Merging Satellite and *in situ* Data to
Assess the Flux of Terrestrial Dissolved
Organic Carbon From the Mackenzie
River to the Coastal Beaufort Sea.
Front. Earth Sci. 10:694062.
doi: 10.3389/feart.2022.694062

In response to global warming, the Arctic is undergoing rapid and unprecedented changes that alter the land-to-sea forcing in large Arctic rivers. Improving our knowledge of terrestrial dissolved organic carbon (tDOC) flux to the coastal Arctic Ocean (AO) is thus critical and timely as these changes strongly alter the biogeochemical cycles on AO shelves. In this study, we merged riverine *in situ* tDOC concentrations with satellite ocean-color estimates retrieved at the land-marine interface of the Mackenzie Delta to make a first assessment of the tDOC export from its main outlets to the shelf. We combined tDOC and river discharge data to develop a regression model that simulated tDOC concentrations and fluxes from daily to interannual (2003–2017) time scales. We then compared the simulated satellite-derived estimates to those simulated by the model constrained by *in situ* tDOC data only. As the satellite tDOC estimates reflect the delta effect in terms of tDOC enrichment and removal, our results inform us of how much tDOC can potentially leave the delta to reach the ocean ($1.44 \pm 0.14 \text{ TgC.yr}^{-1}$). The chemodynamic relationships and the model suggest contrasting patterns between Shallow Bay and the two easternmost delta outlets, which can be explained by the variability in their geomorphological settings. At the seasonal scale and for all outlets, the satellite-derived tDOC export departs from the estimate based on *in situ* tDOC data only. During the river freshet in May, the satellite-derived tDOC export is, on average, ~15% (Shallow Bay) to ~20% (Beluga Bay) lower than the *in situ*-derived estimate. This difference was the highest (~60%) in 2005 and exceeds 30% over most of the last decade, and can be explained by qualitative and quantitative differences between the tDOC_{in situ} and tDOC_{sat} datasets in a period when the freshet is highly variable. In contrast, in summer and fall, the satellite-derived tDOC export is higher than the *in situ*-derived estimate. The temporal difference between the satellite and *in situ*-derived export estimates suggests that predicting seasonal tDOC concentrations and fluxes from remote Arctic deltas to the coastal AO remains a challenge for assessing their impact on already changing carbon fluxes.

Keywords: terrestrial DOC, land-to-sea interface, permafrost, Mackenzie delta, space remote sensing

1 INTRODUCTION

In response to climate change, the Arctic is undergoing unprecedented changes in both its watersheds and coastal ocean. Since the 1970s in the Arctic, the surface air temperature has increased by 2.7°C (Box et al., 2019) resulting into an increase of the sea surface temperature in summer (Timmermans and Labe, 2021). These changes alter the land-to-sea forcing with important regional and basin-wide implications for sea ice formation, ocean stratification and heat flux, underwater light regime, nutrients delivery, and marine ecosystems (Searcy et al., 1996; Mulligan et al., 2010; Brown et al., 2020; Juhls et al., 2020). Arctic rivers' discharge and permafrost are key components of this coupling. Northern permafrost contains 1,460–1,600 Gt of organic carbon in the form of frozen organic matter, nearly twice as much as carbon than is currently in the atmosphere (Tarnocai et al., 2009; Schuur et al., 2015). Most of this carbon is stored in the Arctic, where permafrost covers 65% of Russian (Tumel, 2002) and 50% of Canadian lands (Vincent et al., 2017). This carbon pool represents about half the world's soil carbon (Hugelius et al., 2014).

Riverine freshwater inputs to the Arctic Ocean (AO) are the largest of any ocean per basin volume (Opsahl et al., 1999). The Arctic hydrological cycle has intensified resulting in a steady increase in the liquid flow of pan-Arctic rivers over the past 30 years (Box et al., 2019). Because of rapid permafrost thaw, the export flux of terrigenous dissolved organic carbon (tDOC) to the coastal AO tends to increase (Fritz et al., 2017) and reaches rates of change as high as 39% in the Mackenzie River system during the 1978–2012 period (Tank et al., 2016). In addition, the land-to-sea flux of terrestrial organic carbon mobilized through coastline erosion has nearly doubled between 1955 and 2018 (Bristol et al., 2021). Once in the coastal AO, a fraction of this riverine and eroded tDOC pool can be degraded and further mineralized into inorganic carbon (Lønborg, 2020, and reference therein) that in turn likely unbalances the delicate air-sea gas exchanges on shelves (Manizza et al., 2013; Spencer et al., 2016; Tanski et al., 2016; Tanski et al., 2021).

In this context, there is a growing need to quantify land-to-sea fluxes of tDOC and to investigate the coastal ecosystem response at the seasonal scale, where the physical-biogeochemical interactions play a role on AO shelves. Such an effort has been considerably reinforced since the 2000s with the PARTNERS/ArcticGRO (AGRO) pan-Arctic monitoring program (Holmes et al., 2020; Shiklomanov et al., 2020), which provides high-quality *in situ* measurements of tDOC concentrations. Watershed models also improved considerably to become high-value predictive tools (McGuire et al., 2016) but still require improvements in their ability to resolve the complex mechanistic processes behind tDOC mobilization and transformation within Arctic watersheds (Kicklighter et al., 2013; Liao et al., 2019). Field observations thus remain essential to further understand the coastal ecosystem responses.

The remoteness of Arctic rivers imposes that *in situ*-based tDOC fluxes are estimated up to hundreds of kilometers upstream from their main outlets and based on only a few measurements per year (~4 on average; Holmes et al., 2020). This strongly hampers a robust assessment of the estimated tDOC export from the land-marine transition to the coastal AO waters and, most importantly, precludes

any effect of the delta on concentrations (enrichment/removal) (see Kipp et al., 2020). Using radiometric satellite data, Griffin et al. (2018) more than doubled the number of available data during the open water season and highlighted the strong variability of tDOC estimates that can be observed within Arctic rivers systems. Juhls et al. (2020) highlighted the synoptic (~ 4 days) variability of tDOC concentrations within the Lena Delta and point out the growing need to assess tDOC concentrations within the land-ocean interface. The high-frequency sampling improved the yearly assessment of tDOC export to Laptev Sea and highlighted the strong seasonality of tDOC quality (Juhls et al., 2020).

In the present study, we investigate the value of merging *in situ* tDOC concentrations with radiometric satellite tDOC estimates retrieved within nearshore waters at the three main outlets of the Mackenzie Delta in the assessment of the seasonal to interannual flux of tDOC to the shelf. The paper is organized as follows. First, we provide an overview of the Mackenzie watershed and delta. Second, we describe the approach used to simulate tDOC concentrations and fluxes within the Mackenzie Shelf. Then, we compare the simulated tDOC concentrations and fluxes with and without the inclusion of satellite tDOC concentration estimates. Finally, we discuss the potential of coastal satellite tDOC data in assessing the seasonal to interannual flux of tDOC to the AO with perspectives for future developments.

