HOW TO CITE THIS: *Elmiladi SA (2022) Presentation and character for adult patients with diabetes in Libya. Mediterr J Pharm Pharm Sci. 2 (1): 83-90. https://doi.org/10.5281/zenodo.6390000*

Abstract: Diabetes is a global issue, the diabetes epidemic is expected to continue, and the burden of diabetes causes catastrophic expenditure for healthcare system. The current study aimed to determine the presentation, the clinical feature and cardio-vascular risk factors in patients with diabetes. A retrospective observational study had been conducted in out-patients department at Almustaqpal Almosherq Centre during September, 2013 till September, 2020, the total number of attended out-patients department were 1 024, 820 patients who were selected for this study. A special perform was completed for every patient, which included details about patient's demographics, points in clinical history, relevant investigations and clinical examinations were recorded. The study reported that out of 820 patients, 66% (n = 538) was female and their age range was between 14 - 87 years with a mean age of 56.53 ± 13.49 years, 96% (n = 791) were clinically diagnosed as type II diabetes, 07% of the patients were diagnosed as pre-diabetes, the duration of diabetes ranged from newly diagnosed to more than 10 years, with 46% (n = 379) of the studied population were more than 10 years diabetes duration, 70% (581) were presented with classical symptoms of diabetes. Initial treatment for diabetes also different in the studied sample, were absent of anti-diabetic medications in 30% (n = 248) of the patients, they refused to start glucose lowering drugs, 34.6% (n = 284) of them have morbid obesity (body mass index is more than 40), 80% (n = 662) have high HBA1c (more than 8 g%), 40.3% (n = 240/596) were uncontrolled hypertension on anti-hypertension drugs, 95.6% (n = 682/713) were controlled on treatment of lipid lowering drugs. This study showing the presentation of diabetes were the common, type II diabetes, at age group between 41 - 66 years about 65%, female sex, with high body mass index, high glycated hemglobulin and uncontrolled hypertension. There is concern that diabetic patients were occurring at a high frequency in younger adults, where longer duration of illness could increase the risk of developing more complications in later life. The rate of coexist cardiovascular risk factors (hypertension, dyslipidaemia and obesity) in Libyan patients with diabetes is highlighted.

Keywords*:* Body mass index, diabetes mellitus, Libya, pre-diabetes, hypertension

Introduction

Diabetes kills and disables, striking people at their most productive age depriving families or reducingthe life-expectancy of old people. No country is immune from diabetes is at that does not respect
borders or social class. Diabetes global estimates, in 2017, the prevalence of diabetes among people

aged 20 - 79 years were 424.9 million, this expected to be increased by 2045 to be 628.6 million [1]. Diabetes is a growing global problem. The burden of diabetes drains national healthcare budgets, reduces productivity, slows economic growth and causes catastrophic expenditure for healthcare system. Healthcare expenditure for people with diabetes are assumed to be on average two-fold higher than people without diabetes [1]. Libya is one of the countries in Middle East and North Africa region (regions of International Diabetes Federation). In MENA region, prevalence of diabetes was 39 million in 2017, this will be 82 million by 2045, thus, raising by 110% (this is the second highest raising rate after Africa region, diabetes prevalence is 10.8%, the second highest among IDF regions, the number of people with diabetes is expected to increase by 111.8% by 2045, also in MENA region 50% of deaths due to diabetes were in people under the age of 60 [1, 2]. In Libya, there were 442.500 cases of diabetes in 2017, by 2045 this will rise to 762.500. The prevalence of diabetes in adults were 11.2%. Prevalence estimates of diabetes were equal in both sex before the age of 30 years than will be higher in female than male across the rest of the age groups. Also, mortality due to diabetes is higher in female than male across all the age groups [2]. It is estimated that 80% of people with diabetes live in low- and middle-income countries and the socially disadvantaged in any country are the most vulnerable to the disease, with most deaths occurring under the age of 60 years [3, 4], with type II diabetes being the predominant, accounting for 70 - 90% of the cases [4, 5]. The disease which is now regarded as a pandemic due to rapidly spreading in most developing countries and particularly affecting poor populations in sub-Saharan Africa [2 - 4]. Prevalence of diabetes is on the increase, with ageing of the population and lifestyle changes from a traditional healthy and active life to a modern sedentary, stressful life and over-consumption of energy-dense foods [5 - 8], associated with rapid urbanization and westernization. Diabetes mellitus is a chronic illness that requires continuing medical care and patient self-management education related to diet, exercise and medication in order to prevent acute and chronic complications. Glycemic control plays a major role in the outcome of diabetes mellitus [5, 9]. In this study, we observed clinical characters, presentations and cardio-vascular risk factors in patients presented with diabetes.

