysis of the genotypes according to the method of Senior *et al*. (1998). Markers were selected based on amplification size and quality, and whole genome coverage.The amplification reaction was carried out in 25 μl reaction volume containing 1x enzyme buffer, 2.4 mM MgCl, 200 μM dNTP, 0.5 μM primers, 1xBSA, 1U *Taq* polymerase and 50 ng DNA template. Touch-down amplifying program was applied (thermocycler Biometra Proffesional Standard 96) as follows: initial denaturation at 95°C for 5min, 15 cycles of denaturation at 95°C for 30sec, annealing at 63.5°C for one min (-0.5°C/cycle) and extension at 72°C for 1min, then 22 cycles of denaturation at 95°C for

30sec, annealing at 56°C for one min and extension at 72°C for 1min and finally elongation at 72°C for four minutes. The amplified DNA fragments were separated using 8% polyacrylamide gel electrophoresis for 1.5 hours at 80 mA. After staining with ethidium-bromide for 30 minutes, gels were photographed under UV light using Biometra BioDocAnalyze Live gel documentation system. DNA banding patterns from SSR gels were converted into binary form, where a 'one' indicates the presence of a specific allele and a 'zero' indicates the absence of that allele. Scored data were used to estimate Jaccard's similarity coefficient (Jaccard, 1908) and the obtained similarity matrix was used in cluster analysis. UPGMA method was applied to obtain the dendrogram. All analyses were performed using R 3.3.1 statistical package.

Results and Disscusion

With 12 SSR loci distributed uniformly over all ten maize chromosomes, in total 44 alleles were detected among 28 landraces of which 42 were polimorphic. The number of alleles per primer was in a range from 2 to 7 with an average of 3.67 alleles per locus. The average alleles per marker was higher than that found by Molin *et al*. (2013), who assessed 48 maize landraces with 47 markers with an average of 2.9 fragments per marker. The genetic analysis of maize accessions based on SSR polymorphism categorized landraces into the four gene pools (Fig.1). The accessions were grouped according to collecting sites: in the first sub-cluster were accessions collected in the area surrounding Debar and Skopje. Six of them were from MRIZP gene bank, and three were from MK gene bank. The second group mostly consists of landraces, collected in the western part of Macedonia (Gostivar and Debar). The third and fourth sub-clusters consist of samples collected in the eastern part of Macedonia (Štip, Probištip and Kavadarci).

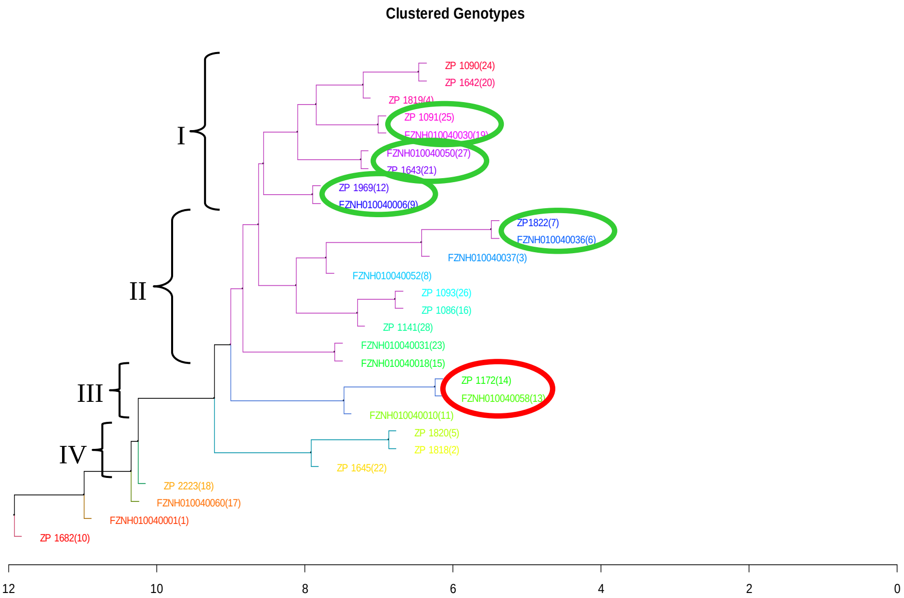

Figure 1. Classification of genetic similarity of maize landraces based on SSR markers, generated by UPGMA cluster analysis.

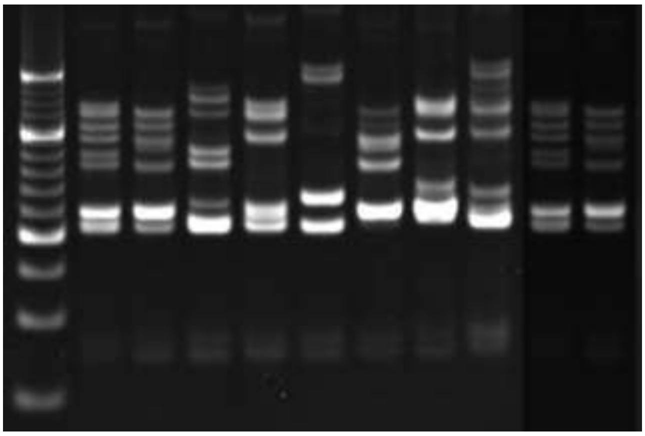
In the present study, based on SSR markers, maize landraces from the same small area were in the group with genetically similar accessions (Fig.1). Interestingly, ten accessions (five from MRIZP gene bank and five from MK gene bank), collected in different time-scale in the same area, were clustered in pairs.

For ten landraces (five from MK and five from MRIZP genebank) that paired together on dendrogram (Fig. 1.), additional SSR analysis with the same set of primers was performed (Fig 2).



1 2 3 4 5 6 7 8 9 10 11

Figure 2 PCR amplification products of 10 landraces with UMC1506 marker. Line 1 20bp DNA Ladder, line 2 ZP 1172, line 3 FZNH010040058, line 4ZP 1643, line 5 FZNH010040050, line 6 ZP 1091, lin 7 FZNH010040030, line 8 ZP 1969, line 9 FZNH010040006, line 10 ZP1822, line 11 FZNH010040036

After pairwise comparison of these samples, by the same set of SSRs, we have obtained high percentage of similarity among pairs (0.687 to 0.844). They were genetically heterogeneous with low probability to be completely identical, but they shared very similar genetic background. The pair ZP 1172 and FZNH010040058, had the highest similarity and could be treated as duplicate for MRIZP gene bank.
As a result of the higher levels of variation that are usually detected with molecular markers, posible duplicates will rarely found to be completely identical. Therefore, verification of probable duplicates using molecular markers is not simply a matter of determining whether two accessions are identical or not, but rather whether they are sufficiently different in order to consider them distinct accessions (Treuren and Hintum, 2003). Application of DNA markers, unaffected by environment, successfully discriminate closely related genotypes and possible duplicate accessions in many crops (Börner *et al*., 2000; Lund *et al*., 2003). Identification of absolute genetically identical samples is possible only by comparison of complete genome, that is not necessary for samples considered as duplicates in genebank (Treuren *et al*., 2001).

Conclusion

Further comparison and molecular analysis of the rest of the accessions originated from Macedonia are recommended for both gene banks, in order to lower costs of maintenance and regeneration of possible duplicates, and to increase efficiency of gene bank management and usage of collections. Assessment of the accessions within gene bank and identification of variation on morphological and molecular level are also, very valuable for development of core collections and utilisation in breeding, as well as for rationalisation and elimination of redundant germplasm.

Abstract

This paper deals with results of the effects of different fertilizers on floristic composition and abundance of weeds in maize. The survey was conducted during two-year period (2014-2015) in white maize hybrid ZP 655b. Trial was set up on chernozem soil type in the experimental field of Maize Research Institute in Zemun Polje, Serbia. The objective of the study was to identify floristic composition of weeds, their abundance and biomass in regard to different fertilization treatment. The treatments of fertilization consisted of following variants: control, mineral fertilizer AN, microbiological fertilizer Uniker and organic fertilizer under the trade name „Humus Vita Stallatico". The fields were surveyed according to the quantitative survey method by using a 1 m x 1 m quadrat with 4 samples of quadrat from each 20m^2 plot. On the basis of two-year results it is obvious that meteorological conditions have very significant influence on floristic composition and abundance of weed community in maize. A total 17 different species in boath seasons, with 3 grasses and 14 broadleaves, were identified. The weediness in both years was relatively high but significanly higher in 2015. Average weed density in the plots was 26 plants per m^2 in 2014 and 31 plants per m^2 in 2015. According to results, the fresh and dry biomass of weeds was significantly higher in treatment with microbiological fertilizer in both years followed by treatment with organic fertilizer. Based on abundance and biomass the annual weeds *Solanum nigrum* L. and *Chenopodium hybridum* L. were the most dominant species in 2014, while perennial weed *Sorghum halepense* L. and annual weeds *Bilderdykia convolvulus* (L.) Dum. and *Portulaca oleracea* L. were the most dominant species in 2015. The major percentage of the species falls under the life forms Therophytes and Geophytes, which have been assessed after comparison with the normal world spectrum as proposed by Raunkiaer.

Keywords: *floristic composition, weed abundance, biomass, maize, fertilizer.*

Introduction

The distribution of weeds can be influenced by ecological and human factors. Human can influence weed flora distribution through agronomic management like plant establishment system, irrigation and use of fertilizer amount and type, rate and effectiveness of herbicides application (Raya et al. 2013; Stefanović et al 2011). Variety of weeds can be found in agricultural fields which could affect the yield potential of crops adversely.
Many agronomic management such as tillage (Kovačević and Momirović 1996; Légère et al. 2008; Swanton et al. 1999), crop rotation (Anderson et al. 1998; Kovačević and Momirović 2008) and fertilization (Pyšek and Lepš 1991; Storkey et al. 2010) have a direct influence on the floristic composition and density of weed communities. Fertilization not only affects the growth of crops but also impacts on a range of selection pressures that potentially affect weed populations, and thus it is an important component of integrated weed management programs

(Simić 2003; Blackshaw and Molnar 2009; Simić et al. 2016). Different soil fertility management practices create a range of microsite conditions for plant species to germinate and establish, and a combination of abiotic (management, climate, etc.) and biotic (pathogens, competition, etc.) 'filters' formed has been considered to constrain weed community assembly (Ryan *et al*. 2010). Previous studies have demonstrated that fertilization greatly affects weed species composition, abundance, density, and diversity (Hyvönen and Salonen 2002; Moss et al. 2004; Wan et al. 2012; Simić et al. 2016). Fertilization may influence weed composition indirectly by influencing nutrient and radiation competition between crops and weeds (Simić and Stefanović 2007; Pyšek and Lepš 1991).

Materials and Methods

A two year (2014-2015) field experiment was conducted at the Maize Research Institute in Zemun Polje, Belgrade, Serbia. Trial was set up on chernozem soil type in the experimental field. White maize hybrid ZP 655b from the collection of Maize Research Institute Zemun Polje was selected for this study. The treatments of fertilization consisted of following variants: control (with no fertilizer), mineral fertilizer AN (ammonium-nitrate 34.4% N) in amount of 75 kg ha^{-1} N, microbiological fertilizer Uniker in amount of 10 l/ha and organic fertilizer under the trade name „Humus Vita Stallatico" in amount of 1.5 t ha^{-1}. Uniker is microbiological fertilizer witch consisted of following strains of bacteria: *Bacillus megaterium*, *Bacillus licheniоirmis* and *Bacillus suptilis.* It is applied by incorporation into soil prior to sowing, in order to improve soil microbiological activity and increase mineralization of organic matter. „Humus Vita Stallatico" is composted organic fertilizer made from cattle and poultry manure with high content of humified organic matter (48%) and fulvo (9%) and humic acid (10%). Content of nitrogen, phosphorus and potassium is nearly equal with over 3% for each macroelement. The objective of the study was to identify floristic composition of weeds, their abundance and biomass in regard to different fertilization treatment. The fields were surveyed according to the quantitative survey method by using a 1 m x 1 m quadrat with 4 samples of quadrat from each $20m^2$ plot. Plants present in quadrats were recorded, sampled, sorted to species level counted and then dried and weighed.
Data was analyzed statistically using analysis of variance and $LSD_{0.05}$ were used for comparison, when main effects or interactions were statistically significant.

Results and Discussion

Meteorological data on the experimental field during two years of trial are shown on Figures 1 and 2. The data shows better meteorological conditions in the first year of this experiment. This year is characterized by big amounts of rainfall (annual sum was 858.4 mm) specially in May and July (Figure 1). Annual temperature mean 13.9 ^oC was significantly higher than long term temperature mean for Zemun Polje. Relatively high average monthly air temperature was in July and August 23.2^{o}C and 22.6 ^{o}C, respectively. The second year of experiment 2015 had significantly smaller amount (587.7 mm) and bad rainfall distribution compared with first year. Severe drought is appeared from June to August (Figure 2). Regarding temperature conditions in this period, extremely high temperature means is recorded in July (26.4 ^{o}C) and August, (25.7 ^{o}C).

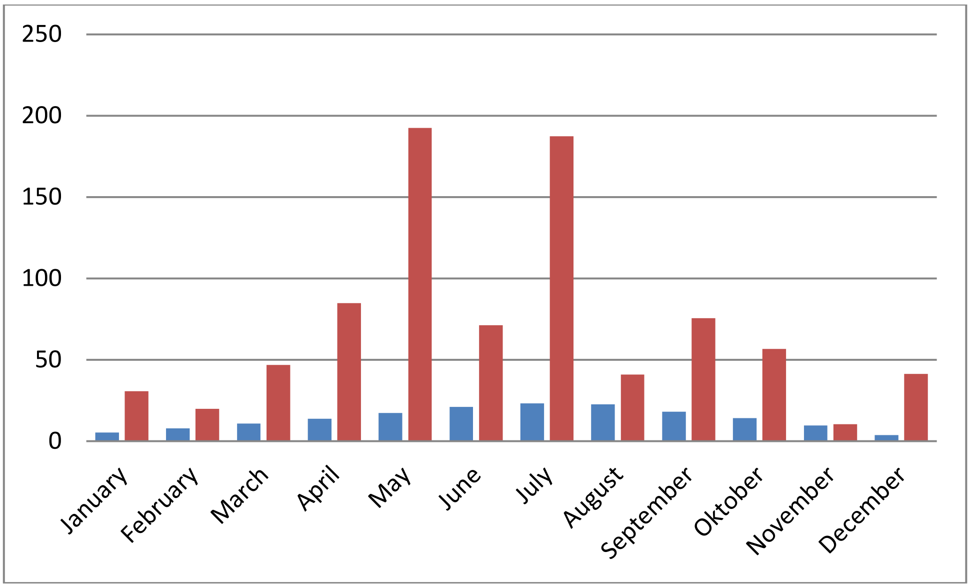

Figure 1. Temperature and precipitation in 2014

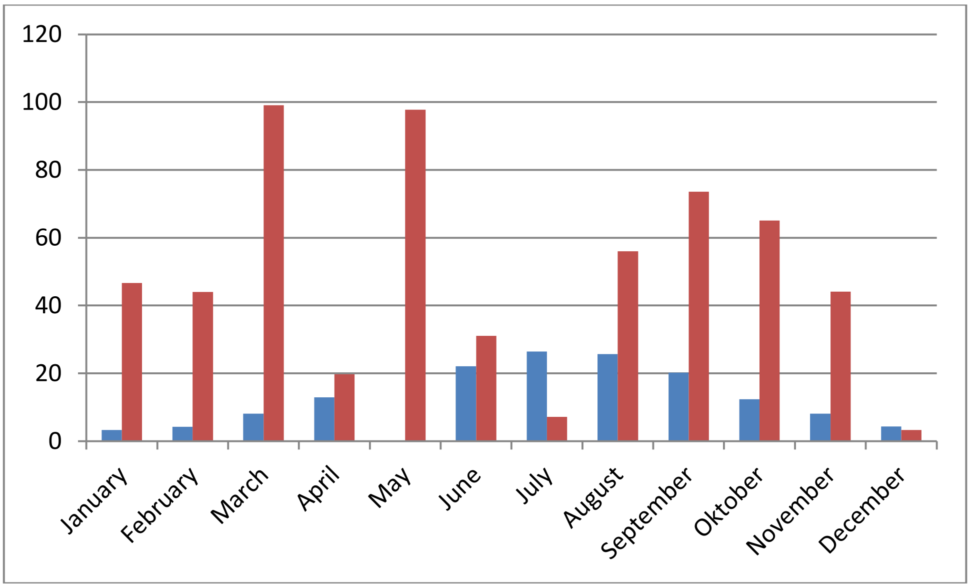

Figure 2. Temperature and precipitation in 2015

A total 17 different species in boath seasons, with 3 grasses and 14 broadleaves, were identified (Table 1). The major percentage of the species falls under the life forms Therophytes (14) and Geophytes (3), which have been assessed after comparison with the normal world spectrum as proposed by Raunkiaer. The weed seed bank of maze fields in Zemun Polje is largely dominated by species of the families *Poaceae* (3), *Amaranthaceae* (3), *Polygonaceae* (3), *Chenopodiaceae* (2) and *Solanaceae* (2). Ecological analysis of weed community of maize indicates that thermophile (T4, T5; average T=4.2), heliophile (L4, L5; average L=4.1) species are dominant, also species with preferences of dry or semi-dry habitats (average F=2.6). All these finding are very similar with the results presented by Stefanović et al 2011. Comparing with ecological requirements of maize (thermophile, heliophile, adapted on semi-dry habitats) these results indicate that weeds are very compatible with these requirements. This is one of the proof which tell us about great weeds adaptability and strong competition ability towards crops.

Based on abundance and biomass the annual weeds *Solanum nigrum* L. and *Chenopodium hybridum* L. were the most dominant species in 2014, while perennial weed *Sorghum halepense* L. and annual weeds *Bilderdykia convolvulus* (L.) Dum. and *Portulaca oleracea* L. were the most dominant species in 2015.

Weeds differ substantially in their response to fertilization. Some weed species (*C. album*) prefer mineral fertilizer AN in favorable 2014 season, while *S. nigrum* and *C. hybridum* gave the highest biomass on plots with organic fertilizer. In dryer 2015 *S. halepense* was abundant in the B3 and B4 treatments (microbiological and organic), whereas *A. theophrasti* dominated in the B2 (mineral fertilizer AN) treatment and *D. stramonium* dominated in the treatment B1 without fertilizer.

The influence of fertilization on weeds depends on the type and quantity of fertilizers, biological crop properties, agronomic management, time and method of fertilization, floristic composition of the weed community. Most of the weed species are characterized by the rapid growth of vegetative biomass and high fertility and because of that they use large amounts of mineral nutrients. Therefore, fertilization can be a powerful factor of influence on weed community in agro-phytocenosis. As some weed species react differently to the content of nutrients, this measure leads to the domination of those species that have adapted to the large amount of nitrogen in the soil (species of the genus *Amaranthus* and *Chenopodium*).

Conclusion

According to the obtained results during investigations of effects of fertilization on floristic composition and abundance of weeds in maize in Zemun Polje the following conclusions can be made: meteorological conditions have very significant influence on floristic composition and abundance of weed community in maize. The weediness in both years was relatively high but significanly higher in 2015.

A total 17 different species in boath seasons, with 3 grasses and 14 broadleaves, were identified. The major percentage of the species falls under the life forms Therophytes (14) and

Geophytes (3). Ecological analysis of weed community of maize indicates that thermophile and heliophile species are dominant, also species with preferences of dry or semi-dry habitats. The fresh and dry biomass of weeds was significantly higher in treatment with microbiological fertilizer in both years followed by treatment with organic fertilizer. Based on abundance and biomass the annual weeds *Solanum nigrum* L. and *Chenopodium hybridum* L. were the most dominant species in 2014, while perennial weed *Sorghum halepense* L. and annual weeds *Bilderdykia convolvulus* (L.) Dum. and *Portulaca oleracea* L. were the most dominant species in 2015.
Better supply of the nutrients causes more emergence of weeds, but at the same time, with the growing competition of crops, weeds are lagging behind in their development and more or less suppressed. Some weed species or ecological groups of weeds can be controled by regulating the content of particular nutrients, pH and other soil properties. Further research on nutrient limitation and on the biology of individual weed species is needed in order to control the negative effects of farmland weeds on crop yield while maintaining a diverse weed community.

Abstract

An increment of human population and limitations of resources on planet Earth require a novel approach in agriculture. One of the ways to fulfill these requirements is to using a less productive land. Utilization of marginally suitable land is an ongoing process. However, a novel genetic variability is required, as well as, the testing of the existing genetic variation for the best possible utilization of these soils. There is about 120000ha of halomorphic soil, solonetz type in Serbia, mainly used as a pasture. The results in this study represent a part of multiyear research of wheat genetic variation grown in abiotically stressful condition of high sodium content of solonetz soil. Three wheat varieties, namely, NSR 5, Pesma and Renesansa were tested for the reaction, through phenotypic variation, in parallel three years trial on chernozem and solonetz soil for plant height and the spike productivity traits, spike length and weight, grain number and weight per spike, and the spike index (SI). Phenotypic variation of individual plants plays more significant role in the grain yield formation in stressful conditions. The variation was examined using AMMI analysis. According to AMMI ANOVA, statistically significant influence of the environment on total trial variation was denoted, as well as, genotype by environment interaction. Results indicate the occurrence of desirable variation within the existing genetic variability that could be exploited to enhance the use-value of less productive land for food production.

Keywords: *wheat, soil, stress, yield components.*

Introduction

The situation human race is facing today and in the future goes as follows - The exact number of people on Earth on 4^{th} of July, 2017, at 13:12 hours was 7,516.011.857. Three minutes later human population grew to 7,516.012.328, souls (Worldometers, 2017). During the 20^{th} Century, the population has grown from 1.7 to 6 billion people. By the 2050, the number of *Homo sapiens* individuals in the World is going to reach 9.1 billion. According to UN estimation food production requires an increment of 70% to meet projected demands in 2050. Annual cereal production will need to rise from 2.1 billion today to about 3 billion tonnes. However, the ongoing processes are urbanization (predicted ratio of urban population in 2050 is 70%, comparing to 49% of today), environmental erosion including arable land degradation and climate change (Wilkinson and McElroy, 2007; FAO, 2009; Myers *et al*., 2017). There is a heavy burden on agriculture to meet the challenge in producing more food, adapt to climate change and adopt more sustainable and efficient mode of production. Moreover, priorities have to be seriously readjusted, for example, according to SIPRI (2017), World military spending in 2016 was 1.69 trillion dollars, while global investments in the food and agribusiness sector in 2013 were a bit more than 100 billion dollars (Goedde *et al.*, 2015). Every available resource is to be utilized, research efforts has to be strengthened, and the attitude towards planet Earth limited resources should be much wiser. In order to contribute to an overall effort, to get more experience and eventual useful results in broadening primary food production, multiyear trials have been established to investigate the influence of halomorphic soil abiotic stress growth conditions on phenotypic variation of broad cereal, bread wheat predominantly, gene pool. The null hypothesis was that the existing genetic variability of semi-dwarf intensive breaded wheat varieties harbor usable gene variation for enhancing tolerance to solonetz soil abiotic stress growth condition. The aim of this article is to follow phenotypic variation of grain yield height and spike traits of three bread wheat varieties that were selected from larger wheat genetic variability.

Material and Methods

Three bread wheat varieties, NSR 5, Pesma and Renesansa were singled out of a large testing sample that have been put in a multiyear trials, because of its performance through the long-term trial. Variety NSR 5, is an early genotype that was better adapted to unfavorable growth conditions, reacting well to agro environmental conditions improvement. Variety Pesma exhibited the favorably variation of genotype by environment interaction (GEI), on average, over positive environmental variation. This reaction was followed with mean grain yield value above trial average. Variety Renesansa reacted to environmental variation showing slightly enhanced GEI that meant favorable response to agro environmental improvement. Though, somewhat more sensitive to environmental variation than variety Pesma, variety Renesansa had grain yield average, commonly, above the experimental mean value (Petrović *et al*., 2008, 2009; Dimitrijević *et al*., 2009, 2011). The experiment was established in three years 2013/14, 2014/15, and 2015/16, at two localities: Kumane village (45.5219940N, 20.1949190E, pH = 9.86) on solonetz soil, and Rimski Šančevi experimental field of the Institute of Field and Vegetable Crops in Novi Sad (45.3249360N, 19.8428830E, pH=6.86) on chernozem, as a parallel control with intensive agricultural practice and the absence of constant stressful growth variation. Plant spike traits, plant height (cm), spike length (cm), spike weight (g), grain weight per spike (g), grain number per spike, and spike index (the ratio between grain weight per spike and spike weight), were followed. The existing genetic variability was tested in Randomized Complete Block Design trial with three replications, in 1m long rows 20 cm apart. 150kg/ha of NPK 15:15:15 fertilizer was applied along with sowing, and 200kg/ha of Potassium ammonium nitrate was additionally applied in spring. Elementary statistics, as well as, AMMI model for sources of variation identification and quantification with the emphasis on genotype by environment interaction have been calculated for studied traits. Statistical significance of mean values was estimated by Fisher's Least Significant Distances (LSD) at the levels of 0.05, and 0.01.

Results and discussion

Statistically significant variation was denoted in the trial. Within additive component of total variation the main source of phenotypic variability was environment, contributing from 60% (plant height) to 75% (grain weight per spike) to the variation of phenotype. Mass traits in contrast to length one, exhibited statistically significant effect of genotype variation in total phenotypic variation. This is the reflection of the gene system that is more quantitative in mass traits than in length one, and the phenotypic variation is more complex in causes. For all the examined yield components genotype by environment (GEI) interaction was statistically significant source of variation showing the presence of cross over interaction, and different reaction to environmental variation wheat varieties in trial. However, the cause of GEI was predominantly carried out on the first principal component (IPCA1), except the spike weight and the grain weight per spike where IPCA2 showed statistically significant, though, rather small effect on GEI (tab. 1).

Table 1. AMMI ANOVA F values statistical significance for plant height (cm), spike length (cm), spike weigh (g), grain weight/spike (g), grain number/spike and spike index for three bread wheat varieties, over six environments

Plant height was close to the trial average for all three varieties over six environments. However, the GEI was quite different. Variety NSR 5 developed the examine trait well in less favorable environmental conditions on this trial results. That is in accordance to Petrović *et al.* (2012), who found NSR-5 as a flexible variety suitable for a wide range of soil conditions. Varieties Pesma and Renesansa performed similarly during the trial (tab. 2).

Spike length had small additive effect differences, with mean values close to trial average, but differed greatly in multiplicative component of phenotypic variation. Varieties Pesma and NSR 5 showed higher GEI. Variety Renesansa was the most stable one, over the examined environmental variation (tab. 3).

Spike weight and grain weight per spike were traits of special interest. Though plant grain yield in intensive agriculture has small positive correlation to grain yield per hectare, in stress conditions, stronger positive correlation exists between these two properties (Denčić *et al.*, 2000). Individual plant performance gains importance in abiotic stress growing conditions. In that sense, individual spike productivity represents an important trait that contributes to grain yield formation per area unit in agricultural practice other than intensive (Dimitrijević *et al.*, 2012). Varieties varied more in GEI than in main effect. The different nature of GEI of NSR 5 and varieties Pesma and Renesansa is evident, where Renesansa was the most stable (tab. 4 and 5).

Grain number per spike showed the similar pattern of variation sources behavior, like the rest of examined traits. Additive component of phenotypic variability was smaller than multiplicative. Variety NSR 5 reacted differently to environmental variation, showing the higher mean value of the trait, but had the higher value of GEI in the same time. Varieties Pesma and Renesansa were reacted similarly to the same environmental variation. Variety Renesansa had the most stable reaction, but somewhat lower average than the mean of the trial (tab. 6).

Table 6. Mean values for grain number/spike, and the first principal component (IPCA) for three bread wheat varieties, over six environments where abbreviations RŠ and KU stand for localities Rimski Šančevi and Kumane

Spike index could be a reliable marker of high yielding varieties that could be recognized "with quite certainty" (in 91% of cases) after spike index between 0.75-0.83, and higher (Kobiljski and Denčić, 1997). If that was so, variety Renesansa appeared to be a very promising one in abiotic stress conditions of solonetz soil at the locality of Kumane, but in 2016, only. Phenotypic variation for this indexed parameter was of complex nature, since it consists of two distinctively polygenic traits. Main and multiplicative sources of variation were observed. Varieties Renesansa and Pesma had considerable higher mean values of SI than NSR 5, with smaller GEI, as well. Once again, varieties Pesma and Renesansa responded better in different environments than the variety NSR 5 (tab. 7).

Table 7. Mean values for spike index, and the first principal component (IPCA) for three bread wheat varieties, over six environments where abbreviations RŠ and KU stand for localities Rimski Šančevi and Kumane

Varieties	Environments						Mean	IPCAg1
	E1 RŠ 2014	E2 KU 2014	E3 RŠ 2015	E4 KU 2015	E5 RŠ 2016	E6 KU 2016

$LSD_{0.05}$=0.04 $LSD_{0.01}$=0.05								

Conclusions

According to the results, the main source of phenotypic variation for examined traits was of multiplicative nature. Additive sources of variation was partly notable, but small number of genotypes of similar ideotype influenced that environmental variation had a greater share in total variation than genotypes. Variety NSR 5 had better performance in less favorable growth conditions, while varieties Renesansa and Pesma reacted similarly to close and more favorable environmental variation, but quite differently than NSR 5. Genetic background of the examined varieties harbor usable genetic variation for further improvement of wheat performance in abiotic soil stress growth conditions, hence all other mode of agricultural practice out of intensive. However, genetic usability of the variety NSR 5 and varieties Pesma and Renesansa differs according to breeding goals and, consequently, selection criteria.