2 MATERIALS AND METHODS

We estimated daily tDOC concentrations ($tDOC_{est}$) and fluxes from the Mackenzie River to the shelf (**Figure 1**) using the USGS load estimator (LOADEST) model (Runkel et al., 2004). This modeling approach was successfully applied in Arctic rivers to simulate tDOC fluxes from sparse *in situ* data (Holmes et al., 2012; Tank et al., 2016; Shrestha et al., 2019). The tDOC data nomenclature further used in the paper and the data treatment and procedure to simulate the daily tDOC fluxes and concentrations are given in **Figure 2**.

2.1 Study Area

The Mackenzie Delta is located in the westernmost Canadian Arctic in the southeastern Beaufort Sea (**Figure 1**). It is the second largest delta in the AO (Burn and Kokelj, 2009), whose waters spread into the most riverine of all pan-Arctic shelves with respect to its size and residence time (Macdonald et al., 1988). The Mackenzie River drains a 1.68 million km² wide area and brings, on average, 306 km³ of fresh water into the AO each year (Mulligan and Perrie, 2019). Permafrost underlies 82% of this massive watershed (Holmes et al., 2013) and the soil organic carbon content of Mackenzie deltaic alluvium is estimated to 34–41 PgC (Tarnocai et al., 2009; Hugelius et al., 2014). Riverine freshwater reaches the coastal ocean through a complex river network made of channels of different sizes of which the main ones end up into three major outlets: Shallow Bay, Beluga Bay and Kugmallit Bay (Morley, 2012). The three coastal bays are shallow but differ by their geology upstream and their ocean geomorphological settings downstream on the shelf. On the West, a flat topography and numerous lakes and

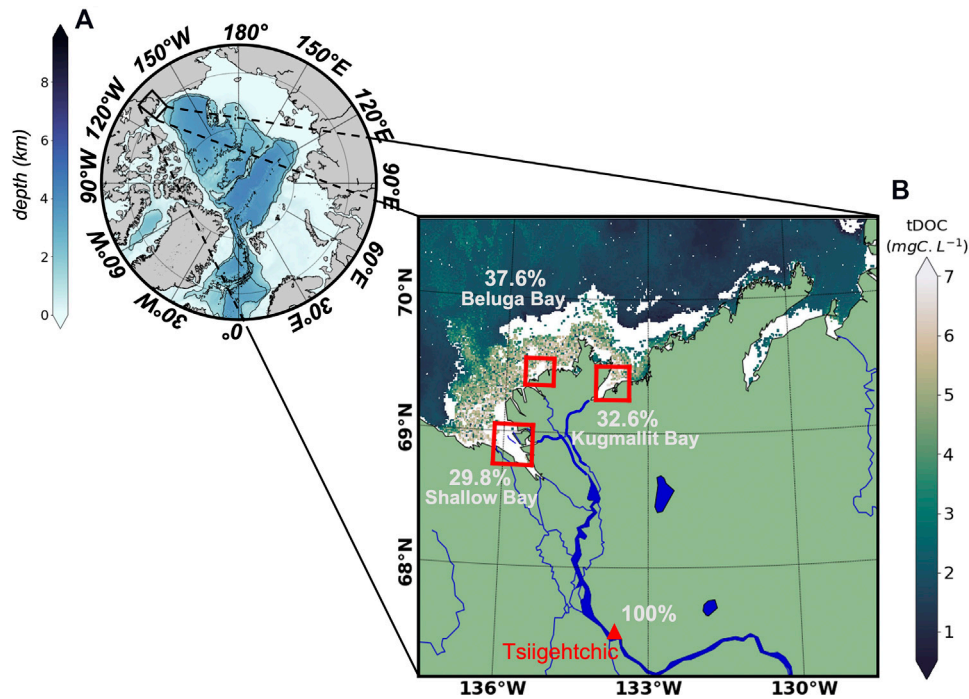

FIGURE 1 | Polar stereographic map of (A) the Arctic Ocean bathymetry with the northeastern Beaufort Sea delimited in black and (B) the Mackenzie Delta area with the *in situ* (ArcticGRO/PARTNERS, red triangle) and satellite (red squares) sampling locations overlaid. For each outlet of the Mackenzie Delta, the weights applied to the total river discharge measured at the Tsiigehtchic station are given. An AMODIS satellite scene of tDOC concentration (28 August 2007) is overlaid.

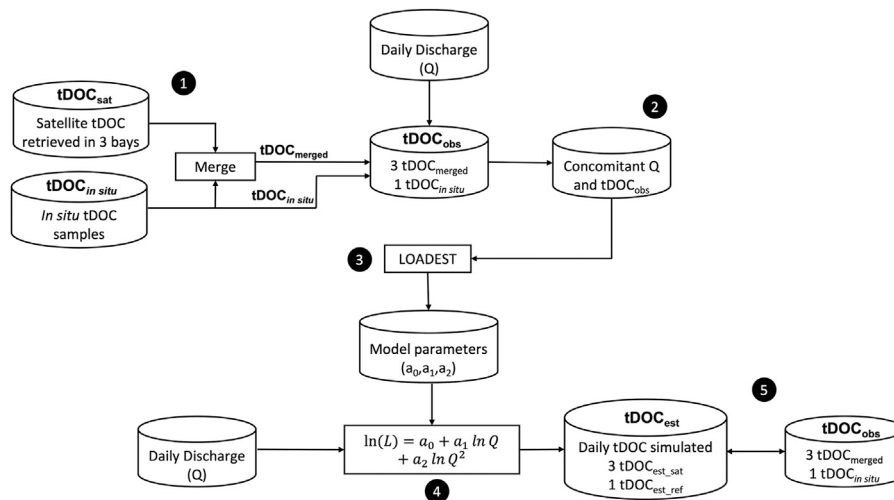

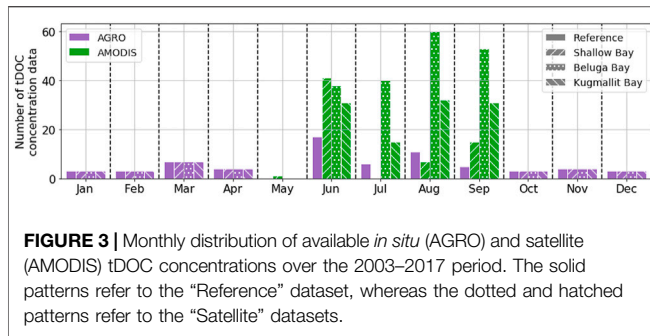

FIGURE 2 | Schematic representation of the procedure used to generate the simulated tDOC flux and concentrations with the LOADEST model. Numbers 1–5 refer to the main steps fully detailed in the Materials and Methods section.

