#### **Abstract**

Barium fluorotellurite glasses doping with Ho<sup>3+</sup>, Yb<sup>3+</sup>, and Ho<sup>3+</sup>:Yb<sup>3</sup> were fabricated using the conventional melt and quenching method, and their optical properties were studied using different optical spectroscopic techniques. The FITR absorption band at 3000 cm<sup>-1</sup> was used to investigate OH- concentrations of the prepared glasses, which increased with Yb3+ content. However, it decreased by substituting a portion of BaF<sub>2</sub> content with Ba<sub>2</sub>CO<sub>3</sub> concentration. The electric dipole line strengths and Judd-Ofelt parameters were estimated using UV-visiblenear infrared (NIR) optical absorption spectra to gain information on the rare earth ions doped glasses for laser applications. The various radiative parameters such as line strengths, optical intensity, and radiative rates from the higher energy levels, including 5F4 + 5S2, 5F5, 5I4, 5I5, 5I6 and 517, to the ground state, 518 have been reported and discussed. The influence of the Yb3+ and Ba<sub>2</sub>CO<sub>3</sub> concentrations on the upconversion and downconversion photoluminescence emission intensities of the glasses prepared have been investigated by pumping with 450 nm and 976 nm excitation sources. Under 450 nm and 976 nm, the NIR photoluminescence emissions reveal a band ranging from 980 nm to 1220 nm attributing to an overlap between Yb<sup>3+</sup> and Ho<sup>3+</sup> transitions. The influence of Yb<sup>3+</sup> concentration on photoluminescence lifetime at the  ${}^2F_{5/2} \rightarrow {}^2F_{7/2}$ ,  ${}^5F_4 + {}^5S_2 \rightarrow {}^5I_8$  and  ${}^5I_6 \rightarrow {}^5I_8$  transitions under 976 nm laser excitation has been studied and reported. The results indicate that lifetime decreases with increasing Yb3+ concentration attributing to an efficient energy transfer from Yb<sup>3+</sup> to Ho<sup>3+</sup> ions. The energy transfer efficiency from Yb<sup>3+</sup> → Ho<sup>3+</sup> has been examined, which rises from 30% to 47% upon increasing Yb3+ content. Nevertheless, it decreases with the mixing of BaF2 and Ba2CO3 lattice modifier contents. The results demonstrated that the 1200 nm ( ${}^{5}l_{6} \rightarrow {}^{5}l_{8}$  transition) has remarkable potential for developing fiber lasers.

**Keywords:** Barium fluorotellurite glass, Ho, Yb, Judd-Ofelt analysis, OH- groups, photoluminescence, lifetime.

#### 1. Introduction

Trivalent rare-earth (RE3+) ions doped glasses and ceramics have received significant attention over the years from visible to near-infrared (NIR) and mid-infrared for numerous applications, including colour displays, a growing field in medical devices, high-density optical data storage and reading, upconversion laser and visible display devices and indicators [1-3]. This is due to various well-defined electronic transitions characterised by their (4fn)6s2 electronic configuration, with the 4f<sup>n</sup>-4f<sup>n</sup> sub-shell being partially shielded by the 5s, 5p, and 6s electron orbits. As a consequence, leading to host-induced splitting and emitting several light emissions at different wavelengths upon doping with glasses or ceramics [4]. Among these RE<sup>3+</sup> ions, holmium (Ho<sup>3+</sup>) is an attractive, active ion because of its several electronic transitions occurring in the visible spectrum, including  ${}^5F_3 \rightarrow {}^5I_8$  (blue),  ${}^5S_2 \rightarrow {}^5I_8$  (green) and <sup>5</sup>F<sub>3</sub>→<sup>5</sup>I<sub>8</sub> (red) transitions. These transition levels have enormous potential for developing white light luminescence, solid-state lasers, efficient fibre lasers, photothermal therapy, temperature sensors, biological imaging, biological labels, and short-wavelength lasers [5-8]. Besides, the Ho<sup>3+</sup> ion emits NIR photoluminescence emission at  ${}^{5}I_{6} \rightarrow {}^{5}I_{8}$  transition corresponding to 1200 nm wavelength. This appeals to the development of optical fibre lasers in the O-band for biological imaging [9,10]. For instance, the  ${}^{5}I_{8}$  transition coincides with the high optical

transparency region of the electromagnetic spectrum, which has the advantages of reduced absorption, scattering, and deep penetration depth for biological tissue imaging.

The currently available 976-980 nm diode lasers cannot be used directly to pump Ho<sup>3+</sup> ions unless it is codoped with a sensitiser such as Yb3+, Tm3+ and Er3+ ions, which have strong absorption bands around 800 and 980 nm [11-16]. For example, the  ${}^2F_{7/2} \rightarrow {}^2F_{5/2}$  transition of Yb<sup>3+</sup> matches with the intermediate transitions of Ho<sup>3+</sup> ions facilitating efficient energy transfer mechanisms from Yb<sup>3+</sup> (<sup>2</sup>F<sub>5/2</sub>) to Ho<sup>3+</sup> (<sup>5</sup>F<sub>4</sub>, <sup>5</sup>S<sub>2</sub>, and <sup>5</sup>I<sub>6</sub>) transitions [6]. Over the years, various glass host materials such as fluorophosphate, silicate, tellurite, and oxyfluoride have been codoped with Ho<sup>3+</sup>:Yb<sup>3+</sup> ions [6-10] to investigate their physical and optical properties for the applications mentioned above. Among these, tellurium oxide-based glasses have been studied extensively. This is due to their remarkable properties in terms of the high solubility of RE<sup>3+</sup> ions, low melting point and stability against crystallisation, non-hygroscopic nature, high refractive index and transmission window, and low phonon energy [3]. Moreover, incorporating alkali oxides, alkaline earth oxides, transition metal oxides and fluoride lattice modifiers into tellurium oxide-based glass hosts tends to decrease the phonon energy. For instance, adding barium fluoride (BaF<sub>2</sub>) to tellurium oxide-based glass decreases tellurite glass's phonon energy from 750 cm<sup>-1</sup> to about 645 cm<sup>-1</sup> owing to BaF<sub>2</sub> low phonon energy of 330 cm<sup>-1</sup> [17]. Consequently, this reduces the nonradiative and multiphonon relaxation mechanism to promote optical transitions in the RE3+ ions and improve the radiative transition probability processes [18].