Abstract

The experiment was established in the experimental field of the Small Grains Research Centre in Kragujevac (Serbia) during the 2011/12 and 2012/13 growing seasons. The objective of this study was to investigate the influence of genotype and environment on the yield of winter barley cultivars (Jagodinac, Maksa, Rekord and Grand). The following characteristics were analysed: grain yield, 1000 grain weight and test weight. The highest yield of all tested varieties of winter barley was achieved by Grand (5.081 t/ha), Maksa (4.902 t/ha) and Rekord (4.871 t/ha), while the lowest yield was obtained by Jagodinac cultivar (4.733 t/ha). The lowest 1000 grain weight for all studied locations/sites and the year was recorded for the cultivar Jagodinac (42.60 g), and the highest the cultivar Grand (49.02 g). The largest two-year average value of test weight was found in the cultivar Grand (69.87 kg/hl), and lowest in cultivar Rekord (69.39kg/hl). Very highly significant influence of the cultivar on 1000 grain weight was established at investigated winter barley cultivars by variance analysis, while genotype influence on grain yields, 1000 grain weight and test weight were highly statistically significant. Significant differences in grain yield at investigated barley cultivars were found relative to the interaction environmental factors and cultivars.

Key words: *cultivar, grain yield, winter barley*

Introduction

Barley is globally cultivated on an area of about 47.5 million hectares, an average yield of 2.6 t/ha being realized making it the fifth grown crops (maize, rice, wheat and soybeans). The total production of 124 million tons of barley ranks it fifth among all cultivated cultures. The largest areas under barley are in Russia, Australia, Ukraine and Canada **(**FAO, 2010). Barley cultivars that were in production until the end of the eighties were characterized by the lower yields, good technological quality and higher stem sensitive on lodging. Due to lower resistance on lodging, that cultivars were grown at modest soils and therefore they had lower yields (Bratković *et al*., 2014; Đekić *et al*., 2012; Jelić *et al*., 2014). Agronomic cultivar value depends not only on its genetic potential for yield, but also on its ability to achieve genetic potential under different conditions of production (Mladenović *et al*., 2009). New varieties are characterized by good technological quality, better resistance to lodging and diseases, shorter stem and more efficient assimilates usage (Pržulj *et al.,* 2004). Malting barley is expected to have 1000 grain weight of 40 and 46 g and test weight of 68 to 75 kg/hl (Paunović *et al*., 2006). The yield per unit area is the result of the action of factors of variety fertility in interaction with environmental factors. Therefore, the yield is a relative term and is determined by the variety, environmental conditions and the level of applied technology. Yield is largely dependent on the genetic potential, which could be defined the yield of variety which was grown in conditions on which it had been adapted, with adequately amounts of water and nutrients and efficient control of pests, diseases, weeds and other stresses (Đekić *et al*., 2011). Yields considerably vary primarily as a result of agro-ecological conditions during the growing season (Đekić *et al*., 2015; Popović *et al*., 2011). Barley is in the usage as an important component of beer and malt production, important and quality component in animal feeding, partially in human nutrition as well as a component in processing industry (Đekić *et al*., 2015; Pržulj and Momčilović, 2002). As a top-quality forage crop plant, barley is used as fodder unit in meals balancing in feed (Đekić *et al*., 2010; Bratković *et al*., 2014). The aim of this study was the determination of the cultivars and environmental factors influence on differences in stability and adaptability of cultivars regard the grain yield, 1000 grains weight and test weight of tested winter barley cultivars, as well as specificity of cultivars exploring regard growing seasons conditions.

Materials and methods

Experimental design and statistical analysis

During the 2011/12 and 2012/13 growing seasons, four cultivars of winter barley (Jagodinac, Maksa, Rekord and Grand), cultivated at the Small Grains Research Centre in Kragujevac (Serbia) were investigated. Experiments have been conducted in randomized block systems, with a plot size of 5 m^2 (2 m x 2.5 m) in five replicates. The usual techniques for barley production were applied, and it was done in the optimum sowing time in late October, 400 kg/ha of fertilizer NPK 15:15:15 was added in the fall on the investigated plots, while during the spring fertilization, 300 kg/ha (KAN) was supplemented. The following properties were analyzed: grain yield (t/ha), 1000 grain weight (g) and test weight (kg/hl). On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Meteorological conditions

Kragujevac area is characterized by a moderate continental climate, which general feature is the uneven distribution of rainfall by months. Data in Table 1 for the investigated period (2011-2013) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average for Kragujevac region, regarding the meteorological conditions.

Table 1 Middle monthly air temperature and the amount of rainfall amount (Kragujevac)

Year	Months									Average
	X	XI	XII	I	II	III	IV	V	VI	
Mean monthly air temperature (^oC)										
2011/12	10.4	3.1	4.6	0.7	-3.7	8.1	12.9	16.1	23.0	8.35
2012/13	13.5	9.5	1.7	2.9	4.0	6.5	13.4	18.2	19.9	9.96
Average	12.5	6.9	1.9	0.5	2.4	7.1	11.6	16.9	20.0	8.87
The amount of rainfall (mm)										
2011/12	33.3	1.3	43.3	117.2	60.1	5.7	74.5	87.3	57.8	480.5
2012/13	56.2	17.7	16.4	62.4	84.3	102.0	41.2	70.8	30.3	481.3
Average	57.6	70.4	71.5	58.5	62.7	45.4	48.9	56.6	58.2	529.8

The average air temperature in 2011/12 was lower by 0.52°C and 2012/13 was higher by 1.09°C. The sum of rainfall precipitation in 2011/12 was lower by 49.3 mm, where the sum of rainfall in 2012/13 was 48.5 mm lower than the average of many years and with a very uneven distribution of precipitation per months. Spring months March and April in 2011/12 were the surplus of precipitation, what affected unfavorable on the crops. During the March in 2012/13 it was 102.0 mm of rainfall, what was 56.6 mm more compared with the perennial average. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall over the growing season 2011/12 were considerably more favorable, what resulted with the increment of yields during that year. Based on the fact that sufficient amounts of rainfall in these months are very important for the successful production of cereal crops it can be concluded that the years in which the researches were conducted were favorable for the barley growing.

Soil and weather conditions

Before the commencement of the experiment, soil samples were taken from the sample surface and the chemical analysis of soil was performed. On the basis of obtained results, it was revealed that the soil belongs to the smonitza type, with relatively high clay content, and unfavorable physical properties. The humus content in the surface layer of soil was low (2.38-2.64%), and a substitution and total hydrolytic acidity were quite high (pH H_2O=5.99, KCl=4.56). The soil was medium provided with total nitrogen (0,11-0,13% N) and easily accessible potassium (10-14 mg/100 g soil K_2O), while the available phosphorus content was low (under 10 mg/100 g of soil P_2O_5).

Results and discussion

Average values of yield (t/ha), test weight (kg/hl) and 1000 grain weight (g) at investigated Kragujevac's winter barley cultivars grown at the Small Grains Research Centre in Kragujevac during two growing seasons, 2011/12 and 2012/13, are presented in Table 2.

Table 2. Average values of investigated barley cultivars characteristics

Traits	Cultivar	2011/12			2012/13			Average		
		x	S	Sx	x	S	Sx	x	S	Sx
Grain yield (t/ha)	Jagodinac	5.680	0.129	0.058	3.786	0.104	0.046	4.733	1.004	0.318
	Maksa	5.474	0.575	0.257	4.330	0.110	0.049	4.902	0.718	0.227
	Rekord	5.662	0.058	0.026	4.080	0.074	0.033	4.871	0.836	0.264
	Grand	5.942	0.301	0.135	4.220	0.202	0.090	5.081	0.939	0.297
1000 grain weight (g)	Jagodinac	45.05	0.414	0.185	40.15	0.392	0.175	42.60	2.610	0.825
	Maksa	50.59	0.850	0.380	44.69	0.850	0.380	47.64	3.211	1.015
	Rekord	51.38	0.766	0.343	45.67	0.465	0.208	48.52	3.068	0.970
	Grand	51.98	0.342	0.153	46.07	0.442	0.198	49.02	3.137	0.992
Test weight (kg/hl)	Jagodinac	68.83	0.539	0.241	70.03	0.699	0.312	69.43	0.864	0.273
	Maksa	68.84	0.576	0.258	69.98	1.037	0.464	69.41	0.993	0.314
	Rekord	68.82	0.829	0.371	69.96	0.723	0.323	69.39	0.948	0.300
	Grand	69.42	0.939	0.420	70.32	0.589	0263	69.87	0.878	0.278

During the first year of investigations, cultivar Grand achieved the highest grains yield (5.942 t/ha), followed by Jagodinac (5.680 t/ha) and Rekord (5.662 t/ha), while the lowest yield was at Maksa cultivar (5.474 t/ha). During the second year of investigations (2012/13), the yield of Maksa cultivar was the highest with 4.330 t/ha, while the slightly lower yield was realized by Grand cultivar (4.220 t/ha). Average grains yield observed in the two-year period was the highest at Grand variety (5.081 t/ha), while the lowest yield was obtained by Maksa cultivar

(4.902 t/ha). Considerable variation in yield depending on years of research have established Jelić *et al*. (2007), Đekić *et al*. (2011), Popović *et al*. (2011) and Bratković *et al*. (2014). During the first and second years of investigation, Grand cultivar achieved the highest average 1000 grain weight (51.98 g and 46.07 g) compared with other tested barley cultivars. During the both years of investigation, the lowest average value of 1000 grain weight achieved the Jagodinac cultivar (45.05 g and 40.15 g). Pržulj *et al*. (2004) state that good quality brewer's grain needs to have the 1000-grain weight of 45-50 g. The barley cultivar Grand has achieved the highest test weight in both years of investigation compared to other tested barley cultivars (69.42 kg/hl and 70.32 kg/hl). The average two-year value of test weight at Grand cultivar was 69.87 kg/hl, while the lowest average was at Rekord cultivar (69.39 kg/hl). Grain of investigated barley cultivars was characterized by good physical characteristics; especially regarding the test weight and 1000 grain weight. Realized average values of these characteristics in the study were slightly higher than the values obtained by Jelić *et al*. (2007), Bratković (2014) and Đekić *et al*. (2015).

Table 3. Analysis of variance of the tested parameters (ANOVA)

Effect of year on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(df1,2) 1, 38	p-level

1000-grain weight (g)	0.573417	0.360812	1.589237	0.211219
Test weight (kg/hl)	0.044250	0.578031	0.076553	0.972202

*Statisticaly significant difference (P<0.05) **Statisticaly high significant difference (P<0.01)

Table 3 shows the impact of the year, cultivar and interaction of year x cultivar on yield, 1000-grain weight and test weight. Analysis of variance in double-rowed barley cultivars tested showed statistically highly significant differences in yield, 1000-grain weight and test weight in relation to the growing season (P<0.01). The ANOVA indicated highly significant effects of the cultivar and 1000-grain weight (F_{exp}=9.596594**). Statistically significant difference in grain yield is determined under the influence of the interaction year x cultivar. Our results are consistent with the results Madić *et al*. (2009), where the authors state that the growing conditions in the observed years had a significant impact on yield. These results are in agreement with the results obtained by Đekić *et al*. (2015) in double-row barley, showing very highly significant effects of the year and grain yield (F_{exp}=18.6766***) and significant effects of the 1000 grain weight (F_{exp}=4.10989**). Achieved statistically significantly higher yields in 2011/12 were, primarily, the result of heavy rainfalls and their good distribution as well as favorable air temperatures during the vegetation period (Table 1). Đekić *et al*. (2015)

in his research states that the air temperatures and the rainfall amount and distribution during the barley growing season have the greatest impact on high yields and grain quality.

Table 4. Correlation coefficients by studied environments in two-rowed barley

	Grain yield ($t\ ha^{-1}$)	1000-grain weight (g)	Test weight ($kg\ hl^{-1}$)
Correlations between the traits analyzed in the 2011/12			
Grain yield (t/ha)	1.00	0.21^{ns}	0.36^{ns}
1000-grain weight (g)		1.00	0.23^{ns}
Test weight (kg/hl)			1.00
Correlations between the traits analyzed in the 2012/13			
Grain yield (t/ha)	1.00	0.72^{*}	0.04^{ns}
1000-grain weight (g)		1.00	0.11^{ns}
Test weight (kg/hl)			1.00

Positive correlations were observed between grain yield, 1000-grain weight and test weight in barley, as well as individual values for each environment, are shown in Table 4. Positive and medium correlations were also found between grain yield and 1000-grain weight in the 2012/13 year ($r=0.72^{*}$). Correlative dependence of yield and test weight depending on the tested environment in barley ranged from 0.36 (2011/12) to 0.04 (2012/13) and none showed significance. The correlation coefficients between 1000-grain weight and test weight had positive values of the correlation coefficient in the external environment. Negative correlations of yield and 1000-grain weight, seeds that are not significant, are confirmed in their study of barley by Dodig (2000). Similar values of correlation coefficients that were not significant for yield were also recorded for the test weight ranging from 0.335 is pointed out by Bratković (2014).

Conclusion

Based on the gain results during the two-year investigation on four Kragujevac's winter barley cultivars, it can be concluded that the grain yield of barley ranged from 4.733 t/ha (Jagodinac) to 5.081 t/ha (Grand). Maksa and Rekord cultivars have achieved satisfactory results (4.902 t/ha and 4.871 t/ha). During 2011/12, statistically significantly higher grain yield per area unit, as well as 1000 grain weight was achieved, compared with 2012/13 year. Very highly significant differences in yield, 1000-grain weight and test weight at investigated barley were found in relation to the year. Furthermore, 1000-grain weight was significantly affected by the cultivar interaction ($p<0.05$). The interaction of grain yield and year x cultivar significant differences at investigated barley cultivars ($p<0.01$). In barley cultivars correlation coefficient between 1000-grain weight and test weight was positive.

Abstract

Effects of mineral nutrition efficiency of wheat have been studied at the stationary field trial of the Small Grains Research Centre in Kragujevac (Serbia) for two years (2008/09 and 2009/10). In this paper, average yields from 7 treatments of increasing doses of nitrogen, phosphorus and potassium nutrients have been studied. The objective of this study was to investigate the influence of mineral nutrition on the yield of winter wheat varieties Takovčanka. Investigation showed a considerable variation of grain yield depending on mineral nutrition. The study showed that most investigated wheat cultivar achieved their highest grain yields less than 120 kg/ha nitrogen rate, phosphorus rate of 100 kg/ha P_2O_5 and potassium rate of 60 kg/ha K_2O (3.622 t/ha). Thousand grain weight of wheat significantly varied across years, the highest average thousand grain weight of winter wheat cultivar investigated was achieved in the NP2K variant with the higher phosphorus rate (42.47 g). Analysis of variance was found to have the highly significant effect of years on 1000 grains weight and test weight, and significant effect of years on grain yield. Different combinations of fertilization had the most highly significant influence on grain yield and thousand grain weight. Positive correlations were observed between grain yield and thousand grain weight in all years. Grain yield was significantly positively correlated with 1000-grain weight only in the 2008/09 ($r=0.66^*$) and 2009/10 ($r=0.79^*$). Significant positively and medium correlations were observed between 1000-grain weight and test weight in P treatment.

Key words: *fertilization, yield, quality, wheat*

Introduction

In the last few decades, a huge experimental material on mineral nutrition and fertilization of wheat have been collected. Constant progress in the selection and creation of new varieties gives strong incentive to the studies of various problems of mineral nutrition of wheat. Thus, with the advent of new varieties of wheat (significantly different in regard to a series of useful properties, especially significantly higher yield potential), it was established that their requirements in terms of mineral nutrition are also significantly higher (Đekić et al., 2014, 2016; Jelić et al., 2014).

Winter wheat uses relatively large amounts of mineral elements during the growing season and has a high demand in regard to the soil fertility (Malešević, 2008; Jelić et al., 2013b). Of all macro elements that are taken from the soil, wheat consumes mainly nitrogen, and to lesser extent potassium, significantly less phosphorus and even less sufhur, magnesium and calcium (Jelić et al., 2013a). The quantities of nutritive elements, which are taken from the soil by wheat during the growing season, depending primarily on the grain yield and mass of vegetative organs. In our conditions, usually the amount of nitrogen to be applied for the high yield, ranges in the total value from 80-120 kg/ha, depending on the agrochemical properties of the soil. According to Malešević et al. (2008), in the ten years of investigation of the impact of increasing nitrogen doses on grain yield, the yield has increased with the increase of the amount of nitrogen. The greatest grain yield was achieved with the highest nitrogen dose, 180 kg ha. However, the average yield achieved in this treatment was not statistically significantly different than the yield obtained with 120 kg/ha N and the authors recommend this quantity as optimum. Similar results are obtained in a number of other studies (Đekić et al., 2014, 2015; Jelić et al., 2014, 2015). In regard to the elements of mineral nutrition, nitrogen plays a major role in increasing the yield of wheat (Malešević, 2008; Kastori et al., 2005). Nitrogen demonstrates the greatest impact when it is used together with phosphorous and potassium, and these two elements, when used without nitrogen, not only do not provide a significant increase in yield of wheat but often suppress it (Đekić et al., 2014; Jelić et al., 2013c). The nutrient deficiency, as well as surplus of fertilizer, can cause a decrease in yield of wheat (Kastori et al., 2005). The use of larger than necessary amounts of fertilizer not only is it economically not justifiable in terms of the direct resources, but in a large number of plant species and varieties such doses may be harmful (lodging and, more intense occurrence of diseases in wheat, etc.), and are common cause of pollution of agroecosystems. The use of fertilizers and certain amendments on extremely acid soils in certain years, particularly those less favorable for production, almost certainly has the different effect on grain filling, resulting in diverse relationships between productive and qualitative traits. The present results confirm the opinion of many authors that the traits analysed and their correlations are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Jelić et al., 2015; Đekić et al., 2016). Because of the appearance of new demanded cultivars at permanent changes in soil fertility level and environmental conditions, still exist need to researches mineral nutrition of wheat, as well as determine optimal rates and balanced nutrition ratios in concrete agro-ecological conditions. The main goal of this research was to investigate the effect of long-term applications of identical amounts and ratios of nitrogen, phosphorus and potassium on the yield components of winter wheat cultivar Takovčanka has grown on a vertisol soil.The study was also aimed at optimizing fertilization for maximum profitability in the future wheat production of Central Serbia.

Materials and methods

Materials and field trials

The study was carried out in a stationary field trial involving fertilization over a two years period from 2008/09 to 2009/10. Trials were first set up in the experimental fields of the Small Grains Research Centre in Kragujevac in 1970. Plot size was 50 m^2. The wheat cultivar used in the experiment was Takovčanka, the dominant cultivar in the production region of Serbia. This investigation included an untreated control and six variants of fertilization: N (120 kg N/ha), P (100 kg/ha P_2O_5), NP1K (120 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O), NP2K (120 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O), NP1 (120 kg/ha N, 60 kg/ha K_2O) and NP2 (120 kg/ha N, 100 kg/ha P_2O_5). A non-fertilized variant served as a control. Total amounts of phosphorus and potassium fertilizers and half the nitrogen rate are regularly applied during pre-sowing cultivation of the soil. The trial was set up in a randomized block design with five replications. Fertilization was regular and followed a long-time scheme.

The crop was harvested at full maturity. Grain yield (t/ha) was harvested and reported at 14% moisture. Three parameters of grain quality, namely test weight (kg/hl) and 1000-grain weight

(g) were analyzed. Thousand grain weight was determined using an automatic seed counter. Test weight is the weight of a measured volume of grain expressed in kilograms per hectoliter.
On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Soil and agroecological conditions
The trial was set up on a vertisol soil in a process of degradation, with heavy texture and very coarse and unstable structure. The humus content in the surface layer of soil was low (2.22%). Soil pH indicates high acidity (pH in H_2O 5.19; pH in KCl 4.27), nitrogen content in soil is medium (0.11-0.15%), while the content of available phosphorus ranges from very low (1.7-2.9 mg/100 g soil) in the N variant to very high (26.9 mg P_2O_5/100 g soil) in the NPK variants of fertilization. Available potassium contents are high, ranging from 19.5 to 21.0 mg K_2O/100 g soil.
This study was conducted over a three-year period in the Šumadija region, Central Serbia, on a Vertisol soil, at Kragujevac location, 173-220 m a. s. l. (44° 22′ N, 20° 56′ E), in a temperate continental climate having an average annual temperature of 11.5°C typical of Šumadija districts in Serbia and a rainfall amount of about 550 mm. The data in Table 1 for the investigated period (2008-2010) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average of Kragujevac region regard the meteorological conditions.

Table 1. *Mean monthly air temperature and precipitation (Kragujevac)*

Year	Months										Aver.
	X	XI	XII	I	II	III	IV	V	VI	VII	
Mean monthly air temperature (°C)											
2008-09	13.1	8.5	4.4	2.3	2.0	6.8	13.4	17.8	20.2	22.5	11.1
2009-10	11.7	8.8	2.6	0.9	3.2	7.2	12.1	16.5	20.2	23.1	10.63
Average	11.8	5.6	1.9	0.6	2.0	6.2	11.2	16.2	19.4	21.3	9.62
The amount of rainfall (mm)											
2008-09	31.3	30.6	29.7	57.7	76.9	40.3	16.8	46.0	137.8	25.2	492.3
2009-10	102.6	77.5	194.2	57.0	150.5	43.3	142.2	116.7	196.7	14.8	1095.5
Average	47.5	50.0	49.5	36.8	33.9	43.5	51.5	64.8	79.3	62.5	479.3

The average air temperature in 2008/09 was higher by 1.48°C and 2009/10 was higher by 1.01°C. The sum of rainfall precipitation in 2008/09 was higher by 13.0 mm, where the sum of rainfall in 2009/10 was 616.2 mm higher than the average of many years and with a very uneven distribution of precipitation per months. Spring months April, May and June in 2009/10 were the surplus of precipitation, what affected unfavorable on the crops. During the April in 2009/10 it was 142.2 mm of rainfall, what was 90.7 mm more compared with the perennial average. During the month of June in 2009/10 it was 196.7 mm of rainfall, what was 117.4 mm more compared with the perennial average.

Results and discussion

Based on the analysis of variance, it can be concluded that are significant differences in grain yield regarding the year of investigation ($F_{exp}=4.490^{*}$) and highly significant differences at thousand grain weight ($F_{exp}=29.345^{**}$) and test weight ($F_{exp}=10.785^{**}$). Highly significant differences in grain yield and thousand grain weight regard the fertilization of investigation ($F_{exp}=5.132^{**}$ and $F_{exp}=8.380^{**}$). In the dual interaction between the year and fertilization, highly significant effects differences in grain yield and thousand grain weight (Table 2).

The use of fertilizers and certain amendments on extremely acid soils in certain years, particularly those less favorable for production, almost certainly has different effects on grain filling, resulting in diverse relationships between productive and qualitative traits. The present results confirm the opinion of many authors that the traits analyzed are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Đekić et al., 2013, 2014, 2016; Jelić et al., 2013c, 2014).

Fertilization had a significant effect on grain yield (Table 3). The grain yield of winter wheat significantly varied across years, from 1.101 t/ha to 4.432 t/ha in 2008/09 and from 1.066 t/ha to 2.883 t/ha in 2009/10 (Table 3). In the two-year period, the highest average grain yield of winter wheat cultivar investigated was achieved in the NP2K variant with the higher phosphorus rate (3.622 t/ha). The average grain yield was lowest in the unfertilized control (1.083 t/ha) and significantly higher in fertilized treatments, ranging from 3.284 t/ha (NP2-treatment) to 3.622 t/ha (NP2K). NP1 fertilization induced a significant increase in grain yield, which 2.039 t/ha higher as compared to the control, respectively. The study showed that most investigated wheat cultivar achieved their highest grain yields less than 120 kg/ha nitrogen rate, phosphorus rate of 100 kg/ha P_2O_5 and potassium rate of 60 kg/ha K_2O. Grain yield showed a significant dependence on the year and very significant dependence of fertilization (Table 2).

The significantly lower wheat grain yields achieved in the N and NK trial variants than in the NPK and NP variants resulted from the existing phosphorus deficit in the soil, and low pH and high content of mobile Al in soil solution (Jelić et al., 2013b).

Nitrogen, phosphorus and potassium application, particularly on acid soils poorly supplied with these nutrients, has a high effect on the grain yield of oats and other cereal crops (Browne et al., 2006; Jelić et al., 2013a; Mohr et al., 2007; Rashid et al., 2007). Presented results confirm the opinion of many authors that the traits analyzed are genetically determined, but strongly modified by the nutrient status and weather conditions (Đekić et al., 2014; Jelić et al., 2013c).

The control and P-treatment achieved the lowest average 1000 grain weight during the both years of investigation compared with other tested treatments (Table 3). Thousand grain weight of wheat significantly varied across years, from 37.20 g to 44.86 g in 2008/09, from 33.16 g to 40.08 g in 2009/10. During the first year of investigations, the highest average value of

1000-grain weight achieved the NP2K (120 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O), NP1 (120 kg/ha N, 60 kg/ha P_2O_5) and NP2 (120 kg/ha N, 100 kg/ha P_2O_5) treatments (44.86 g, 44.10 g and 44.30 g). During the second year of investigations (2009/10), the highest average value of 1000 grain weight achieved the NP2K (120 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O) treatment (40.08 g). In the two-year period, the highest average thousand grain weight of winter wheat cultivar investigated was achieved in the NP2K variant with the higher phosphorus rate (42.47 g). Furthermore, 1000-grain weight was significantly affected by the year x fertilization interaction (Table 2). A number of authors (Browne et al. 2006; Đekić et al. 2013, 2016; Jelić et al., 2013a, 2014) underline that thousand grain weight is a cultivar-specific trait, with considerably higher variations being observed among genotypes than among treatments or environmental factors.

	NP2	70.20	4.083	1.826	71.09	3.132	1.401	70.64	3.462	1.095

Test weight is an indicator of grain quality, particularly grain monetary value. Table 3 presents average values for grain test weight across years and treatments. All testing fertilization variants had test weight greater than 70 kg/hl, except control, N and P variants. During the first year achieved the highest test weight at NP1-treatmet (70.69 kg/hl), followed by NP2 (70.20 kg/hl), while the lowest test weight was the control (66.03 kg/hl). During the second year of investigations, the test weight of NP1K was the highest with 72.45 kg/hl, while the slightly lower test weight was realized by NP2K (72.05 kg/hl). The average two-year value of test weight at NP1K was (70.86 kg/hl) and NP2K (70.96 kg/hl), while the lowest average two-year value was at control treatment (68.69 kg/hl). Grain test weight showed a very significant dependence on the year (Table 2). In all years, the use of different treatments induced a significant increase in grain test weight.

Table 4. *Correlations between the traits analyzed during 2008-2010*

Traits	Correlations in 2008/09			Correlations in 2009/10		
	GY, t/ha	1000 GW, g	TW, kg/hl	GY, t/ha	1000 GW, g	TW, kg/hl
Grain yield (t/ha)	1.00	0.66*	0.52*	1.00	0.79*	-0.09^{ns}
1000-grain weight (g)		1.00	0.36*		1.00	0.05^{ns}
Test weight (kg/hl)			1.00			1.00

Positive and significantly correlated correlations were observed (Table 4) between grain yield and thousand grain weight in all years. Testing the correlation coefficients between grain yield and test weight of wheat (Table 4) was found positive and medium significantly correlated between in 2008/09, but negative and low correlations between in 2009/10. However, thousand grain weight were medium significantly positively correlated with grain yield only in the first year (r=0.66*) and strong significantly positively correlated in the second year (r=0.79*). The results suggest that grain yield and quality formation is affected by both genetic and environmental factors (Đekić et al., 2014, 2016; Jelic et al., 2015).

Table 5. *Correlation coefficients for the traits analyzed across treatments*

Correlations between the traits analyzed in the unfertilized control

Grain yield, t/ha	1.00	0.79**	-0.20^{ns}
1000-grain weight, g		1.00	-0.17^{ns}
Test weight, kg/hl			1.00
Correlations between the traits analyzed in the 80 kg/ha N and 100 kg/ha P_2O_5			
Grain yield, t/ha	1.00	0.80**	0.19^{ns}
1000-grain weight, g		1.00	-0.14^{ns}
Test weight, kg/hl			1.00

Table 5 shows the correlation coefficients between the studied fertilization treatments and analyzed traits. Positive correlations were observed between grain yield and thousand grain weight in all treatments. Negative correlations were observed between thousand grain weight and test weight in all treatments. Positive and strong correlations were also found between grain yield and thousand grain weight in the NP1-treatment ($r=0.79^{**}$) and NP2 treatment ($r=0.80^{**}$). The present results confirm the opinion of many authors that the traits analyzed and their correlations are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Đekić et al., 2014; Jelić et al., 2013a; 2015). Đekić et al. (2016) stated positive correlation between grain weight and grain yield.

