## ANNEX A. DATA ANALYSIS FOR SMORP

The total area of microalgae cultivation is calculated using Eq. (1):

$$\text{Total area} = \text{Single pond surface} \cdot \text{Number of ponds.} \quad (1)$$

The total volume of microalgae culture using Eq. (2):

$$\text{Total volume} = \text{Total area} \cdot \text{water depth} \quad (2)$$

The total energy needed for microalgae growth is calculated using Eq. (3):

$$\text{Total energy} = \frac{\text{PAR requested} \cdot \text{Total area}}{2.1}. \quad (3)$$

The factor for downtime by crash ( $F_{crash}$ ) is calculated using Eq. (4):

$$F_{crash} = \frac{365 - (\text{number of crashes} \cdot \text{prod downtime per crash})}{365}, \quad (4)$$

where *number of crashes* is the crash occurrence per year, and *prod downtime per crash* is the estimated mean time necessary to empty, clean, inoculate a new strain, and to be able to restart the harvest in the pond.

The optimal temperature for microalgae growth is species-dependent and decreases according to specific law, moving away from this optimal value. This law calculates a temperature factor ( $T_f$ ) as an exponential limitation caused by sub-optimal temperatures, based on James and Boriah law [1] as described in Eq. (5):

$$T_f = e^{-K(T-T_{opt})^2}, \quad (5)$$

where the difference between actual ( $T$ ) and optimal temperature ( $T_{opt}$ ) is used to calculate the production limitation through an empirical constant ( $K=0.004$ ).

The evaporation rate is expressed in  $\text{kg} (\text{m}^2 \text{h})^{-1}$  and calculated in Eq. (6):

$$M_{ev} = \text{Total area} \cdot \frac{(30.6 + 32.1 \cdot V_{wind}) \cdot (P_w - P_a)}{DH_v}, \quad (6)$$

where ( $P_w$ ) is the saturation of vapor pressure at water temperature, ( $P_a$ ) is the saturation vapor pressure at air dew point, and ( $DH_v$ ) is the latent heat of water at the pond temperature, multiplied by the surface area of the ponds (*Total area*). ( $V_{wind}$ ) is assumed to be equal to 0, values of 30,6 and 32,1 are two empirical constants. The water flow inevitably influences the evaporation rate. Thus, the calculated evaporation rate is considered indicative. ( $P_a$ ) is expressed in kPa and calculated using equation (11):

$$P_a = 0.6108 \cdot \frac{17.27 \cdot T_{air}}{e^{273.15+T_{air}}}, \quad (7)$$

where ( $T_{air}$ ) represents the air dew point temperature. The same equation can be used to calculate ( $P_w$ ) while substituting ( $T_{air}$ ) by ( $T_w$ ) representing the average water temperature. The latent heat of water at pond temperature ( $DH_v$ , expressed in  $\text{kJ kg}^{-1}$ ) is calculated as showed in Eq. (8) [2]:

$$DH_v = 2500.8 - 2.36 \cdot T_w + 0.0016 \cdot T_w^2 - 0.00006 \cdot T_w^3. \quad (8)$$

After converting evaporation rate in  $\text{m}^3 \text{month}^{-1}$  ( $E_r$ ) for the total pond surface, is therefore possible to calculate heat loss in  $\text{kWh month}^{-1}$  through evaporation rate using Eq. (9):

$$\text{Heat loss evaporation} = DH_v \cdot E_r \cdot 1000 \cdot 0.000278, \quad (9)$$

where 0.000278 is the conversion factor from kJ to kWh.

A simplified heat loss calculation for crashes was made through the number of crashes multiplied for the total water volume and the water-specific heat capacity assuming  $10^\circ \text{C}$  difference from the tap water and the pond temperature calculated by Eq. (10):

$$R_h = \frac{(E_r + \text{H}_2\text{O}_{\text{overflow}} \cdot \frac{\text{day}}{\text{month}}) \cdot 10 \cdot 4180}{0.001}, \quad (10)$$

where (Rh) represents the heat required to warm up the refill water lost for evaporation and the recirculation water that cools down outside the heated pond, (H2O overflow) represents the daily recirculation water that goes into the settling tank and returns into the pond, and 4180 J (kg °C)<sup>-1</sup> is the water-specific heat capacity.