channels surround Shallow Bay (Nill et al., 2019). The bay is supplied by three main river channels and its plateau rapidly ends up as a deep canyon. By contrast, Beluga Bay extends far into the coastal ocean. The low-lying grounds of this northernmost part of the delta are mainly inundated tundra composed of sedge and lakes grading into marshes

(Harper, 1990; Burn and Kokelj, 2009). The easternmost part of the delta, Kugmallit Bay, which is characterized by rolling hills and termorkarst lakes is highly subject to environmental changes (Nill et al., 2019). The Mackenzie River outflow into the ocean is modulated by the presence of a persistent ice barrier (stamukha; Carmack et al., 2004) close to the shelf,

whose break-up results into pulses of freshwater discharge (Doxaran et al., 2015; Matsuoka et al., 2016).

2.2 The *in situ* and Satellite-Derived Data: tDOC Concentration and River Discharge

We used *in situ* tDOC ($tDOC_{in\ situ}$) concentrations and freshwater discharge data (2003–2017) from the water quality dataset provided by the Arctic Great River Observatory (ArcticGRO; Holmes et al., 2020; Shiklomanov et al., 2020). Data encompassed the PARTNERS (2003–2007), ArcticGRO I (2009–2012), II (2012–2016) and III (2017–2020) campaigns. Data were sampled at the Tsiigehtchic station (67.45°N, 133.74°W) about 200 km upstream of the Mackenzie Delta (Figure 1). River discharge was measured daily over the whole period (2003–2017), whereas the sampling frequency of tDOC concentrations was year-dependent (0–7 measurements per year).

Satellite-derived tDOC ($tDOC_{sat}$) concentration estimates were determined for the same time period as *in situ* data (2003–2017) from radiometric spectral reflectance data retrieved with a 1 km horizontal resolution at nadir by the Moderate-Resolution Imaging Spectro-radiometer (MODIS) aboard the Aqua satellite (AMODIS). 1,051 scenes constituted the satellite dataset for the entire period (2003–2017). Colored dissolved organic matter (CDOM) absorbance at 443 nm ($a_{CDOM(\lambda=443)}$) was derived from spectral reflectance data using the semi-analytical algorithm of Matsuoka et al. (2013). $tDOC_{sat}$ concentrations were estimated by applying satellite-derived $a_{CDOM(\lambda=443)}$ data to an empirical relationship between *in situ* tDOC concentration and $a_{CDOM(\lambda=443)}$. This relationship ($DOC = 10^{2.532 \cdot a_{CDOM(443)}^{0.448}}$) was established using data across different seasons and areas, allowing its application to the whole AO (Matsuoka et al., 2017). The mean uncertainty of the satellite estimates of DOC concentrations was 28% (Matsuoka et al., 2017). The seasonal contribution to both *in situ* and satellite-derived tDOC data used in this study is given in Figure 3.

2.3 Merging the *in situ*/Satellite tDOC Data

We generated one *in situ*/satellite merged dataset for Shallow Bay, Beluga Bay and Kugmallit Bay. Between May and September (open water season), we substituted the $tDOC_{in\ situ}$ concentrations by the $tDOC_{sat}$ concentrations available. We then merged the satellite data with the $tDOC_{in\ situ}$ concentrations available between October and

April to generate a merged tDOC ($tDOC_{merged}$) dataset for each outlet (step 1, Figure 2). For each satellite scene, we subsampled $tDOC_{sat}$ concentrations within a 600 km², 306 and 441 km² surface area for Shallow Bay, Beluga Bay and Kugmallit Bay, respectively (Figure 1). We calculated the median of all valid pixels only when 50% had non-missing $tDOC_{sat}$ values to limit biases due to sea ice or cloud cover. To compute the $tDOC_{sat}$ flux, we weighted the freshwater discharge at the three delta outlets based on the channels contributions reported by Morley (2012). We estimated the percentage of the total river discharge measured at the Tsiigehtchic station that was delivered to Shallow Bay, Beluga Bay and Kugmallit Bay to 29.8, 37.6 and 32.6%, respectively (Morley, 2012; Blackburn et al., 2015) (Figure 1). To account for the water transport between the Tsiigehtchic station located 250 km upstream on the river path and the delta outlets, we applied a +1 day offset on the river discharge data. We estimated this value by multiplying the daily river discharge with the mean distance between the Tsiigehtchic station and the delta outlets (250 km), the mean width of the Mackenzie River at Tsiigehtchic (1 km) and the water level measured by the Water Survey of Canada at Tsiigehtchic station. We obtained four $tDOC_{obs}$ datasets: three based on $tDOC_{merged}$ data for each delta outlet (hereafter “Satellite”) and 1 based on $tDOC_{in\ situ}$ data only (hereafter “Reference”).

2.4 The LOADEST Modeling Approach

2.4.1 The Model Selection

We constrained the LOADEST model with time coincident observations of tDOC concentration ($tDOC_{obs}$) and freshwater discharge (Q) data to build up a logarithmic relationship between the tDOC load (equivalent to daily flux) and river discharge based on the following general Equation 1:

$$\ln(L) = a_0 + a_1 \ln Q + a_2 \ln Q^2 + a_3 \sin(2\pi dtime) + a_4 \cos(2\pi dtime) + a_5 dtime + a_6 dtime^2 \quad (1)$$

where L is tDOC load (kg.day⁻¹), Q the river discharge (m³.s⁻¹), $dtime$ the decimal time (YYYYMMDD) and a_n ($ne[0; 6]$) the n regression coefficients. The multicollinearity between the explanatory variables $\ln Q$ and $dtime$ was handled by a centering procedure as follow:

$$X_{LOADEST} = X - \bar{X} + \frac{\sum (X - \bar{X})^3}{2 \cdot \sum (X - \bar{X})^2} \quad (2)$$

where X was either $dtime$ or $\ln Q$.

Based on the Akaike Information Criterion (AIC) (Akaike, 1974), the LOADEST approach allowed to select the best fitting model through nine different combination of the terms included in Equation (1) (Supplementary Table S1).