Conclusion

Based on the gain results during the two-year investigation on seven treatments fertilization, it can be concluded that the highest yield achieved the treatment NP2K (3.622 t/ha). The highest average thousand grain weight of winter wheat cultivar investigated was achieved in the NP2K variant with the higher phosphorus rate (42.47 g). All testing fertilization variants had test weight greater than 70 kg/hl, except control, N and P variants. Considering the average values during the 2008-10 period, it was evident that the 1000 grain weight and test weight were highly statistically significantly different between the years ($p<0.01$) and significantly different between of years on the grain yield ($p<0.05$). Effect of fertilization treatments on the grain yield and 1000-grain weight was highly statistically significant. Also, the effect of the interaction of the year x fertilization on the grain yield and 1000-grain weight was significant. Investigations of year x fertilization interactions present the important basis for the further more successful growing, breeding and zoning of wheat. Significantly positively and medium correlated with yield and 1000 grain weight both in 2008/09 (0.66^{*}, respectively), and significantly positive and strongly correlated in 2009/10 (0.79^{*}, respectively). Significant positively and medium correlations were observed between 1000-grain weight and test weight in P treatment.

Abstract

Vegetable production is one of the most intensive forms of agricultural production, although the areas of that production are getting smaller and smaller, regardless of our favourable ecological conditions. In Serbia, in 2006, vegetables were grown on 8% arable land. According to the latest data concerning the structure of planted arable land and gardens, vegetable accounts for 2.5%. Large regional deviations (differences) in achieved yield of the observed cultures can be noticed in Serbia. This paper tried to determine the place of Serbia when vegetable production is in question, in relation to the other neighbouring countries of the former Yugoslavia. In 2014, only Bosnia and Herzegovina had lower yield than Serbia. But, all the regional countries have something in common: lower average yield than EU. What encourages is the fact that the yield significantly increased in 2015 in relation to the previous year, making us approach the average production of our neighbouring countries. Having in mind that the vegetable fields are becoming smaller and smaller, production mainly stagnates. All 5 observed cultures are mostly imported in our country, but since the last five years, we haven't noticed any regularity, i.e. that one culture distinguishes more than the others, or that the import is only of seasonal character. The aim of this paper is to examine the conditions in vegetable production in Serbia, to compare them with those in our neighbouring countries which also went through the transition period in order to determine the problems of vegetable production in Serbia and how to reduce them.

Key words: *Vegetable production, Yield, Serbia.*

Introduction

The reason for decreasing vegetable areas, in spite of favourable agroecological conditions as well as long tradition in the families of our producers is connected to the fact that they are faced with a lot of problems, among which are the following:
Low yield which influences incompatibility on the foreign market.
Our market is too open for import, both in off-season and season, not considering the needs of our domestic producers. Serbia exports vegetables annually in the value of only $ 96.3 million, although real opportunities are far greater (Ilin et al, 2013). Generally, trends in vegetable trade are getting worse in Serbia year after year, which points to deep structural problems in production, processing and trade (Živkov et al, 2012).
The production is not coordinated, making a great variety of quantity and quality supply.
In the private sector, there is a much more pronounced fragmentation of the property. In European Union, the average size of the farm is 20.7 ha, which is five times greater than the average size of the family farm in Serbia (Pejanović, 2013).
The main problem of the producer is not how to produce, but how to sell some sort of vegetable, due to poorly organized purchase of vegetable products in a larger territory of our country.

All the above mentioned problems have been recognized for several generations, not nowadays.
In order to recognize where Serbian vegetable growing is now, we compared our production with the production in the region, which are in a sense similar according to the degree of development and production conditions. The aim of this paper is to suggest the measures of strategy vegetable growing development, as well as agricultural production in general, after making the analysis of vegetable growing production.

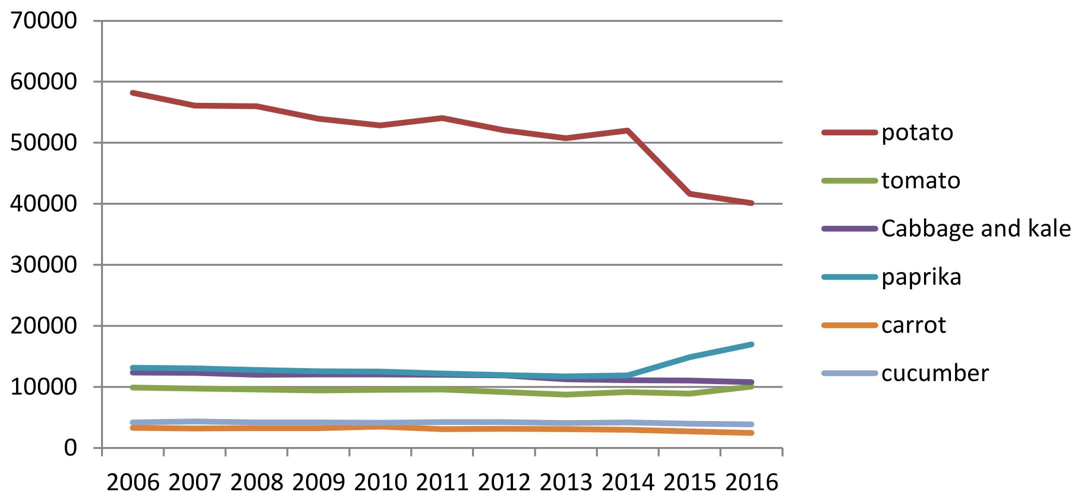
Materials and methods

In this paper we used data from the following sites: *Food and agriculture Organization of the United Nations* (FAOSTAT), *Trade Map* of *International Trade Centre* (ITC) *Statistical Office of the Republic of Serbia* (RZS) and *System of market information of agriculture in Serbia* (STIPS). Data from different literature sources have been compared and on the basis of that conclusions were drawn.

Results and discussion

The production of vegetables and potatoes in Serbia in the last 10 years

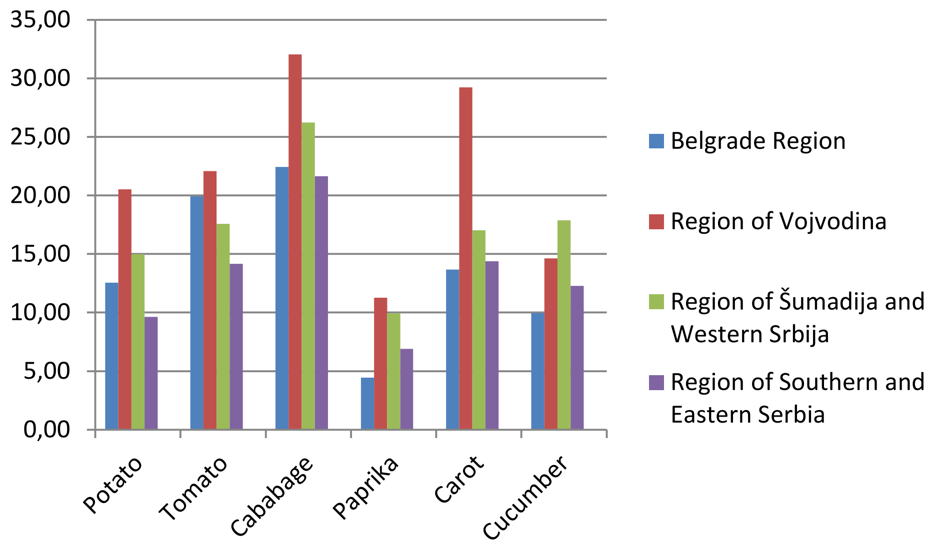
Potato has been a dominant crop for the last ten years. There are many reasons for that. As it is already known, potato is an industrial crop used in many ways (starch, alchocol, spiritus, even in electric current production), it is a tradition and habit that potato is a dominant crop in nutrition, it can easily be kept and storaged in contrast to some other crops, as well as in some regions it is the most acceptable crop for growing due to edaphic and ecological conditions. During the period of ten years, potato production covered the area of 41,9% in relation to totally 10 sorts whose areas are noticed by RZS, i.e. 53000 ha were used for potato growing. The expected potato production in 2016/ 2017 leads to decreasing areas to 40000ha which is 19% lower than the previous year.



Graph. 1. The areas with potatoes and vegetables from 2007 – 2016 in ha

The analogy can be made between average potato producers and average vegetable producers. The most potato producers 36% are on 2 – 5ha farms (data taken by MPZZS). Speaking about the crops, increasing and decreasing depend on their refunding in the previous year, and potato production is the most illustrative example. In 2014, the yield in the Republic was 11,4 t ha^{-1}, in 2013 it was 15,1 t ha^{-1} , i.e. 24,5% higher. In the year when the yield was better, it could be sold at 35 – 40 RSD., while in 2014 the price at the market was 32 – 35 RSD.(STIPS). In 2015 these oscillations in profit influenced on decreasing the areas to 10000ha or 25%. The opposite example is that pepper in Šumadija region (Kraljevo – market) in September 2014 was sold at 70 RSD., but in the same period in 2013 at 40 RSD (STIPS). That's why the areas with pepper,in the region, increased in 2015 to 1380 ha or 23,3%. According to this it is obvious that the producers are left to their own, the " smaller " ones cannot afford one " bad " year and are forced to give up. Another group presents " ad hoc " producers who follow the principle of profit.

In our country there is a pronounced incompatibility regarded the choice of crops, areas and the most important – achieved profit. The region of Šumadija is the best-known for vegetable growing, but Vojvodina has more areas with carrot (RZS). Previous researches (Živkov at all, 2012) as well as ours determined that Vojvodina (Graph.2.) had the highest average yield and in relation to some other regions, is the closest to European average.



Graph.2 Average yield (t ha^{-1}) of vegetables by the regions of Serbia (2010-2015)

The problems of Serbian vegetable growing noticed ten years ago are still current. In 2006, Biljana Persnall concluded that the problems are as follows:

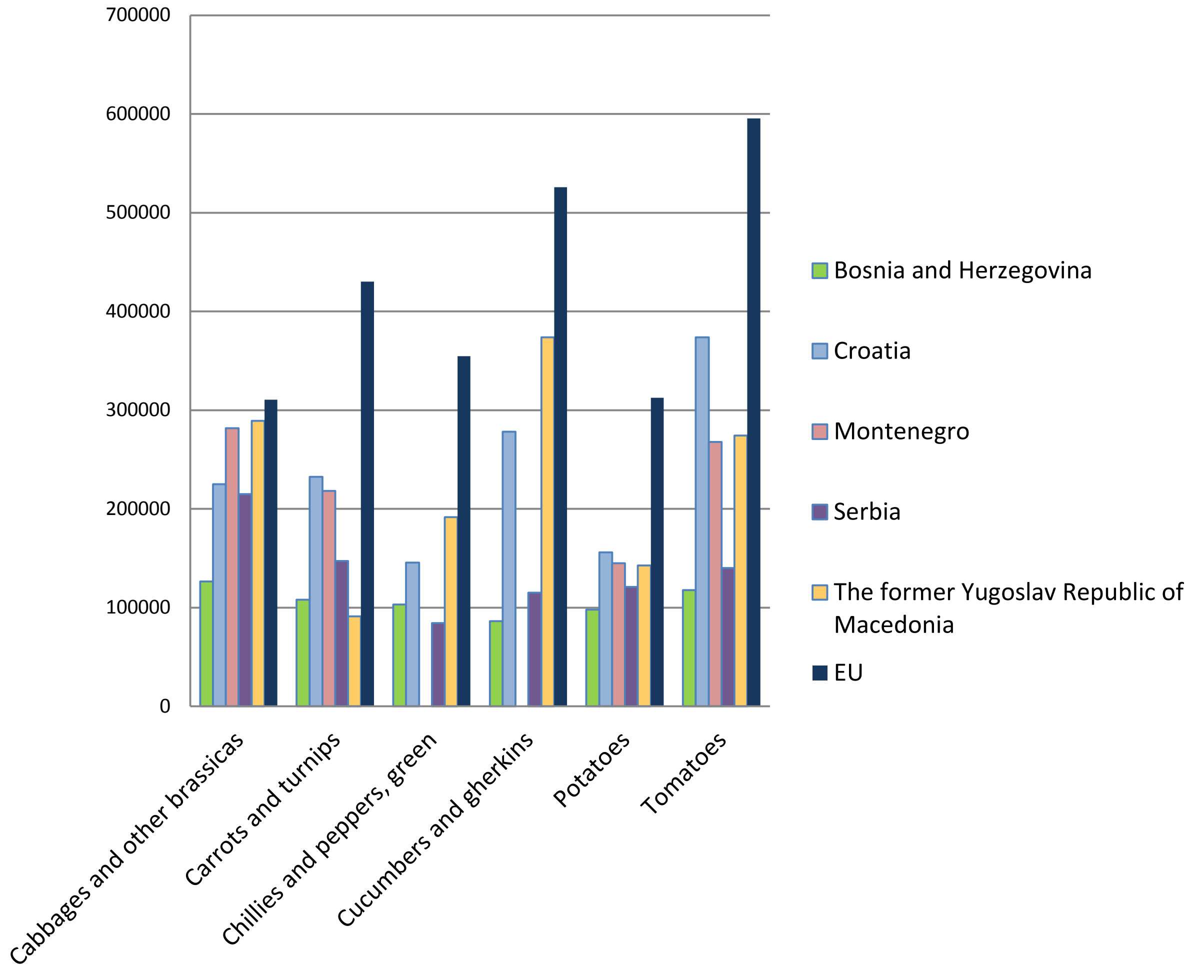
-The lack of modern cold storage plants with controlled atmosphere, and not enough centers for purchase. In some regions, technology is out of date (machinery), small supply that can only satisfiesthe needs of domestic market, nonstandard production, inadequate packaging, organized import lobby, bad or none organized export, inadequate initiative policy for vegetable producers.

Something that we worry about is bad age distribution and low educational structure of rural population. Constant migration from villages to towns makes the most important problem since these producers should already be retired (Rašković et al, 2016).

Vegetable growing in relation to the countries in Region and EU

With the increasing of world population, the market of world food is in constant growth, too (Milošević et al. 2012). According to Ilin (2010) there is a great incompatibility in production and demand on our planet. EU is very significant world producer of food, where about 55 million vegetables are produced, for approx. 450 million people. It is very interesting that vegetable growing covers 4% of arable areas in EU countries. The total food value is 15%.

The same author concludes that it is very clear that food production as well as vegetable growing are above the needs of population.
According to graph.3, it can be seen that the average vegetable growing in EU until 2014 was significantly higher than the average in Serbia and our neighboring countries. Only Croatia almost reached EU average since it became the member of EU in 2013.

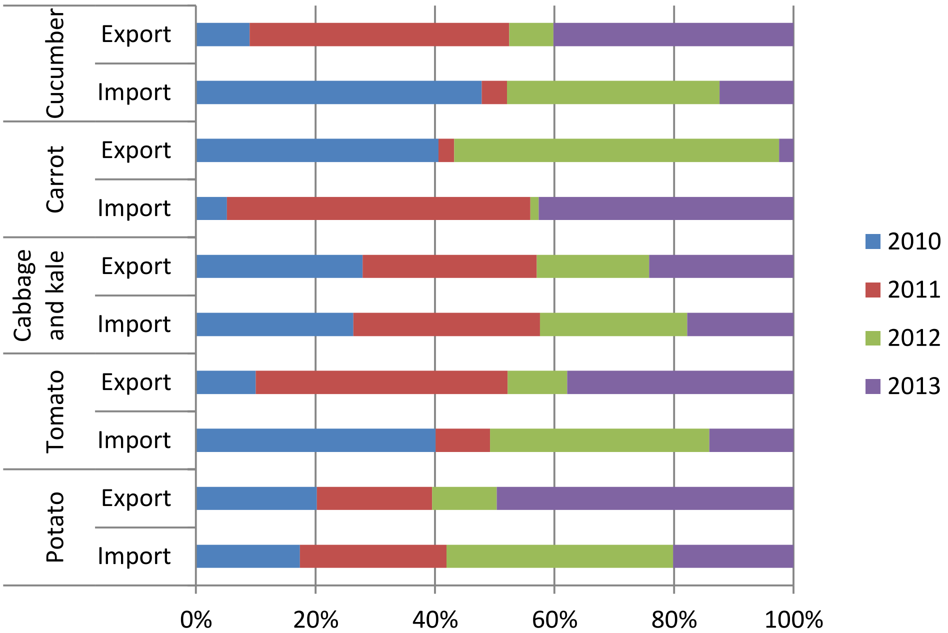


Graph.3.Vegetable yield in t ha^{-1} in regional countries and average yield in EU

According to the last official data, yields per area unit are increasing, but due to area decreasing, our competitiveness at the world and European market is still at the bottom of the scale. Our chance, especially for smaller producers, besides investing in conventional production, is to enlarge organic agricultural production – vegetable growing. It is something that most of the authors agree with in Serbia (Ilin et all, 2013, Lazić, 2011, Raškovič at all 2013).
It is also noticed at the global market that there are less big producers and more associated producers (Dehnen – Schmutz et al, 2010).
The market of expensive products of higher nutritive quality, both fruit and vegetables, is bigger and bigger (Sophia Wu Huang, 2004, Bojnec and Ferto, 2008). In EU producers are aware how important the local products are, so we have to take measures and interests for local sorts of high quality, not price.

Import and export of vegetables in The Republic of Serbia

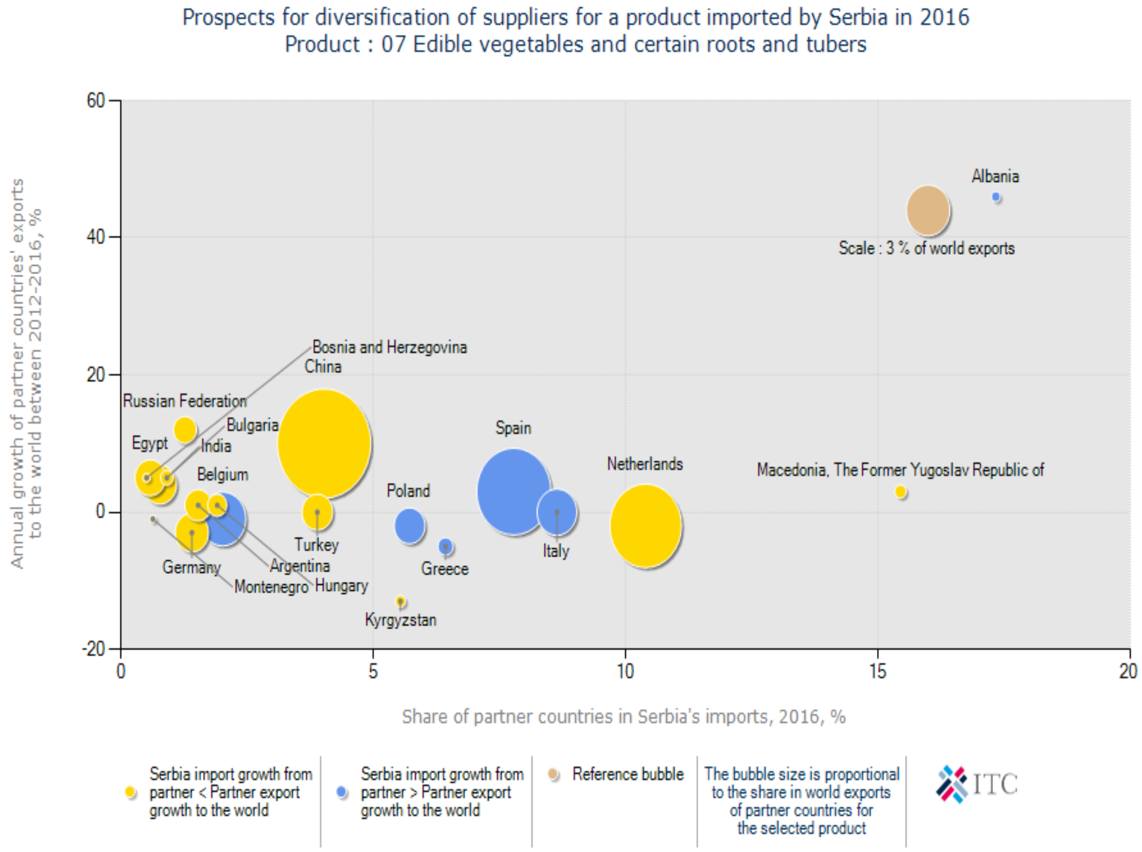
By analysing competitive economy of Serbia, speaking about fruit and vegetable growing in 2006, Biljana Persnal at all consider that " Negligible part (in promiles or some percents) of totally produced quantities are exported. Export of these products, and other vegetable growing crops is dominantly directed to the markets of neighbouring countries."
Slightly different opinion is written in Ilin's paper in 2012. It is said that at this level of production, market surpluses of middle late and late vegetables are accomplished, but only 96,3 million vegetables are exported. He also thinks that Serbia has to overcome the deficit of early and middle early vegetables, which according to the author lasts already two centuries due to increasing the production in protected area.
According to the researches of Marković (2016) about the export structure of agricultural-food processing products of The Republic of Serbia, the most represented are cereals, fruit and vegetables, totally exported at approx.. 24%. On the other hand, the most important products that are imported speaking about the import field of agricultural-food processing are fruit and vegetables, approx. 24%.



Graph.4.Import and export of vegetables from Serbia from 2010-2013 (FAO)

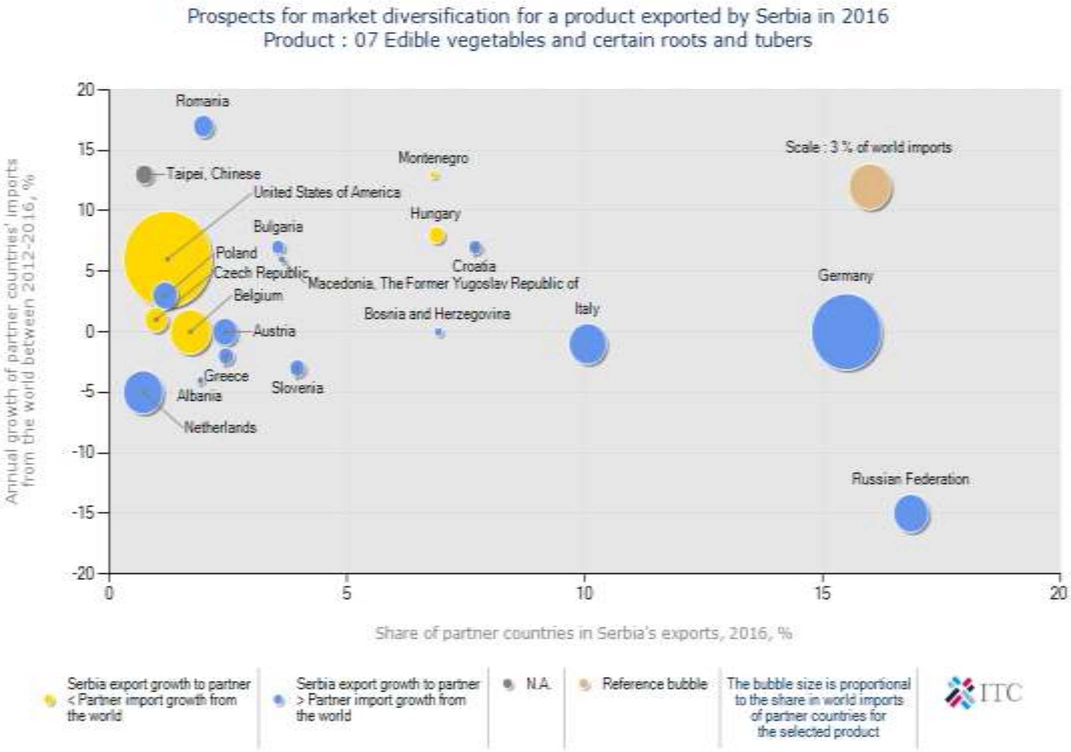
Import-export was analysed by FAO until 2013. Four last years were taken into account.
Unfortunately, every attempt for logical conclusion regarded oscillation between import and export was unsuccessful.
If we try to analyse the relation between production and import, we can notice that the production has no big deviations in examined years, while oscillations in import – export were significant.
Partial connection is seen in the example of tomato. The lowest yield (but not so drastic) was in 2010 and 2012. That's why, the largest quantities of this vegetable were imported then. It is not clear why in 2012, when it was a poor crop of carrot, export was 20 times higher than import. If we say that import is of seasonal character, i.e. tomato and cucumber, the oscillations must not be so high. So, it can happen that in one year we can have dominated import of one crop, and in the next year dominated export of the same crop.

The largest quantities are imported from Albania 17,34%, then Macedonia 15,45 %, The Netherlands 10,4%, Italy about 9%, Spain 8%, Greek 7% and Poland 6%.



Graph.5. Import of vegetables in Serbia in 2016

These data show that the largest quantities are imported from neighbouring countries with warmer climate and cheap labour force, at lower prices (early vegetables) but the import continues even when we do have vegetables in our country (i.e. tomato, watermelon, melon…) which negatively influence on our domestic vegetable market. Growth of import from Albania, approx.. 46% at annual level, is very significant. Vegetable growing has always contained a sociological characteristic which helped small farms to survive. There are very favourable ecological conditions for vegetable growing in Serbia, no matter that tomato imported from Albania, Macedonia, Turkey etc. is cheaper, it must not be allowed to lose this battle which means survival for many farms, making them exporters of their vegetables.
The Netherlands is an important exporter since it belongs to the group of countries that give high subventions for agriculture. It has high level of technology and yields, so its production price is lower than ours. Our producers cannot take abreast with such prices.The supply for any kind of vegetable that comes from Serbia is at minimum level, so we do not have influence on the price at world market, but that price determine the price in our country. Our total production is not large, and we export only few per cent, i.e. out of 639,410 t of potatoes, we export 1.919t or 0.3% (mpzzs)



Graph.6.Export of vegetables from Serbia in 2016
Source:trademap.org

The biggest export is in Russian federation, about 17%, Germany 15,5 %, Italy 10%. The problem is that all these three countries have a trend for decreasing annual export, most decreased is to Russia, even 15%. Significant annual increasing export is noticed toward neighbouring countries, Montenegro about 13%, Hungary 8% and Croatia about 7%. Higher yield and better product qualities can be maintained only by using modern technology in vegetable growing, leading to bigger competitiveness at foreign market. So, it is possible through higher investment in production. Producers can get subventions (*Published in "Official Gazette of Republic of Serbia", No 38/16, April 13, 2016)* All suggested measures have only one aim – production increasing, better quality and better disposal of goods. For small producers, it is very important if more cold storage plants and storages become easily available, if they can easily sell their vegetables, specialize in the production of certain crop, increase the capacities (machinery), as well as advance their knowledge.

Conclusion

According to the analysis of important elements of Serbian vegetable growing (areas, yield, trade, available financial resources) during the last five years, and parallel with previous researches, the following conclusions can be made:
In spite of the fact that there are favourable ecological conditions in Serbia, there is a trend for decreasing vegetable areas.
There is a clear regional incompatibility when choice of crops, areas, and the most important –achieved yield are in question. The region of Šumadija is the best-known for vegetable growing, but the highest yield is in the region of Vojvodina autonomous province.
Producers are left totheir own**,** the decision what to grow and on which areas depend on financial (un) success in the previous production year.

Yields of all the countries in the region are under EU average. Among neighbouring countries, only Bosnia and Herzegovina has worse position than Serbia.
It is optimistic that the vegetable yields in Serbia are increasing from year to year, but since the areas decrease, we are not on the list of important world or European vegetable producers.
Supply of vegetables at European market is bigger than demand, so production and market change in order to encourage local production, the production of specific crops in the region where quantity is more important than quality.
Organic production is on very low level in Serbia, and that's why it should be offered as a part of ethno-tourism.
Our producers have the only chance and it is their mutual supply, if not for world market, but for European or Russian.
Organized purchase is necessary, and its result should be supplying at the market of standard quality products.
More cold storage plants are necessary, as well as to offer fresh fruit, secondary products, i.e. secondary industry should be enlarged.
To fulfil all these nice wishes, more investment is of great importance, and that should be done through price supports credits.

EARLY PHYTOTOXIC EFFECTS OF SULFONYLUREA HERBICIDES IN MAIZE LINES

Vesna DRAGIČEVIĆ*, Milan BRANKOV, Milena SIMIĆ

Maize Research Institute "Zemun Polje", Slobodana Bajića 1, 11185 Zemun Polje, Serbia

Abstract

Maize lines are susceptible to various stressful conditions. One of the main problems in maize seed production is weed control and absence of registered herbicides, while the herbicides commonly used in hybrid crop could express phytotoxicity to maize lines. The susceptibility of six maize lines to sulfonylurea herbicides (Motivell 6 OD – H1 and Equip – H2), applied in recommended dose – RD and double dose –DD was tested during 2015 and 2016. Herbicides were applied in 5-6 leaves phase (15-16 BBCH). Aboveground parts of maize plants were sampled for phytic phosphorus (P_{phy}) determination 48 hours after herbicide application. Grain yield was determined after harvest. Irrespective to the variations in grain yield between years, H1 treatment in average increased grain yield of L1, L3, L5 and L6 (mainly in RD) and decreased yield of L2 and L4, while H2 increased average grain yield of L3, L4 and L6 and decreased it of L1, L2 and L5, with slightly higher values obtained by DD, when compared to control. H1 treatment induced mainly decrease in P_{phy} concentration, while H2 induced increase in P_{phy} concentration in comparison to control, as a consequence of induced stress. This was underlined mainly by DD of applied herbicides. Variations in P_{phy} concentration in maize leaves showed significant and positive correlation with grain yield in L2, L3, L4 and L6, while the correlation was negative in L1 and L5. In those lines, H2 mainly induced yield reduction. The highest yield reduction by both herbicide treatments were obtained in L2, line with the highest P_{phy} increase induced also by herbicides, which defines it as a sensitive genotype. For its production, sulfonylurea herbicides are not recommendable for use.

