11 **Abstract:** Analyzing temporal and spatial variability of river discharge and the impacts of
12 large-scale climate oscillations on hydrological systems are of particular interest in Alpine
13 catchments, which have been proved to be especially sensitive to climatic drivers. The impact
14 of climate oscillation indexes may show a delayed response and therefore the correlation
15 between climatic drivers and streamflow is challenging to be properly identified. For this
16 purpose, wavelet transform (WT) is recognized as a suitable tool able to determine the crucial
17 scales of variability. In this work, first we explore the periodicities and the coherence among
18 several climatic indexes: North Atlantic Oscillation Index (NAO), Mediterranean Oscillation
19 Index (MO), Greenland Blocking Index (GB), and Artic Oscillation Index (AO). This analysis
20 shows the complementary information that different oscillation indexes provide and the need
21 to consider their impacts on streamflow simultaneously. Previous work revealed a
22 heterogeneous and complex response of the Inn river basin at long temporal scales, which
23 could not be linked to analyzed anthropogenic impacts such as dams' construction and
24 hydropower plants operation. Therefore, the trigger of changes in streamflow variability
25 remained unclear. In this study, we elaborate a classification based on all considered indexes'
26 coherence with fifty gauging stations of the Inn river catchment. We quantify similarity
27 among stations with a focus on yearly and longer temporal scales. The results highlight the
28 heterogeneous response of the streamflow towards changes in climatic indexes and give an

29 overview of the possible drivers of detected long-term alterations. NAO and GB extreme
30 phases are connected with cold winters and hot summers. We observe that from the 1980s
31 changes detected in the streamflow behavior at yearly and longer temporal scales are in line
32 with emerging patterns of the climatic indexes, such as the shift from constant to intermittent
33 periodicities of the MO index. AO coherence displays a higher complexity able to capture
34 singular hydrologic behaviors (i.e., particular hydrological regime only detected for one
35 gauging station, often connected to high altitude small basins). From the cluster analysis we
36 can also derive how mean catchment elevation and geographical location can contribute to
37 the explanation of the influence and teleconnection to the oscillation indexes, while
38 glacierized area is not identified as a dominant characteristic. Thus, this research contributes
39 to a better understanding of streamflow variability over the Eastern Alps, and the role of
40 teleconnection patterns on this variability. These relationships can be also used to improve
41 hydrological forecasting and water resources management in the Alpine region.

42 **Keywords:** Streamflow variability, wavelet analysis, climatic indexes, spatiotemporal
43 patterns, teleconnections.

44 **Highlights**

- 45 - Wavelet coherence applied for climate oscillation indexes and streamflow analysis
- 46 - Investigated periodicities proof complementarity among NAO, MO, GB and AO indexes
- 47 - Heterogeneous response of Alpine catchments towards changes in climatic indexes
- 48 - New streamflow classification method based on all considered indexes coherence
- 49 - Hydrological changes in the 1980s are detected with the proposed methodology

50 **1. Introduction**

51 Exploring streamflow variability in space and time and identifying relevant periodicities and
52 alterations, which might be associated with large-scale climate indexes, is relevant to achieve
53 a better understanding of hydrological systems (Pasquini and Depetris, 2007). Analyzing
54 long-term variability is particularly important to understand the hydrological behavior of a
55 catchment and its evolution. River discharge in Alpine catchments is very sensitive to climatic
56 drivers, though climate variability may affect specific temporal scales and streamflow time
57 series could show a delayed response to alterations (Beniston, 2006; Bocchiola, 2014; Quadrelli
58 et al., 2001; Wanders and Wada, 2015). Hence, the correlation between climatic drivers and
59 streamflow is challenging to be properly identified (Blöschl et al., 2019; Pérez Ciria and
60 Chiogna, 2020; Rottler et al., 2020). The topographic characteristics of Alpine catchments lead
61 to a more complex response of river discharge to climate change than catchments
62 characterized by low elevation gradients (Engel et al., 2019). Previous work revealed a
63 heterogeneous streamflow behavior at long temporal scales in the Inn river basin (Pérez Ciria
64 and Chiogna, 2020). However, at temporal scales larger than one year we could not link the
65 observed streamflow variability to anthropogenic impacts investigated in the region, such as
66 dams' construction and hydropower plants operation (Pérez Ciria et al., 2019). Therefore, the
67 trigger of changes in streamflow variability remained unclear. We aim at detecting the cause
68 of hydrological anomalies by looking at the lagged correlation of climate oscillations to river
69 discharge time series at targeted temporal scales.