We chose the model by calculating a first estimate of both $\ln(L)$ and $tDOC_{est}$ concentrations based on time coincident ArcticGRO $tDOC_{in\ situ}$ and discharge data through the automated regression model selection set in LOADEST (model 0). According to the AIC, LOADEST selected two different models as best fitting models (models 2 and 7, Supplementary Table S1). By referring to the Schwarz Posterior Probability Criterion (SPPC) also computed as an AIC comparative parameter, model 2 (Eq. (3)) was identified as the most accurate:

$$\ln(L) = a_0 + a_1 \ln Q + a_2 \ln Q^2 \quad (3)$$

Furthermore, model 2 precluded any spurious numerical trend induced by the *dtime* explanatory variable present in model 7. We thus assumed model 2 (Eq. (3)) as the best regression model to assess daily tDOC fluxes and concentrations entering the Mackenzie shelf.

2.4.2 Simulated Daily tDOC Concentration and Flux

We applied model 2 to all tDOC_{obs} datasets to highlight the effect of satellite data on the tDOC flux assessment. For each tDOC_{obs} dataset, we first extracted river discharge data concomitant with available tDOC_{obs} data from the entire daily river discharge dataset (step 2, Figure 2). In LOADEST, these data were then used to constrain model 2 to retrieve the regression coefficients (a_0 , a_1 and a_2) of the model (step 3, Figure 2). Finally, we ran model 2 using the regression coefficients thus obtained and forced it with the entire daily river discharge data to simulate the tDOC flux at the daily scale (step 4, Figure 2). From the simulated flux, we calculated back the tDOC_{est} concentrations at daily scale by dividing the daily flux by the river discharge. We thus obtained a “Reference” estimate of tDOC concentration (tDOC_{est_ref}) from model 2 ran with the regression coefficients derived from the tDOC_{in situ}/Q relationship (see step 3, Figure 2). Similarly, we obtained three “Satellite” estimates of tDOC concentration (tDOC_{est_sat}) derived from each outlet-specific tDOC_{merged}/Q relationship (step 3, Figure 2) for Shallow Bay, Beluga Bay and Kugmallit Bay. We give the constants obtained for each regression model in Supplementary Table S2.

2.5 Comparison of Simulated Versus Observed tDOC Concentrations

We used four comparison metrics to compare the tDOC concentrations simulated by model 2 (tDOC_{est}) based on the *in situ* data (hereafter tDOC_{est_ref}) and merged *in situ*/satellite data (hereafter tDOC_{est_sat}) with the time coincident observed (tDOC_{obs}) (step 5, Figure 2). We calculated the correlation coefficient (r), the Nash-Sutcliffe model efficiency index (NSE), the unbiased Root Mean Square Error (URMSE), and the Median Percent Error (MPE) as follows:

$$r = \sqrt{1 - \frac{\sum_{n=1}^N (tDOC_{obs} - tDOC_{est})^2}{\sum_{n=1}^N (tDOC_{est} - \langle tDOC_{est} \rangle_n)^2}} \quad (4)$$

$$NSE = \frac{\sum_{n=1}^N (tDOC_{obs} - \langle tDOC_{obs} \rangle_n)^2 - \sum_{n=1}^N (tDOC_{obs} - tDOC_{est})^2}{\sum_{n=1}^N (tDOC_{obs} - \langle tDOC_{obs} \rangle_n)^2} \quad (5)$$

$$URMSE = \sqrt{\frac{\sum_{n=1}^N ((tDOC_{est} - tDOC_{obs}) - (\langle tDOC_{est} \rangle_n - \langle tDOC_{obs} \rangle_n))^2}{N}} \quad (6)$$

$$MPE = Median\left(100 \cdot \left| \frac{tDOC_{est} - tDOC_{obs}}{tDOC_{obs}} \right| \right) \quad (7)$$

The NSE (unitless) relates the residual variance (i.e. the “noise”) between the tDOC_{est} and tDOC_{obs} values to the

variance within the tDOC_{obs} values (i.e. the “information”) (see Nash and Sutcliffe, 1970). A NSE value of 1 indicates that the noise is null. A NSE value near 0 means the noise is comparable to the observed variance suggesting that the simulated values are as accurate as the observed mean. A negative NSE value suggests that the mean value of observations is a better predictor than the model. The URMSE measures the size of the discrepancies between the simulated and observed values. The MPE is the median of the absolute percentage error and provides insights on the regression model accuracy.

We also calculated the relative error between the “Reference” and “Satellite” daily tDOC flux estimates as follows:

$$\delta\alpha_r = 100 \cdot \frac{\sum \phi_{Sat} - \phi_{Ref}}{\phi_{Ref}} \quad (8)$$

where ϕ_{Sat} and ϕ_{Ref} are the “Satellite” and “Reference” daily tDOC flux, respectively.

3 RESULTS

3.1 Chemodynamic Q-tDOC_{obs} Relationships

The relationships between the tDOC_{obs} concentrations and associated freshwater river discharge suggested the presence of two distinct clusters, which distinguished by the river discharge intensity and the source of available tDOC data (Figure 4). A first cluster corresponded to the sea-ice covered season (October to april) characterized by a low river discharge and tDOC_{in situ} concentrations only. A second cluster reflected open water (May to September) conditions with a higher river discharge and mostly tDOC_{sat} concentrations. We used the Spearman correlation coefficient (r) to assess the strength of the relationships between the coincident river discharge Q and the tDOC_{obs} concentrations (i.e. tDOC_{in situ} or tDOC_{merged}) in the full dataset (January to December) and the same dataset but restricted to the open water season (May to September) (Table 1). The tDOC_{obs} concentrations did not follow a Normal distribution (Shapiro test, $p < 0.05$), except for tDOC_{in situ} during the open water season (Shapiro test, $p > 0.05$) for which a Pearson correlation coefficient was used. In all datasets, r was positive when accounting for the full ($0.48 < r < 0.79$) and open water ($0.39 < r < 0.79$) data. Compared to Q-tDOC_{in situ} relationships, the strength of the correlation in the merged datasets varied amongst the delta outlets. The merging of satellite-derived and *in situ* tDOC concentrations increased the Q-tDOC_{obs} correlation in Shallow Bay in both datasets ($r = 0.79$) compared to Q-tDOC_{in situ} ($0.59 < r < 0.68$). In Kugmallit Bay, r was similar in the full dataset ($r = 0.58$ versus $r = 0.59$) but decreased in the open water season ($r = 0.43$ versus $r = 0.68$). In Beluga Bay, r decreased in both the full ($r = 0.48$ versus $r = 0.59$) and open water ($r = 0.43$ versus $r = 0.68$) datasets. This suggests that the strength of the Q-tDOC_{merged} relationship was sensitive to the tDOC_{sat} concentration retrieved nearby each outlet of the delta, with Beluga Bay differing markedly from the other two bays.