Keywords: *Maize lines, Sulfonylurea herbicides, Phytic phosphorus, Grain Yield.*

Introduction

Weed control, which imply herbicide application is one the most important measures in maize seed production. In general, maize lines have smaller habitus, enabling better conditions for higher weed infestation, than maize hybrid crop. In some cases, when weed infestation is high enough, this could lead to the total yield devastation (Stefanović et al., 2007). What is more, maize lines have increased susceptibility to various stressful factors, including herbicides (Stefanović et al., 2010), what means that herbicide application in maize seed crop is necessary and difficult measure to apply. The signs of herbicide phytotoxicity on maize plants are frequently linked to growth delay, reduction in plant height, leaf area, and as it was upper mentioned, it could lead to total destruction of the plants. Due to the crop susceptibility, agro-ecological conditions and type, herbicides could induce temporary stress, when plants are able to regenerate in lesser or greater extent and to achieve grain yield or permanent stress, when greater plant damages exist, having as a consequence greater yield losses or yield absence (Carvalho, 2007). Weed control was successfully achieved by the introduction of sulfonylurea herbicides. Auškalnienė and Auškalnis (2006) stated that the green biomass of maize was 1–18.4 t ha^{-1} higher in plots treated with sulfonylurea herbicides, than in the untreated plots. On the other hand, sulfonylurea herbicides could express high phytotoxicity on maize lines in comparison to herbicides from the other groups (Stefanović et al., 2010). The signs of phytotoxicity could vary among seasons, with severe injuries during colder seasons with low precipitation level (Dragičević et al., 2012). The same authors indicate that in susceptible lines, increase in dry matter and free energy could be considered as an early sign of phytotoxicity, while the individual herbicides affect plants energetic system differently. For instance, nicosulfuron increases energy consumption, while the foramsulfuron increases plant potential energy, mainly from metabolism.

Phytic acid is the main phosphorus storage in the plants and it is mostly seed constituent. Nevertheless, it also has an important role in green parts of plants in protection during stressful conditions, particularly when environmental pollutants are considered. Dutta et al. (2014) found that vegetables with increased phytate content such as radish, are the most tolerant to arsenic, with least reduction in germination and dry mater production, the lowest lipid peroxidation value and highest chlorophylls and carotenoids stability indices. Dragičević et al. (2011a) and Brankov et al. (2015) also suggested that phytate plays an important role in expression of herbicide tolerance in maize, particularly when sulfonylurea herbicides are considered. The insignificant variation in phytate content, as well as slight yield reduction was observable in tolerant maize lines.The aim of this study was to examine response of six maize inbred lines to two sulfonylurea herbicides (nicosulfuron and foramsulfuron) applied in recommended and double dose and to define tolerant lines, based on alterations in phytic phosphorus content and grain yield.

Material and Methods

The field experiment was conducted during 2015 and 2016 in the field of the Maize Research Institute, in Zemun Polje on a slightly calcareous chernozem soil type under rain-fed conditions. During both experimental years, winter wheat was a preceding crop. The influence of two sulfonylurea herbicides applied in recommended (RD) and double doses (DD) were tested: H1 - Motivell Extra 6 OD (nicosulfuron 60 g a.i. l^{-1}), applied in 0.75 and 1.5 l ha^{-1}, respectively and H2 - Equip (foramsulfuron 22.5 g a.i. l^{-1}), applied in 2 and 4 l ha^{-1}, respectively and C – control (without herbicide application), on set of 6 ZP inbreed lines. 48 hours after application, plant shoots were sampled for chemical analysis. The experiment was conducted by RBCD design with four replications: main plots encompassed 4 rows of each line, while subplots included two herbicides and control, without herbicide application.

The sowing was performed at the end of April in 2015 and at the middle of April in 2016, due to the meteorological conditions, while the herbicides were applied in the 5–6-leaf phase. The content of phytic phosphorus (P_{phy}) was determined after drying at 60 °C and milling of the samples, by the method of Dragičević et al. (2011b). At the end of vegetation, the maize grain yield was measured and calculated to 14 % of moisture.

The experimental data are presented with standard deviation (SD) and the dependences between grain yield and the content of phytic phosphorus were obtained by correlation (Pearson’s coefficients).

Meteorological conditions. The experimental years were relatively similar accordingly to the average temperature and precipitation sum (Table 1). The main differences were expressed between first (April-June) and second (July-October) part of vegetative period, when average monthly temperatures were slightly lower in the first part of 2015 and higher during the second part of 2015, when compared to 2016. 2015 was also characterized with the lower precipitation sum during anthesis period (Jun-July) in regard to 2016.

Table 1. Average monthly air temperatures and precipitation sums for vegetative period (April-October) in 2015 and 2016 at Zemun Polje

Month	IV	V	VI	VII	VIII	IX	X	Aver./Sum
Year	Monthly average temperatures							
2015	12.9	19.1	22.1	26.4	25.7	20.2	12.4	19.8
2016	15.3	17.6	23	24.2	22.3	19.4	11.2	19.0
	Precipitation sum							
2015	19.7	97.8	31.1	7.2	56	73.6	65.1	350.5
2016	51.9	47.4	107.4	33.6	43.2	36.6	60.3	380.4

Results and Discussion

The relatively unfavourable conditions present during anthesis period of 2015 reflected negatively on grain yield, with lover values achieved, when compared to 2016 (Figure 1). Only L6 had similar yields in 2015 and 2016 (4.14 and 3.92 t ha^{-1}, respectively), what is from 0.98-2.86 t ha^{-1}, higher than other lines in 2015 and from 0.11-1.60 t ha^{-1}, higher than L1 and L2 in 2016. Tested lines, also expressed high variability in response to applied sulfonylurea herbicides. It is important to underline that sulfonylurea herbicides express good efficiency in weed control, but in parallel, they also expressed increased phytotoxicity in maize crop, particularly when inbred lines are considered (Stefanović et al., 2007; Malidža, 2007).

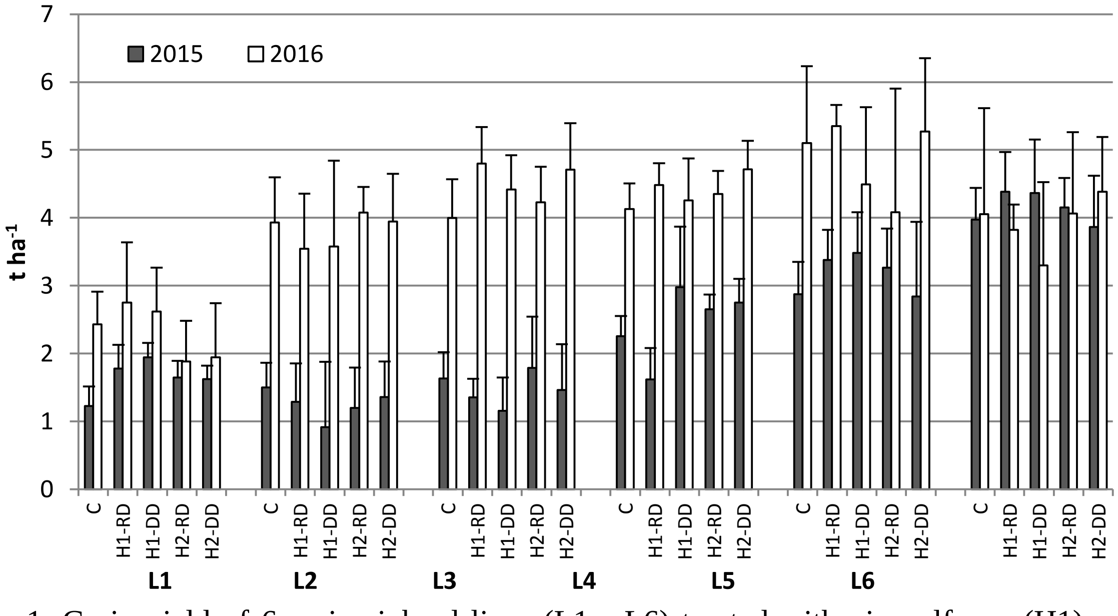

Figure 1. Grain yield of 6 maize inbred lines (L1 - L6) treated with nicosulfuron (H1) and foramsulfuron (H2) applied in recommended dose (RD) and double dose (DD) and control (C) – without herbicide treatment

H1 treatment (nicosulfuron) was reflected on the increase of grain yield values in L1, L4, L5 and L6 in 2015 (mainly in DD treatment), as well as in L1, L3, L4 and L5 in 2016 (mainly RD treatment), when compared to control and other treatments. Nevertheless, grain yield reduction in both years by H2 treatment (foramsulfuron) was observable in L1 and L5, meaning that this treatment induced permanent stress and so, the higher yield losses, in regard to the nicosulfuron (Carvalho, 2007). The lowest values of grain yield were noticed in 2015 by H1-DD combination in L2 and in 2016 by H2-RD in L1, while the highest values were obtained by H1-RD treatment in L5 and L6 (for 2015 and 2016, respectively). Accordingly to the results of Stefanović et al. (2010) and Brankov et al. (2015), reduction in maize grain yield was slight in tolerant lines, when sulfonylurea herbicides were applied, while in sensitive genotypes visible damages were connected to the losses of grain yield. Phytate is important metabolite that plays key role in tolerance to herbicides (Dragičević et al, 2011a). The examined genotypes reacted variously to applied herbicides, with negligible difference between seasons (average values for 2015 and 2016 were 2.00 and 1.92 mg g^{-1} of P_{phy}, respectively). The difference between genotypes in average P_{phy} content varied from 4.3% (between L2 and L3) to 20.1% (between L2 and L4). Examined lines reacted mostly to nicosulfuron treatment by reduction of the P_{phy}, while foramsulfuron increased P_{phy} content in shoot (Figure 2). RD increased P_{phy} content in L2, L5 and L6, while DD increased in the shoots of L1, L3 and L4, irrespective to the season). The highest values were obtained in 2015 by H2-RD in L6 and in 2016 by H1-DD in L4. In sensitive lines, particularly during the stressful seasons (like 2015), when higher losses of grain yields were present, the increase in phytate content is observable (Brankov et al., 2015). What is more, the obtained difference between applied sulfonylureas could lay in their diverse impact on plant energetic system, since nicosulfuron increases energy depletion, while foramsulfuron increases energy from metabolism (Dragičević et al., 2012).

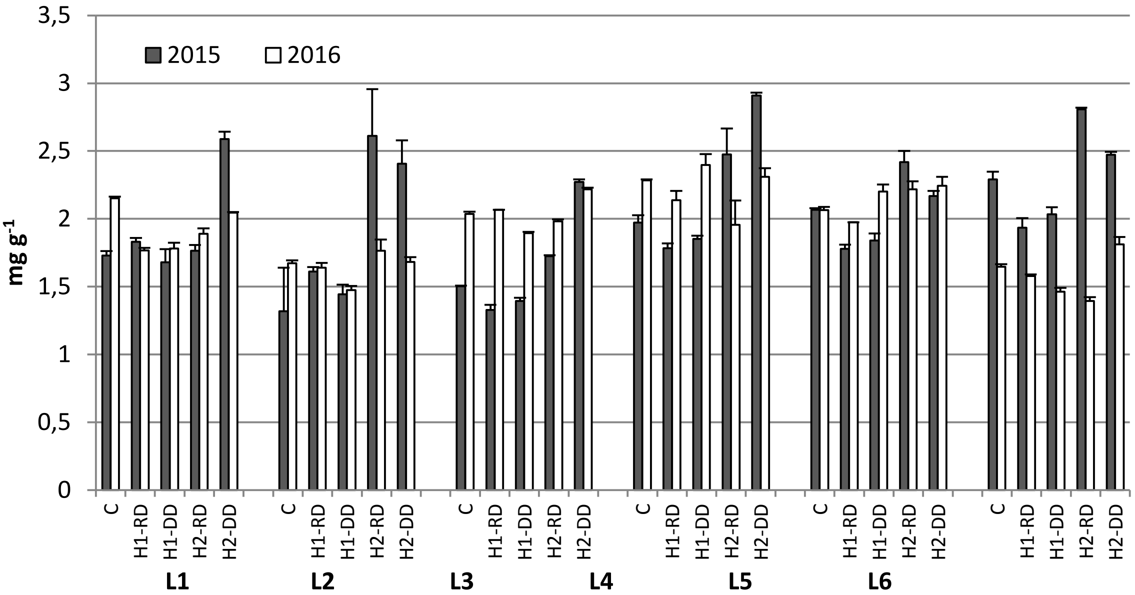

Figure 2. Contewnt of phytic phosphorus of 6 maize inbred lines (L1 - L6) treated with nicosulfuron (H1) and foramsulfuron (H2) applied in recommended dose (RD) and double dose (DD) and control (C) – without herbicide treatment

The results present in Table 1 indicate significant correlation between grain yield and P_{phy} content in maize shoots, 48h after herbicide application. The significant and positive correlation was obtained with application of both herbicides and the higher coefficient (0.565) was noticed by the application of nicosulfuron (H1), indicating that alterations in P_{phy} content are good indicators of plant reaction to herbicide stress, particularly when sulfonylureas are considered. Brankov et al. (2015) also underlined that phytate is an important factor that contributes to herbicide tolerance in maize lines. The highest coefficients were achieved for L4 and L5 (0.78 and -0.87, respectively). In L2, L3, L4 and L6, P_{phy} increase was connected to the grain yield raise, while in L1 and L5, P_{phy} increase was linked to the grain yield reduction.

Table 1. Correlation between grain yield and phytic phosphorus in maize grain

Line	H1	H2	L1	L2	L3	L4	L5	L6
Correlation coefficient	0.565*	0.338*	-0.62*	0.50*	0.58*	0.78*	-0.87*	0.62*

*The significant values at the level of significance of 0.05.

Conclusions

Obtained data indicated that variations in phytate content in maize leaves during the first 48h after herbicide application are the good indicator of genotype tolerance to sulfonylureas. Phytate is also an important factor that regulates tolerance to herbicides, irrespective to the diverse response observed in different lines. In general lines with high P_{phy} content in leaves are potentially more tolerant to sulfonylureas and environmental stressful factors (such as meteorological factors) having the least yield losses in relation to the susceptible lines.

Abstract

Sweet potato is becoming more popular culture for cultivation because of its nutritive values and pleasant taste. It is one of the most significant vegetable cultures in the world, while in our region people do not know much about it and it is not frequently cultivated vegetable. Sweet potato does not have much in common with potato except that they are used in the same way for the meal preparation. Latin name for sweet potato is *Ipomea batatas* and it belongs to the family of Convolvulaceae, while *Solanum tuberosum* potato belongs to the family of Solanaceae. Cultivation of sweet potato requires special climatic conditions and the right choice of soil. Agroecological conditions of our country are suitable for a successful cultivation of sweet potato, which is evident in the results of the trial conducted in PSS Sombor. On the trial field of PSS Sombor , the trial with two varieties of sweet potato was conducted during the period of three years. The trial is conducted in two variants with mulching with black foil and without mulching in ’’drop by drop’’ system. During the vegetation, no chemical treatments for protection from diseases and insects were applied. The trial results showed that with the application of modern growing technology, sweet potato can be successfully grown in Vojvodina.

Keywords: *sweet potato, vegetable, cultivation*

Introduction

In recent year the demand for sweet potatoes in the Serbian market has increased. Sweet potato is tropical plant, but it can be successfully cultivated in moderate climates, where it is grown from seedlings. It is suitable for organic production because it is highly resistant to diseases and pests. Sweet potato (*Ipomea batatas L.*) is a perennial tropical plant, widely grown and used in Asia, America and Africa, but in Serbia it is less cultivated plant species. Sweet potato is a biennial plant, but in Serbia it is cultivated as annual plant. Secondary bundle tuber of root and young leaves are used in consuming. Taste of sweet potato is specific for its sweetness after what it has been named. One plant can develop four to eighteen tuberous roots, every root can weight 100-500 grams. A stem can reach the length of 60 cm to 5 m Leaves are heart-shaped and smooth, colour of flowers is light pink to light violet. The plant is high in calories,and it contains a lot of starch, but it contaons no fat and it has low content of sugar. Content of vitamins (A, B6, C, E) and minerals (K, Ca, Mg, Fe) is very high. Sweet potato is especially suitable for people who are diabetics because of low glycemic index. In food preparation, it is used in same way as an ordinary potato. It can be cooked, fried and flour can be made of it. Young leaves can be cooked in a similar way as spinach. Yellow coloured sweet potato is suitable for salted food and sweets can be prepared with orange and red sweet potato. It can be boiled faster than ordinary potato.

It is the best to produce sweet potato on deep and fertile soil. It needs high humidity and production can be high only under irrigation. Sweet potato also requires moderate climate, minimum four months without frost. Temperatures below 15^0C and higher than 30^0C hinder the development of plant and can decrease yield. Temperatures below 10^0C can cause internal damage of plant. In our climatic conditions sweet potato flowers in autumn, seeds do not maturate, so seedlings are produced in a green house under controlled conditions. Nursery plants are ready for planting after four to six weeks, when they are in stage of 5 to 6 leaves and their height is 15 -25 cm. In order to make the production successful, a primary tillage should be performed in autumn with fertilization with farmyard manure (20-30 t/ha) and usage of other fertilizers is based on the results of the analysis of soil fertility. Seedbed finishing is in spring, and it is about 5-10 cm deep. Planting time is after spring frosts, and at least 2 – 3 nodes must be in ground during the planting. Spacing between rows is 100-120 cm and 30-50 cm between plants in a row. Favorable conditions for the plant growth can be achieved with application of black mulch foil. In the same time, the irrigation system „drop by drop" is applied. Sweet potato can be produced on the same parcel after three years. Three month after planting sweet potato is ready to harvest. Sometimes harvest can occur later if a producer wants to have bigger roots and higher yield. Common length for market is 15-20 cm and recommended weight is 150-400 grams. In our climatic conditions harvest of sweet potato is in the period from August to October, always before first frosts. Tuberous roots will develop firm crust if plant parts that are above ground are cut several days before harvest. Firm crust and tuberous roots reduce the possibility of mehanical damage during harvest and storage of sweet potato. Harvest of sweet potato can be done by hand or by a potato digger. Before storage, it is necessary to separate damaged roots from healthy ones, with the aim to prevent infections and losses. For longer storage, sweet potato requires temperature around 15^0C and relative humidity 85-90%

Material and Methods

Trial was set up on the trial field of PSS „Sombor" in three years (2014, 2015, 2016) on soil type grassland black soil. These three years were different regarding percipitation amount. First year (2014.) had enough amount and good disposition of rainfall, while 2015. and 2016. were deficient in precipitation during vegetation period. Trial was set up with two varieties of sweet potato with different colours of flesh in two variants. Varieties with orange and white flesh colour were in variants with and without black malch foil under the irrigation by „drop by drop" system. In all observed years, planting of sweet potato was in the stage of four leaves, in first decade of May. Row spacing in planting was 120 cm between rows an 40 cm betweeen plants in one row. The elementary parcel had 250 plants. The aspects that were observed in the trial during the years mentioned above are the following: yield, dry matter and sugar content.

Picture 1: Nursery plants of sweet potato

Results and Discussion

Sweet potato with orange flesh colour with usage of mulch foil achieved average yield of 105,3 t/ha, while variant without usage of foil achieved averge yield of 68,8 t/ha (Table 1). Achieved difference in yield was 36,5 t/ha, it is for 53% higher than the yield in the variant with usage of foil. Dry matter content in sweet potato with orange flesh colour was 19,4 % in the variant with usage of foli, without foil usage it was 18,5 %. Difference in dry matter content in variant with and without folil was 0,9 %, it is about 4 % higher than in variant with usage of foil. Sugar content in orange coloured flesh sweet potato variety with usage of foil was 11,0 % without usage of foil was 10,8%. It is for 2% higher in variant with foil usage.
Sweet potato with white flesh colour with usage of mulch foil achieved average yield of 118,1 t/ha, while variant without usage of foil achieved average yield of 81,9 t/ha (Table 2). Difference between average yield was 36,2 t/ha, which is 42% higher yield in variant with usage of foil. Dry matter content in sweet potato with white flesh was 18,2 % in variant with and without foil usage. Sugar content in white coloured flesh sweet potato variety with usage of foil was 10,0% , without usage of foil was 9,5%. It is for 5% higher in variant with foil usage.

Table 1: Average yield, dry matter content, and sugar content in orange sweet potato variety during 2014-2016. year

	variety	Average yield t/ha	Dry matter %	sacch mass %
Without the use of foil	Orange batat	68,8	18,5	10,8
With the use of foil	Orange batat	105,3	19,4	11,0
different		36,5	0,9	0,2
%		53	4	2

Table 2: Average yield, dry matter content, and sugar content in white sweet potato variety during 2014-2016. year

	variety	Average yield t/ha	Dry matter %	sacch mass %
Without the use of foil	White batat	81,9	18,2	9,5
With the use of foil	White batat	118,1	18,2	10,0
different %		36,2	0	0,5

Conclusion

Sweet potato-batat is becoming more popular culture for cultivation because of its nutritive values and pleasant taste. Batat is suitable for organic production because the plant is resistant to diseases and pests. The results of the three-year trials with sweet potato show that due to the application of mulch foil the yields are higher than in the cases without usage of foil.

Picture 2: Orange and white flesh varieties of sweet potato

The trial results on the trial field of PSS „Sombor“ in three years (2014, 2015, 2016) showed that with the application of modern growing technology, sweet potato can be successfully grown in Vojvodina.

Abstract

The investigation was conducted in the experimental field of the Maize Research Institute Zemun Polje, Serbia, during 2013/14-2014/15. The experiment was established as a block design with four replications. As winter cover crops-CC (factor A) the following plants were grown: CV–common vetch (*Vicia sativa* L.), FP-field pea (*Pisum sativum* L.), WO-winter oats, (*Avena sativa* L.), FK-fodder kale **(***Brassica oleracea* (L.) *convar. acephala*), two variants with mixture of legume crops and oats (CV+WO and FP+WO) and two control treatments: a variant in which the surface was covered with dead organic mulch (DOM) and traditional variant (TV) in which, after ploughing in the fall, plot stayed uncovered during the winter. Green biomass of the cover crops was incorporated into the soil, immediately after cutting. A half of the elementary plot was infested with bio-fertilizer Uniker (BF), in an amount of 10 l ha^{-1} (factor B). The bio-fertilizer Uniker contains the strains of cellulolytic and proteolytic bacteria to support the mineralization of entered crop residues. The seeds of sweet maize ‘ZPSC 421*su* (FAO 400) were sown at the arrangement of 70 cm between rows and 22 cm between plants in the row (65,000 plants per ha). Preceding crop in both years was winter wheat. The content of vitamin C (L- and D – ascorbic acid) was determined by iodometric titration method. The data were processed by ANOVA. The investigated factors (CC and BF) and their interactions showed very significant effect on vitamin C content in both years. The greatest impact on vitamin C content was exhibited in variant of fodder kale but the lowest in variant with winter oats. The vitamin C content usually increased after all the leguminous cover crops compared with DOM and TV. Application of bio-fertilizer influenced positively content of vitamin C only in favourable meteorological conditions in 2015.

Keywords: *Sweet maize, cover crops, content of vitamin C, microbiological fertilizer*

Introduction

Sweet maize, as a vegetable crop, is a special type of maize with particular characteristics, such as sweet taste, thin pericarp and endosperm with delicate texture, and with a high nutritional value (proteins, sugars, and most of vitamins and microelements) (Santos *et al*., 2014). The content of nutrients depends on the genotype, meteorological conditions and the selected growing technology. It is clear that the way to the exploitation of sweet maize is through maize breeding, requiring the evaluation of the response of cultivars to environmental conditions, of the variability within and between the germplasm under study and the selection of superior genotypes for agronomic traits of interest (Revilla *et al*., 2010). For the improvement of sweet maize, two strategies can be applied: (1) the introduction of the "sweet" trait into a genotype with normal endosperm, adapted to the growth environment, or (2) the incorporation of sweet maize genotypes into a conventional breeding program. Weather conditions during the growing season, in particular air temperature, have the greatest influence on sweet maize growth, yield and yield quality (Stone *et al*., 1999). In order to obtain high yields of good quality the scientists have been searching for the most appropriate growing practices (Dolijanović *et al*., 2013). In selecting growing technology of sweet maize, climate change must be taken in account, particularly the occurrence of drought periods in the growing season of crops. It is very important to provide enough organic matter, due to the lack of manure which was previously the most applied, it is necessary to search for alternative sources of organic matter. Cover crops used as green manure are a valuable source of organic matter. In the last decades, the evidence of negative impact of agriculture to the environment renewed interest in growing cover crops in autumn and winter, the effect of which is to take up nitrogen that would otherwise be lost, resulting in decreased nitrate concentrations in leachate (Collins *et al*., 2007). Studies on an application of cover crops had secondary effect of green manures on the yield quality and nutritive value of sweet maize (Zaniewicz-Bajkowska *et al*., 2012). Bio-fertilizers have an important role in keeping high soil fertility and crop yields increasing (Mahdi *et al*., 2010; Janošević *et al*., 2017). The positive impact of microbiological fertilizers is also observed in regards to quality of plant products, as for example increase in lycopene and vitamin C accumulation in sweet maize (Rosa, 2015) and in tomato fruits (Verma *et al*., 2015; Ochoa-Velasco *et al*., 2016) and higher glutathione content in maize grain (Dragicevic *et al*., 2013). Data obtained in this study from field experiments provides valuable knowledge regarding the (i) influences of different type of cover crops and (ii) the applied form of fertilizers (i.e. microbiological) on content of vitamin C in grain of sweet maize.

Material and methods

A field experiment was carried out in 2013/14–2014/15 growing seasons, at the Experimental Field of Maize Research Institute in Zemun Polje near Belgrade (44°52'N; 20°20'E). The soil was slightly calcareous chernozem with 47% of clay and silt and 53% of sand. The soil at 0-30-cm layer contained 3.22% of organic matter, 0.19% of total N, 1.9% of organic C, 16.2 and 22.4 mg per 100 g soil of available P and extractable K, respectively, 1.38% of total $CaCO_3$ and had pH 7.3. The experiment was established as a block design with four replications. As winter cover crops (factor A) the following plants were grown: CV–common vetch (*Vicia sativa* L.), FP-field pea (*Pisum sativum* L.), WO-winter oats, (*Avena sativa* L.), FK-fodder kale (*Brassica oleracea* (L.) *convar. acephala*), two variants with mixture of legume crops and oats (CV+WO and FP+WO) and two control treatments: a variant in which the surface was covered with dead organic mulch (DOM) and traditional variant: after ploughing in the fall plot stayed uncovered during the winter (TV). The cover crops (CC) were sown in the amount: common vetch – 120 kg, field pea – 150 kg, oat – 160 kg, and fodder kale 15 kg per ha, and in mixture relation between legume and oats was 70:30. The plot size was 17.5 m^2. The seeds from the Department for Forage Crops of the Institute of Field and Vegetable Crops in Novi Sad was used for planting of cover crops in both years. Sweet maize hybrid ZPSC 421*su* (FAO 400) was sown at the arrangement of 70 cm between rows and 22 cm between plants in the row (65,000 plants per ha). Preceding crop in both years was winter wheat.The soil preparation in autumn (ploughing and seedbed preparation) was performed immediately before sowing, when also soil samples were taken for available N analysis at depths of 0-20 cm and 20-40 cm. Further soil sampling from all CC and control treatments was done in the spring, after CC harvest, as well as after sweet maize harvesting. Before the sowing of CC (autumn) and sweet maize (spring) mineral fertilization was applied in order to obtain 120 kg ha^{-1} N, 90 kg ha^{-1} P and 60 kg ha^{-1} K. The total amount of P and K fertilizer was applied in autumn with mono-potassium phosphate fertilizer (a.m. 0:52:34) and the required N amount was incorporated together with sweet maize sowing (urea 46% a.m). Nitrogen fertilization followed: for non-legume crops and control treatments it was 120, for sole legume it was 80 and for mixture it was 90 kg ha^{-1} N. The remaining 40 or 30 kg ha^{-1} N was considered to be provided by nitrogen fixation. Green biomass of the cover crops was incorporated in the soil immediately after. Half of the elementary plot was infested with bio-fertilizer (BF) - Uniker (mobilizer of nutrients) in an amount of 10 l ha^{-1} (factor B). The bio-fertilizer contains the strains of cellulolytic and proteolytic bacteria to support the mineralization of entered crop residues. The ears were harvested at the stage of milk maturity of kernels. The schedule of the main works on the experiment is shown in Table 1.