Heat loss for convection (H<sub>lc</sub>) is calculated according to Stefan-Boltzmann's fourth power law using alpha parameter (α=1.146240), ponds total area, and the difference between pond and air temperature, as shown in Eq. (11):

$$H_{lc} = \frac{a \cdot (\text{pond temp} - \text{air temp}) \cdot \text{Total area} \cdot \frac{h}{\text{gg}} \cdot \frac{\text{gg}}{m}}{1000} \quad (11)$$

Assumption for wall dispersion represents the quantity of heat which, through the walls of the pond, is dispersed in the surrounding environment (D<sub>w</sub>). The material chosen for its good optical and mechanical characteristics for the construction of the SMORP pilot is the PMMA, which has a thermal transmission coefficient (k), expressed in W (m<sup>2</sup> °C)<sup>-1</sup> equal to 5.80. For the calculation of total heat losses through ponds walls in kWh month<sup>-1</sup> Eq. (12) has been used:

$$D_w = \frac{\Delta T \cdot k \cdot (Ba + Wa) \cdot \frac{h}{\text{gg}} \cdot \frac{\text{gg}}{m}}{1000} \quad (12)$$

where (ΔT) represents the difference between air temperature inside the greenhouse and water temperature, (Ba) is the total base area of the ponds and (Wa) the total area of the ponds walls.

Solar radiation represents the sun's thermal energy in the infrared area, which contributes to pond heating. It was calculated first by converting the global radiation expressed in J (m<sup>2</sup> month)<sup>-1</sup> to kWh (m<sup>2</sup> month)<sup>-1</sup> using Eq. (13):

$$\text{Grad(kWh)} = \frac{\text{Grad(J)}}{1000} \cdot 0.000278, \quad (13)$$

where 0.000278 is the conversion factor from kJ to kWh. The heat input is expressed in kWh month<sup>-1</sup> calculated using Eq. (14):

$$H_{in} = \text{Total area} \cdot (1 - Pe) \cdot \text{Grad(kWh)}, \quad (14)$$

where (H<sub>in</sub>) is the heat input from solar radiation, Total area the total area of the ponds, and (Pe) the photosynthetic efficiency, the part of the radiation that is absorbed by microalgae and does not contribute to the medium heating.

The power requirement for each hydraulic pump in J s<sup>-1</sup> is dependent on the gravitational acceleration g, total lift expressed in m, flow rate in m<sup>3</sup> s<sup>-1</sup>, the density of fluid in kg (m<sup>3</sup>)<sup>-1</sup>, hydraulic (η<sub>hydr</sub>), organic (η<sub>org</sub>), and electric (η<sub>el</sub>) efficiency of the electric motor as summarized in Eq. (15):

$$\text{Power} = \frac{g \cdot \text{Tot lift} \cdot \text{Flowrate} \cdot \text{Fluid density}}{\eta_{hydr} \cdot \eta_{org} \cdot \eta_{el}}, \quad (15)$$

where Tot lift in metres is the sum of static lift and pipe head loss. Pipe head losses are calculated with the Darcy–Weisbach equation and is presented in Eq. (16):

$$hf = \frac{f \cdot L \cdot V^2}{2 \cdot g \cdot D}, \quad (16)$$

where  $hf$  is head loss due to friction expressed in (m),  $L$  is the length of the pipe (m),  $V$  is the mean velocity of the flow ( $\text{m s}^{-1}$ ),  $g$  is the acceleration of gravity ( $\text{m/s}^2$ ),  $D$  is the pipe diameter (m), and  $f$  is the friction factor. The Swamee–Jain equation is used to solve for the Darcy-Weisbach friction factor  $f$ , and is presented in Eq. (17):

$$f = \frac{0.25}{[\log_{10}(\frac{\varepsilon}{3.7 \cdot D} + \frac{5.74}{\text{Re}^{0.9}})]^2}, \quad (17)$$

where  $\varepsilon$  is the pipeline roughness (m), and  $Re$  is the Reynolds number for fluid flow in a pipe (unitless). The Reynolds number is calculated with Eq. (18):

$$\text{Re} = \frac{Q \cdot D_H}{A \cdot \nu}, \quad (18)$$

where  $Q$  is the volumetric flowrate ( $\text{m}^3 \text{s}^{-1}$ ),  $D_H$  is the hydraulic diameter of the pipe (m),  $A$  is the pipe cross sectional area ( $\text{m}^2$ ), and  $\nu$  is the water kinematic viscosity in ( $\text{m}^2 \text{s}^{-1}$ ). The mean velocity of the flow in ( $\text{m s}^{-1}$ ) is expressed in Eq. (19):