Most tellurium oxide-based glasses doped or codoped with Ho<sup>3+</sup> or Ho<sup>3+</sup>:Yb<sup>3+</sup> ions focused on the 2 µm wavelength for laser application with limited information on the visible and NIR around 1.2 µm wavelength lasers. Here are some examples of Ho<sup>3+</sup> and Ho<sup>3+</sup>: Yb<sup>3+</sup> doped/codoped glasses and ceramics for upconversion and NIR laser applications reported. Wang et al. [19] fabricated various Ho<sup>3+</sup>/Yb<sup>3+</sup> codoped TeO<sub>2</sub>-BaF<sub>2</sub>-Yb<sub>2</sub>O<sub>3</sub> glasses by varying BaF<sub>2</sub> concentration and investigated the luminescence properties at 1200 nm under 915 nm excitation [19]. They reported increases in the luminescence intensity at 1200 nm with increasing the BaF<sub>2</sub> concentration and obtained an optical gain of 1.884 dB/cm for 5 cm long fluorotellurite microstructure fiber. Azam et al. [18] recently synthesised Ho3+/Yb3+ doped and codoped TeO<sub>2</sub>-ZnO<sub>2</sub>-ZnO<sub>2</sub>-WO<sub>3</sub> and TeO<sub>2</sub>-ZnO-WO<sub>3</sub>-TiO<sub>2</sub>, which were optically characterised by employing the optical absorption and upconversion photoluminescence. It was reported that the upconversion emission intensity at 549 nm, 658 nm, and 754 nm was enhanced about 57 times, 342 times, and 480 times upon codoping with 3 mol% of Yb3+ under a 980 nm excitation laser. Similarly, Kamma et al.[20] prepared Ho3+ doped lead-germanotellurite glass and investigated its upconversion emission at room temperature under 532 nm and 762 nm excitation. They observed that the upconversion intensity improved significantly after the glass was heat-treated. Additionally, Neto et al.[21] fabricated Ho3+ doped PbGeO3-PbF<sub>2</sub>-CdF<sub>2</sub> transparent glass ceramic. An intense red upconversion emission was detected by exciting with a 980 nm diode laser. Besides all these, Ho3+:LiLuF4 and Ho3+:LaF3 have been studied as active gain media for solid-state lasers emitting in the green emission spectral region [22].

In this report, we synthesised and characterised Ho<sup>3+</sup>, Yb<sup>3+</sup>-singly doped and Ho<sup>3+</sup>: Yb<sup>3+</sup> codoped barium fluorotellurite glasses by changing Yb<sup>3+</sup> and lattice modifier to understand the local structural environment and optical properties. The spectroscopic properties, including hydroxyl (OH-) concentration in the mid-infrared and lasing properties such as Judd-Ofelt (JO) intensity parameters ( $\Omega_2$ ,  $\Omega_4$  and  $\Omega_6$ ), were evaluated from the UV-visible-NIR absorption spectra. The JO parameters are utilised to determine various radiative parameters such as spontaneous emission or radiative transition probabilities ( $A_R$ ), radiative lifetimes ( $\tau_R$ ), and photoluminescence branching ratios ( $\beta_R$ ). The photoluminescence (PL) emissions and lifetime

properties were obtained using 450 nm and 980 nm excitation sources. The energy transfer mechanism between Ho<sup>3+</sup> and Yb<sup>3+</sup> was looked into under 450 and 980 nm excitations.

### 2. Experimental Methods

#### 2.1 Glass preparation

High-purity materials such as TeO<sub>2</sub> (≥99.99%), ZnO (99.99%), BaF<sub>2</sub> (99.99%), Yb<sub>2</sub>O<sub>3</sub> (99.99%), and Ho<sub>2</sub>O<sub>3</sub> (99.99%) purchasing from Alfa Aesar were utilised to synthesise the based glasses. Melting and quenching techniques were employed to prepare Yb<sup>3+</sup>, Ho<sup>3+</sup>-singly doped and Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped glasses of nominal composition range in mol%: (80-x-y)TeO<sub>2</sub>- $10ZnO-10BaF_2-yHo_2O_3$  (where y=0, 0.5)-xYb<sub>2</sub>O<sub>3</sub> (where, x=0, 0.25, 0.5) [named: HTBZ1(y=0), HYTBZ2 (x=0), HYTBZ3, HYTBZ5] and (80-x-y)TeO<sub>2</sub>-10ZnO-10(BaF<sub>2</sub>-Ba<sub>2</sub>CO<sub>3</sub>)-0.5Ho<sub>2</sub>O<sub>3</sub>-0.25Yb<sub>2</sub>O<sub>3</sub> [assigned to HYTBZ4]. About 30g batch of high purity stoichiometric composition was initially weighed with an appropriate amount of each raw material, mixed thoroughly using a mortar and a pestle for about 20 min. The powdered mixture in the mortar was collected into a gold crucible and melted at 750-800 °C for about 3 h using an electrical furnace (Elite Thermal Systems Limited, Market Harborough, UK) under a dry oxygen atmosphere until a homogeneous mixture was obtained. The main purpose of purging with high-purity oxygen gas is to control and minimise moisture and OH-ion content in the glass melt. The molten glass was decanted into a pre-heated brass mould at 300 °C for 3 h and placed in the annealed furnace for about 4h to eradicate thermal strains, stress, and air bubbles. Finally, glass blocks prepared with dimensions of  $2 \times 4 \times 1$  cm<sup>3</sup> were obtained and polished for optical and photoluminescence property characterisations.

### 2.2 Characterisation

The polished glasses' refractive index and density were measured using a Prism Coupler (Metricon model 2010/M) with a 633 nm excitation laser and Thermo Pycnomatic ATC Helium Pycnometer. Mid-infrared optical absorbance spectra were collected using a Vertex 70 FITR spectrometer (Brucker, Coventry, UK) over 8 cm<sup>-1</sup> resolution between 4000 and 400 cm<sup>-1</sup> to evaluate the hydroxy (-OH) content in the as-prepared glasses. A Perkin Elmer UV/VIS/NIR Lambda 950 spectrometer of 0.1 nm spectral resolution was employed to record the UV-visible-NIR absorption spectra at room temperature (20 °C) in the spectral range between 250 nm and 2500 nm. An Edinburgh FS920 spectrometer (Edinburgh Instruments, Livingston, UK) was also utilised to collect photoluminescence emission by exciting with 450 and 976 nm diode laser sources in the wavelength range of 500–800 nm and 900–1500 nm at room temperature. Similarly, the photoluminescence decay curves for the glasses prepared were obtained using an FS920 spectrometer equipped with a 976 nm source at room temperature to determine the lifetime.