Table 1. Chronology of field operations and length of vegetation period of sweet maize

Cover crops sowing	October, 30 2013	November, 13 2014
	2014	2015
Cover crops sampling	April, 23	May, 12
Cover crops and microbiological fertilizer incorporated	May, 12	May, 21
Sweet maize sowing	May, 20	May, 21
Hand weeding 1	June, 27	June, 22
Hand weeding 2	July, 17	July, 15
Sweet maize harvest	August, 14	August, 21
Length of vegetation period of sweet maize (in days)	86	92

The total content of vitamin C (L-ascorbic acid D-ascorbic acid) in the grain of sweet maize was determined by iodometric titration method (Rikovski et al., 1989). The obtained data were processed using analysis of variance for two-factorial experiments (ANOVA). Statistical analysis was performed by SPSS 15.0 (IBM Corporation, Armonk, New York, USA) for Windows Evaluation version. For the individual comparisons, the least significant difference (LSD test) was used.

Meteorological conditions

The meteorological conditions during the growing season are presented in Table 2.

Table 2. Average air temperatures and precipitation sums from April to September at Zemun Polje

Months	Temperature (°C)		Precipitation (mm)	
	2014	2015	2014	2015
April	13.7	12.9	84.8	19.7
May	17.4	19.1	192.5	97.8
June	21.1	22.1	71.2	31.1
July	23.2	26.4	187.4	7.2
August	22.6	25.7	41.0	56.0
September	18.0	20.2	75.6	73.6
Average/Sum	19.3	21.1	652.5	285.4

More favourable conditions in term of quantity and distribution of precipitation were in the first year of the investigation. The first year examination also characterized by optimal air temperatures, which has had an effect on the investigation parameter of sweet maize. Precipitation in June and July 2015 were the lowest and air temperatures were the highest but, in this year application of microbiological fertilizer caused a higher content of vitamin C in all investigation treatments.

Results and discussion

Representative conclusions about the effects of different cover crops and microbiological fertilizer on the content of total amount of vitamin C in grain of sweet maize are obtained by the insight into the results shown in Table 3. The investigated factors (CC and BF) and their interactions showed very significant effect on vitamin C content in both years. The greatest impact on vitamin C content was exhibited in variant of fodder kale but the lowest in variant with winter oats and common vetch. Application of bio-fertilizer influenced positively content of vitamin C only in favourable meteorological conditions that were in 2015. Microbiological fertilizers, usually have positive influence on crop immunity to stressful conditions, particularly drought.

Table 3. The vitamin C content (mg %) in sweet maize grain

p<0.01 very significant (**); p<0.05 significant (*); p>0.05 no significant (ns)

The chemical composition of vegetables is genetically conditioned but it could be also modified by factors affecting the growing plant (Lee and Kader, 2000). Content of vitamin C in sweet maize kernels ranged from 21.42 to 30.51 mg% in first and 23.18 to 30.80 in second year of investigation. In general, winter catch crops significantly increased vitamin C content of sweet maize compared with control treatments (Table 3). In addition, legume crops (CV and FP) grown alone contributed to lower concentrations of vitamine C compared to legumes and WO mixtures. Zaniewicz-Bajkowska *et al.* (2011) reported no significant differences in ascorbic acid content of sweet corn following serradella, faba bean summer catch crops, FYM and after mineral fertilisation alone. On the contrary, the kernel ascorbic acid content of sweet corn grown after phacelia and amaranth were significantly higher than the control without organic manure (Zaniewicz-Bajkowska *et al.*, 2012). Other studies have indicated that an application of green manures favourably affected vitamin C and sugar contents of onion, red beet (Jabłońska-Ceglarek et al. 2002), white cabbage (Jabłońska-Ceglarek and Rosa, 2003) and leek (Rosa and Jabłońska-Ceglarek, 2009). Salama *et al.* (2014) reported substantially higher vitamin C levels in fennel with organic cultivation compared with mineral cultivation alone. Many studies have found that lower yields, better taste, more Vitamin C, and higher antioxidant levels in organic vegetables are correlated with lower levels of readily available nitrogen (Theuer, 2006). A major focus on many organic farms is increasing the supply of nitrogen for crops, in order to narrow the differences in yields between conventional and organic production systems. Will success in increasing the nitrogen available to plants on organic farms erase the quality advantages of organic produce? Organic potatoes generally

contain more ascorbic acid (Vitamin C) (Hajšlová *et al*., 2005). Both of these phenomena are associated with lower plant tissue nitrate levels and correspondingly slower growth rates and greater physiological maturity at harvest. This highlights a major difference between organic management and conventional management: the nitrogen economy of the plant. Nitrogen economy has both a quantitative aspect – the amount of nitrogen applied – and a qualitative aspect – the source(s) of that nitrogen. Organic cropping technology frequently is a low-nitrogen input system. This probably is responsible for the generally lower yields of organically cultivated produce, even by technically capable organic farm managers.
Worthington (2001) cited that organic manuring increased vitamin C in lettuce, potato, cabbage and spinach compared to cultivation without organic manuring, the effect being negative for carrot. However, Ismail and Fun (2003) observed increased vitamin C levels only in organically manured swamp cabbage; the organic matter had no effect on vitamin C in Chinese mustard, lettuce and spinach. Warman and Havard (1998) have claimed that it is difficult to indicate which sweet maize cultivation method- mineral fertiliser or organic manure-based one, more favourably influences vitamin C content in sweet corn kernels. The vitamin C content can be influenced by kernel maturity, fertility and moisture content in the soil, cultivation, meteorological conditions and even time of the day (Shewfelt, 1990).

Conclusion

Based on the results, obtained effects of the cover crops, with and without microbiological fertilizer, on content of vitamin C in grain of sweet maize grown on chernozem under rain fed conditions, the following can be concluded: Meteorological conditions during the trial had an important impact on content of vitamin C in all the cropping systems. In favorable year (such as 2014), biofertilizer did not show an effect on the content of vitamin C, and in the second year application of this fertilizer have shown efficacy trough very significant increases in the content of vitamin C. The greatest impact on vitamin C content was exhibited in variant of fodder kale but the lowest in variant with mixture of winter oats and common vetch.

Acknowlegdement

Abstract

Oxygen is an essential component of our life, but imbalance in metabolism and production of reactive oxygen species (ROS) generate some disorders such as Alzheimer's disease, Parkinson's disease, aging and many other neural disorders. The high level or incorporation of free radicals to living system leads to processes of neurodegeneration. The antioxidant system of body plays important role in prevention of many diseases caused by the effect of radicals. The perspective therapeutic resource is a diet rich in natural antioxidants. Nowadays, research is focused on medicinal herbs as a commercial source of antioxidants. This study was conducted to evaluate the potential antioxidant properties of ethanol extracts *Salvia officinalis* L., *Rosmarinus officinalis* L. and commercial tincture from sage (Florsalmin®). The extracts were prepared from dried and fresh plant material. The antioxidant activity was measured spectrophotometrically by DPPH method. The results were expressed by the percentage of DPPH radical inhibition (%) and statistically evaluated. The results of the investigation indicated that *Rosmarinus officinalis* ethanol extract from fresh plant material showed the higher inhibitory capacity of DPPH radical. The inhibition value of DPPH by ethanol extract of *Rosmarinus officinalis* L. was 48.13% (in t = 0 minutes) and 67.46% (t = 35 minutes). Statistical significance in DPPH inhibition values was found in comparing fresh sage ethanol extracts and Florsalmin® at t = 10 and t = 15 ($p < 0.04$). By comparing dries sage and Florsalmin® statistical significance $p<0.008$ was found. We did not found a statistical significance between rosemary extracts and Florsalmin®.

Keywords: *DPPH, Free radicals, Neurodegenerative diseases, Fresh plant material, Dried plant material.*

Introduction

The human organism is exposed to free radicals in everyday activities. Free radicals come not only from the outside environment, but also from the internal environment due to various reactions of metabolism or energy production. Antioxidant and oxidative compounds are in a certain equilibrium in the organism, and this condition is disturbed by changes in free radical concentration. Oxidative damage to the central nervous system can have a serious impact on human health. Damage to some of the central nervous system may accumulate free radicals and cause degenerative processes. The result of these processes is the emergence of neurodegenerative diseases. The most well known are Alzheimer's disease, Parkinson's disease, Huntington's disease and amyotrophic lateral sclerosis.

In connection with neurodegenerative diseases, the relationship between neurodegeneration, free radicals and antiradical properties of natural substances is increasingly being discussed. The natural substances contained in the plant material show different positive properties for the human organism. Antiradical activity has been proven in several plant species belong in to the family (*Lamiaceae*), e.g. *Teucrium polium* L. showed a mild correlation between flavonoid content and antiradical activity determined by the DPPH method (Malki et al., 2015). Several studies (Obulescu *et al*, 2011; Özcan *et al*., 2015; Abuashwashi *et al*., 2016) have pointed to antiradical activity of *Salvia officinalis* L. and *Rosmarinus officinalis* L..

Material and method

Salvia officinalis L. and *Rosmarinus officinalis* L. contain rosemary acid and carnosic acid, which belong to important antioxidants. To compare antiradical activity, we used extracts from dried and fresh plant parts as well as purchased product FLORSALMIN® tincture of salvia, which is commonly available for inflammatory diseases of the oral cavity, gums and pharynx.

The plants were grown in the village Petkovce (49 ° 00'06 "S 21 ° 35'53" V), in the southwest part of Ondavska vrchovina at an altitude of about 205 meters, east of the river Topľa. The surface of the village Petkovce consists of loess and slopes. The plants were grown without any chemical preparations and other preparations that could affect the result.

Florsalmin® - medicinal salt tincture is a dilute hydroalcoholic salt extract of medical with anti-inflammatory and antimicrobial effect. It is liquid greenish to brown, strong aromatic scent. The medicine is used for inflammatory diseases of the oral cavity, gingivitis and pharynx, such as supportive treatment for angina and after surgery in the oral cavity, to suppress odor from the mouth. It is used internally for supportive treatment of increased potency of various origins in disorders of balance in the area of vegetative nerve, stress, obesity, increased activity of the thyroid and in the transition period in women with inappropriate hormonal treatment. The medicine can be taken by adults, adolescents and children. The medication is a medical salvia tincture (1: 6.6). The excipients are 60% ethanol (alcohol), purified water. Manufacturer: Saneca Pharmaceuticals a.s., Hlohovec, Slovakia. (Florsalmin®, 2010).

A study by Amaral et al. (2013) demonstrated that, according to the literature, ethanol extract of medicinal rosemary from other high concentrations of carnosic acid and rosmarinic acid, which are recognized as natural antioxidants, reinforces the importance of ethanol plant extracts as strong antioxidant compounds (Amaral *et al*., 2013). Therefore, we have decided to prepare ethanol extracts of selected plant species. For the preparation of ethanol extracts we used 25 grams dried and fresh plants.

The plants were extracted into 50 ml of 96% ethanol. The solutions were kept in a cool and dark place for 24 hours. The extracts were collected by filtration and the obtained extracts were stored in cold and dark place for 12 hours.

Determination of antiradical activity by DPPH method

For determination of antiradical activity we used DPPH method (Brand a Williams, 1995; Sachéz-Moreno *et al*. 1998). The DPPH solution was prepared daily from the DPPH radical in 96% ethanol. We used 0.006 g of DPPH radical and 250 ml of 96% ethanol. The solution was mixed by ultrasonic stirrer and stored in a cold and dark place.

For determination of antioxidant activity of analyzed samples we used the mixture of DPPH solution (in volume 5 ml) and analyzed extract or tincture Florsalmin® (in volume 10 ul). The reaction between active substances of extract and DPPH solution ran for 35 minutes at room temperature in the dark. For each analysed extract we used four measurement. Antioxidant activity was measured spectrophotometrically by spectrophotometer UV-1800 (Schimadzu, Japan). The kinetic reaction was manifested by decoloration of solution and as a decrease in measured absorbance at λ = 517 nm. This reaction was observed at time intervals - in 5 minute at 8 times. Activity of antioxidants in the analyzed extracts was presented by inhibition of DPPH radical. Formula for inhibition of DPPH radical is presented as:

$$\text{Percentage (\%) of inhibition DPPH radical} = [(A_{C0}-A_{AT}) / A_{C0}] * 100$$

Percentage (%) of inhibition DPPH radical represents the ability of the monitored extract to remove DPPH at a certain time, A_{C0} is the absorbance value of DPPH solution at time t = 0 minutes and A_{AT} presents the sample absorbance value in the presence of antioxidant at time t = 0 minutes to t = 35 minutes (Habanová *et al.*, 2008). The results were statistically evaluated.

Results and discussion

The antioxidant activity was determined in the extracts of *Salvia officinalis* L., *Rosmarinus officinalis* L. and in tincture Florsalmin®. Plants were selected on the base of their basic properties - they contain rosaric acid and carnosic acid, which are strong antioxidants compound. Recent studies have shown that *Salvia officinalis* L. and *Rosmarinus officinalis* L. have similar properties and composition of phenolic compounds and their antioxidant activity were especially attributed to rosinic acid and carnosic acid (Erkan *et al*., 2008).

For preparation of ethanol extracts was used 96.3 % ethanol. This concetration of ethanol increase the leaching of polyphenols - anthocyanins in the extracts (Li *et al*., 2007; Angela *et al.* 2008).

In all analysed samples and tincture Florsalmin® was detected a decrease in absorbance. A more pronounced decrease in absorbance was measured in the first half of the measurement (at 0 minutes, 5 minutes, 10 minutes). In the second half of the measurement, the decrease in absorbance significantly slowed, respectively, stagnated at one absorbance value. That indicated finished reaction of active substance and DPPH radical. From obtained values of absorbance was calculated percentage of inhibition of DPPH radical by active substance in extracts and tincture.

The highest antiradical activity was shown by the Florsalmin® tincture sample. The percentage of inhibition at the beginning of the measurement at t = 0 minutes was 63.07 % and at the end of the measurement at t = 35 minutes showed percentage of inhibition 85.55 %. This indicates a good ability to free radicals uptake. The lowest antioxidant activity determined by DPPH method showed a sample of dried *Salvia officinalis* L.. The percentage of inhibition of DPPH radical in the start of the measurement was 30.17% at time t = 0 min, and in the end of measurement, at the time t = 35 minutes was the value of percentage of inhibition 42.05%. The extract from fresh *Salvia officinalis* L. showed the ability to uptake DPPH radical at t = 0 minutes 32.28% and at time t = 35 minutes 44.16%. In compare of antioxidant properties of extracts showed the extract from fresh *Salvia officinalis* L. the highest antioxidant ability. Similar results were found in extracts from fresh (t = 0 minutes, I = 48,13 %; t = 35 minutes, I = 67,46 %) and dried (t = 0 minutes, I = 35,66 %; t = 35 minutes, I = 51,61 %) *Rosmarinus officinalis* L..

A different methodology was used to measure antioxidant properties of *Salvia officinalis* L. in study Roman, Neagu and Radu (2009). They measured the antioxidant properties of the methanol extract of *Salvia officinalis* L. The measurement run at a wavelength of 516 nm. Percentage of inhibition was higher than in our case - 85% (Roman *et al*., 2009). According to the study by Kaledaite et al. (2011), *Salvia officinalis* L. had a low DPPH inhibition values and it contained fewer phenolic compounds (Kaledaite *et al*. 2011). Tepe et al. (2007) found that the antiradical effect of Salvia officinalis L. does not depend on the number of phenolic compounds but on the position of *ortho*- and *para*- hydroxyl groups, which increases the polarity of the compound and increases its ability to capture free radicals (Tepe *et al*., 2007).

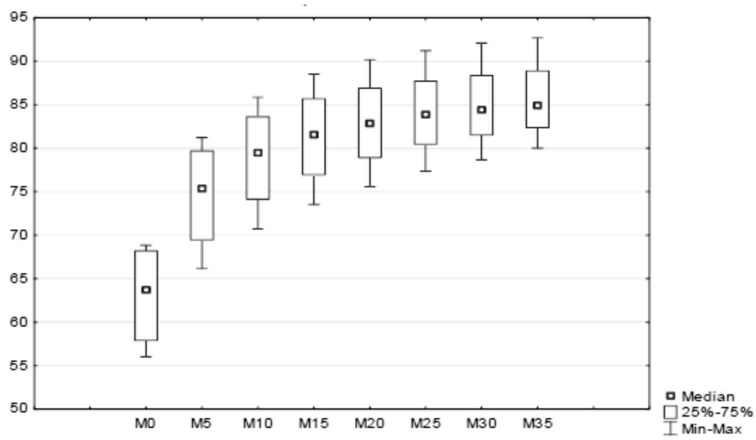
According to Papageorgiou et al. (2008) has *Rosmarinus officinalis* L. a more potent antioxidant activity and higher antiradical activity during February as during May, so the ability to free radicals also affects the vegetation state and harvest time (Papageorgiou et al., 2008). Luis and Johnson (2005) studied antioxidant properties of *Rosmarinus officinalis* L. and they claimed, that the extracts of leaves are dependent on the concentration of rosmarinic acid and carnosic acid as well as the presence of other important constituents such as carnosol. The content of substances also affects the ecological growth conditions that affect the antioxidant potential of *Rosmarinus officinalis* L. (Luis *et al*., 2005).

The STATISTICA program was used to statistical process the results obtained. Friedman's analysis of variance revealed by significant differences. From the resulting values we found that Florsalmin® tincture has the highest increments among other extracts depending on time. The highest differences was detected at time t = 5 - 0 min, where Florsalmin® tincture had the highest increase (11,51). The increment in extracts of fresh *Rosmarinus officinalis* L. are significant at t = 5 - 0 min (6,41). The least significant is the average increment for dried Rosmarinus officinalis L. over a period of 5-0 min..

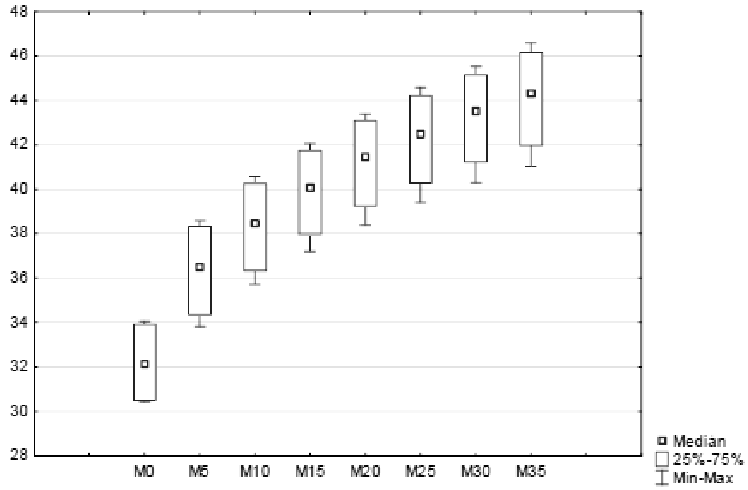
The difference between increments at time t = 5 - 0 min in fresh *Salvia officinalis* L. (4,13) and dried *Salvia officinalis* L. (3,93) are not significant. Extract from dried *Rosmarinus officinalis* L. showed the smallest differences. From 15 minutes, the differences between the samples were insignificant.

To test the significance in differences in the mean of the observed extracts, we used a variance analysis – ANOVA. Based on Kendall's conformity factor, the median represented a mean value. We were interested in the value p = 0.00022, which showed that the results of the measurements varied, depending on the time, by increasing the values. The graphs show that there are bigger differences in the diameters between the samples and Florsalmin® tincture, fresh and dried sage, fresh and dried rosemary. Interestingly, Florsalmin® tincture sample and the rosemary dried sample showed a decrease in data variability, although the other variability of data increased.

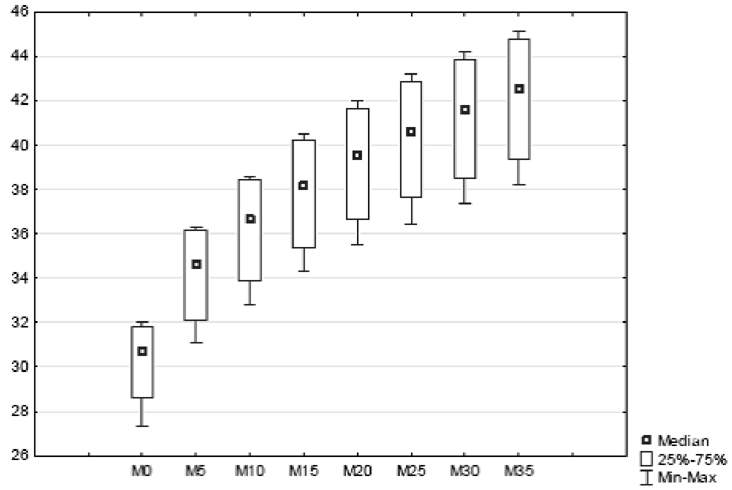
To statistically assess the significance of differences in the antiradical capability of selected samples, we used the Kruskal-Wallis test. The significant differences were confirmed in each measured time (0-35 min) between Florsalmin® tincture and fresh *Salvia officinalis* L. (in all cases at the level of 0.05) and between Florsalmin® tincture and dried *Salvia officinalis* L. (at level 0.01). Based on the Kruskal-Wallis test, multiple values of p values were statistically significant for Florsalmin® tincture, fresh and dried *Salvia officinalis* L. at time t = 0 minutes. On the based of the comparison of the values, the association between tincture and fresh Salvia officinalis L. was found (0,041236) and dried *Salvia officinalis* L. (0.008180). At time t = 5 min, associations between Florsalmin® and *Salvia officinalis* L. were found in extracts of fresh *Salvia officinalis* L. (0,041236) and dried *Salvia officinalis* L. (0,008180). At time t = 10 minutes and 15 minutes, there was also a statistically significant relationship found between tincture and extracts from *Salvia officinalis* L. fresh (0.041236) and *Salvia officinalis* L. dried (0.008180). The relationship between Florsalmin® and extracts from fresh *Salvia officinalis* L. (0.018862) and dried *Salvia officinalis* L. (0.003362) at t = 20-35 min was also statistically significant.



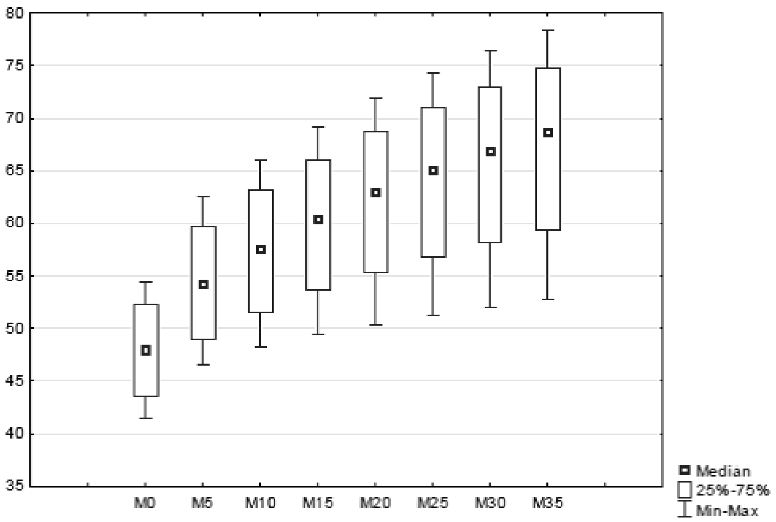
Graph 1: Florsalmin®



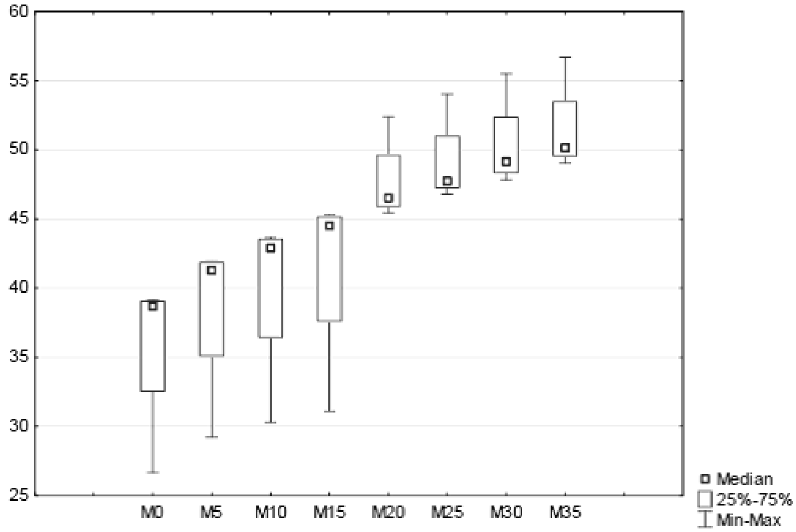
Graph 2: Extracts of fresh *Salvia officinalis* L.



Graph 3: Extracts of dried *Salvia officinalis* L.



Graph 4: Extracts of fresh *Rosmarinus officinalis* L.



Graph 5: Extracts of dried *Rosmarinus officinalis* L.

Conclusion

The statistically significant difference is between Florsalmin® and extract from dried and fresh *Salvia officinalis* L., similarly statistically significant difference was also determined by ANOVA in a study by Nickavar, Kamalinejad and Izadpanah (2007). *Rosmarinus officinalis* L. did not have a significant relationship with Florsalmin® or *Salvia officinalis* L. on the basis of a comparison of *p* values.

GRAIN AND PROTEIN YIELD OF SELECTED GRAIN LEGUMES IN SUB-ALPINE AND PANNONIAN GROWING CONDITIONS

Aleš KOLMANIČ

Crop Science Department, Agricultural Institute of Slovenia, Ljubljana, Slovenia
*Corresponding author: ales.kolmanic@kis.si

Abstract

The present article discusses the productivity of selected grain legumes in integrated production systems in sub-alpine (Jablje) and pannonian (Rakičan) growing conditions in Slovenia. With the decline in legume cultivation Slovenia is a net importer of grain legumes. Furthermore, almost all soybean is imported and approximately 97% of imported soybean is GM. To support the introduction of soybean and reintroduction of selected grain legumes, a three year state project was started in autumn 2014. Twenty-six cultivars of soybean, four cultivars of peas, two faba-beans, blue, yellow and white lupin were tested in two growing conditions in 2016 and yields and content of protein were evaluated. Results in Jablje show that the average grain yields of soybean, faba-beans, peas, white, blue and yellow lupins were 4761, 3724, 3675, 3658, 2188 and 644 kg/ha, respectively. Average protein yields per hectare were 1718, 975, 579, 1277, 632 and 252 kg/ha, respectively. At Rakičan, unfavorable conditions with late spring frost, drought and high temperatures interrupted development of lupins. Therefore only soybeans, faba-beans and peas could be evaluated. Nevertheless, drought conditions during summer also significantly affected soybean development, reducing yields and crude protein content. Average grain yields of soybean, peas and faba-beans were 3223, 4295 and 2291 kg/ha, respectively. Average protein yields per hectare were 895, 799 and 588 kg/ha, respectively. Results show that soybean had higher average yields of grain compared to other legumes at Jablje while yields of peas were competitive at Rakičan. Nevertheless, overall high crude protein content of soybean resulted in highest protein yield per hectare at both locations.

Keywords: *Soybean, pea, faba-bean, lupin, grain yields, protein yields*

Introduction

General trends in agriculture towards simplification and specialization are partly responsible for a significant decline in legume cultivation and plant diversity at the farm level in Europe (Brouwer, 2006). However, the resulting high deficiency of high quality plant proteins for animal feeding in Europe is the main driver of high grain legume imports, especially imports of soybeans from North and South America (Nemecek et al., 2008). Soybean is globally the most important legume in agriculture and one of the four most important crops worldwide in providing food security (Ray et al., 2013). Slovenia is a net importer of grain legumes with close to 70% of legumes imported. The share of imported soybean is even higher and the fact that 97.5% of the imported soybean is genetically modified creates additional important negative public opinion. To decrease the production deficit of plant proteins and dependence on the import of plant protein the general consensus in the EU was to promote the cultivation of protein crops (Bues et al., 2013). As a result, the CAP 2014-2020 is supporting grain legumes with a number of measures. Legumes are an important part of agriculture, providing many environmental benefits and ecosystem services (Zander et al., 2016). Intensive production systems in Slovenia rely mainly on high external nitrogen inputs to achieve high production levels. The negative side of such systems is the range of environmental issues, as discussed by Van Grinsven et al. (2014) and Bavec et al. (2015). An important benefit of legumes is also the possible reduction of mineral nitrogen fertilizer applications, as most of the legumes have the ability to develop root nodules and fix N_2 with compatible rhizobia in symbiosis (Bues et al., 2013; Graham and Vance, 2003). Soybean cultivation in Central Europe is relatively new as breeding of early-maturing varieties suited to growing conditions in central Europe started a few years ago (Zimmer et al., 2016). In Slovenia only a small percentage of fields was cultivated with soybean until 2015 (STAT, 2017). However, the introduction of early varieties and financial stimulation in the CAP 2014-2020 (ca. 2,759,740 EUR in 2015 or ca. 330 EUR/ha in Slovenia) resulted in a rapid increase of legume cultivation in 2015 and 2016, especially the cultivation of soybean. Soybean cultivation increased from 404 ha in 2014 to 1705 and 2466 ha in 2015 and 2016, respectively. Cultivation of peas also increased from 221 ha in 2014 to 447 and 611 ha in 2015 and 2016, respectively. The Slovenian Ministry for Agriculture, Food and Forestry started a three-year state research project named "Soybean" in the late summer of 2014. Two faculties and two research institutes have participated in the project with the main goal to increase the cultivation of grain legumes in Slovenia. As the name suggests, soybean is the main focus of the project. Nevertheless, the potential of pea, faba-bean and lupin production in different pedo-climate conditions are also studied.