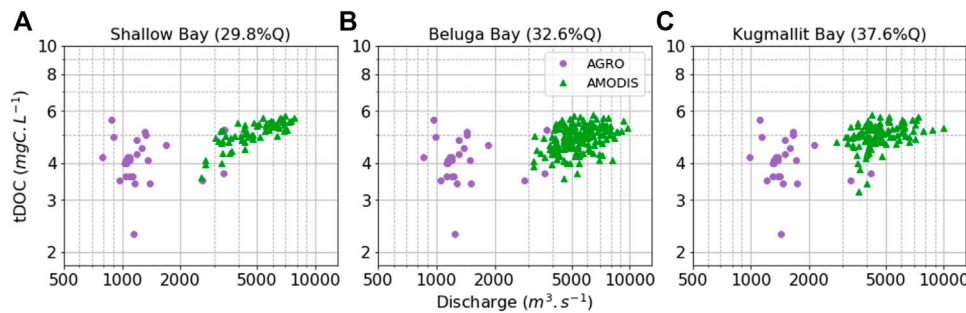

FIGURE 4 | Q-tDOC relationships for the merged in situ-satellite dataset ($tDOC_{merged}$) on (A) Shallow Bay, (B) Beluga Bay and (C) Kugmallit Bay. Green triangles indicate the satellite tDOC concentration estimates (AMODIS). Purple dots indicate the *in situ* tDOC measurements (AGRO). Note the logarithmic scales on both axes.

3.2 Simulated tDOC Concentrations: Merged vs. *in situ* Datasets

We used quantitative metrics to compare the simulated $tDOC_{est,ref}$ and $tDOC_{est,sat}$ concentrations with the observed $tDOC_{in situ}$ and $tDOC_{merged}$ concentrations, respectively (Table 2). The number of $tDOC_{obs}$ data increased with the inclusion of the remotely sensed $tDOC_{sat}$ estimates. In Shallow Bay, the increase reached 38% while it was 2-fold and 3-fold in Kugmallit and Beluga Bay, respectively. The data dispersion (URMSE) between $tDOC_{in situ}$ and $tDOC_{est,ref}$ concentrations was $0.82 mgC L^{-1}$. When using $tDOC_{est,sat}$ estimates, URMSE decreased by 39–45%. The median percent error (MPE) between the $tDOC_{in situ}$ and the $tDOC_{est,ref}$ concentrations was 12.7%. The MPE decreased by 2-fold (Kugmallit and Beluga bays) to 3-fold

TABLE 3 | Comparison metrics between the simulated $tDOC_{est,sat}$ and the $tDOC_{merged}$ concentrations (“Satellite”), in Beluga Bay according to the C50 (50% valid pixels), C40 (40% valid pixels), C60 (60% valid pixels) and 2C50 (2-fold larger surface area +50% valid pixels) subsampling conditions.

Metrics	C50	C40	C60	2C50
N	218	303	120	258
R	0.52	0.50	0.50	0.42
NSE	0.27	0.25	0.25	0.18
URMSE	0.45	0.47	0.47	0.45
MPE	5.68	5.83	5.01	5.66

n, Number of data available; *r*, correlation coefficient; NSE, Nash-Sutcliffe efficient index; URMSE, Unbiased Root Mean Square Error ($mgC.L^{-1}$); MPE, median percent error.

(Shallow Bay) with the $tDOC_{est,sat}$ estimates. The correlation coefficient (*r*) varied little among the Reference and Satellite datasets and was relatively high (0.52–0.76), which suggested a high goodness-of-fit. With respect to the “Reference” estimates ($r = 0.66$), *r* increased in Shallow Bay but decreased in Beluga Bay. The Nash-Sutcliffe model efficiency index (NSE) showed a pattern similar to that depicted by *r*. The NSE between the $tDOC_{in situ}$ and $tDOC_{est,ref}$ concentrations was 0.44 suggesting that the regression model was a fairly good predictor of the observed concentrations. Using $tDOC_{est,sat}$, the NSE remained positive increasing in Shallow Bay (NSE = 0.58) but decreasing in Beluga Bay (NSE = 0.27). Overall, $tDOC_{est,sat}$ estimates simulated in Beluga Bay departed the most from the observed $tDOC_{merged}$ concentrations (Table 2). These results mirrored with the lowest Q- $tDOC_{merged}$ correlation coefficients estimated in Beluga Bay (Table 1).

3.3 Sensitivity Analysis on the Remotely-Sensed Data Subsampling

We tested the hypothesis that the predictive ability of the regression model applied to Beluga Bay was sensitive to the AMODIS data subsampling conditions. We then calculated the median of $tDOC_{sat}$ concentration estimates for each of the three new conditions: 40% of valid pixels (C40), 60% of valid pixels (C60), and a 2-fold subsampling surface area along with 50% of valid pixels (2C50). From these conditions, we simulated three

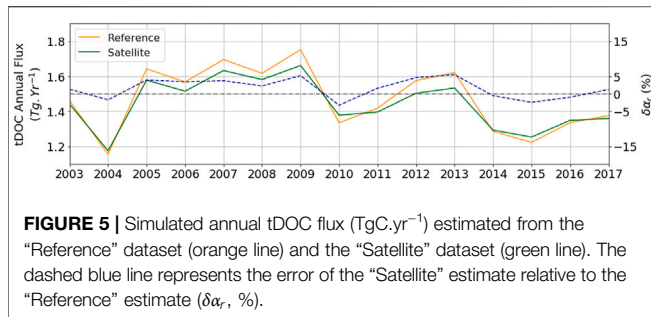

FIGURE 5 | Simulated annual tDOC flux (TgC.yr^{-1}) estimated from the “Reference” dataset (orange line) and the “Satellite” dataset (green line). The dashed blue line represents the error of the “Satellite” estimate relative to the “Reference” estimate ($\delta\alpha_r$, %).

new $\text{tDOC}_{\text{est_sat}}$ concentration estimates based on the three new $\text{tDOC}_{\text{merged}}$ datasets obtained according to the same method described in Section 2. For each subsampling condition, we used the metrics to compare with the subsampling condition of 50% of valid pixel (C50) we previously applied (Table 3). Between the C50 and C60 conditions, the data quantity dropped by 45%. The correlation coefficient, the NSE and the URMSE were similar, whereas the MPE was slightly improved. Between the C50 and C40 conditions, the data quantity increased by 39% and all metrics showed limited variations. Overall, the amplitude of change of the comparison metrics between C40, C50 and C60 (Table 3) was much lower than between the “Reference” and “Satellite” estimates (Table 2, 3). By contrast, a doubling of the sampled surface area (2C50, +18% of tDOC_{sat} data) led to a decrease of r and the NSE compared to C40, C50, C60 and “Reference” estimate. However, no marked changes in the URMSE and MPE were observed. Increasing the number of tDOC_{sat} data by widening the subsampled area decreased the strength of the correlation and increased the noise between the simulated $\text{tDOC}_{\text{est_sat}}$ and the observed $\text{tDOC}_{\text{merged}}$ concentrations. Overall, the simulated $\text{tDOC}_{\text{est_sat}}$ concentrations obtained in 2C50 departed the most from the simulated $\text{tDOC}_{\text{est_ref}}$ estimates (Table 2, 3).