# 3. Results and discussions

#### 3.1. Physical Properties and Hydroxyl (OH) concentration Analysis

The refractive index and density values of Yb³+, Ho³+ singly doped and Ho³+-Yb³+ codoped barium fluorotellurite glass series fabricated are shown in Table 1. The refractive index increases slightly with increasing Yb³+ and replace a portion of BaF₂ content with Ba₂CO₃ concentration. This is attributed to the rising molar and electronic polarisabilities of oxide ions. On the other hand, the density of the glasses remains relatively the same. The hydroxyl (OH¹) groups in tellurite base glasses have a strong absorption from 2500 cm⁻¹ to 3500 cm⁻¹, which is attributed to the fundamental stretching vibration. The presence of the OH⁻ group in a glass network can quench visible and NIR photoluminescence emission intensity and lifetime through phonon-assisted processes and interactions with RE³+ ions. The mid-infrared

absorption spectra of samples HTBT1, HYTBT2, HYTBT3, HYTBT4 and HYTBT5 [inset pictures shown in Figure 1 were measured using a Brucker Vertex 70 FTIR spectrometer at room temperature. The absorption coefficient ( $\alpha_{OH}$ ) of the OH<sup>-</sup> vibration peak centred at 3000 cm<sup>-1</sup> was determined for each sample with a thickness of L using the Beer-Lambert law equation [3], which is given by:

$$\alpha_{OH} = \frac{\ln(T^{(\%)}/_{100})}{L} = \frac{2.303xA}{L} \tag{1}$$

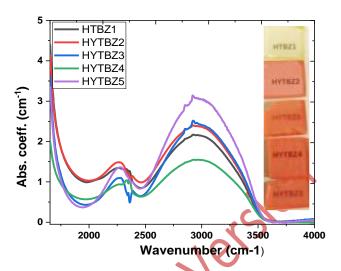

Figure 1: Infrared absorption spectra of singly Yb<sup>3+</sup>, Ho<sup>3+</sup> doped, and Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped fluorotellurite glasses and the inset showing photographs of various glasses prepared.

Table 1: OH absorption coefficient,  $\alpha_{OH}$  (cm<sup>-1</sup>), and concentration,  $N_{OH}$  (ions/cm<sup>-3</sup>), at mid-infrared wavelengths of 3000 cm<sup>-1</sup>.

Sample ID	Refractive index	Density(g/cm³)	$\alpha_{OH}(cm^{-1})$	OH- conc. (ppm)
HTBZ1	1.987	5.623	2.16	43.9
HYTBZ2	2.007	5.675	2.37	48.9
HYTBZ3	2.013	5.618	2.44	49.8
HYTBZ4	2.162	5.650	1.54	30.9
HYTBZ5	2.029	5.663	3.09	62.8

The OH<sup>-</sup> content,  $N_{OH^-}(ppm)$ , in the glass was estimated from equation (2) by using the OH<sup>-</sup> absorption coefficient obtained from the equation (1). The results were converted into part per million (ppm) [3,23].

$$N_{OH^{-}} = \frac{N_{AVO}}{\varepsilon} \alpha_{OH} \tag{2}$$

where L is the glass thickness (cm), A is the absorbance,  $\epsilon$  is the OH $^{-}$  group molar absorptivity in the tellurite glass (4.91 × 10<sup>4</sup> cm $^{2}$ mol $^{-1}$ ) [23], and N<sub>AVO</sub> represents Avogadro's constant (6.02 × 10<sup>23</sup> mol $^{-1}$ ). Figure 1 shows that the absorption coefficient of the OH $^{-}$  vibration band occurring at 3000 cm $^{-1}$  for sample HTBZ1 is lower than the remaining glass samples. Nonetheless, the rest of the glass samples codoping with Ho $^{3+}$ :Yb $^{3+}$  increase in absorption coefficient by increasing Yb $^{3+}$  content leading to a surge in OH- concentration, as shown in Table 1. On the other hand, sample HYTBZ4 exhibits a very low OH concentration compared to the other glasses.

### 3.2. Optical absorption spectra and Judd-Ofelt analysis

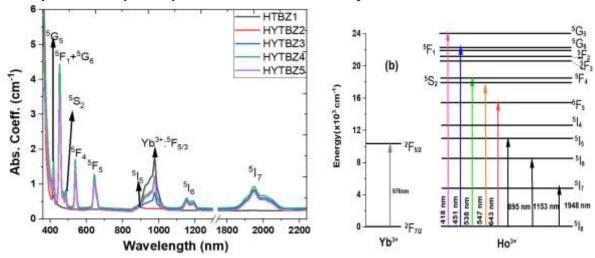

Fig. 2: (a) UV-visible-NIR absorption coefficient spectra of Yb<sup>3+</sup>, Ho<sup>3+</sup> single doped and Ho<sup>3+</sup>-Yb<sup>3+</sup> codoped barium fluorotellurite glass series, (b) Partial energy level diagram of Ho<sup>3+</sup> ion.

As-prepared glasses' absorbance spectra ranged from 250 nm to 2500 nm were measured using a UV-visible-NIR spectrophotometer, which was converted to absorption coefficient using equation(1). The absorption peaks centred at 418, 451, 487, 538, 643, 952, 976, 1153 and 1948 nm are attributed to 4f-4f intra manifold transitions of  $\text{Ho}^{3+}$  ion and  $\text{Yb}^{3+}$  ion from the ground state to the various excited states as illustrated in Fig 2(b). The  $\text{Ho}^{3+}$  ions peaks correspond to transitions from the ground state to distinctive excited states, namely  ${}^5\text{I}_8 \rightarrow {}^5\text{G}_5$ ,  ${}^5\text{F}_1 \& {}^5\text{G}_6$ ,  ${}^5\text{S}_2$ ,  ${}^5\text{F}_4$ ,  ${}^5\text{F}_5$ ,  ${}^5\text{I}_6$ ,  ${}^5\text{I}_7$  and  ${}^2\text{F}_{7/2} \rightarrow {}^2\text{F}_{5/2}$  for  $\text{Yb}^{3+}$  ion, respectively. The crystal field surrounding each of these RE<sup>3+</sup> ions is inhomogeneous because of the distinguishability of the absorption transitions retained by the  $\text{Ho}^{3+}$  and  $\text{Yb}^{3+}$  ions and site-to-site disparities in the crystal field strengths [18, 24].