Materials and methods

This is a retrospective study carried out with diabetic Libyan patients attended out-patients unit at Almustaqpal Almosherq Centre during the period of September 2013 to September 2020, where demographical data of the patient including gender, age at presentation, away of presentation, duration of diabetes, type of diabetes as clinically determined (auto-antibodies not available), follow up visits, body weight, with body mass index were all recorded. Presence of hypertension, treatment with glucose lowering drugs were also taken presenting HBA1c, intake of lipid lowering drugs. An ethical approval was obtained from Bioethics Committee at Biotechnology Research Center, Tripoli, Libya with refenence number of BEC-BTRC 11-2022).

Statistical analysis: Data for continuous variables are expressed as mean ± standard deviation and analyzed. Chi-square test and Pearson coefficient were used (2-sided) as p value 95% confidence interval (95% CI) with $P < 0.05$ is considered statistically significant. All data were performed with Statistical v10.0 (StatSoft, Tulsa, OK, USA) or STATA v11 (StataCorp LLC, College Station, Texas, USA).

Results

A total of 1 024 Libyan patients were enrolled in this study, 820 patients were included in the study (80%). Their age were ranged from 14 to 87 years with a mean ± SD of 56.53 ± 13.49 years. Female patients represent 66% of the studied sample, and female to male ratio is 1.9 : 1. At presentation, five patients were not known to be diabetic (three patients are females and two patients are males) and 815 patients were known to be diabetic. Diabetes type I were 21 patients (11 are female and 10

patients are male), 791 patients with diabetes type II (521 are female and 270 patients are male), gestational diabetes were in two female patients, secondary diabetes (steroid induced or pancreatic disease) were found in five female patients and one male patient. There were different duration of diabetes among studied sample which vary from newly 198 patients (122 female patients and 76 male patients). 110 patients (70 female patients and 40 male patients) were varied from two to five years. 133 patients (88 female patients and 45 male patients) were varied from five to ten years. Above ten years of diabetes duration were 379 patients (259 female patients and 120 male patients). The classical symptoms of diabetes (polyuria, polydipsia and weight loss) were presented in 581 patients (378 female patients and 203 male patients) and diagnosis by chance were presented in 239 patients (161 female patients and 78 male patients). In **Table 1**, initial treatment for diabetes is different in the studied sample, where absent of anti-diabetic medications in 248 patients (162 female patients and 86 male patients), only start biguanides were in 96 patients (67 females and 29 males), on dipeptidyl peptidase-4 inhibitors were presented in 12 patients (7 females and 5 males), sulfonyurea intake were in 114 patients (62 females and 52 males), combined oral hypoglycemic drugs usually biguanides is the main drug were presented in 57 patients (38 females and 19 males), insulin use alone in 103 patients (62 females and 41 males) and combined insulin therapy and oral hypoglycemic

Discussion

The present study evaluated the clinical character and presenting feature of patients with diabetes who attended during seven years, and assessed the associated risk factors for cardio- vascular disease including obesity, hypertension and hyperlipidaemia and shown type II diabetes is the commonest type in both sexes (diabetes affected female more than male by 1.9 : 1). Female affected more across all the age groups, at age 54 to 66 years, the common age group for female patients account for 26% while in male patients, the common age group is earlier (41 to 53 years), revealing for 10%. Clinically diagnosed as type I diabetes showed that female preponderance with 52% females versus 48% males; such female preponderance is also observed in previous studies [1, 9, 10]. On other studies, male preponderance, with male-to-female ratio of 1.3: 1 which reported in UK, Denmark and India [9, 11 - 13]. With regard to duration of diabetes, different from less than one year to more than ten years, common period of this presentation where more than 10 years. Regarding female and male, 30% and 15% respectively, this indicates that most of the patients don't seek consultant advice with later in their disease duration. For patient's follow-up and patients' self-care where noticed is more common with female patients record for 68% but patients with irregular follow up were 39.6%.

Obesity has increasing epidemic, worldwide and nearly tripled, it is recognized as a disease eight, the risk of hypertension up to five times higher in obesity [5, 7], about 75% of hypertension attributable to weight [7, 10]. Patients with obesity have higher triglycerides, lower HDL-C11, they estimated that each unit change in body mass index increases ischemic events [6, 14, 15]. As evidence

based weight loss prevents progression from impaired glucose tolerance to diabetes, as well as weight loss can lead to remission of diabetes [14, 15]. This effect varies across individuals. Usually, patients presented with high body mass index reflect high risk for obese individual to develop diabetes. These facts are in line with the present study, type II diabetes and obesity are more common in female, over weight were 12.5% in female, but male patients were 08%. For obese range, also female (18%) in contrast to male (6%), as well as morbid obesity in female were five times of male patients. Even though a wide range of choices are now available for treating type II diabetes, including several new pharmacological classes of drugs that are indicated in the current American Diabetes Associations - European Association for the Study of Diabetes (ADA/EASD) and American Association of Clinical Endocrinologists (AACE) recommendations. About 50% of the patients with type II diabetes fail to achieve adequate glycemic control (glycated hemoglobin, HbA1c, < 7%) [16, 17]. Using data from the National Health and Nutrition Examination Survey, targets for glycemic control (HbA1c) were achieved by about 50% of the participants. In a multicenter study conducted in Eastern Europe, Asia and Latin America showed that 95% of the study participants had poor glycemic control [18 - 20]. Similarly, high proportions of type II diabetic patients with poor glycemic control ranging from 50 to 95.8% were reported in Brazil, South Indian, Karnataka, Uganda, Mthatha and Ghana [19 - 20]. In Ethiopia, hospital-based cross-sectional studies done at Gondar, Ambo, Jimma and Limmu indicated that 57.5%, 50.0%, 70.9%, 63.8% of participants had poor glycemic control, respectively [21]. These findings were similar with the current findings which shown glycaemic control as reflected with HBA1c level are 35.6% were above 10 g%, and 45% were above 8 g% that indicates with bad or uncontrolled diabetes even with intake of glucose lowering drugs, in the other hand, patients in target control (HBA1c < 7 %) were in 11.9%.