3.4 Annual and Seasonal Patterns of the Simulated tDOC Flux

Over 2003–2017, we simulated the yearly flux of tDOC based on the simulated $\text{tDOC}_{\text{est_ref}}$ and the $\text{tDOC}_{\text{est_sat}}$ concentrations obtained for the three delta outlets. We estimated the total “Satellite” flux by summing the flux simulated at each outlet. The total yearly flux was 1.47 ± 0.18 ($\text{min } 1.15 - \text{max } 1.75$) and 1.44 ± 0.14 ($\text{min } 1.17 - \text{max } 1.66$) TgC.yr^{-1} for the “Reference” and “Satellite” datasets, respectively. Both flux estimates showed comparable interannual patterns. The relative error between the “Satellite” and the “Reference” estimates did not exceed 5% (Figure 5). The yearly flux increased between 2004 and 2009 ($1.17\text{--}1.66 \text{ TgC.yr}^{-1}$) and tended to decrease between 2010 and 2017. However, the yearly flux did not show any significant interannual trend over the 15 years ($r = -0.3$, $p > 0.05$).

Although we reported no substantial differences between the simulated “Reference” and “Satellite” tDOC_{est} flux estimates at the annual scale, both departed at the seasonal scale (Figure 6). During the seasonal peak of river discharge in May, the “Satellite” flux estimate was lower than the “Reference” flux estimate by 15% (Shallow Bay) to 20% (Beluga Bay) on average. Such a difference in the tDOC flux estimates coincides with unevenly distributed tDOC concentrations amongst the datasets in June (Figure 7). By contrast, between mid-July and November the “Satellite” flux estimate was on average higher than the “Reference” flux estimate. In November, the mean difference reached 12 and 17% in Shallow Bay and Kugmallit Bay, respectively. At the interannual scale, the relative error on the total simulated tDOC flux reported at the spring river freshet exhibited a high variability (Figure 8). From 2011 to 2017, the “Satellite” flux estimate was generally more than 30% lower than the “Reference” flux estimate. The highest interannual difference was reached in 2005, when the “Satellite” flux estimate was ~60% lower than the “Reference” flux estimate.

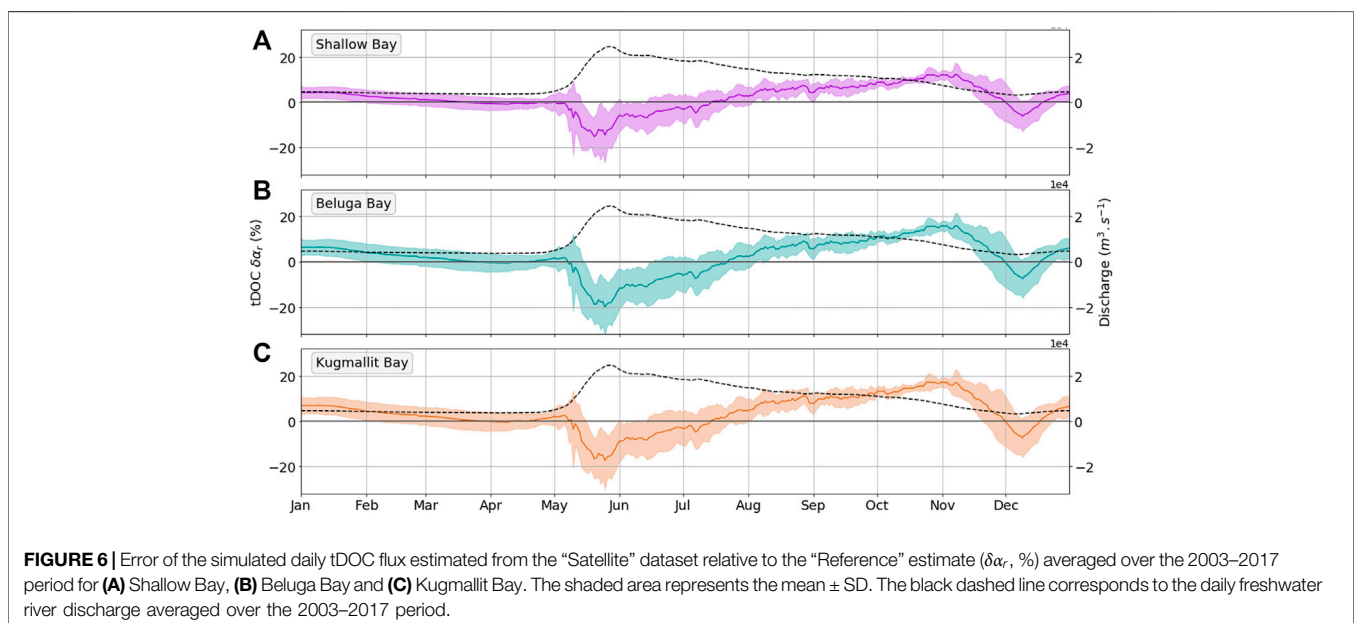

FIGURE 6 | Error of the simulated daily tDOC flux estimated from the “Satellite” dataset relative to the “Reference” estimate ($\delta\alpha_r$, %) averaged over the 2003–2017 period for (A) Shallow Bay, (B) Beluga Bay and (C) Kugmallit Bay. The shaded area represents the mean \pm SD. The black dashed line corresponds to the daily freshwater river discharge averaged over the 2003–2017 period.