70 At the global scale, Labat (2010) connected long-term mean-monthly flow fluctuations with
71 climate indexes, showing that the dominant climate fluctuations that impact Europe are the
72 North Atlantic Oscillation (NAO) and Arctic Oscillation (AO). Increasingly positive phases of

73 NAO index since 1980 have triggered persistent periods of high pressure over the Alps and
74 have led to an amplified impact on the pressure field (Beniston and Jungo, 2002). In fact, snow
75 cover throughout the European Alps has been decreasing during the 20th century, but
76 especially since the 1980s (Matiu et al., 2021; Stewart, 2009). Glacier retreat has an impact on
77 streamflow at long temporal scales, although basins might show a delayed response (Stahl et
78 al., 2008). Moreover, there is evidence that the AO has a wide-ranging effect over the Northern
79 Hemisphere and it is strongly coupled to surface air temperature fluctuations over the
80 Eurasian continent (Kerr, 1999; Thompson and Wallace, 1998; Thompson and Wallace, 2000).
81 Greenland Blocking (GB) episodes are connected to sea-ice losses, which have a global impact
82 (van den Broeke et al., 2016). The assessment of these events' periodicities has become
83 therefore relevant, since they are sporadic and exhibit a large natural variability (Michel et al.,
84 2021; Woollings et al., 2018). Recently, related driving mechanisms (e.g.: increased anti-
85 cyclonic conditions over Greenland, deep solar minimum) have been identified as triggers for
86 NAO, AO and GB variability (Hanna et al., 2015). Furthermore, extensive research has been
87 conducted to evaluate the influence of the MO index over southern Europe and vicinity areas
88 (Cenk and Turgay, 2019; Dünkeloh and Jacobeit, 2003; Feidas et al., 2007; Törnros, 2013),
89 where the main focus has been temperature and precipitation. Yearly correlation was found
90 between MO and wet days in the Northeast of Italy (Brunetti et al., 2002) and annual
91 precipitation of Mediterranean basins (Redolat et al., 2019). Additionally, the Mediterranean
92 Oscillation (MO) has shown to be a relevant pattern in the North of Italy and Eastern Austria
93 (Soja et al., 2013; Tsimplis and Shaw, 2008). From several studies we can infer that anomalies
94 in the MO index will influence the alpine region (Corella et al., 2016; Criado-Aldeanueva and
95 Soto-Navarro, 2013). However, in comparison with other large-scale indexes (e.g.: NAO
96 index), little effort has been done to link anomalies and periodicities with streamflow in the

97 Alps. Additional indexes, such as the Atlantic Multidecadal Oscillation or El Niño-Southern
98 Oscillation did not display however clear results in the Central Alps (Fraedrich, 1994; Ranzi
99 et al., 2021) and are defined as having a weak impact on Alpine climate (Efthymiadis et al.,
100 2007).

101 Our analysis tests therefore the hypothesis that the impacts of climatic indices are propagated
102 to the river discharge variability at yearly and longer temporal scales. Among the oscillation
103 indexes affecting the Alpine region climate, we consider in this study the North Atlantic
104 Oscillation (NAO), the Mediterranean Oscillation (MO), Greenland Blocking (GB), and the
105 Arctic Oscillation (AO). This choice is motivated by previous studies that were able to
106 correlate these indexes with hydroclimatic alterations in the Alps or surrounding regions
107 (Casty et al., 2005; Lehr et al., 2012; Marzeion and Nesje, 2012) and underlined the necessity
108 for further research (Bartolini et al., 2009; Hanna et al., 2016; Marzeion and Nesje, 2012;
109 Scherrer et al., 2004; Soja et al., 2013; Steirou et al., 2017).

110 To determine and investigate the crucial scales of variability we apply wavelet transform (WT)
111 techniques. Wavelet analysis has shown to be a very promising tool to analyze non-stationary
112 hydro-climatic time series (Marcolini et al., 2017; Sang et al., 2018; Yeditha et al., 2021; Zolezzi
113 et al., 2009). In the past decades, it has found application in a wide range of climatological
114 studies based on oscillation indexes (Das et al., 2020; Fu et al., 2012; He et al., 2021; Jevrejeva
115 et al., 2003; Massei et al., 2010; Ranzi et al., 2021) and has been applied to investigate
116 streamflow variability in selected rivers worldwide (Agarwal et al., 2016; Labat, 2008; Labat,
117 2010; Labat et al., 2004; Massei et al., 2011; Nalley et al., 2012; Nalley et al., 2016; Nalley et al.,
118 2019; Pérez Ciria et al., 2019; Rossi et al., 2009). Our work introduces an original wavelet
119 transform approach to analyze the linkages between streamflow and the teleconnection

120 patterns variability. This technique allows us to identify common patterns between discharge
121 and climatic indexes, to investigate the impact of the climatic indexes on the gauging stations
122 and their complex and heterogeneous responses at multiple temporal scales. Furthermore, we
123 are able to identify the most relevant indexes for each region and the specific temporal periods
124 in which the impact is relevant.