In the current study, duration of symptoms before diagnosis was widely varied from seven days to seven months based on severity of hyperglycaemia, explained the cause why many patients with newly diagnosed diabetes remain without treatment. About 20% of the female patients remain without glucose lowering agents and 10% of the male refused drugs for hyperglycaemia. Regarding treatment given for hyperglycaemia, 10% were on biguanides alone, 1.5% were on dipeptidyl peptidase-4 Inhibitors alone, while in combination was 07%, sulfonylurea were common oral hypoglycaemic drug alone and in combination with biguanides and DPP-4 Inhibitors (15%). Insulin therapy is mandatory and life saving for type I diabetes which represents 2.5%, also insulin therapy is important for type II diabetes, in total insulin therapy account for 12.5% and with combination with oral hypoglycaemic drugs were 23%. The study revealed that hypertension and diabetes usually coexist, norm-tension 25% mostly in female and young patients, but hypertension may present before or during or after diabetes presentation (75%) who are hypertensive diabetes patients; diagnosed and under anti-hypertensive treatment (40%). Prevalence was positively correlated with age in general, with the peak value at 54 - 66 years old and then decreased.

For clinical purposes, hypertension, among diabetic patients, is a worldwide public-health challenge the frequency of hypertension among diabetic population is almost twice that of non-diabetic patients [19]. Compared with other cardiovascular disorders, hypertension is the most common comorbid disease in diabetic patients and its effects are devastating if not controlled [23]. Concentrating on detecting and managing hypertension in patients with diabetes is one of the most effective things that can be done to prevent diabetes complications [22 - 23]. There is a lack detailed basic data on the prevalence and determinants of hypertension in many countries in sub-Saharan Africa including Ethiopia [24]. The overall prevalence of hypertension among diabetic patients was 75%. This is in line with several studies conducted so far. Accordingly, studies conducted in Benghazi, Libya, in Morocco in Jordan in Iraq and in Botswana [20 - 29]. However, the current study is higher than a study conducted

in Pakistan, in Bahrain, in Taiwan and in Jos, Nigeria [30 - 36]. Also, higher than a study conducted in Southern Ethiopia at Sidama zone, in Turkey and in India [28, 34]. The possible reason for such discrepancy might be due to differences in study population, socio-demographic characteristics, study settings, study design, habit of visits to health setups and differences in lifestyle of the participants.The peak age at presentation were 54 - 66 years old, this might be due to aging being generally associated with a decline in various physiological functions and non-communicable diseases including hypertension. Furthermore, increasing age has also been linked with a high incidence of disease [5, 37]. Dyslipidemia is one of the risk factors for vascular complications in diabetic patients because it increases free fatty acid flux secondary to insulin resistance and aggravated by increased inflammatory adipokines [38]. According to the Framingham Heart Study, in diabetic patients, the prevalence rate for high cholesterol was double in females and this rate for high plasma triglyceride is similar in male and female patients [37 - 39]. A cross-sectional, multicenter, hospital-based diabetes registry conducted in Thailand showed more than 80% of diabetic patients had dyslipidemia but 40% of patients who received lipid-lowering medications achieved the target low-density lipoprotein cholesterol level. This is similar with our study which shown most of the patients are taken statin and well tolerated, some patients don't reach the target control even with drug intake. Regarding treatment of dyslipidaemia which is recommended as primary prevention for all the patients with diabetes above 40 years of age and or diabetes duration more than ten years, and as secondary prevention for all diabetes to prevent vascular events.

Conclusion: Type II diabetes is the most common type in Libya, which can be prevented delayed and controlled as well as can avoid disability and mortality related to diabetes. Education is the corn-stone to diabetes management. Health-care priority should be directed to prevention programme for diabetes rather than treatment of complications, as nearly 50% of diabetes who are asymptomatic, so in the concern of treatment of only the iceberg is not cost-effective. Application of good selective screening for high-risk group is mandatory to avoid acute and chronic diabetes complications. Risk factors of cardio-vascular disease can be minimized by screening patients for obesity, hypertension and hyperlipidemia.