The Judd-Ofelt (JO) intensity parameters that signify interactions between the Ho³+ ions and the fluorotellurite host material crystalline field were calculated using the UV-visible-NIR absorption coefficient shown in Fig. 1 (a). The JO method has been extensively used to study the radiative and non-radiative rates of RE³+ ions doped with different host materials for laser application. An integral absorption coefficient  $(\int \alpha(\lambda)d\lambda)$  of each absorption band comprises of electric dipole  $(S_{ed(mes)}(J \to J'))$  and the magnetic dipole  $(S_{md}(J \to J'))$  line strength contributions. Henceforth, the measured experimental  $S_{ed(mes)}(J \to J')$  line strengths from the initial transition, J, to the upper energy levels , J', were obtained using the following expression [25-29];

$$S_{ed(mes)}(J \to J') = n \left[ \frac{3}{n^2 + 2} \right]^2 \left[ \frac{3ch(2J+1)}{8\pi^3 e^2 N_{Ho}} \frac{1}{\bar{\lambda}} \int \alpha(\lambda) d\lambda - \left[ \frac{(n^2 + 2)^2}{9n} \right] n^3 S_{md}(J \to J') \right]$$
(3)

where **c** is the velocity of light, **h** is the Planck's constant, **e** is the charged electron, n is the refractive index,  $\bar{\lambda}$  is the average absorption peak wavelength for the transition under consideration,  $N_{Ho}$  being the concentration of Ho<sup>3+</sup> ions, and **2J+1** is the degeneration of the initial (emitting) state delineated.

The magnetic dipole  $S_{md}(J \to J')$  transition contribution of the line strength is given by an expression [25,26, 29].

$$S_{md}(J \to J') = \mu_B^2 |[| < J||L + 2S||J' > |]|^2 \tag{4}$$

where  $\mu_B$ = (ħ/2mc) and the magnetic dipole matrix elements are located in the bracket terms, orbital L and spin S angular momenta even-parity tensors. The transitions between different energy levels must conform to the selection rules as  $\Delta S = \Delta L = 0$  and  $\Delta J = 0$ ,  $\pm 1$  for a magnetic dipole line strength to exist. Based on the selection rule, the only transition with magnetic line strength contribution is  ${}^5I_8 \rightarrow {}^5I_7$ , which was subtracted from the experimental result to obtain  $S_{ed(mes)}$ .

Thus, the JO parameters,  $(\Omega_t)$ , are calculated from the electric-dipole transition line strengths by using the expression shown below [26,27, 30]:

$$S_{ed(cal)}(J \to J') = \sum_{t=2,4,6} \left| | < J | \left| U^{(t)} \right| | J' > | \right|^2$$
 (5)

Where  $U^{(t)}$  is the squared doubly reduced matrix of the unit tensor operator of the rank t = 2, 4, 6. The eight absorption peaks from Figure 2 (a) were employed to determine the JO parameters via the least square fit method. As shown in Table 2, the magnitude of JO intensity parameters of as-prepared glasses follows the same trend as  $\Omega_4 > \Omega_2 > \Omega_6$  for samples HYTBZ2, HYTBZ3, HYTBZ4 and HYTBZ4. The  $\Omega_2$  parameter describes asymmetry and covalency. Thus, the  $\Omega_2$  parameter increases from samples HYTBZ2 to HYTBZ4 by codoping with Yb3+ ions and substituting a portion of BaF2 with Ba2CO3 content suggesting structural changes. Besides, the visible to near-infrared absorption peaks are hypersensitivity to covalency parameters, increasing the ligand surrounding the RE3+ ions. Similarly, the  $\Omega_4$ intensity parameter rises with the additive of Yb<sup>3+</sup> concentration can be ascribed to an increase in viscosity due to the highly polarised surrounding  $Ho^{3+}$  [31, 32]. Furthermore, the  $\Omega_6$ parameter increases with the addition of Yb3+ and Ba2CO3 into the glass composition, indicating a decrease in the Ho<sup>3+</sup>-O covalency and fraction of non-bridge oxygen ions [33,34]. Likewise, as the concentration of the Yb3+ ions increased the JO intensity parameters of sample HYTBZ5 diminished with the same trend as  $\Omega_4 > \Omega_2 > \Omega_6$ , which correlates with Ho<sup>3+</sup> doped lead tungsten tellurite glasses reported elsewhere [33]. The difference in the JO parameters for as-prepared glasses is ascribed to structural transformation. However, substituting a low concentration of Ba<sub>2</sub>CO<sub>3</sub> in exchange for BaF<sub>2</sub> (HYTBZ4) resulted in sizeable structural modification and rearrangement in the glass network owing to increased JO parameters, as shown in Table 2.

Furthermore, the spectroscopic quality factor  $(\Omega_4/\Omega_6)$  is an important parameter to predict stimulated emission and intensity of lasing in the gain medium. The  $\Omega_4/\Omega_6$  factor of Ho<sup>3+</sup> singly doped fluorotellurite glass is greater than those glass samples fabricated by codoping with Ho<sup>3+</sup>: Yb<sup>3+</sup>. On the other hand, the  $\Omega_4/\Omega_6$  factor for Ho<sup>3+</sup>: Yb<sup>3+</sup> ions doped fluorotellurite glasses decreases with increasing Yb<sup>3+</sup> ions content but increases slightly with mixing BaF<sub>2</sub> with Ba<sub>2</sub>CO<sub>3</sub> contents.