The aim of this paper is to present an overview of grain and the protein production potential of different varieties of soybean (*Glycine max* L. Merrill), peas (*Pisum sativum* L.), faba-beans (*Vicia faba* L.), blue lupin (*Lupinus angustifolius* L.), yellow lupin (*Lupinus luteus* L.) and white lupin (*Lupinus albus* L.) in two climates (semi-arid pannonian and sub-alpine) and soil conditions (sandy and clay soils) observed in 2016.

Materials and Methods

Experimental fields are located at Jablje, (central Slovenia, 46°8′N, 14°33′E, altitude 307 m, pH 5.9) and Rakičan (east Slovenia, 46°39′N, 16°11′E, altitude 186 mm, pH 6.4). The Jablje climate is categorized as sub-Alpine (cool and wet growing conditions, average yearly precipitation 1367 mm, average yearly temperature 8.96 °C) and the Rakičan climate is categorized as Pannonian (semi-arid conditions, average yearly precipitation 812 mm, average yearly temperatures 9.77 °C). Soil texture at Jablje is a clay loam, characterized with slow infiltration and good water retention capacity. At Rakičan a brown loamy sand soil is characterized with high infiltration and low retention capacity. Twentysix varieties of soybean, four varieties of pea, two varieties of faba-bean and one variety of blue, yellow and white lupin were included in the experiment in 2016. The experiment was arranged as a completely randomized block design with four replications. Each experimental plot was 6x2.5 m^2. At both locations soils were prepared for sowing with the use of minimum tillage. Seeding density was 50-120 plants per m^2 (depending on grain legume, maturity and the germination percentage) and row spacing was 25 cm. Seeds were sown using a Wintersteiger experimental seeder for small grain cereals. Prior to seeding, all soybeans seeds were inoculated with *Bradyrhizobium japonicum*. However, as limited nodulation was observed, 60 kg of N was added with mineral nitrogen fertilisers during growth. P_2O_5 and K_2O were applied according to the results of AL analysis. Blocks were sprayed with post-emergence herbicides to prevent weed development. Crops were harvested with a Wintersteiger plot harvester when most of the varieties achieved full maturity. Grain was then weighed and samples were prepared for further analysis. Grain moisture was measured immediately after harvest and if necessary samples were dried to 9% moisture at 40°C. Moisture was determined by heating the samples at 103°C for 4 h (EC 152/2009 App. III A). Dried samples from all the repetitions were then taken and combined to estimate average of crude protein content of the variety. Crude proteins were analysed using the method ISO 5983, with a conversion factor of 6.25. Protein yields were calculated by multiplying the crude protein content on dry matter (DM) basis with the yields of dry matter per hectare.

Results and Discussion

Jablje: Weather conditions in 2016 were not optimal for soybean cultivation. Monthly precipitation was close to average for most of the growing period (Table 1). Sowing and early development was affected with intense rain resulting in water-saturated fields. Average monthly temperatures were above the long-term average (1981-2010) with peak temperatures (+33 °C) occurring during soybean flowering and pod formation. During harvest, intense rain delayed harvest and increased grain moisture contents. Solar radiation in 2016 was slightly above average.

Table 1: Basic weather parameters at Jablje

months	I	II	III	IV	V	VI	VII	VIII	IX	X
Average temperatures in 2016	-1	3.6	5.5	10.4	13.9	18.5	21.3	18.9	16.4	8.7
Long term average temperatures	-1.7	-0.2	4.1	8.8	14.1	17.4	19.4	18.7	14.2	9.6
Average precipitation in 2016	67.5	191.3	90.2	100.2	113.8	147.8	90.7	114.9	43.3	137.4
Long-term average precipitation	66	65	90	95	107	145	122	135	140	137

Long-term=1981-2010

Relatively favourable growing conditions resulted in very high yields of grain legumes (Figure 1). Average grain yields of soybean (9% moisture) varied from 3778 kg/ha to 5387 kg/ha. Average yields of peas varied from 3424 kg/ha to 4009 kg/ha. Average yields of faba-bean varied from 3302 kg/ha to 4145 kg/ha. Average grain yields of lupins were 643 kg/ha, 2188 kg/ha and 3658 kg/ha for yellow, blue and white lupin, respectively. Overall, the highest grain-yielding variety of soybean was 'Silvia PZO' (5387 kg/ha, 21.5% grain moisture at harvest), maturity group 0/00. The second highest-yielding variety was 'PR91M10' (5381 kg/ha, 21.9% grain moisture), maturity group 0. Ten varieties of soybean achieved average yields of above 5000 kg/ha with no significant differences observed among them (data not shown). The highest-yielding variety of pea was 'Astronavte', yielding 4009 kg/ha at 15.2% moisture. The highest-yielding variety of faba-bean was Slovenian variety 'Zoran', yielding 4145 kg/ha at 13.6% moisture.

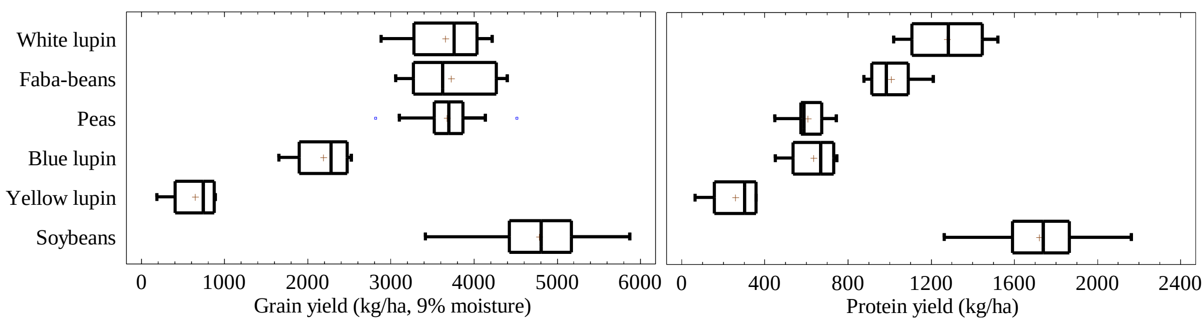

Figure 1: Comparison of average yields of different legumes at Jablje in 2016

Some variability was observed with grain yields. High volatility of grain yields of legumes has been much discussed and yield instability is a major obstacle in increasing legume cultivation. Nevertheless, agronomic measurements to improve yield stability are limited

(Zander et al., 2016). Crude protein content of soybean ranged from 362 g/kg DM, the lowest, to 430 g/kg DM, the highest. The content was higher compared with peas (167-186 g/kg DM), faba-bean (282-294 g/kg DM) and blue lupin (299-326 g/kg DM). Protein content of white lupine (358-396 g/kg DM) was comparable to soybean and protein content of yellow lupine (386-449 g/kg DM) was higher. Protein yields per hectare were highest with soybean and varied from 1349 kg/ha, the lowest, to 1945 kg/ha the highest. The difference between the soybean variety with the highest ('Shouna') and the lowest ('Smuglyanka') protein yield was 30%. Protein yields of pea, faba-bean, blue and yellow lupin were lower. Furthermore, yellow lupin and pea were overall the lowest protein-yielding legumes at Jablje (252-633 kg/ha. However, the protein yield of white lupin variety 'Energy' (1277 kg/ha was comparable to the lowest yielding varieties of soybean.

Rakičan: Conditions for legume growth and development in 2016 were not optimal for legumes (Table 2). A drought period in April and intense frost in late April severely affected lupins. Therefore no yield data for lupins were collected on this location. Average monthly temperatures were above the long-term average (1981-2010) with peak temperatures (+35°C) occurring during the soybean reproductive stage. Monthly precipitations were close to average from May to July. Low water-holding capacity of soils, below average precipitation and high temperatures occurred at the end of August and persisted almost to the end of September. This resulted in premature maturation of soybean. Solar radiation in 2016 was slightly above average.

Table 2: Basic weather parameters at Rakičan

months	I	II	III	IV	V	VI	VII	VII	IX	X
Average temperatures in 2016	-0.2	5.9	6.9	12.2	15.6	19.8	22.0	19.5	17.4	9.6
Long term average temperatures	-0.8	0.9	5.3	10.2	15.4	18.6	20.4	19.6	15.1	10.3
Average precipitation in 2016	34.6	108.9	37.9	37.0	123.4	110.3	81.9	53.1	27.9	78.3
Long-term average precipitation	37	36	58	61	86	114	98	111	106	88

Long-term=1981-2010

Average yields of soybeans varied from 2760 kg/ha to 3835 kg/ha (Figure 2). The highest yield was achieved with variety 'Giuliette' (3835 kg/ha), maturity group 1. Nevertheless, this variety was too late maturing, having 43.2% grain moisture at harvest. The second highest yielding soybean variety was 'ES Mentor' (3659 kg/ha, 15.9% moisture), maturity group 00. Eight varieties with grain yield above 3340 kg/ha showed no statistical differences among them (data not shown). Average yields of peas varied from 4248 kg/ha to 4343 kg/ha. No significant differences were observed amongst the varieties. Average yields of faba-beans varied from 2108 kg/ha to 2474 kg/ha. Yields of variety 'Merkur' were significantly higher. Average grain yields (9% moisture) of soybean at Rakičan were lower compared to Jablje, indicating more unfavourable growing conditions. Faba-bean also showed low adaptability to conditions at Rakičan, with a high infection rate with *Botrytis fabae* and very low competitiveness with weeds. On the contrary, yields of peas were higher compared to soybeans at Rakičan. The highest average yielding legumes were peas (4294 kg/ha), followed by soybeans (3223 kg/ha) and faba-beans (2291 kg/ha). Crude protein content of soybeans ranged from 257 g/kg DM to 343 g/kg DM. Protein content was higher compared to peas, 189-198 g/kg DM, and faba-beans, 279-284 g/kg DM. The highest calculated protein yield was observed with variety "ES Mentor" (1142 kg/ha). Lowest calculated protein yield was observed with the variety "Sanda" (770 kg/ha). Difference between the highest and the lowest protein yield was ca 60.3%. Protein yields of peas varied from 779 kg/ha to 814 kg/ha.

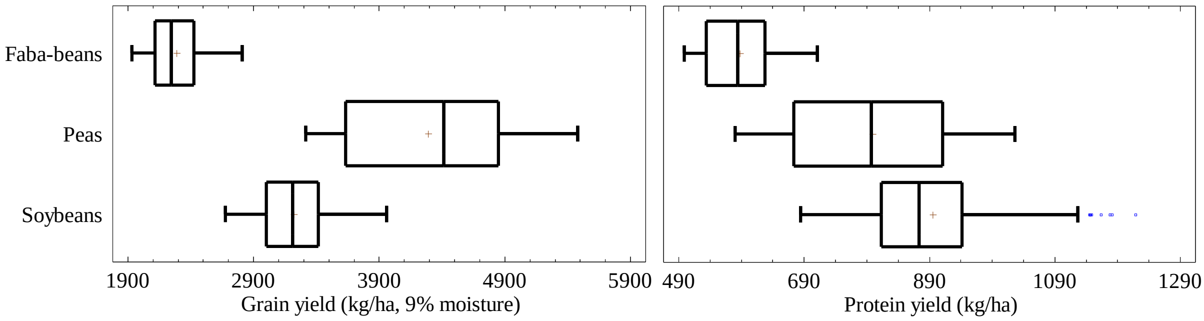

Figure 2: Comparison of average yields of different legumes at Rakičan in 2016

Water deficit can result in smaller plants and more pods per plant, correlating with less biomass and lower 1000-seed weight (Dogan et al., 2007). Drought also affects protein and fat content in the grains. Therefore, cultivation of soybean in semi-arid growth conditions could be risky. Peas are in theory more appropriate for semi-arid conditions. However, at both locations the varieties of peas showed high tendencies to lodge and some varieties were showing a tendency for grain loss. Lodging is a serious problem in dry pea cultivation, significantly affecting yields (Singh and Srivastava, 2015) and consequently reducing its competitiveness with soybean in semi-arid conditions. Nevertheless, various agronomical managements can be implemented to minimize this tendency (Schouls and Langelaan, 1994). Faba-beans, blue and yellow lupin varieties used in the experiment were shown not to be competitive with soybean and peas. Reasons for this can be partially found in a high rate of infection with fungal diseases, poor competition with weeds and considerable late spring frost damage.

Conclusions

Results of trials showed that soybean had higher average yields of grain compared to other legumes at Jablje (sub-alpine climate) while average yields of peas were higher at Rakičan (pannonian climate). Nevertheless, with its high crude protein content, soybean gave the highest protein yield per hectare at both locations. With the exception of white lupin at Jablje, yields of lupins and faba-beans were not competitive. Optimal soybean maturity groups for Slovenia were 00-000, though maturity group 0 could also be recommended for sowing. Intensive production systems in Slovenia rely mainly on high external nitrogen inputs to achieve high production levels. Increase of the share of soybean in cropping systems could have multiple environmental benefits, not only on reducing imports of plant proteins but also on reducing nitrogen inputs. However, symbiotic fixation was questionable with only a few nodules per plant observed in the 2016 trials. Therefore the expected reduction of nitrogen inputs with an increasing share of soybean cultivation could also be questionable and needs further evaluation.

EFFECT OF OPTIMIZED REGULATED DEFICIT IRRIGATION ON THE PROFITABILITY OF PURPLE GARLIC IN A SEMIARID REGION OF SPAIN

Abstract

In the semiarid areas of Spain the main limitation factor for agriculture is the availability of irrigation water. MOPECO (model for the economic optimization of the irrigation water) aims to maximize the profitability of irrigated farms through a more efficient use of available irrigation water and cultivable area. For reaching this objective, the model combines the "optimized regulated deficit irrigation" (ORDI) methodology with the typical meteorological year. A two years experiment (2015 and 2016) was conducted in Albacete in order to determine the effect of ORDI on the yield, quality and profitability of the purple garlic cultivar "Morado de Las Pedroñeras". The crop received five irrigation doses: Non deficit (control), 100% of typical irrigation requirements (IR) of the crop in the area, 90% IR, 80% IR, and 70% IR. As expected, yield increased with the volume of irrigation water supplied to the crop (from 8256 to 10055 kg ha^{-1} of 70% IR and Non deficit treatments, respectively). Nevertheless, the water productivity in economic terms was higher for the ORDI treatments (from 3.34 to 5.53 € m^{-3} of Non deficit and 70% IR treatments, respectively). In consequence, for a similar volume of available irrigation water, producers can increase the profitability of their farms by cropping a higher area (that cannot be irrigated due to the lack of water) applying a volume of water per hectare (managed by using the ORDI methodology) lower than the irrigation requirements of the crop.

Keywords: *Water productivity, MOPECO, crop modelling, ORDI, typical meteorological year.*

Introduction

Farms are businesses that intend to get profits through the production of food. This sector is highly conditioned by numerous economic (i.e. harvest price, labor costs…), political (i.e. customs duty, production subventions, laws for the protection of the environment…), social (i.e. food security, maintain rural population…), technical (i.e. machinery, crops…), and environmental (i.e. climate, soil, diseases…) factors.

In arid and semiarid areas, the lack of water resources for irrigation is a relevant determinant for agricultural production. Moreover, the progressive price increase of the energy required for supplying irrigation water to crops, as well as the low price of harvests in the international market (FAO, 2017), are conditioning the profitability of irrigated farms in these areas.

Garlic (*Allium sativum* L.) is one of the most disseminated crops in the world (around 1.5 Mha) (FAO, 2017). The 58% of the total cultivated area in Spain (21.000 ha) is located in Castilla-La Mancha (CLM) region (MAGRAMA, 2015). In this area it is cropped a high quality purple cultivar called "Ajo Morado de Las Pedroñeras", which is affected by the competence of white cultivars (higher yields and lower cultivation costs).

More than the 95% of the garlic cultivated area in CLM is irrigated (MAGRAMA, 2016). However, the amount of water that farmers can use for irrigating is limited due to the scarcity of water resources in this region. This fact, in addition with the high cost of the energy required by the pressurized irrigation systems, has caused that farmers demand strategies to improve the efficiency of water use and make more profitable the cultivation of purple garlic (Fabeiro et al., 2003).

MOPECO model (Ortega et al., 2004) was conceived for optimizing the gross margin (GM) of irrigated farms, especially in arid or semiarid areas with water scarcity and/or high crop costs that may affect the profitability of agricultural activities. The model determines the area and the amount of water to be dedicated to each crop for maximizing the GM of a farm, depending on the availability of both irrigable land and volume of irrigation water (López-Mata et al., 2016). The volume of irrigation water is translated into full irrigation or into the level of deficit that must be reached at the end of the cropping period. Leite et al. (2015) developed a methodology for optimizing the allocation of a certain volume of irrigation water (lower than the typical irrigation requirements of the crop) during the cropping season for maximizing yield, which is based on the "optimized regulated deficit irrigation" (ORDI) (Domínguez et al., 2012) and the "typical meteorological year" (TMY) (Domínguez et al., 2013) methodologies.

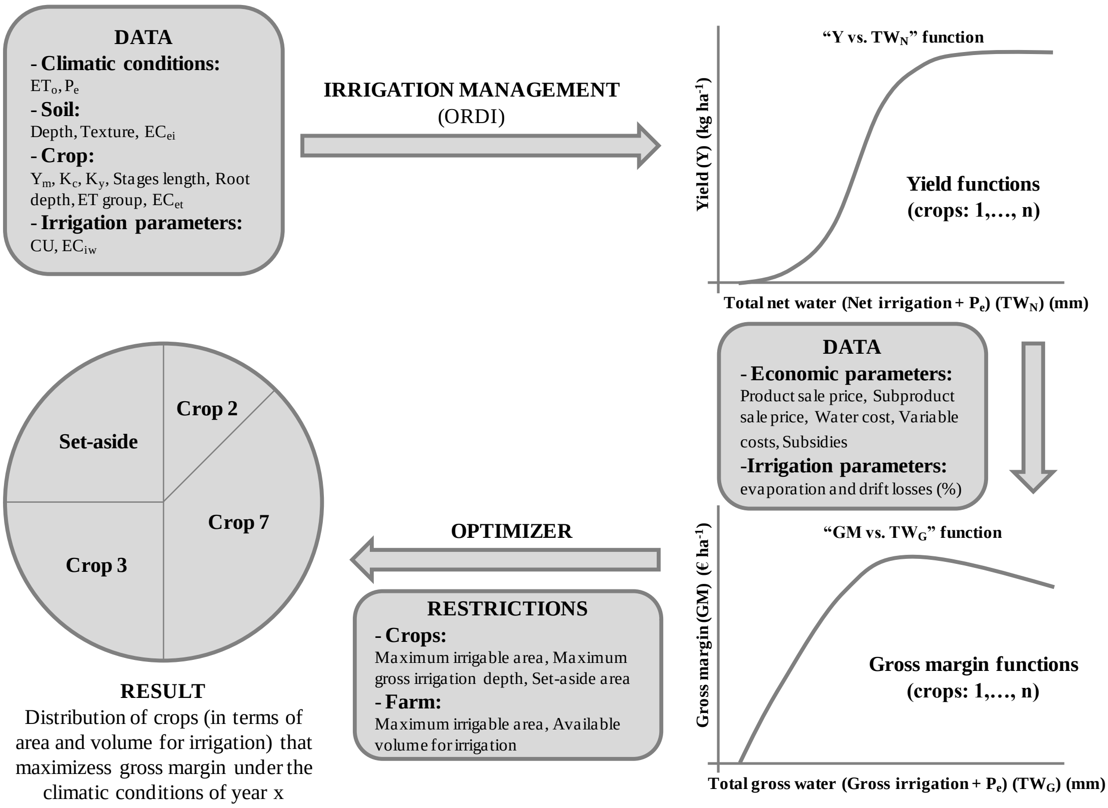
The main aim of this work was to validate the methodology "ORDI for limited volumes of irrigation water" on a garlic crop, and to analyse the effect of this methodology on yield, diameter of bulbs, and farms profitability under the semiarid conditions of CLM.

Material and Methods

The two years field experiment was conducted during years 2015 and 2016 in Albacete (Spain). Bulbs were manually seeded with 0.08 m between plants and 0.50 m between lines. There were four experimental plots (2.5 x 18.0 m) per deficit treatment randomly distributed, while in the case of the T100 and SD treatments there were three. The irrigation system was drip irrigation (0.5 x 0.5 m between pipes and emitters) with self-compensating emitters (flow: 3,8 l h^{-1}). In each treatment a precision flowmeter was installed for measuring the total amount of water received by the crop. Moreover, in each plot two tensiometers (at 20 and 40 cm depth) and one volumetric probe (four sensors at 10, 20, 30 and 40 cm depth) were installed. The climatic data were registered by a climatic weather station placed at the experimental farm. The soil of the experiment was classified as Xeric Torriorthent with a loam texture while the average soil depth was 40 cm. The electrical conductivity of the irrigation water is the usual in the area (0.8 dS m^{-1}).

Five volumes of irrigation water were supplied to the crop: no deficit "SD", and other four with different limited volumes of available irrigation water: 100% "T100", 90% "T90", 80% "T80", and 70% "T70" of the net irrigation requirements for the climatic conditions of the typical meteorological year (TMY), which were calculated as 2750 m^3 ha^{-1} = T100.

The aim of MOPECO is to maximize gross margin (GM) through the efficient use of irrigation water. A set of data is required for the simulation of the optimal "Yield vs. Total Net Water" (Y *vs.* TW_N) function of each crop under the climatic conditions of a certain year. In this function, TW_N = net irrigation (I_N) + effective rainfall (P_e). To obtain Y *vs.* TW_N, the model simulates a range of deficit irrigation schedules using the optimized regulated deficit irrigation (ORDI) methodology, considering the effects of irrigation uniformity and electrical conductivity of water on yield. The Y *vs.* TW_N function is translated into "Yield vs. Total Gross Water" (Y *vs.* TW_G), where TW_G = gross irrigation (I_G) + P_e, to include the application efficiency of the irrigation system. The GM *vs.* TW_G function is then calculated using economic data of the crop. Finally, the model calculates the optimal distribution of crops that fulfil the restrictions imposed by the user (crops, irrigable area, and available amount of water for irrigation) (Fig. 1).



ET_o: daily reference evapotranspiration (mm); P_e: daily effective rainfall (mm); EC_{ei}: water conductivity of the saturated soil extract at the beginning of the irrigation season (dS m^{-1}); Y_m: potential yield of the crop in the area (kg ha^{-1}); K_c: crop coefficient (dimensionless) (Allen et al., 1998); K_y: crop yield response factor by growing stage (dimensionless) (Doorenbos and Kassam, 1979); EC_{et}: water conductivity of the saturated soil extract that decreases the evapotranspiration capacity of a crop (dS m^{-1}); ET group: it conditions the daily value of the fraction of the total available water (TAW) that a crop can extract without suffering water stress (Danuso et al., 1995); CU: uniformity coefficient of the irrigation system; EC_{iw}: electrical conductivity of the irrigation water in the area (dS m^{-1}).

Figure 1. Flowchart of MOPECO model.

From sowing to harvest, it was monitored the phenological progression of the crops by using the BBCH scale (Bleiholder et al., 2001). This monitoring allowed to determine the duration in growing-degree-days (GDD) (ºC) of each phenological stage.

The "ORDI for limited volumes of irrigation water" methodology (Leite et al., 2015) determined the actual versus maximum evapotranspiration rate (ETa/ETm) objective for each phenological stage of the crop depending on the availability of irrigation water and the forecasted climatic conditions according to the TMY. A TMY (Hall et al., 1978) represents the conditions considered "typical" over a long time period and it was adapted by Domínguez et al. (2013) for forecasting irrigation schedules. A TMY consists of 12 months selected from individual years and concatenated to form a complete year with daily values. These ETa/ETm objectives changed with time depending on the progression of the weather conditions during the cropping season.

The moment and the amount of irrigation water applied to each crop was determined by the soil water balance module of MOPECO (Domínguez et al., 2011), and corroborated by the readings of the soil moisture sensors installed in the experimental plots.

At harvest, several parameters were evaluated: yield, bulbs diameter distribution, and water productivity (WP) in terms of yield (kg mm^{-1}) and profitability (€ mm^{-1}). Harvest prices were obtained from Coopaman (Cooperativa de ajos de La Mancha), while cultivation costs were calculated by using real data of one standard farm.

Results and Discussion

As expected, the SD was the one that achieved the highest total yield in the two seasons, and the T70 the lowest, with significant differences observed between some treatments (Table 1). In consequence, SD was the treatment that reached the highest profitability per unit of area, while T70 reached the lowest (Table 1). On the contrary, the water productivity in terms of yield and profitability was highest for the T70 treatment (Table 1).

Table 1. Volume of irrigation water (IW), yield (Y), profitability (P), and water productivity (WP) in terms of yield (WPY) and profitability (WPP).

Year	Treatment	IW (m^3 ha^{-1})	Y (T ha^{-1})	P (€ ha^{-1})	WPY (kg m^{-3})	WPP (€ m^{-3})
2015	SD	2672	9.92a	9939.84	6.34c	3.72c
	T100	2672	9.92a	9939.84	6.34c	3.72c

a, b, c: significant homogeneous group ($p \geq 0.05$) between treatments (Duncan´s test)

The distribution of bulbs per diameter (Fig. 2) corroborates the P results in Table 1. The distribution of bulbs in 2015 was similar for all the treatments. However, in 2016 due to drier climatic conditions that increased the irrigation water requirements of the crop (Table 1), only SD reached a distribution of bulbs similar to 2015. In the rest of strategies, the distribution of bulbs was moved to the left (lower price categories).

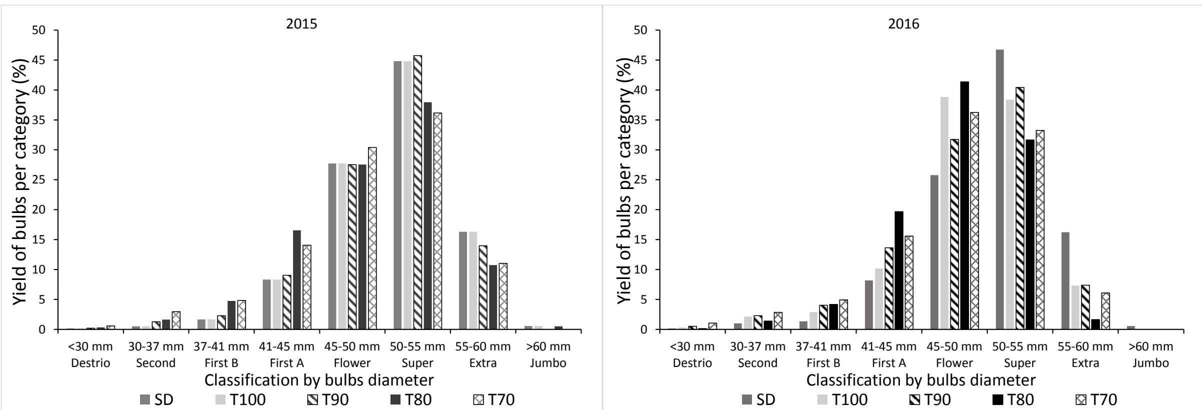

Figure 2. Yield of bulbs per diameter and year.

These results were used for analysing an example where a producer is planning the distribution of crops on its farm for the next season. In the last 20 ha this person wants to crop garlic, but the total amount of available irrigation water is 35,000 m^3, which is lower than the typical irrigation requirements of the crop (2750 m^3 ha^{-1}). So, the famer can opt by cropping a

lower area using the T100 strategy (no-deficit conditions under intermediate typical conditions) or by cropping a higher area applying the 70% of the typical irrigation requirements (T70). The rest of the area will be cultivated with a rain-fed crop that generates 150 € ha^{-1}. Moreover, three climatic conditions were considered: a dry year (irrigation requirements higher than typical), an intermediate year (irrigation requirements similar to typical), and a humid year (irrigation requirements lower than typical). The distribution of dry, intermediate and humid years in the area for ten years is 3, 4 and 3, respectively.
As expected, the profitability per unit of cropped area with garlic was higher for the T100 strategy in the three climatic scenarios (Table 2). However, due to it is possible to cultivate a higher area by using the T70 strategy (Table 2) and its higher WPP (Table 1), for the 20 ha of the farm, the T70 strategy reached a higher total profitability than T100 in the three climatic scenarios. This way, for the climatic distribution of dry, intermediate and humid years, the average profitability increase per unit of area of the farm would be around 890.45 €.