$$V = \frac{Q}{A}, \quad (19)$$

where  $A$  is the pipe cross sectional area ( $\text{m}^2$ ), and  $Q$  is the volumetric flow rate ( $\text{m}^3 \text{s}^{-1}$ ). The cross-sectional area of a circular pipe is expressed in Eq. (20):

$$A = \pi \cdot \left(\frac{D}{2}\right)^2, \quad (20)$$

where  $D$  is the diameter of the pipe (m). For each pump 2 meters of pipe with concentrated losses at the inlet and outlet are considered. Each pump has a daily working time of 30 minutes, composed of 3 sessions of 10 minutes, each to respect the microalgae growth rate assuming an 8 hours retention period. Flowrate is calculated scaling data related to another study. [3] According to estimate, the hydraulic pumps have a lower consumption compared, for instance, to mixing or artificial lighting.

Electricity consumption for spraying flue gas inside the pond has been taken from literature. [63] As this value is expressed in  $\text{kWh kg}^{-1}$  of flue gases. The algal biomass quantity is related to  $\text{CO}_2$  consumption [4] according to Eq. (21):

$$\text{CO}_2 \text{ flue gas} = \text{kg biomass DW realised} \cdot \frac{\text{kgCO}_2}{\text{kg biomass DW}}. \quad (21)$$

Consequently, the quantity of flue gases in kg that is sprayed into the pond to ensure the correct amount of  $\text{CO}_2$  needed for algal growth is expressed as given in Eq. (22):

$$\text{Flue gas spraying} = \frac{\text{CO}_2 \text{ from flue gas}}{\text{CO}_2 \text{ uptake eff} \cdot \% \text{CO}_2 \text{ in flue gas}}. \quad (22)$$

The actual average pond temperature is equal to set desired average temperature when the heat system is activated and equal to the air temperature when higher than the set temperature, calculated with Eq. (23):

$$\text{Actual pond temp} = \text{MAX}[T_{\text{airGH}}; \text{setTemp}], \quad (23)$$

where  $T_{\text{airGH}}$  represent the average air temperature inside the greenhouse and  $\text{setTemp}$  is the desired set pond temperature. Factor for sub-optimal pond temperature, as seen in the Temperature-Growth curve, represents the limiting growth factor for the particular microalgae species when the medium temperature is not optimal.

Biomass potential production is the quantity of biomass that SMORP pilot can theoretically produce if no culture crashes occur during the production. The monthly values are obtained with Eq. (24):

$$\text{pot biom.prod} = \text{biomass prod} \cdot \text{Total area} \cdot T_f \cdot P_f, \quad (24)$$

where  $\text{biomass prod}$  is the biomass daily production and  $P_f$  the production factor considering that the plant is not operative 365 days per year, due to holidays and festivities, and in these days the harvest stops. It is assumed that this factor limits only the algae production but not the energy consumptions.  $P_f$  value is calculated according to Eq. (25):

$$P_f = \text{days of the month} - \frac{365 - \text{total working days}}{12} \quad (25)$$

Biomass realized production represents a hypothetical actual biomass production. It is calculated multiplying the potential biomass production with the crash production factor,  $F_{\text{crash}}$ . Lost biomass by crashes is the difference between theoretical and actual production. Wasted water by crashes ( $W_{\text{wcrashes}}$ ) represents the amount of water ( $\text{m}^3 \text{ year}^{-1}$ ), which is wasted based on the number of annual crashes, considering that in each subsequent washing it is necessary to fill the tank twice to clean it from any contamination that could compromise the restart of the culture, as shown in Eq. (26):

$$W_{\text{wcrashes}} = \text{Number of crashes} \cdot \text{Tot vol} \cdot 2 \quad (26)$$

Evaporation value is taken from the heat parameters and useful for the total water calculation, represents the quantity of water ( $\text{m}^3 \text{ month}^{-1}$ ) that evaporate from the pond surface.

Biomass to centrifuge is the amount of biomass expressed in kg, extracted after the centrifugation system. Biomass losses due to centrifuge inefficiency or due to recirculation to the pond are not considered.