Table 2: Judd-Ofelt parameters  $(\Omega_{\lambda} \times 10^{-20} cm^2)$  of Ho<sup>3+</sup> ions in fluorotellurite glasses compared with other fluoride glasses

Sample ID	$\Omega_2$	$arOmega_4$	$\mathcal{Q}_6$	$\sum \Omega_t$	$\Omega_4/\Omega_6$	Trend	Ref
HYTBZ2	3.562	4.666	2.260	10.488	2.26	$\Omega_4 > \Omega_2 > \Omega_6$	Present work
HYTBZ3	3.787	4.343	2.902	11.032	1.49	$\Omega_4 > \Omega_2 > \Omega_6$	Present work
HYTBZ4	3.906	5.034	3.052	11.992	1.65	$\varOmega_4>\varOmega_2>\varOmega_6$	Present work
HYTBZ5	3.393	3.850	2.503	9.746	1.54	$\Omega_4 > \Omega_2 > \Omega_6$	Present work

The calculated JO parameters obtained from equation (3) shown in Table 2 were used to predict  $S_{ed(cal)}$  values via the multiple regression, which are in close approximation to the measured values. The calculated and measured electric dipole line strengths with small RMS values of Ho³+ and Ho³+:Yb³+doped fluorotellurite glasses for various ground state absorption bands are illustrated in Table 3. The variation in trends of the measured and calculated electric dipole line strengths are comparable to JO parameters for increasing Yb³+ ions concentration and substituting a portion of BaF₂ with Ba₂CO₃ content. Some of the inter manifold 4f-4f absorption bands and spectral intensities of the RE³+ ions are sensitive to their environment, which is characterised by higher values of electric dipole line strengths. Such hypersensitive transitions of RE³+ions must satisfy the selection rules  $\Delta J \leq 2$ ,  $\Delta L \leq 2$  and  $\Delta S = 0$  [27]. For instance,  ${}^{5}\mathbf{I}_{8} \rightarrow {}^{5}\mathbf{F}_{1} + {}^{5}\mathbf{G}_{5}$  and  ${}^{5}\mathbf{I}_{8} \rightarrow {}^{5}\mathbf{I}_{7}$  transitions are hypersensitive transitions due to significant variation in the electric dipole line strength values upon increasing Yb³+ concentration or replacing a portion of BaF₂ content with Ba₂CO₃.

Table 3: Experimental  $(S_{ed(mes)} \times 10^{-20})$  and calculated  $(S_{ed(cal)} \times 10^{-20})$  line strengths and  $\delta_{rms}$  deviation of Ho ions in fluorotellurite glass systems

<sup>5</sup>   <sub>7</sub>	5.100	5.019	4.941	<b>4.895</b>	5.590	5.728	4.569	4.693
$\delta_{rms}$	$1.06 \times 10^{-21}$		$0.93 \times 10^{-21}$		$2.05 \times 10^{-21}$		$0.94 \times 10^{-20}$	

Moreover, the JO parameters obtained from the above were utilised to analyse other important parameters such as radiative or spontaneous transition probabilities of emission, branch ratios, and radiative lifetime. The radiative transition probability  $(A_r(J \to J'))$  of different energy transitions (between J and J') associating with the electric  $S_{ed(cal)}$  and magnetic  $S_{md}$  line strength can be expressed as [26-28].

$$A_r(J \to J') = \frac{1}{4\pi\varepsilon_0} \frac{64\pi^4 v^3}{3hc^3(2J+1)} \left[ n \left[ \frac{n^2+2}{3} \right]^2 S_{ed(cal)}(J \to J') - n^3 S_{md}(J \to J') \right]$$
 (6)

The total radiative transition probability  $(A_T)$  is defined as the sum of all excited transitions, which is represented as follows.

$$A_T = \sum A_r(J \to J') \tag{7}$$

The excited state radiative lifetime,  $\tau_R$ , and theoretical branch ratio,  $\beta_R$ , are calculated from the total radiative transition probability as:

$$\tau_R(J) = [A_T(J)]^{-1} \tag{8}$$

$$\beta_R(J,J') = \frac{A_r(J \to J')}{\sum A_r(J \to J')} \tag{9}$$

The radiative spectroscopic parameters such as radiative transition probabilities, branching ratios, and radiative lifetime were further determined by employing equations (3) to (6) for all relevant energy transitions of the Ho<sup>3+</sup> ions, which are summarised in Table 4. The transitions with high values of radiative transition probabilities and branching ratios represent more probability of radiative transition from the excited states to lower energy levels.

Table 4: Predicted spontaneous emission probabilities, total transition probability  $(A_T)$ , radiative lifetime  $(\tau_R)$  and the branching ratio of the possible transition levels in the Ho<sup>3+</sup>/Ho<sup>3+</sup>:Yb<sup>3+</sup> doped HYTBZ glass series.

For example, the  ${}^5F_4 + {}^5S_2 \rightarrow {}^5I_8$  transition (~545 nm) has the most significant values of radiative transition probabilities, and branching ratios in all the samples synthesised ranging from 700.05 s<sup>-1</sup> to 1785.8s<sup>-1</sup> for ( $A_T$ ) and 48.8 to 53.6 % for  $\beta$ . This indicates that most of the photons in the  ${}^5F_4 + {}^5S_2$  states would radiate into the  ${}^5I_8$  ground state transition. Thus, such high radiative parameters validate and agree with the strong green photoluminescence intensity observed experimentally under 450 nm and 976 nm excitations. Similarly, higher radiative transition probabilities and branching ratios were obtained from the  ${}^5F_5 \rightarrow {}^5I_8$  (650 nm)  ${}^5F_4 + {}^5S_2 \rightarrow {}^5I_7$  (750) transition, as listed in Table 4. In addition, the radiative transition probabilities or rates from  ${}^5I_6 \rightarrow {}^5I_8$  transition predicted by JO theory range from 253.7 to 315.6 S<sup>-1</sup> leading to longer radiative lifetimes with an average branching ratio of ~86%. This result corroborates with the intense NIR photoluminescence emission observed experimentally at 1159 nm transition.

# 3.3. Photoluminescence emissions and energy transfer under 450 nm and 980 nm excitations

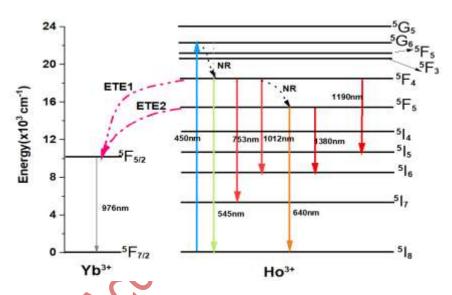

Fig.4: Partial energy level diagrams for Ho<sup>3+</sup> and Ho<sup>3+</sup>:Yb<sup>3+</sup> visible and NIR photoluminescence emission observed under 450 nm excitation.