Table 2. Comparison between the T100 and T70 strategies under real conditions.

Strategy	Area (ha)	IW (m^3 ha^{-1})	Profitability of garlic (€ ha^{-1})			Profitability of the farm (20 ha)		
			Dry	**Intermediate**	**Humid**	**Dry**	**Intermediate**	**Humid**
T100	11.36	2,750	7,485	9,700	10,161	86,353	111,523	116,761
T70	16.23	1,925	5,608	7,219	9,762	91,601	117,751	159,039

Conclusions

The SD treatment was the one that reached the best combination between yield and calibre of bulbs with high commercial value in both seasons Nevertheless, this work has demonstrated that it is possible to increase the profitability of irrigation farms by cropping a higher percentage of the irrigable area but supplying the same amount of irrigation water using the ORDI methodology. This result is possible thanks to a greater water productivity of the deficit treatments (the average WP increment of T70 was 26% with regards SD).

Abstract

Brassica spp. have a great economic significance. They are widely distributed, and extensively cultivated throughout the world. Galega kale (*Brassica oleracea* var. *acephala* cv. Galega) is an important biennial crop in the Iberian Peninsula, especially in northern parts of Spain and Portugal. Some varieties of Galega kale have smooth leaves while others have curly or crinkly leaves. *Brassica* vegetables are important sources of dietary minerals. However, their content depends on factors such as species, variety, ecotype, maturity, agricultural practices, postharvest conditions and the plant part. The aims of this study were both, to investigate the six nutritionally important minerals of different edible portions of Galega kale (leaves, stems and whole plant) and to differentiate the curly- and smooth-leaved phenotypes. Curly- and smooth-leaved varieties of Galega kale were obtained from local markets supplied by six production areas in the province of Ourense (Galicia, NW Spain). All plants were harvested in the vegetative growth period. The edible portions were sorted into leaves and stems before being washed. The plants were also analysed whole (75% leaves and 25% stems). Minerals were assessed using an atomic absorption spectroscope. Galega kales is an excellent source of potassium, calcium or iron. Potassium was, quantitatively, the most important element in the sample analysed. Comparison of the varieties revealed higher K content and lower Fe content in whole curly kale than in whole smooth kale. Ca, Mg, Fe, Zn and Cu contents were higher in leaves than stems. However, K content was higher in stems than in leaves.

Keywords: *Minerals, Galega kale, Curly leaves, Smooth leaves.*

Introduction

Brassica spp. are considered health food protective and highly beneficial for the maintenance of health and prevention of diseases, as they are a rich source of bioactive compounds, such as vitamin C, polyphenols, glucosinolates, carotenoids, calcium or iron.
Kale (*Brassica oleracea* var *acephala*) is a nutritionally important crop grown all over the world whose the beneficial effects have been known for a long time (Kurilich *et al*., 1999; Podsędek, 2007). Kales are a rich source of minerals such as calcium, phosphorus, iron, magnesium, copper, and potassium (Lisiewska *et al.,* 2009; Martínez *et al*., 2011; Sikora and Bodziarczyk, 2012). Some of these minerals are commonly deficiencies micronutrient in both developed and developing countries (Welch and Grahan, 2002; White and Broadley, 2005).
Galega kale (*B. oleracea* var. *acephala* cv. Galega) is one of the oldest crops in Iberian Peninsula, especially in northern parts of Spain and Portugal. This vegetable has different varieties and ecotypes; some may have leaves with smooth or curly edges (Cartea *et al*., 2002). Generally, curly leaves are more appreciated by consumers than smooth leaves; however, smooth leaves are more expended because of the farmers use them for fodder.

Although some nutrients of Galega kales have been quantified in previous works no study has been conducted that includes data on the differences in mineral composition between curly and smooth kales.
The aims of this work were to investigate the six nutritionally important minerals of different edible portions of Galega kale (leaves, stems and whole plant) and to differentiate between the curly- and smooth-leaved phenotypes.

Material and Methods

Fresh curly and smooth Galega kales (*B. oleracea* var. *acephala* cv. Galega) were purchased from local markets serving different production areas in the province of Ourense (Galicia, northwest Spain). All plants were harvested in the vegetative growth period during 2015. Samples were uniform size, and appearance and were free of defects. For analytical purposes, inedible parts were discarded, and the edible portions were sorted into leaves and stems and washed. The plant was also analyzed whole (in this case, the proportion of leaves of stems was 75% leaves and 25% stems).
Determination of mineral content was performed in the central laboratory facilities (CACTI) at the University of Vigo. Samples (leaves, stems and whole plants) (0.5 g) were digested in a microwave oven (CEM MARSX press model, Matthews, NC) (1600 W, 20 min) after adding 1 mL of H_2O_2 and 10 mL of HNO_3. Potassium (K), calcium (Ca), magnesium (Mg), zinc (Zn) and iron (Fe) were assessed using an atomic absorption spectrosphotometer (Varian Spectra A-220 Fast Squencial; Agilent Technologies, Santa Clara, CA, USA). An inductively coupled plasma mass spectrometer (ICP-MS X Series, Thermo Fisher Scientific Inc., Waltham, MA) was used for copper (Cu) determination. The calculations of the minerals were based on the comparison of absorption of samples against known concentration of standards and results were converted. The results are expressed as dry weight basis.
Each sample was analysed at least in triplicate. Data are expressed as the means ± standard deviation (SD) of the measurements. Statistical analysis were conducted using two-way ANOVA with a confidence interval of 95 % ($P < 0.05$) and a least squares difference (LSD) test were performed using Statistica 8.0 software for Windows (Statsoft Inc. 1996, Tulsa, OK, USA). A canonical discriminant analysis (CDA) was performed in order to differentiate cooking procedure as a function of different studied parameters. The variables were selected for CDA by extraction of principal components (PCA) through a factor analysis, i.e. Those variables with the greatest discriminant capacity were selected.

Results and Discussion

Table 1 shows mineral contents of leaves, stems and whole Galega kales (curly and smooth). Galega kales are an excellent source of mineral, such as potassium, calcium or iron.
Potassium (K) was, quantitatively, the most important element in the sample analysed, followed by calcium and magnesium. The concentrations of K were higher in the stems (42.88-47.15 g/kg) than in the leaves (29.12-23.88 g/kg). In the leaves and whole plant, K contents were higher in curly kales than smooth kales; however, in the stems, those were higher in smooth kales. These data are consistent with the results reported by Kmiecik *et al.* (2007) in white and green cauliflower (30.35 and 32.47 g/kg, respectively) and Puupponen-Pimia *et al.* (2003) in cauliflower (40.8 g/kg). Mansour *et al*. (2015) also reported similar values to those we have found in broccoli and in cauliflower (40 and 39 g/kg, respectively). Rosa and Heaney (1996) also found that K content was higher in the stems than in the leaves of Portuguese cabbages and Galega kales.

Table 1. Minerals contents of the edible portions of two phenotypes of Galega kales (dry weight).

	Edible portions	K (g/kg)	Ca (g/kg)	Mg (g/kg)	Fe (mg/kg)	Zn (mg/kg)	Cu (mg/kg)
Curly kales	*Leaves*	29.12±2.62[a]	46.04±3.63[a]	3.62±0.30[a]	147.32±21.38[a]	28.07±2.07[a]	4.94±0.43[ac]
	Stems	42.88±1.61[b]	26.04±2.89[b]	2.94±0.26[b]	31.88±3.34[b]	17.59±2.18[b]	3.03±0.28[b]
	Whole	33.47±3.78[c]	33.42±5.20[c]	3.08±0.72[ab]	99.17±8,63[c]	27.97±1.04[a]	4.54±0.25[c]
Smooth kales	*Leaves*	23.88±2.11[d]	38.39±4.49[d]	3.29±0.42[ab]	103.04±17.43[c]	30.07±1.48[a]	5.32±0.22[a]
	Stems	47.15±3.75[e]	17.22±1.58[e]	2.08±0.23[c]	40.64±4.69[b]	16.43±5.46[b]	3.18±0.11[b]
	Whole	26.73±1.54[ad]	36.02±2.83[c]	2.97±0.32[b]	76.04±3.18[d]	28.34±0.98[a]	5.05±0.24[ac]

[a–e] Mean values of at least three determinations ± standard deviation (dry weight) with different superscript in the same column were significantly different ($P < 0.05$).

Calcium (Ca) was also found in an appreciable amount in Galega kales (33.42 and 31.21 g/kg in whole curly and smooth kales, respectively). Calcium content was higher in leaves than in stems, and curly kales showed higher calcium content than smooth kales. Rosa and Heaney (1996) obtained in kales values of Ca between 23.8 and 33.8 g/kg dry matter. Ali (2015) found calcium contents of 35.95 g/kg in cauliflower.

Magnesium (Mg) was found in higher concentrations in Galega kales (3.08-2.97 g/kg). Leaves showed higher values than stems. No significant differences were found between leaves and whole plant of curly and smooth kales. The results are consistent with those Ayaz *et al.* (2006) (2.4 g/kg) and Martínez *et al.* (2011) (2.9 g/kg) in kales.

Galega kales are also a good source of iron (Fe) (99.17-76.04 mg/kg). Leaves and whole plant in curly kales showed higher Fe content than those of smooth kales; however, stems of smooth kales had higher Fe content than those of curly kales. These results were similar to those reported by Rosa and Heaney (1996), and Martínez *et al.* (2011) in Galega kales. Ayaz *et al.* (2006) reported Fe content of 72.6 mg/kg in leaves of kale. Puupponen-Pimia *et al.* (2003) observed lower iron contents (45.7 mg/kg) in cauliflower.

The zinc (Zn) content was also higher in the leaves than the stems, and no significant differences between curly and smooth kales were observed. The results are similar to those reported by Rosa and Heaney (1996), and Martínez *et al.* (2011) in Galega kales. Puupponen-Pimia *et al.* (2003) found Fe content of 35.8 mg/kg in cauliflower.

The copper (Cu) content in whole Galega kales was at the level of 4.54-5.05 mg/kg. The leaves showed higher Cu content than stems. The Cu content in curly and smooth kales was similar. The results are consistent with those Ayaz *et al.* (2006) (5.1 g/kg) and Martínez *et al.* (2011) (5.77 g/kg) in kales.

The data were examined by multivariate statistical techniques with the aim of discriminating among samples. All the minerals studied were analyzed after factorial analysis carried out to identify the most important variables in the classification. Canonical discriminant analysis was performed on these variables. Minerals analysis revealed a discriminate structure. The analysis correctly classified 100% samples according to the edible part (leaves, stems and whole plant) (Figure 1), but not according to the phenotypic.

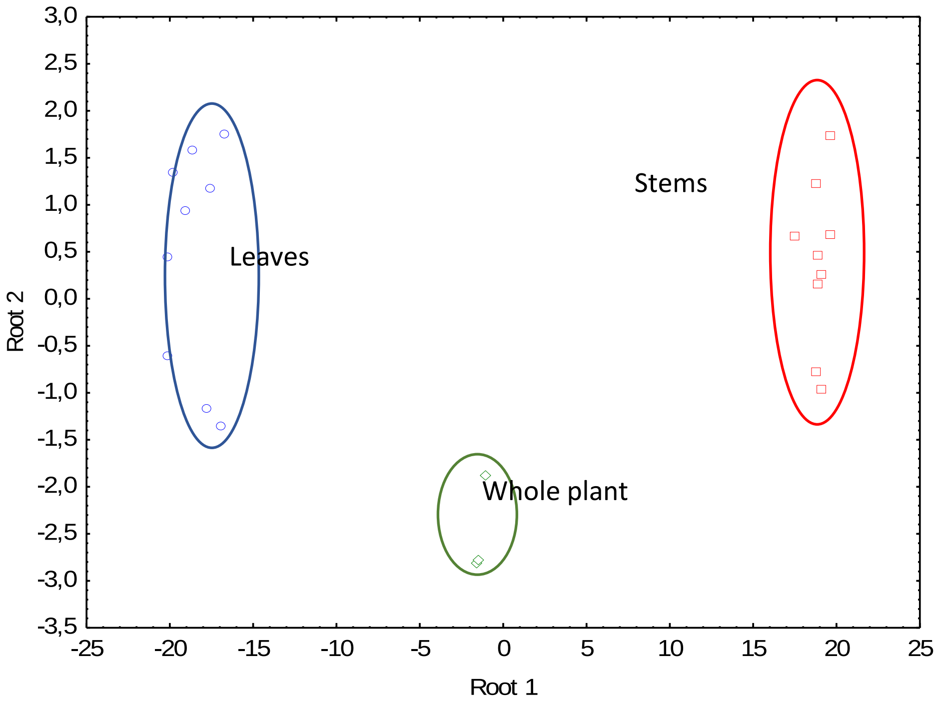

Figure 1.- Principal component analysis of minerals elements for edible parts Galega kales.

Conclusions

Most of these minerals are essential nutrient and has an important role in the body human. In general, Galega kales have high mineral elements content, and their consumption in adequate amount could contribute to normal body growth and adequate protection against some diseases. Levels of Ca, Mg, Fe, Zn and Cu were higher in the leaves than stems, whereas K was higher in the stems. Phenotype had a significant influence (P < 0.05) on the K and Fe contents.

EVALUATION OF THREE INTRODUCED WINE GRAPE VARIETIES UNDER A RAIN-FED SYSTEM OF AGRICULTURE IN SYRIA

Ola T. ALHALABI*, Bayan M. MUZHER, Alaa ALZGAIR

General Commission for Scientific Agricultural Research, Syria
*Corresponding author: ola_halabi@msn.com

Abstract

The present study was carried out by the General Commission for Scientific Agriculture Research – Pome and Grapevine Division in Sweida Province (Syria) during 2014 and 2015 to evaluate three introduced wine varieties Carignan, Cabernet Sauvignon and Chardonnay, under a rain-fed system of agriculture. The results indicated that bud burst in the two varieties, Carignan and Chardonnay, happened on 25th April, and in Cabernet Sauvignon it was on May2nd.Carignan and Cabernet Sauvignon significantly were more vigorous than Chardonnay in blade length and width, internode length and diameter. Cabernet Sauvignon had the highest length of bunch (158 mm), while there was no significant variance in bunch width among all the studied varieties. Carignan significantly showed higher values of bunch weight (328.4 g), berry length, width and weight, must yield and tree yield. A chemical analysis of must showed that Chardonnay variety insignificantly had higher total soluble solids (23.2%) than the two other varieties, and there was no significant variation in total sugar as well among studied varieties, while Chardonnay significantly showed the lowest total acid content (5.5 g/L) than the other two varieties. Consequently, the results revealed distinct traits that encourage us to use the studied wine varieties in the similar environmental conditions.

Key words:*Grape, Carignan, Cabernet Sauvignon and Chardonnay cultivars, evaluation.*

Introduction

Grape is widely spread across the world and can be divided into four main groups: European, American, French/American hybrids, and Muscadine, which are used for different purposes: table fruit, wine, juice, jam, jellies and raisins (Maughan *et al*., 2016). There are many wine grape varieties produced different types of wine such as Cabernet Sauvignon which is considered as the most of the noble French varieties (Galet, 1998); Chardonnay is one of the eminent varieties for the production of high quality white wines in the world (Bettiga, 2003), Tempranillo is a very famous Spanish variety, gives 28 dissimilar types of wines (Dimovska *et al*., 2015), Carignan is used to produce red table wine (Dokoozlian, 2003), and Riesling and Silvaner are German white wine variety (Sweet, 2009).

The evaluation of grape varieties adaptation to new region with special microclimates, is an important work, however requirement of heat accumulation during fruit maturation is generally the limit factor (Reynolds *et al*., 2004; Moulton *et al*., 2008; Wise, 2015). Influence of different locations, with various topography in western Colorado, on fruit quality and production of 35 wine grape varieties was studied to select the most suitable one in each microclimate (Hamman and Dami, 1999). Six varieties of German white wine were evaluated in Romania to compare their qualitative and quantitative performance with the country of origin (Store and Ioana, 2015). Evaluation of 11 wine grape varieties in

Karnataka for the variation in growth and yield was done to choose the proper one to the conditions of the studied area (Hachcholli *et al*., 2016).
In Syria, grape is the main tree, it occupies the second position of deciduous fruit trees in production after apple tree depending on old local cultivars. Thus, it is very important to improve viticulture by using new introduced varieties beside our local ones. Since, the aim of this study is to evaluate three introduced wine grape varieties under rain fed agriculture at high altitude in the south of Syria.

Materials and Methods

This investigation was achieved during 2014-2015 at Pome and Grapevine Division-GCSAR in Sweida province which located in the south of Syria at 1525 m altitude. The mean rainfall 525mm. The monthly average temperature of growth season, during the period of study, was as following: 10.8℃, 16℃, 19.5℃, 20.5℃, 19℃, 21℃ and 16℃ in April, May, June, July, August, September and October respectively.

Plant materials

Three introduced grape wine varieties, they are 25 years old, grafted on the rootstock Polsen 1103, the training system is cordon, the distance between vineyards and between the rows is 2.5 x 3 m under rain fed system agriculture. These varieties are:
- Carignan: is a Spanish variety, the bunch is broad conical, the berry is short oval, with dark purple- black skin (Dokoozlian, 2003).
- Cabernet Sauvignon: is a French variety, the bunch is conical, the berry is round, with blue black skin (Wolpert, 2003).
- Chardonnay: is a French variety, the bunch is cylindrical, the berry is round, with yellow to amber skin (Bettiga, 2003).

Methods

Evaluation of the studied varieties was done depending on the descriptors IPGRI (1997) and OIV (2009) as the following:
Time of bud burst.
Full maturity of the berry: maximum sugar content of the berry.
Length of internodes (very short ≤60 mm, short ~ 90 mm, medium ~120 mm, long ~150 mm and very long > 180 mm).
Diameter of internodes (very small ≤5 mm, small ~ 8 mm, medium ~ 11 mm, big ~14 mm and very big >17 mm).
Length of the leaf blade
Width of the leaf blade
Length of the bunch (very short≤80 mm, short ~ 130 mm, medium ~180 mm, long ~230 mm and very long > 280 mm).
Width of the bunch (very narrow ≤40 mm, narrow~80 mm, medium ~120 mm, broad ~160 mm and very broad > 200 mm).
Single bunch weight (very low ≤100 g, low 150-250 g, medium 350-450 g, high 650-950 g and very high > 1200 g).
Yield: kg/ tree
Berry length (very short ≤8 mm, short ~ 13 mm, medium ~18 mm, long ~23 mm and very long > 28 mm).
Berry width (very narrow ≤8 mm, narrow~13 mm, medium ~18 mm, broad ~23 mm and very broad > 28 mm).
Single berry weight (very low ≤1g, low 1.7-2.3 g, medium 3.5 g, high 7-9 g and very high > 12 g).

Must yield of berries (very little <50 ml juice/ 100 g berries, little 50-65 ml/ 100 g, medium 66-75 ml/ 100g, high 76-90 ml/ 100g and very high >90 ml/ 100 g).
Total soluble solids content of must
Sugar content of must (low ~ 15%, medium ~18% and high ~21%).
Total acid content of must: tartaric acid g/L (very low ≤3, low 6, medium 9, high 12 and very high 15).

Experimental design and statistical analysis

The experiment was designed in complete randomized blocks design, using 15 trees from each variety in three replications. The variance among varieties was analyzed for each trait by one way ANOVA analysis, LSD5% was calculated to compare means.

Results and discussion

The time of bud burst happened on 25th April in Carignan and Chardonnay varieties, earlier than Cabernet Sauvignon variety, which was on 2nd May, the late time of bud burst is preferable in the regions which are subjected to spring frost like the studied region. Studies on Cabernet Sauvignon indicated that it is a late bud burst (Sweet, 2008). Hamman and Dami (1999) considered bud burst on 25th April as an early date, and on 10th May as a late one. The time of full maturity of berries was late in all studied varieties, it was at the first of October in Cabernet Sauvignon, while in Carignan and Chardonnay were on 10th October, due to the moderate summer temperatures in the studied region. These results are in agreement with literature studies, that Cabernet Sauvignon considered as a mid to late season variety, depending on heat unit accumulations, thus ripening occurs in late August to late October (Wolpert, 2003), Carignan is a late season variety, ripens in late September to mid October (Dokoozlian, 2003), and Chardonnay is an early season variety, but in cold regions it ripens in mid to late October (Bettiga, 2003).

Blade length of Carignan was the highest one among studied varieties, showed significant difference with Chardonnay. Likewise, Chardonnay significantly revealed the smallest blade width among studied varieties (Table 1), this result is in agreement with IPGRI (1997) that the size of Carignan blade is classified as large one. The internodes of studied varieties were very short to short, Chardonnay significantly has the shortest internodes (62 mm), while Cabernet Sauvignon showed the highest one (78 mm). However, the internode length of Cabernet Sauvignon is considered a short one according to OIV (2009). The length of internode varies along the cane according to changeable growth rates through the season (Hellman, 2003). The internodes diameter of Chardonnay and Carignan varieties were very small, while it was very small to small in Cabernet Sauvignon, which showed significant variance with Chardonnay (Table 1), which depends on growth vigor of the variety.

Table 1: Blade length and width (mm), internodes length and diameter (mm) in the studied varieties.

Variety	Blade length (mm)	Blade width (mm)	Internodes length (mm)	Internodes diameter (mm)
Carignan	108 a	141 a	75 a	5 ab
Cabernet Sauvignon	106 ab	142 a	78 a	5.6 a
Chardonnay	99 b	130 b	62 b	4.6 b
LSD5%	8	9	8	0.7

Means in columns having the same letters are not significantly different

The bunch length of studied varieties was short to medium according to IPGRI (1997) and OIV (2009) descriptors. However, Carignan significantly showed the shortest bunch (128 mm) among studied varieties. On the other hand, the bunch width was medium to broad in

Carignan variety, and narrow to medium in Cabernet Sauvignon and Chardonnay varieties, the variances were insignificant among the studied varieties (Table 2). The highest bunch weight was 328.4 g in Carignan, which is classified as low to medium weight, while the bunch of Cabernet Sauvignon and Chardonnay varieties had low weight, they significantly differed than Carignan. In addition, Carignan revealed the highest significant yield (30.5 kg/tree) among studied varieties (Table 2), this indicates to the high yield of this variety under rain fed system of agriculture. However, the yield of varieties mainly depends on genetic factors which regulate the fertility of buds, then on the environmental conditions, age of tree and fertilizing management (Lisek, 2014). In comparison with literatures reviews, our results revealed higher bunch length, lower bunch weight and yield in Cabernet Sauvignon than the obtained results in Karnataka which were 132 mm, 276 g and 17.6 kg/tree for bunch length, bunch weight, and yield respectively (Hachcholli *et al*., 2016) . On other hand, Chardonnay showed higher values of bunch weight and yield than the results obtained by Wise and Gardner, (2016) in the Long Island.

Table 2: Bunch length and width (mm), bunch weight (g) and yield kg/tree in the studied varieties.

Variety	Bunch length (mm)	Bunch width (mm)	Bunch weight (g)	Yield kg/tree
Carignan	128 b	121	328.4 a	30.5 a
Cabernet Sauvignon	158 a	106	202.3 b	14 b
Chardonnay	143 a	106	217 b	12.3 b
LSD5%	25		71.9	10.4

Means in columns having the same letters are not significantly different

The berry length and width of Carignan (16 mm and 15.3 mm respectively) were significantly higher than the other studied varieties (Table 3), however its berry was short to medium and narrow to medium for length and width respectively, while in the other studied varieties were very short to short and very narrow to narrow according to IPGRI (1997) and OIV (2009). Moreover, the berry weight of Carignan variety (2.32 g) was low, and showed significant variance with the other studied varieties, which their berry weight were very low to low, which revealed significant difference between each other (Table 3). This result is in agreement with Dokoozlian, (2003); Wolpert, (2003) and Bettiga, (2003) which reported that Carignan has medium berry, while Cabernet Sauvignon and Chardonnay have small berry. In addition, the berry weight in Cabernet Sauvignon and Chardonnay was higher than the results obtained by Hachcholli *et al*., (2016) and Hamman and Dami, (1999) which were 1.81 g and 1.63 g respectively. The must yield of berries was medium (75 ml/100 g) in Carignan, followed by Cabernet Sauvignon, they showed significant differences with Chardonnay (Table 3). However, the berries must yield of Cabernet Sauvignon and Chardonnay varieties was low to medium.

Table 3: Berry length and width (mm), berry weight (g) and must yield (ml/ 100g) in the studied varieties.

Variety	Berry length (mm)	Berry Width (mm)	Berry weight (g)	Must yield (ml/100 g)
Carignan	16 a	15.3 a	2.32 a	75 a
Cabernet Sauvignon	12 b	12 b	1.22 c	73 a
Chardonnay	12 b	12.7 b	1.45 b	68 b
LSD5%	0.7	1	0.9	2.6

Means in columns having the same letters are not significantly different

The figure (1) showed that Chardonnay had insignificant highest total soluble solids of must content (23.2%) among studied varieties, and there was insignificant difference between the other studied varieties. The must content of sugar was medium to high in all studied varieties (20, 18.8 and 18.5% in Cabernet Sauvignon, Chardonnay and Carignan respectively), with insignificant differences among them. The total acid content of must was significantly very low to low in Chardonnay (5.5 g/L), and low to medium in the other studied varieties (7.1 g/L), the difference between Cabernet Sauvignon and Carignan was insignificant (Figure 1). Carignan showed the lowest value of total soluble solids and total sugar among studied varieties, this indicated to its high requirement of heat accumulation. Cabernet Sauvignon showed less little total soluble solids content and more total acid than the literature reviews which were 23 % and 5.8 g/L respectively (Hamman and Dami, 1999; Wise and Gardner, 2016). On the other hand Chardonnay showed less total acid content than the result obtained by Hamman and Dami (1999) which was 6.8 g/L. Climatic factors, mainly temperature, have a most important influence on fruit composition at maturity, that hot climates help higher sugar content and lower acidity; while cool climates cause little sugar accumulation and keep extra acidity (Hellman, 2003).

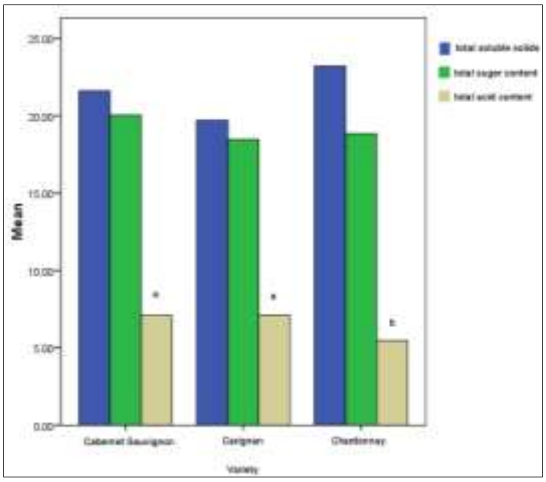

Figure 1: The must content of total soluble solids, total sugar and total acidity in the studied varieties. (LSD5% for total acid content= 0.68, means above bars of same colors having the same letters are not significantly different).

Conclusion

Evaluation of the studied wine grape varieties, Carignan, Cabernet Sauvignon and Chardonnay, indicated that they can succeed under rain fed system of agriculture at high altitude 1525 m. As well as, it is necessary to evaluate their performance in lower altitude, and under irrigated system of agriculture.

EVALUATION OF THE BEHAVIOR OF SOME *PISTACIA VERA* FEMALE GENOTYPES IN THE SOUTH OF SYRIA

Najwa Motaeb ALHAJJAR*, Bayan Mohammad MUZHER

General Commission for Scientific Agricultural Research, Syria
*Corresponding author: najwa81hj@yahoo.com

Abstract

This investigation was conducted by the General Commission for Scientific Agricultural Research- Scientific Agricultural Center in Sweida and in pistachio fields during 2012- 2015. The aim of the investigation was to evaluate the behavior of some *P.vera* female genotypes (6 Ashouri, 2 Batouri, 2 Ajami, 1 Beadi and 2 Turkish genotypes) through determining the most important parameters used for evaluating the adaption and success of pistachio cultivation. All studied Ashouri genotypes tended to bloom earlier (12-21th March) than other genotypes, whereas the full flowering period of the two Turkish genotypes werelate (1-4thApril). The largest nut dimension was 1.95cm in BatouriGhrahibeing significantly differentthan all other studied genotypes. The percentage of dried kernel weight to total dried nut weight was 50.55% in fluffy AshouriMawardi genotype, while it was 39.63% in AshouriLesan Altair genotype. The split nuts percentage ranged between 7-93%.Three cases of blank nuts were defined; some of them are newly registered: 1. The barthinocarpy phenomena: The oval grows for a short time without fertilization. 2. Abnormal kernels:The kernel occupies just 1/3 of the shell plenum, and in some cases the kernelseemed to be sticky. 3. The decomposition of the cotyledon's endosperm into a sweet liquid, also the kernel in this case occupies just 1/3 of the internal space inside the shell. The current results indicate there is a huge genetic diversity of female *P.vera* species, which are still cultivated marginally and have important commercial traits as BatouriGhrahi and Fluffy AshouriMawardi genotypes. These genotypes are supposed to be separated cultivars and need to be identified at molecular level for the purpose of identification; i.e. to be confidently credited as commercial cultivars by the governmental nurseries within the Ministry of Agriculture in Syria.