4 DISCUSSION

4.1 A Complex Land-To-Sea Interface

The presence of a chemodynamic Q-tDOC relationship, i.e. the higher the river discharge the higher the tDOC concentration,

reported upstream in the Mackenzie River path is widely accepted (Raymond et al., 2007; Holmes et al., 2012; Shrestha et al., 2019). In the Peel River catchment, Shrestha et al. (2019) suggested a significant Q-tDOC correlation ($r = 0.52$), which is in the range of the values we report in this study ($0.48 < r < 0.79$). This result

suggests that the positive Q-tDOC chemodynamic relationship estimated more than 200 km upstream from the delta also applies to the fluvial-marine interface farther downstream. Our results show that the chemodynamic Q-tDOC_{merged} relationship varies amongst the three delta outlets and is the weakest in Beluga Bay ($r = 0.48$). Such a decrease in the Q-tDOC_{merged} relationship for Beluga Bay suggests a less conservative behavior of the tDOC concentrations. After the spring freshet, the river water is stored in deltaic lakes and floods the vegetated floodplain (Normandin et al., 2018), which can modify its chemistry before draining to the delta channels and ultimately to the Mackenzie Shelf (Emmerton et al., 2008a). Processes like autotrophic production and leaching can enhance tDOC levels in river water over a wide range of variability (15–350%) as tDOC is transported through the delta (Emmerton et al., 2008a; Kipp et al., 2020). In the upper part of the delta, tDOC removal through the flocculation process (up to 45%; Kipp et al., 2020) can occur at low salinities in the more estuarine waters and can outbalance the delta enrichment effect. All these processes likely play a role in explaining the distinct Q-tDOC_{merged} relationship we observe for Beluga Bay. In this part of the delta, the alluvial plain is low-lying (<2 m) and intersected by an important network of lakes and channels. In spring, the delta is flooded with freshwater during the freshet (Mackay, 1974). In summer and fall, it is very exposed to the ocean influence and occasionally flooded when strong North-Northwestern winds trigger storm surges and marine intrusions into the delta (Mackay, 1974; Marsh and Schmidt, 1993; Manson and Solomon, 2007). Storm surges can be severe and flood the delta with saline waters over tens of kilometers inland from the coast leading to substantial changes in vegetation (Pisarcic et al., 2011; Kokelj et al., 2012; Lantz et al., 2015). High surface area flooding in Beluga Bay compared to the east and west of the upper delta area (Kuenzer et al., 2015) may lead to differences in the mobilization and biogeochemistry of tDOC at the fluvial-marine transition. As satellite tDOC estimates retrieved at the fluvial-marine transition reflect the delta effect in terms of tDOC enrichment and removal, our results inform on how much tDOC can potentially leave the delta to reach the coastal ocean.

The weaker Q-tDOC_{merged} relationship reported in Beluga Bay ($r = 0.48$), and to a lesser extent in Kugmallit Bay ($r = 0.58$), likely explains the difference in the model performance between the three delta outlets. Overall, the use of tDOC_{sat} data in the model improves the match between the simulated (tDOC_{est_sat}) and observed (tDOC_{obs}) concentrations. This is particularly true for Shallow Bay for which the Q-tDOC_{merged} relationship is the strongest ($r = 0.79$) even compared to the Q-tDOC_{in situ} relationship ($r = 0.59$). There is growing evidence that tDOC concentrations and quality vary in the course of the main channels of the Mackenzie Delta (Emmerton et al., 2008b; Griffin et al., 2018; Kipp et al., 2020; Schwab et al., 2020). The use of satellite tDOC retrieved in nearshore waters in the very close vicinity of the delta outlets allows for the effect of regional biogeochemical signatures to be considered in the estimated land-to-sea fluxes of tDOC. The satellite tDOC concentrations are most likely due to bio- and photo-degradation processes (Gonçalves-Araujo et al., 2015; Matsuoka et al., 2015) that

occur upstream along the river path and that watersheds model are not yet able to represent (Rawlins et al., 2021). Our approach implicitly accounts for these processes without explicitly describing them as their weight on the downstream fate of tDOC is not yet well understood. Nevertheless, caution should be addressed to local non-deltaic sources of tDOC to the ocean. Offshore the delta, strong winds erode the shoreline permafrost of the Beluga Bay Islands, which may deliver extra carbon to the coastal waters (Lim et al., 2020). These inputs, however, may be limited compared to those originating from the delta (Tanski et al., 2016). Assuming a shoreline of 2,077 km for our study area (Harper, 1990) and a tDOC flux of $1.37 \text{ kgC.m}^{-1}.\text{yr}^{-1}$ (Bristol et al., 2021), coastal erosion would translate into a tDOC flux of $\sim 3.10^{-6} \text{ TgC.yr}^{-1}$ into the shelf. This flux is several order of magnitude lower than the riverine flux estimated between 1.04–1.76 TgC.yr⁻¹ (Macdonald et al., 1988; Dittmar and Kattner, 2003; Raymond et al., 2007; Holmes et al., 2012; Le Fouest et al., 2013).

4.2 The Seasonal Shift of tDOC Flux

The mean annual flux of tDOC we estimated using satellite-derived tDOC data (tDOC_{est_sat} = $1.44 \pm 0.14 \text{ TgC}$) fits within the reported range, which was estimated from different methodologies using punctual field measurements, climatologies and/or regression model (1.04–1.76; Macdonald et al., 1988; Dittmar and Kattner, 2003; Raymond et al., 2007; Holmes et al., 2012; Le Fouest et al., 2013). The use of satellite data has no marked impact on the interannual variability but on the seasonality of the simulated tDOC concentrations and fluxes. From May to June, when the river freshet occurs, the tDOC_{est_sat} export flux represents up to ~40% of the total annual flux. Compared to the simulated tDOC export flux estimated from *in situ* data only, we report a decrease in the tDOC_{est_sat} flux in May at the onset of the seasonal peak of river discharge. According to the delta outlet, this decrease reaches 15–20%, on average, but can reach up to 60%. This decrease occurs between winter and the beginning of the open water season, when the data quantity and temporal distribution of tDOC_{in situ} and tDOC_{sat} start to differ (April–June, **Figure 3**). In June, the tDOC_{sat} data quantity is higher ($31 < n < 41$) than in the tDOC_{in situ} dataset ($n = 17$). While the medians of the tDOC concentration compare among the datasets (tDOC_{in situ} = 5.3 mgC.L^{-1} , $5.0 < \text{tDOC}_{\text{merged}} < 5.4 \text{ mgC.L}^{-1}$), the amplitude of variation is lower in the tDOC_{merged} dataset ($4.1\text{--}5.8 \text{ mgC.L}^{-1}$) than in the tDOC_{in situ} dataset ($4.2\text{--}8.1 \text{ mgC.L}^{-1}$). The tDOC_{in situ} data quantity is mostly evenly distributed throughout June, whereas it increases in Beluga Bay, and to a lesser extent in Kugmallit Bay, to reach a maximum at the end of June (**Figure 7**). Such differences between the tDOC_{in situ} and tDOC_{sat} datasets likely constrain the constants obtained for each regression model (**Supplementary Figure S1**), which in turn translate into different tDOC flux estimates in this period of the year when the freshet occurs (**Figures 6, 7**). Ocean color data are usually not available in May due to the presence of landfast ice in the Mackenzie Delta. Some data could be available between the landfast and pack ice but could be unreliable due to the high snow/ice albedo. New space sensors such as Sentinel-2/MSI or Landsat-8/OLI could

help overcome this drawback by significantly improving the spatial resolution of imagery (~30 m). Nevertheless, caution should be addressed to the pixel contamination due to the adjacency effect or sub-pixel-contamination, especially for landfast ice problematics. For now, uncertainties related to the lack of data during the freshet period hamper the model capacity to simulate the land-to-sea flux of tDOC in this critical period of the year.