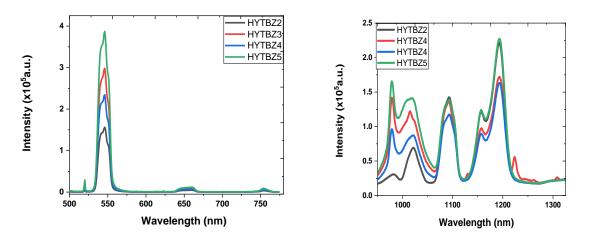

Fig. 5: Downconversion photoluminescence emission of  $Ho^{3+}$  and  $Ho^{3+}$ : $Yb^{3+}$  doped fluorotellurite glasses under 450 nm excitation (a) visible and (b) NIR wavelength ranges.

Figure 4 illustrates a partial energy diagram for Ho<sup>3+</sup> and Yb<sup>3+</sup> ions under a 450 nm excitation source to measure visible to NIR photoluminescence emissions. The Ho3+ ion is initially excited with 450 nm from the ground state, <sup>5</sup>I<sub>8</sub>, to the excited state, <sup>6</sup>G<sub>5</sub>, through the ground state absorption process. These electrons in the <sup>6</sup>G<sub>5</sub> level undergo non-radiative decay to the <sup>5</sup>F<sub>4</sub> energy level via a multi-phonon relaxation process. This is followed by radiative relaxation to <sup>5</sup>I<sub>8</sub> transition, leading to the intense green emission at 545 nm, shown in Figure 5 (a). The electrons in the <sup>5</sup>F<sub>4</sub> state further depopulate through the multi-phonon relaxation process to the <sup>5</sup>F<sub>5</sub> state, which relaxes radiatively to the ground state <sup>5</sup>I<sub>8</sub> emitting weak red emission at 640 nm. It is vital to mention that the photoluminescence emission at 545 nm is less intense for Ho<sup>3+</sup> singly doped fluorotellurite glass. However, codoping with Yb<sup>3+</sup> and substituting a portion of BaF<sub>2</sub> content with Ba<sub>2</sub>CO3 lead to increased photoluminescence emission intensity. Besides, the NIR photoluminescence emissions centred at 1156 and 1192 nm match the <sup>5</sup>F<sub>4</sub>  $\rightarrow$   $^{5}I_{5}$  transition, as depicted in Figure 5(b). In contrast, the photons absorbed by the Ho<sup>3+</sup> ions under 450 nm excitation can further be transferred to Yb3+ from either  $^5F_4 \rightarrow ^2F_{5/2}$  or  $^5I_5 \rightarrow ^2F_{5/2}$  through the energy transfer process and phonon-assisted ET1 and ET2. This emits intense overlap photoluminescence emission range from 950 to 1070 nm for Ho<sup>3+</sup> and Yb<sup>3+</sup> as illustrated in Figure 4, ascribing to  ${}^5F_4 \rightarrow {}^5I_6$  and  ${}^2F_{5/2} \rightarrow {}^2F_{7/2}$  transitions.

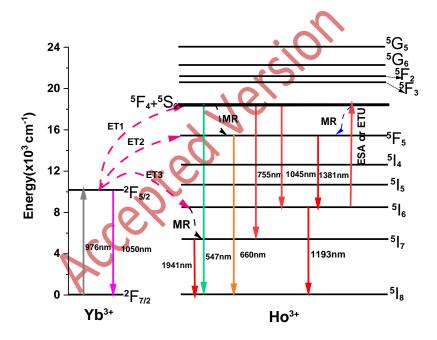

Fig.6: Partial energy level diagrams for Ho<sup>3+</sup> and Ho<sup>3+</sup>:Yb<sup>3+</sup> visible and NIR photoluminescence emission observed under 976 nm excitation.

The visible and NIR photoluminescence emission properties of Ho<sup>3+</sup> singly doped and Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped fluorotellurite glasses were investigated under a 976 nm diode laser excitation wavelength, as shown in Figure 6. Ho<sup>3+</sup> ions in singly-doped glass do not absorb at 976 nm by themselves. Therefore, no emission is observed experimentally from visible to NIR. Moreover, upon exciting the Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped glass samples with a 976 nm pumping scheme, the ground state of Yb<sup>3+</sup> ( $^2F_{7/2}$ ) is absorbed to populate the excited state of Yb<sup>3+</sup> ( $^2F_{5/2}$ ) via the ground state absorption process. Most of the photons in the Yb<sup>3+</sup> ( $^2F_{5/2}$ ) excited state can be de-excited radiatively, leading to a NIR emission peak at 1050 nm. This corresponds to the  $^2F_{5/2} \rightarrow ^2F_{7/2}$  transition. Additionally, some of the photons in the Yb<sup>3+</sup> ( $^2F_{5/2}$ ) excited state can be transferred utilising the phonon-assisted energy transfer process to the neighbouring

Ho³+ through three main routes ET<sub>1</sub> (Yb³+:²F<sub>5/2</sub>  $\rightarrow$  Ho³+:⁵F<sub>4</sub> + ⁵S<sub>2</sub>), ET<sub>2</sub>(Yb³+:²F<sub>5/2</sub>  $\rightarrow$  Ho³+:⁵F<sub>5</sub>), and ET<sub>3</sub> (Yb³+:²F<sub>5/2</sub>  $\rightarrow$  Ho³+:⁵I<sub>6</sub>), respectively.

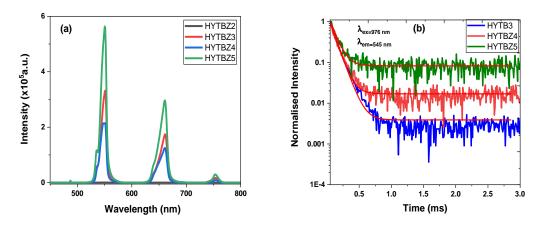

Fig 7: (a) Upconversion photoluminescence emission spectra of Ho doped and Ho<sup>3+</sup>: Yb<sup>3+</sup>-codoped glasses under 978 nm excitation source, (b) photoluminescence–decay curves at 545 nm.