Keywords: Pistachio, *P.vera*, behavior evaluation, blank nuts, split nut percentage.

Introduction

The genus *Pistacia* belongs to *Anacardiaceae* family comprises more than 11 different species, whereas *Pistaciavera*is one of the most prominent horticultural plants from an economic and commercial point of view(Afzadi*etal*.,2007).The main cultivated areas are the middle and west Mediterranean basin countries, basically Iran, Turkey and Syria. Since this species has a great adaption to harsh environmental circumstances, its cultivation spreads widely in the boor societies and in arid and semi-arid regions (Padulosi *et al*., 1996) where other fruit treespracticallycan not grow, pistachio with its powerful root system and shady patulous crown is of great soil and water-protective importance. It may be grown in desert areas since it needs long hot summers for fruit maturation and high winter chilling (Chatti*et al*.,2017). Pistachio with dioeciously and heterozygous nature has a high genetic diversity(Aliakbarkhani*etal*.,2013). In Syria the main produced regions of *P.vera*crop are Aleppo, Hama and Idleb provinces. In the last few decades, this cultivation was widely spread to other provinces at the south of Syria. However, there are a lot of genotypes belong to the same cultivar with different local names especially in the new cultivated areas. Even though this cultivation is still depends on a narrow genetic platformin spite of a wide number of important genotypeswhich are still marginally cultivated and recognized of valuable commercial characters (Basha*et al*., 2007). Some of these individuals could be genetically important for breeding and fertilization programs. Hence, this investigation aimed to evaluate the behavior, and the main limited parameters as blank nuts of different forms, split nutpercentageand the productivity of the most spread genotypes of different local names to assess a base of genetic identifications for further genetic relationships among genotypes and cultivars.

Materials and methods

This research was conducted during 2012-2015 in the South of Syria.

Plant material

Thirteen different genotypes related to different commercial cultivars(25 yearsold) were studied:6 Ashouri genotypes (Common Ashouri, Fluffy Ashouri Mawardi, Ashouri Mawardi,white Ashouri, Ashouri Lesan Altair, and Ashouri Abu Reha)-2 Batouri genotypes (Batouri Ghrahi, and red Batouri)-2 Ajami genotypes (Ajami Ras Alkharouf, and Common Ajami)-Beadi cultivar – and2 Turkish genotypes (Turk.1 and Turk.2).

Methods

Phonological stages:According to (IPGRI,1997).

Morphological parameters:Nut diameter$D_p=(L.W.T)^{1/3}$andNut sphericity$Ø= (D_p/L) \times 100$according to (Mohsenin, 1980;Galedar*et al*., 2008; Kardoush*et al*., 2009).Kernel weight/ total nut weigh (wet and dry weight)according to (AOAC, 1995).Split nuts percentage according to (Kashaninejad*etal*.,2002)Blank nuts percentagein each panicle, and the Production which's estimated as(Kg/tree).

Results and discussion

Phonological stages

The Phonological stages are affected by soil structure(Tunc*et al*., 2013), and the temperature of winter and spring seasons (Javanshah, 2010). The major genotypes of Ashouri cultivar (Ash) were recognized by their early blooming period, so the full blooming stage of the genotypes (Common Ash., White Ash., and Lesan Altair)was from 11-15th march, whereas it was between 14-21th march in the genotypes (FluffyMawardi, Mawardi and Abu Reha) as it is illustrated in Table (1). In Batouri cultivar the both genotypes bloomed on 16th and 22th march. However, Red Batouri genotype was bloomed earlier than BatouriGhrahi of about 3-4 days. The both genotypes of Ajami cultivar varied of their full blooming date, and it was earlier in the Common genotype of about 3-4 days than the genotype RasAlkharouf (20-23thmarch).The full flowering date of Turkish genotypes (Turk.1 and Turk.2) was somehow late in comparison with all Syrian genotypes, now that thefull flowering date was during 1-4th April. Kebour*et al* (2013) mentioned that the full flowering period of some Syrian cultivars planted in Algeria ranged from 10-20th April according to their environmental circumstances.

Table1:Phonological stages of all studied *P.vera* genotypes.

cultivar	**genotype**	**budswelling**	**Pre-bloom**	**full bloom**	**flowerset**
Ashouri	Common.	2-4Feb.	8-11Mar.	12-15Mar.	15-17Mar.
	Fluffy mawardi	5-6Feb.	12-13Mar.	14-17Mar.	18-20Mar.
	Mawardi	7-9Feb.	12-14Mar.	15-18Mar.	19-22Mar.
	White	3-4Feb.	8-10Mar.	11-14Mar.	15-17Mar.
	Lesanaltair	2-4Feb.	7-10Mar.	11-14Mar.	15-18Mar.
	Abu reha	7-9Feb.	14-17Mar.	18-21Mar.	22-23Mar.
Batouri	Ghrahi	9-11Feb.	15-18Mar.	19-22Mar.	23-25Mar.

Ajami	Rasalkharouf	7-8Feb.	13-16Mar.	17-19Mar.	20-22Mar.
	Common	10-12Feb.	17-19Mar.	20-23Mar.	24-25Mar.
Beadi	Beadi	9-11Feb.	14-17Mar.	18-21Mar.	22-24Mar.
Turkey	Turk.1	14-16Feb.	28-31Mar.	1-4April	5-7 April
	Turk.2	16-18Feb.	29-31Mar.	1-3 April	4-6 April

Nut diameter and sphercity

The mean of the nuts diameter varied among all studied specimens.The largest diameter was 1.95 cm in Red Batouri genotypeof significant differences (P≤5%) in comparison with all other studied genotypes. the largest nuts diameter among the genotypes belong to Ashouri cultivar was 1.82 cm inMawardi of significant differences in comparison with all other genotypes except for Fluffy Mawardigenotype which was 1.79 cm (Table.2). These results were closed to the average of Ashouri nuts dimensions 1.45x1.50x2.70 cm as indicated by (Hadj-Hassan, 2003)on the same cultivar. Ajami nut diameters were closely in both genotypes, it was 1.81 cm in the Common genotype and 1.83 cm in Rasalkharouf.A notable difference of nuts diameter was noticedbetween the two Turkish genotypes. However, the smallest nuts diameterwas 1.56 cm in Turk.2 which was closed to some Turkish genotypes according to (Ak and Acar, 2001)as their results showed nuts dimension of 1.93-2.03 cm for length, 0.94-1.15 cm for width and 0.72-1.1cm for thickness. The highest percentage of nuts sphericity was 74.9% in Fluffy AshouriMawardi of significant differences with all estimated genotypes, followed by Beadicultivar 70.8% which was also of significant differences in comparison with all other genotypes. The nut sphericitypercentage of both Ashourigenotypes (Common,andLesan Altair) was identical (66.7%). The bothAjamigenotypes(Common and,Rasalkharouf)showed close percentages of nut sphericity 68.8% and 69.1% respectively. The percentage of the genotype Batourighrahi was lightly low (65%) cause the nut'slength is extremely large and reaches in average 3 cm. These variances among all genotypes indicated to a huge genetic variance inside each cultivar and this might indicates that some of these genotypes are not descended from the same cultivar and this confusion occur due to the frailer of grafting accompanied with low experience of the farmers to differentiate between the grafted and non-grafted seedlings, now that these differentiations are as a result of seed genetic segregation.In comparison with previous literature, the current results of nuts sphericitywere lower than the results showed by (Polat*et al.*, 2007) whereat the nuts sphericitypercentage was 82%.

Wet and dried kernel weight to the total nuts weight

The highest ratio of kernel/ wet nut weight was 37.55% in the genotype Turk.2 of significant differences with other genotypes except Turk.1 and Ajam.1 genotypes (37.27% and 37.45%) respectively. As it is illustrated in Table (2), the highest percentage of kernel weight/ wetnut weight within Ashouri genotypes was 36.37% in Lesan Altair, even though this genotype had the smallest kernel size, and this might be due to a highcontent of kernel'smoisture, Whereas the lowest percentage was 31.36% in Ashouri AbuRehagenotype,which indeed hasthick,andwet shell nut that reduce the percentage of the total kernel wet weight to the total nut weight. Significant differences was shown between the two Batouri genotypes (34.55 and 31.61 %), this result also confirm our previous prediction that the genotype BatouriGrahi is not descendedfromBatouri cultivar. Hadj- Hassan (2003) indicated that the ratio of kernel/ nuts wet weight could be estimated of 1/3 in a general sight, and there were differences between the cultivars (40% in Oliemi, 36% in Batouri and 34% in Ashouri). The highest percentage of dried kernels and nuts weight was 50.55% in Fluffy AshouriMawardi genotype of significant differences (P≤5%) in comparison with all studied specimens. In Batouri cultivars the ratio of dry kernel weight to total dry nut weight was 42.92% in BatouriGhrahi and 47.85% in RedBatouri of significant differences. The percentage of both Turkish genotypes was almost the same (47.72 and 47.81%). the current results were higher in comparison with Misirli and Ozeker (2001) that their results indicated to a percentage of dry nut and kernel weight between 34.86-37%.

Split nut percentage

The highest split nuts percentage was 93% in the genotype Fluffy Mawardi of significant differences with all studied genotypes except the genotype AshouriMawardi which was 89% (Table,2). In the red Batouri genotype the split nuts percentage was low (36%), while it was median (62%) inBatouriGhrahigenotype. Alhajjar*etal*.(2013) mentioned that the split nut percentage of different pistachio genotypes in Syria ranged between24-96%,whereasKayimov*et al*. (2001) indicated to a split nut percentage of only 21% for Batouri cultivar. The two Ajami's genotypes showed median nut split percentages 61%and 78% of significant differences between each other. The split nut percentage was also low in Beadi cultivar (45%), which was lower than the split percentage in comparison with Kayimov*et al*. (2001) for the same cultivar (57%). However. the split nut percentage was too low in both Turkish genotypes(less than 20%). In parallel to previous review for Turkish cultivars,Gokce and Akcay (1993)indicated to ratios of split nutpercentageranged between 32-71%, and (Ak and Acar, 2001) mentioned that this ratio ranged between 37-92% in different Turkish genotypes.

Blank nuts percentage

This percentage is evaluated at maturity time. In the current study the blank nut phenomena was estimated from two weeks after fruit set until one month before maturity time. The highest blank nut percentage was obtained in AshouriLesan Altair 13.98% of significant differences with all other genotypes, whereas the lowest percentage was 4.22% in Fluffy AshouriMawardigenotype.The variance of blank nuts percentage in Ashouri genotypes is higher than the other cultivars. The blank nut percentage in BatouriGhrahi 5.4%which issignificantly less than the blank nut percentage in red Batouri(6.8%).Ghrab*et al*.(2010) indicated to a high percentage of blank nut ranged between 2-60% in *P.vera* genotypes inTunisia. Several blank nuts cases were identified, some of them were due to Parthinocarpy phenomena (Fig 1-A1)as the oval grows for a short time without fertilization.Other blank nuts cases were defined as incorrect fertilization, the phenomena that the embryo dose not continue its naturally growth 'which is known as an abortionphenomena'. Moreover, other three blank nuts cases were registered for the first time:Abnormal kernelsas the kernel occupies just 1/3 of the shell plenum(Figure,1-A2), and in some cases the kernelseemed to be sticky(Figure1-A3), and the decomposition of the cotyledon's endosperm into a sweet liquid(Figure1,A4), also the kernel in this case occupies just 1/3 of the internal space inside the shell. The reason for each blank nut case needs to bedeeply identified.

A1 A2 A3 A4

Figure 1: Blank nut phenomena: A1:Parthincarpy, A2: Abnormal kernels, A3:The decomposition of the cotyledon's endosperm into a sweet liquid.

The production

The production was estimated as Kg per tree under rainfed cultivation, and the results indicated to a large variance within the studied genotypes especially in Ashouri genotypes and it ranged between 5 to 25 kg/tree(Table,2).

Table 2: The main characters of different studied genotypes of *P.vera* L.

genotype	Diameter cm	Sphericity %	Kernel size	Total weight %		Split nut%	Blank nut%	Production Kg/tree

LSD5%	0.08	0.62	0.15	0.96	1.27	5.21	0.98	1.98

Conclusion

This investigation allows the identification of parallelism in ancestral variability of close genotypes within*P.vera*species. It allows development of new variants and races of practical interest as Fluffy AshouriMawardi and BatouriGhrahigenotypes.These genotypes are supposed to be separated cultivars and need to be identified at molecular level to be confidently credited as commercial cultivars by the governmental nurseries within the Ministry of AgricultureinSyria. Hence, collecting of genotypes and variants acquire new meaning with the purpose of management of plant genetic resources.

OPTIMAL HARVEST DATE OF THE APPLE ROYAL RED CULTIVAR FOR LONG STORAGE IN THE SOUTH OF SYRIA

Bayan M. MUZHER*, Ola T. ALHALABI

General Commission for Scientific Agricultural Research, Syria
*Corresponding author:bmuzher@hotmail.com

Abstract

This investigation was done during 2011-2012 by the General Commission for Scientific Agriculture Research- Pome and Grapevine Division in Sweida province (Syria), to determine the optimal harvest date of the Royal Red apple cultivar for long-term storage. The fruits were harvested five dates in one-week intervals from 20^{th}September to 18^{th} October, and then stored at 0̊ c and 95% relative humidity for seven months. The changes in main physical and chemical indicators were measured on monthly basis. The results showed that after 7 months of storage the lowest significant weight loss was 2.2% in the fruits harvested on11^{th} October, while it was 5.1% and 4.3% in the fruits harvested on 20^{th} September and 18th October, respectively. The highest fruit flesh firmness was 5.4 kg/cm2 in the fruits harvested on 4th October, followed by 5.2 kg/cm2firmess in the fruits harvested on 11^{th} October and 27^{th} September. The highest total soluble solids and total sugars were 18.6°B and 16.7%, respectively, in the fruits harvested on 11th October. Consequently, 11th October was the best harvest date for the fruits to achieve high storability with the following indicators: temperature accumulation 1943° c. days, 164 days after full bloom, starch index 4, flesh firmness 6.6 kg/cm2 and total soluble solids 14.5%. These results indicate the importance of determining the harvest date for each cultivar in order to reduce weight loss and improve fruit quality during long storage.

Key words: *Apple, long-term storage, harvest date and weight loss*.

Introduction

Apple is one of the most important fruit trees in Syria, the total area arrived 51574 ha produced 307199 metric tons (Annual agricultural Statistical abstract, 2015). General commission for Scientific Agricultural Researches introduced the main commercially important apple cultivars which evaluated in different climatic regions (Muzher and Alhalabi, 2012). Apples are climacteric fruits need sufficient understanding about the harvest date according to the final purpose of production. Long term storability depends on harvest date, if the fruits picked at late maturity they will not remain for long time even under optimal storage conditions (Vielma *et al.*, 2008; Galmarini *et al.*, 2013). Likewise, Valiuskaite *et al.*, (2006) found that fruit rot raised on fruits which picked at early or late maturity date. On the other hand, fruits that harvested at advanced maturity having short storage life and are more susceptible to mechanical injury, pathogens and physiological disorders (Juan *et al.*, 1999). However, the degree of maturity affected apple fruits quality during shelf life (Juhnevica-Radenkova *et al.*,2014). Many quality parameters are useful to predict and determine the optimal harvest date in apple fruits like firmness, starch conversion, total soluble solids, and titratable acidity (DeLong *et al.*, 1999; Babojelic *et al.*, 2007). However, growers concentrate on the determination of optimal harvest date which minimize the weight loss, and maximize fruit quality during storage period (Kviklienė *et al.*, 2008). Each apple cultivar should picked before entering the climacteric period to get optimal quality during the storage period (Little and Holmes 2000). On the other hand, maturity time for the same cultivar may change every year depending on bloom date and the environmental conditions during the growth season (Papamihal, 2013). Since, the taste and flavor are the most important sensory indictors that determine the acceptability of fruits for marketing (Abbott *et al*., 2004; Abbas *et al*., 2012). Soliva-Fortuny *et al*., (2002) suggested that the storability of apple fruits depends on the thickness of wax layer, while Gregersons, (2009) stated that the harvest date depends on chemical composition especially the content of water and sugar.

Apples are the main favorite fruits for consumers in Syria, which led to introduce new competitive commercial cultivars and determine their storability and the changes of quality indicators during storage period. Therefore, the aim of the present investigation was to determine the optimal harvest date for long term storage with good quality parameters for Royal Red apple cultivar depending on efficient physical and chemical indicators.

Materials and methods

The present research has been conducted during 2011-2012 in the orchards and laboratory at Pome and Grapevine Division which located at 1525m altitude, under rain fed conditions, the mean rainfall 525mm.

Plant material

Royal Red apple cultivar: Fruits are conical, dark red, the average weight 205.7 g. Trees are 20 years old grafted on seedling rootstock *Malus domestica* Borkh.

Methods

Fruits were picked during five dates in one week intervals from 20th September to 18th October, which correlated with 143, 150, 157, 164, and 171 days after full blooming (DAFB) and linear temperature accumulation 1750, 1803, 1875, 1943 and 2033°. Days, respectively, then stored at 0̊ ±0.5 c and 95% relative humidity for seven months. Initial physical and chemical parameters for fruits were achieved at each harvest date and repeated on monthly basis, and the following indicators were studied:

Fruit weight loss%: It was calculated by weighing the same fruits at each interval and at the end of cold storage duration using the following formula:

Weight loss (%) = [(W1-W2)/W1]*100

where w_1 is initial weight of fruit samples and w_2 is Weight of fruit samples at each storage periods.

Fruit firmness (kg.cm^{-2}): using penetrometer for 10 fruits from each replicate.

Starch index: using Iodine with potassium iodine solution using 1-8 scale depending on (Blanpied and Silsby, 1992)

Total soluble solids (°Brix): using digital refractometer (Schwallier, 2005)

Total sugar%: using Fehling solution depending on (Lane and Eynon.1923).

Titratable acidity %: which was determined by titrating fruit juice against 0.1 NaOH with phenol phethalin as indicator and calculated as gram per 100ml Malic acid (Graham,2004)

Experimental design and statistical analysis

Complete randomized block design was used. The analysis of variance to compare means of measured parameters for each indicator during each storage period was done using one way ANOVA by LSD test ($p < 0.05$).

Results and discussion

Weight loss

Data in Table (1) showed the effect of harvest date on weight loss percentage during storage period. Generally noticed an increase in weight loss % with the advancement of storage period in all harvest dates which also observed by (Kaur and Dhillon, 2015). After three months of storage period, the second harvest date (27/9) significantly showed the lowest weight loss (0.8%), while the highest significant loss was in the first harvest date (2.2%) due to pick fruits at early date .After seven months of storage, the fourth harvest date (11/10) showed the lowest weight loss% (2.2%) which was in significant with all other harvest dates, while the fifth and first harvest dates revealed the highest significant weight loss% which were (4.3 and 4.2%, respectively) which may due to the fact that fruits were picked at the fifth and the first dates were harvested at late and early maturity dates, which was in agreement with (De Belie *et al*., 2000, and Kvikliene *et al*.,2011).

Fruit firmness

There were no significant variances between all harvest dates at the picked time (0 days). After three months of storage, the first harvest date significantly showed the lowest fruit firmness (4.1Kg. cm^{-2}) in the comparison with all other harvest dates, while the second harvest date revealed the highest fruit firmness (6.5Kg. cm^{-2}) with significant variance in the comparison with all other harvest dates except the fifth one (6.2 Kg. cm^{-2}). After seven months of storage, the first harvest date also significantly showed the lowest fruit firmness (3.6 Kg. cm^{-2}) when compared with all other harvest dates, followed by the fifth date (4.1 Kg. cm^{-2}),while the third one showed the highest fruit firmness with no significant variance with the second and the fourth dates (Table 1). The decrease in fruit firmness might be due to the respiration rate and enzymatic activity (Ganai *et al*., 2014), and occurs through different stages depending on the increase of readily soluble pectin (Herregods, 1999). However, firmness of qualitative apple should be not lower than 4.4 kg cm^{-2} (Kupferman, 1992).

Table 1: Effect of harvest dates on weight loss percentage and firmness during storage period.

Harvest date	Weight loss percentage		Firmness(kg.Cm^{-2})		
	3 months	7 months	0 days	3 months	7 months
20/9	2.2 a	4.2 a	6.6a	4.1 c	3.6 c
27/9	0.8 e	2.9 c	6.6a	6.5 a	5.2 a
4/10	1.4 c	3.5 b	6.6a	6.0 b	5.4 a
11/10	1.3 d	2.2 d	6.6a	5.8 b	5.2 a
18/10	1.6 b	4.3 a	6.3a	6.2 ab	4.1 b
LSD 5%	0.05	0.27	0.37	0.48	0.39

Means in columns having the same letters are not insignificantly different

Starch conversion

The starch continued broken up in apple fruits with the advancement of harvest date and storage period. The lowest starch index was in the fruits were picked in the first three interval dates (3), while fruits were picked in the fifth date significantly showed the highest starch index (5.6) which was in agreement with (Kvikliene *et al*., 2006) . Juhnevica- Radenkova *et al*., (2014) stated that the suitable starch index(1-10) of different type of storage for determination of optimal harvesting time ranged between 4 -5 depending on apple cultivar. After three months starch index increased in all harvest dates and the fifth one showed the highest value (6.3) in significant variance with all other harvest dates except the fourth one (5.7). After seven months starch was broken up in all fruits of all harvest dates (Figure 1). Lopez - Camelo, (2004) reported that apple fruits remain untangled even starch is broken up.

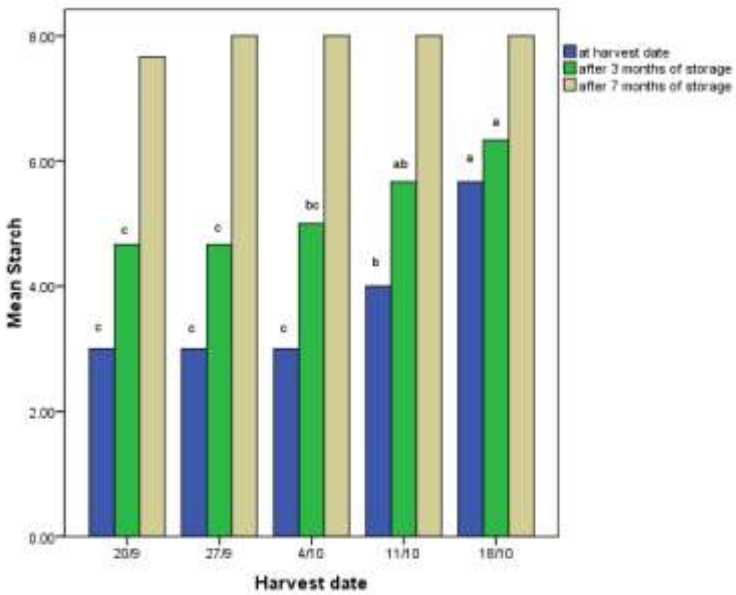

Figure 1: Effect of harvest date on starch conversion during storage period in Royal Red apple fruits. LSD 5% (for 0 days and after three months was 0.49 and 0.9, respectively.
(Means above bars in each color having the same letters are not insignificantly different

Total soluble solids (TSS° B)

The harvest date and the storage period affected TSS content in apple fruits. TSS increased with the advancement of harvest date (Table 2). The lowest TSS was found in the first harvest date which was in significant variance with all other harvest dates except the second one. The fifth date which is the latest date revealed the highest TSS (17.2°B) in significant variance with all other harvest dates. After three months of storage the fifth harvest date significantly showed the highest TSS (20.5°B) which indicated that the fruits are at the ripening process due to biochemical changes especially the increase of enzymes responsible of the hydrolysis of starch to soluble sugars (Kaur and Dhillon, 2015). The lowest TSS was in the first harvest date (15.9°B) in significant variance with the fourth and fifth harvest dates, while there were no significant variance between the other harvest dates. After seven months, the fourth one significantly revealed the highest TSS% (18.6°B) in the comparison with all other dates (Table 2). The results revealed a decrease of TSS in the fifth harvest date which related to the fast decline of quality parameters (Kvikliene *et al*. 2011). Our results were in agreement with (Kvikliene *et al*. 2008) which found that the TSS decreased after 90 days of storage in fruits that picked at late maturity.

Total sugars% (TS%)

The rate of total sugar increased with the advancement of harvest date(Table 2). The picked fruits at the fifth date significantly revealed the highest TS% (15.5%), while the first one showed the lowest TS% (12.3%). After three months, continually the fifth harvest date revealed the highest TS% (17.5%) in significant variance with all other dates, while the first one revealed the lowest TS% (14.3%) in significant variance with the fourth date (15.5%). After seven months, the fourth harvest date significantly revealed the highest TS% (16.7%). The increase of TS% may be due to the hydrolysis of insoluble polysaccharide into simple sugar (Wijewardane and Guleria,2013).

Titratable acidity% (TA%)

The results showed the decrease of TA% with the advancement of harvest dates and with the storage period (Table 2). Fruits that picked at the first date significantly revealed the highest TA% (0.36%), while fruits that picked at the fifth harvest date showed the lowest TA%

(0.23%) in significant variance with all other dates except the fourth one. Titratable acidity considered as an efficient tool in predicting taste of apples and in the assessment of fruit quality (Harker *et al*., 2002).After three months of storage TA% was decreased in all harvested dates except the second one which significantly revealed the highest TA% (0.30%), followed by the first date (0.26%). After seven months of storage, TA% continued the decreasing in all harvest dates except the fourth one and all harvested dates showed the same TA% (0.20%) except the fifth one which significantly revealed the lowest TA% (0.16%). The decrease of TA% in fruits might be due to the diminishing of their organic acids as respiratory substrates during storage (Keditsu *et al*., 2003; Wijewardane, 2013).

Table2: Effect of the harvest date on TSS, TS and TA in Royal Red apple cultivar during storage period

Harvest date	TSS (°B)			TS%			TA%		
	0days	3 months	7months	0 days	3months	7months	0 days	3months	7 months
20/9	13.7d	15.9c	16.6c	12.3d	14.3c	14.9c	0.36a	0.26b	0.20a
27/9	14.3cd	16.3bc	17.5b	12.8cd	14.7bc	15.3bc	0.30b	0.30a	0.20a
4/10	14.5c	16.7bc	16.5c	13.1c	15bc	14.9c	0.28bc	0.23bc	0.20a
11/10	15.5b	17.2b	18.6a	13.9b	15.5b	16.7a	0.26cd	0.20c	0.20a
18/10	17.2a	20.5a	17.6b	15.5a	17.5a	15.6b	0.23d	0.20c	0.16b
LSD 5%	0.73	1.04	0.46	0.66	0.9	0.41	0.03	0.03	0.03

Means in columns having the same letters are not insignificantly different

Conclusion

Obtained results based on the physicochemical parameters during storage period indicate that the optimal harvest date for Royal red apple cultivar which picked for long term storage is at 164 days after full blooming which correlated with the linear temperature accumulation 1943°c. days, with starch index 4, flesh firmness 6.6 kg/cm2 and total soluble solids 14.5%. These results indicate the importance of determining the harvest date for each commercial cultivar.

Abstract

A magnetic treatment of water is an innovative technology in the field of agriculture. Hence, a study was run to evaluate the impact of magnetized salt waters on seeds germination (tomato, corn and turnip). A comparison was made for germination percentage (%) and root length (mm) between the treatments and the control. In addition, the effect of the magnetic treatment on water properties was investigated. A magnetic treatment device (MTD) with a magnetic field of 13.5 mT was used. Three ranges of salinity (2.1 g/L; 4.2 g/L and 6.6 g/L) were used in addition to distilled water as a reference. The results showed a decrease in the electrical conductivity values after passing the water samples through the MTD. The pH showed an increasing tendency that stabilized after 24 hours. The germination percentage (%) and root length (mm) were higher than in the control group for the different ranges of salinity, for all the seeds. Corn germination under the magnetized salt water of 4.2 g/L showed the highest ratio, reaching 28% higher than control. The best root development was observed in the tomato seeds with 24% longer, always with the magnetized salt water of 4.2 g/L comparing to control. In conclusion, our study shows that a magnetic treatment improves the germination ratio and root length of seeds.

Introduction

The scarcity of water is a major problem in many countries of the world. Farmers in arid and semi-arid areas don't only suffer from the luck of water quantities, but also from its poor quality in particular the high level of salinity. The magnetic treatment of irrigation water, which was developed during the last two decades, could be a partial solution to this problem.

This novel technology is known to be an eco-friendly and non-expensive (Otsuka and Ozeki, 2006). Review of literature suggests that water can be magnetized when exposed to a magnetic field (Maffei, 2014). After magnetization, water pH increase slightly while its electrical conductivity and total dissolved salts decrease (U. *et al.*, 2016). This technology enhance evaporation ratio (Guo *et al.*, 2012) (Holysz *et al.*, 2007) and the viscosity of treated waters (Cai *et al.*, 2009). It reduce the scale deposit (Calcite deposit) according to many authors (Latva *et al.*, 2016) (Mahmoud *et al.*, 2016) (Myśliwiec *et al.*, 2016).