The temporal shift in the seasonal distribution of the land-to-sea flux of tDOC induced by the use of satellite tDOC data, i.e. a decrease in May-June and an increase in July-November, may have implications on both the physical and biogeochemical settings of the coastal Beaufort Sea. In the Mackenzie Delta, tDOC has a high potential for biological degradation at the spring freshet (Gareis and Lesack, 2020; Behnke et al., 2021). A decrease of the riverine flux in May-June would imply that a lesser fraction of bioavailable tDOC would be delivered and potentially processed by heterotrophic bacteria within the marine ecosystem (Colatrigano et al., 2018; Vaqué et al., 2019). In turn, as most of the tDOC is colored (~94%; Matsuoka et al., 2017) and then absorbs light, phytoplankton might leverage more favorable light conditions in this period because less tDOC would be delivered by the Mackenzie Delta to the coastal waters. Whether such a decrease of the tDOC flux at the spring freshet will have a substantial impact on the heterotrophic-autotrophic balance remains to be determined. In contrast, tDOC is rather refractory in summer, because the biological removal is enhanced and the enrichment limited along the river path (Holmes et al., 2008). A steady increase of the tDOC flux between July and November as we report in our study could then translate into a greater proportion of tDOC that escapes remineralization and accumulates in the oceanic waters. Because the interannual variability of this seasonal shift is high, such biogeochemical responses might be exacerbated in the future. This is particularly true in a context of Arctic warming, which is expected to alter both the river discharge seasonality and the quality of the tDOC exported (see Behnke et al., 2021).

4.3 Future Developments

Using satellite tDOC data, we increased the size of the dataset available during the ice-free period by more than 39%, which is comparable to the study of Griffin et al. (2018) focused on inland waters within the Mackenzie River. The chemodynamic relationships and metrics we estimated for Beluga Bay suggest that the median of the satellite-derived tDOC concentration was sensitive to the subsampling procedure of the remote sensing scenes. The sensitivity analysis suggests that the model is not highly sensitive to the number of valid pixels in satellite scenes but rather to the size of the subsampled surface area. As a larger subsampled area may reflect more contrasted environmental conditions, it may alter the value of the tDOC concentration median. Compared to the other two delta outlets, the differences between the simulated and observed tDOC concentrations reported for Beluga Bay could then indicate a different tDOC dynamics within the land-to-sea interface. For all bays, the

robustness of the model to the number of data within a subsampled area allows for some flexibility in the methodology, because it may offset potential issues related to cloud and/or sea ice cover. In addition, we will leverage newer space sensors such as Sentinel-2/MSI or Landsat-8/OLI to improve the spatial and temporal resolution (i.e. high-resolution ocean color data are available every 3–5 days when all available sensors are used) of radiometric records in nearshore Arctic environments. If the pixel contamination due to sea ice could be overcome, such remotely sensed data would provide tDOC concentrations estimates at the immediate vicinity of the streams' mouth, hence limiting the effect of tDOC degradation/enrichment occurring upstream on the delta estimate. With respect to river discharge, we used daily time-series measured ~100 km upstream the delta to constrain the regression model within the upper part of the delta at the land-ocean transition. The forthcoming Surface Water and Ocean Topography (SWOT) space mission that aims to measure river water surface elevation, top width, and free-surface slope might allow periodic estimation of freshwater discharge for Arctic rivers wider than 50 m (Biancamaria et al., 2016; Durand et al., 2016). As tDOC concentrations are also related to the watershed slope (Connolly et al., 2020), these new promising data combined with satellite tDOC retrievals in nearshore waters might help refine the land-to-sea flux of tDOC in the upper Mackenzie Delta.

Since the past 17 years, the ArcticGRO/PARTNERS program led to a large and very highly valuable dataset of water quality for the Mackenzie River. The sampling frequency is on a monthly basis spanning from January to December with a mean sampling frequency of about 4 days each year. In the Arctic, the retrieval of tDOC from space is limited to the open water season (mostly from June to September). *In situ* measurements of freshwater discharge and tDOC concentrations at the sea ice break-up and spring freshet are hence essential to constrain a regression model as we used in our study and to generate a realistic seasonal cycle of tDOC concentration and flux. In a context of Arctic warming, it is important to maintain and eventually extend such a water quality monitoring to gain robustness in model predictions. Besides, new datasets such as for the Mackenzie river temperature (Tokuda et al., 2019) could further be used to improve the regression models and then to better predict the seasonal to interannual tDOC dynamics (see Shrestha et al., 2019) in response to climate change.

5 CONCLUSION

This study investigated the value of merging riverine *in situ* tDOC concentrations with satellite ocean-color estimates retrieved at the three main outlets of the second largest Arctic Delta to assess the seasonal to interannual flux of tDOC to the coastal AO. By using satellite observations, we show that we can substantially increase the quantity of data available during the open water season to constrain predictive

regression models. We also identified a spatial variability in the tDOC concentrations and flux amongst the three main delta outlets likely reflecting distinct biogeochemical patterns within the land-to-sea interface. The robustness of the approach suggests it could be applied to other Arctic deltas/estuaries to assess the pan-Arctic flux of tDOC if reliable remotely sensed tDOC data are available in such complex land-to-sea interfaces (see Juhls et al., 2019). However, our results also highlight that such predictive models would require more *in situ* and satellite-derived tDOC data especially in fall-winter and at the sea ice breakup to improve their ability to resolve the strong seasonal variability that prevails in such critical and remote environments. There is evidence now that the Arctic permafrost thaw alters both quantitatively and qualitatively the coastal waters biogeochemistry. It then motivates the need to quantify the land-to-sea fluxes of terrestrial organic matter at high spatial and temporal resolution to further investigate the coastal ecosystem response at the synoptic and seasonal time scales at which operates the physical-biogeochemical coupling in the ocean. In addition, the fraction of terrestrial organic matter outgassed into CO₂ through marine physicochemical and microbial processes remains very uncertain although it might unbalance the delicate air-sea gas exchanges. Assessing in a robust way the terrestrial fluxes of organic matter to the coastal ocean is thus paramount to better understand and predict how changes in the land-sea linkages might alter the coastal carbon budget and air-sea CO₂ fluxes at regional scale in the AO.