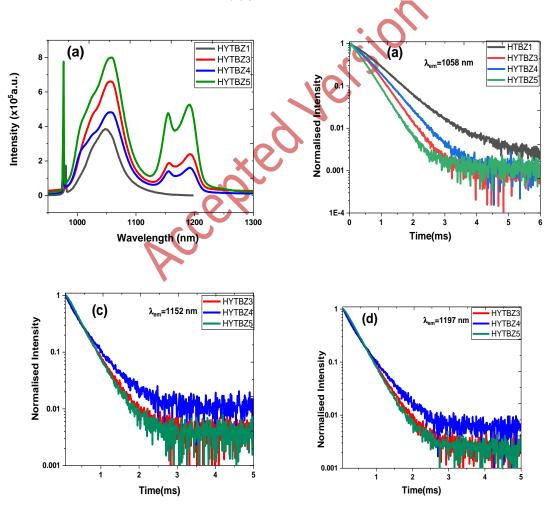

Fig. 8: (a) Near-infrared photoluminescence emission spectra of Ho-doped and Ho<sup>3+</sup>: Yb<sup>3+</sup>-codoped glasses under 978 nm excitation source: (b)-(d) photoluminescence–decay curves Ho<sup>3+</sup> at  $^{5}F_{4}$  and  $^{5}I_{6}$  transitions.

The photons transfer through ET<sub>1</sub> (Ho<sup>3+</sup>: $^5F_4$  +  $^5S_2$ ) path by excited state absorption or energy transfer process from Yb<sup>3+</sup>: $^2F_{5/2}$  state undergo radiative decay to emit Ho<sup>3+</sup>: $^5F_4$  +  $^5S_2$   $\rightarrow$   $^5I_8$  and Ho<sup>3+</sup>: $^5I_7$   $\rightarrow$   $^5I_8$  leading to the intense upconversion emissions at 552 nm and 755 nm, as shown in Figure 7(a). Likewise, part of the photons in the Ho<sup>3+</sup>: $^5F_4$  +  $^5S_2$  state can undergo non-radiative decay by multi-phonon relaxation to Ho<sup>3+</sup>: $^5F_5$  or ET<sub>2</sub>(Yb<sup>3+</sup>: $^2F_{5/2}$   $\rightarrow$  Ho<sup>3+</sup>: $^5F_5$ ) energy transfer process can occur and then decay radiatively to the ground state Ho<sup>3+</sup>: $^5I_8$  emitting 660 nm upconversion. On the other hand, energy transfer processes occur via ET<sub>1</sub> (Yb<sup>3+</sup>: $^2F_{5/2}$   $\rightarrow$  Ho<sup>3+</sup>: $^5F_4$  +  $^5S_2$ ), and ET<sub>3</sub> (Yb<sup>3+</sup>: $^2F_{5/2}$   $\rightarrow$  Ho<sup>3+</sup>: $^5I_6$ ) can generate NIR emissions at 1050 nm and 1196 nm matching with  $^5F_4$  +  $^5S_2$   $\rightarrow$   $^5I_6$ , and  $^5I_6$   $\rightarrow$   $^5I_8$  transitions depicted in Figure 8(a), respectively. Alternatively, part of the Ho<sup>3+</sup>: $^5I_6$  ions can further populate to the higher energy levels such as Ho<sup>3+</sup>: $^5F_4$  +  $^5S_2$  state through excited-state absorption or energy transfer upconversion process (ETU) to generate the upconversion emission shown in Figure 6.

# 3.4. Yb $^{3+}$ , Ba $_2$ CO $_3$ modifier, and OH- effect on the Yb $^{3+}$ : $^2$ F $_{5/2}$ , Ho $^{3+}$ : $^5$ F $_4$ + $^5$ S $_2$ and Ho $^{3+}$ : $^5$ I $_6$ transitions lifetime.

The upconversion and downconversion photoluminescence decay curves for all the fabricated samples were analysed to determine the energy transfer efficiency mechanism. Many studies have suggested that the lifetime of the rare earth ions transitions depends on the glass system's phonon energy. This relates to the base glass composition network former and added lattice modifier network [35-37]. Besides, it is well established that the existence of the OH group in the glass host can significantly promote the non-radiative process resulting in lifetime quenching. Therefore, the photoluminescence decay lifetimes of singly Yb3+ and Ho<sup>3+</sup>:Yb<sup>3+</sup>doped glasses were measured for Yb<sup>3+</sup>: ${}^{4}F_{5/2}$ , Ho<sup>3+</sup>: ${}^{5}F_{4}$  +  ${}^{5}S_{2}$  and Ho<sup>3+</sup>:  ${}^{5}I_{6}$  transitions by exciting the samples with 976 nm excitation source at room temperature. Figures 7(b) and 8(b-d) show photoluminescence decay curves for singly doped Yb3+ and codoped Ho3+:Yb3+ at Yb3+:2F5/2 and Ho3+: 5l6 transitions, which were fitted with single exponential function to determine the measured lifetime. The measured lifetime obtained from various samples and transitions is summarised in Table 5 below. The lifetime of the  $Ho^{3+}$  at  ${}^5F_4 + {}^5S_2$  transitions increases slightly with increasing Yb3+ and doping with BaF2 and Ba2CO3 contents. However, the Yb3+:2F5/2 transition decreases with increasing Yb3+ concentration. This is attributed to highly energy transfer efficiency, as shown by a significant reduction in the Yb3+ lifetime in the Yb<sup>3+</sup>-Ho<sup>3+</sup> glasses in contrast to the Yb<sup>3+</sup> singly-doped glass. The lifetime of sample HYTBZ4 rises by 11% over sample HYTBZ3 at Yb3+:2F5/2 and Ho3+:5I6 transitions ascribing to the inadequacy in energy transfer efficiency and difference in OH ion concentration discussed in Table 1.

Table 5: Measure lifetime obtained from Yb<sup>3+</sup> and Ho<sup>3+</sup>: transitions and energy transfer efficiency.

Sample		$ au_m($	(ms)	$\eta_{ET(Yb \to Ho)}$	$W_{MP}(s^{-1})$	$W_{MP}(s^{-1})$	
ID	Ho <sup>3+</sup> : <sup>5</sup> F <sub>4</sub> + <sup>5</sup> S <sub>2</sub>	Yb <sup>3+</sup> : <sup>2</sup> F <sub>5/2</sub> ,	Ho <sup>3+</sup> : <sup>5</sup> I <sub>6</sub>	Ho <sup>3+</sup> : <sup>5</sup> I <sub>6</sub>		<sup>5</sup> F <sub>4</sub> + <sup>5</sup> S <sub>2</sub> → <sup>5</sup> I <sub>8</sub>	<sup>5</sup>   <sub>6</sub> → <sup>5</sup>   <sub>8</sub>
			(1152nm)	(1196nm)			
HTBZ1	-	0.769	-	-			
HYTBZ2	-	-	-	-