To calculate electricity consumption in centrifuge, the specific centrifugation consumption per  $\text{m}^3$  of water treated is multiplied by the volume of treated water (see Eq. (27)), calculated by scaling down a larger pond system [5]:

$$\text{Elec. centrif.} = \frac{\text{days}}{\text{months}} \cdot \frac{\text{day}}{1000} \cdot \frac{I_{\text{treated}}}{\text{specific consumption}} \quad (27)$$

## ANNEX B. HEAT BALANCE IN SMORP

**ANNEX C. SMORP PILOT PARAMETERS**

TABLE 2. SUMMARY OF SMORP PILOT PARAMETERS

Parameter	Unit	Value	Source
Single pond surface	m <sup>2</sup>	3.6	[6]
Single pond water depth	m	0.4	[6]
Number of ponds	number of units	3	[6]
Photosynthetic efficiency	%	1.5	[1]
Biomass concentration	kg DW/m <sup>3</sup>	0.3	[1]
Biomass daily production	g (m <sup>2</sup> day) <sup>-1</sup>	20	[7]
Digestate needed	kg/kg DW	6	[1]
Total working days	days year <sup>-1</sup>	300	Estimation
Culture crashes	crash year <sup>-1</sup>	3	Estimation
Culture downtime per crash	days	7	[1]
Production downtime per crash	days	14	[1]
Electricity for CO <sub>2</sub> spraying	kWh/kg flue gas	0.0222	[8]
Electricity for mixing	kWh/kg DW	8,9	[9]
Electricity for centrifuge	kWh/m <sup>3</sup>	8	[8]
CO <sub>2</sub> uptake efficiency	%	30	[10]
CO <sub>2</sub> required	g/g DW	1.8	[11]
% CO <sub>2</sub> in flue gas	%	7	[1]
PAR requested	μmol phot (m <sup>2</sup> s) <sup>-1</sup>	50	Estimation

**ANNEX D. LIFE CYCLE INVENTORY OF SMORP PILOT**

TABLE 1. SUMMARY OF INPUTS FOR SMORP PILOT OPERATION

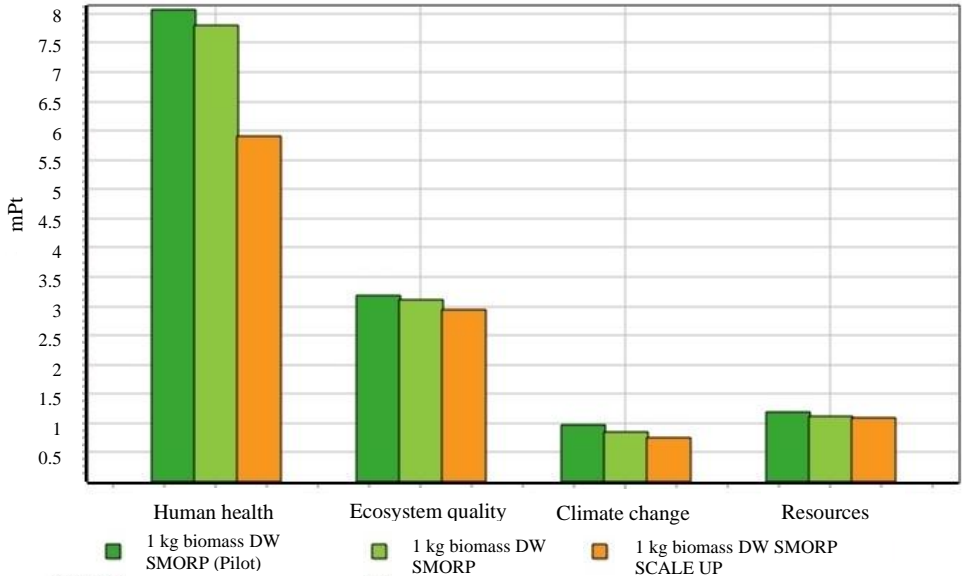

Process inputs	Value	Unit
Cultivation inputs		
Electricity for CO <sub>2</sub> spraying	2640	kWh
Electricity for mixing	28620	kWh
Heat	60455	MJ
Tap water	774	m <sup>3</sup>
Electricity for lighting	7500	kWh
Cultivation avoided products		
Carbon dioxide biogenic	1958.19	kg
Nitrogen fertiliser	29,64	kg
Harvesting inputs		
Electricity for inflow to settler	5840	kWh
Electricity for outflow to pond	5610	kWh
Electricity for centrifuge	1260	kWh
Harvesting outputs		
DW algae biomass	1025.4	kg

# ANNEX E. SMORP PILOT ENERGY CONSUMPTIONS AND BIOMASS PRODUCTION

Calculation of production	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	units	total	unit