HYTBZ4	0.113	0.596	0.377	0.373	0.23	7057.8	1857.8
HYTBZ5	0.131	0.410	0.347	0.366	0.47	6145.1	2522.0

The photoluminescence lifetime measured was employed to determine whether the Yb<sup>3+</sup> ion is a suitable sensitiser for the Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped fluorotellurite glasses fabricated by determining energy transfer efficiency ( $\eta_{ET(Yb\to Ho)}$ ) from Yb<sup>3+</sup> ions to Ho<sup>3+</sup> ions. The energy

transfer efficiency between Yb3+ ions and Ho3+ ions was evaluated by the following equation [37]:

$$\eta_{ET(Yb\to Ho)} = 1 - \frac{\tau_{Yb(Ho)}}{\tau_{Yb}} \tag{10}$$

where  $\tau_{Yb(Ho)}$  is the lifetime at Yb<sup>3+</sup> :  ${}^2F_{5/2}$  transition in the Ho<sup>3+</sup>: Yb<sup>3+</sup> ions codoped glasses and  $au_{Yb}$  being a singly doped glass with Yb<sup>3+</sup>, respectively. It is observed that the energy transfer efficiency increases with Yb3+ concentration, as illustrated in Table 4.

Furthermore, the multiphonon de-excitation rate,  $W_{MP}$ , component of the non-radiative decay rate contribution for depopulation of the metastable state from Ho3+: 5F4 + 5S2 and 5I6 transitions to the ground state Ho3+: 518 were calculated by [25,37]:

$$W_{MP} = \tau_m^{-1} - \tau_r^{-1} - W_{OH} \tag{11}$$

where  $\tau_m^{-1}$  and  $\tau_r^{-1}$  are the measured radiative rate and estimated radiative decay rates obtained from JO analysis of the Ho³+:5F₄ + 5S₂ and Ho³+: 5I₆.  $W_{OH}$  is the energy transfer rate between Ho3+ and the OH-. According to Dai et al. [36], the energy transfer rate between Ho3+ and the OH- groups can be expressed:

$$W_{OH} = 8\pi C_{Ho,Ho} N_{Ho} N_g \tag{12}$$

where  $N_{Ho}$  is the Ho<sup>3+</sup> concentration (acceptor concentration) and  $N_q$  is the density of the quenching site, which is proportional to OH- concentration [ $N_q = \chi N_{OH}$ ,  $\chi$  is the empirical factor, which is about  $\chi=15\%$  for the modified tellurite glass], and  $C_{Ho,Ho}$  is the microparameter of the transfer process. The value of  $C_{Ho,Ho}$  for modified tellurite glass can be estimated based on the Forster-Dexter theory as follows [37]:  $C_{Ho,Ho} = \frac{{}_{3}c_{A_{P}}(2J+1)}{{}_{8}\pi^{4}n^{2}(2J+1)}\int \sigma_{ems}^{D}(\lambda)\,\sigma_{abs}^{A}(\lambda)d\lambda$ 

$$C_{Ho,Ho} = \frac{3cA_{c}(2l+1)}{8\pi^{4}n^{2}(2l'+1)} \int \sigma_{ems}^{D}(\lambda) \, \sigma_{abs}^{A}(\lambda) d\lambda \tag{13}$$

where  $\sigma_{ems}^D(\lambda)$  and  $\sigma_{abs}^A(\lambda)$  donor acceptor energy transfer overlap between the emission and absorption bands of the donor and acceptor. Table 4 shows the  $W_{MP}$  for Ho<sup>3+</sup>:  ${}^5F_4 + {}^5S_2 \rightarrow {}^5I_8$ and <sup>5</sup>I<sub>6</sub>→<sup>5</sup>I<sub>8</sub> transitions increases with increasing Yb<sup>3+</sup> concentration. Nevertheless, the mixing addition of BaF<sub>2</sub> and Ba<sub>2</sub>CO<sub>3</sub> leads to a significant decrease in the multiphonon relaxation rate. which could be attributed to the variation in the host material and its local field symmetry surrounding the rare earth ion site [38]. Furthermore, the significant increase in multiphonon relaxation rate of Ho<sup>3+</sup>:  ${}^5F_4 + {}^5S_2 \rightarrow {}^5I_8$  and  ${}^5I_6 \rightarrow {}^5I_8$  transitions could boost the 976 nm pumping efficiency in the Ho<sup>3+</sup>:Yb<sup>3</sup> codoped glass series.

#### 4. Conclusions

Series of Yb<sup>3+</sup> singly, Ho<sup>3+</sup> singly, and Ho<sup>3+</sup>:Yb<sup>3+</sup> doped/codoped barium fluorotellurite glasses have been prepared and characterised by optical absorption, photoluminescence, and decay studies. The intensity parameters and radiative properties of the dominant transition energy levels of the Ho<sup>3+</sup> ion have been investigated using the JO theory. The JO parameters obtained from the Ho³+ singly doped and Ho³+:Yb³+ codoped glasses follow the trend  $\Omega_4>$  $\Omega_2 > \Omega_6$ . The change in the  $\Omega_2$  with Yb<sup>3+</sup> and Ba<sub>2</sub>CO<sub>3</sub> contents is ascribed to variation in the asymmetry of the ligand field around the rare earth ion site and the degree of covalency of the Ho-O bond. While  $\Omega_4$  and  $\Omega_6$  values are related to viscosity and stiffness of the host glass, which decreases with Yb3+ content. The effect of Yb3+ and Ba2CO3 contents on the upconversion and NIR downconversion photoluminescence emission of the Yb3+ singly doped and Ho<sup>3+</sup>:Yb<sup>3+</sup> codoped glasses have been studied. The upconversion, NIR emission intensity, and lifetime centred at 550, 661, 742, and 1196 nm increase significantly with Yb3+ concentration, which is accredited to an efficient energy transfer from Yb³+ → Ho³+;

nonetheless decreases with substitution of a small fraction of  $BaF_2$  with  $Ba_2CO_3$  content. Even though the OH- ions concentration increases remarkably with  $Yb^{3+}$  content, the measured photoluminescence lifetimes at 550 and 1196 nm are not affected but upsurges slightly. This confirms that OH- concentration is not affected by the visible and NIR photoluminescence emission property, suggesting energy transfer from these transition levels to OH- is inefficient. The optical properties of  $RE^{3+}$  doped barium fluorotellurite glasses are attractive for developing NIR fibre laser around 1200 nm wavelength.