125 Due to the singular hydrological and climatic conditions of the Alps (Bartolini et al., 2009;
126 Schaepli et al., 2007) a specific study targeting the heterogeneous correlation of climatic
127 indexes with river discharge is crucial. Our study aims at filling this research gap for the
128 Eastern Alps, trying to identify possible triggers of streamflow alteration at long-term
129 temporal scales. The innovative contribution of this work lies in i) the development of a
130 streamflow classification procedure for long temporal scales based on coherence values with
131 individual climatic indexes ii) the possibility to better understand heterogeneous relationships
132 at specific long temporal scales for individual indexes and all climatic indexes simultaneously,
133 and iii) the attribution or link of previously detected heterogeneities in streamflow variability
134 and the detection of stations with singular behavior (i.e., particular hydrological regime only
135 detected for one gauging station, often connected to high altitude small basins). Consistent
136 coherence patterns help us understand the sensitivity of particular regions within the Eastern
137 Alps to large-scale climate related impacts.

138 **2. Study area and data**

139 **2.1. The Inn River basin and its importance for climatic studies**

140 The study domain consists of the middle and upper part of the Inn river basin (Fig. 1a),
141 selected due to its topographic complexity, data availability (including a wide range of
142 catchment size and catchment mean elevation), and relevance of the Eastern Alps in Europe.

143 Moreover, the temporal variability of streamflow time series in the catchment was already
144 investigated by Perez Ciria et al. (2019) and Perez Ciria and Chiogna (2020). The former work
145 allows us to exclude as cause of detected changes in variability the effect of dams and
146 hydropower plants construction and operation. While Perez Ciria and Chiogna (2020) offers
147 us a term of comparison for the clustering analysis performed in this study. The region has a
148 typically hydrological alpine regime, which implies humid and warm summers and autumns,
149 snow and glacier-melt in spring and relatively dry winters (Korck et al., 2012). The mean
150 annual air temperature in this area has a large variability, ranging from 2.8 °C in upper Inn
151 catchment (above 1800 m a.s.l.) to 7.9 °C in Wasserburg (period 1961 to 1990) (Auer et al.,
152 2001), where the last gauging station considered in our study is located. The mean annual
153 precipitation is 1200 mm (period 1990 to 2011) (Malagó et al., 2017; Ntegeka et al., 2013).

154 In this study, we consider daily streamflow time series (Q) from 50 gauging stations located
155 along the Inn River basin and its tributaries (Table 1, Fig. 1a). The datasets and metadata used
156 for this study were provided by the Swiss Bundesamt für Umwelt (Abteilung Hydrologie)
157 (<http://www.bafu.admin.ch>), the Austrian Bundesministerium für Nachhaltigkeit und
158 Tourismus (<http://ehyd.gv.at>), the Bavarian Hydrological Service, Bavarian Environmental
159 Agency (<http://www.gkd.bayern.de>), the Austrian Glacier Inventory (Buckel and Otto, 2018)
160 and the Swiss Glacier Inventory (Linsbauer et al., 2021). The physiographic characteristics and
161 key features of each watershed are tabulated in Table 1. In our study only gauging stations
162 that have more than 40 years of complete consecutive records were selected, which is
163 considered as a valid length for meaningful statistical results for long-term analyses (Kahya
164 and Kalaycı, 2004; Partal, 2010). Fig. 1b shows the classification obtained from the analysis of
165 streamflow dynamics at multiple temporal scales from which the present study emerged.

166 **Figure 1**

167

168 **Table 1.** Characteristics of the selected watersheds of the Inn catchment (gauging station id, gauging
 169 station name, river name, latitude, longitude, catchment area, percentage of glacierized area, mean
 170 elevation of the catchment, and analyzed period, which is constraint by the length of both streamflow
 171 time series and selected climate oscillation indexes time series).

173

174 2.2. Climate index data

175 In this study we will focus on the impact of NAO, MO, GB and AO indexes.

176 The North Atlantic Oscillation (NAO) is a prominent pattern of climate variability defined as
 177 the difference of atmospheric pressure at sea level between two regions, one typically located
 178 near Iceland (sub-polar low) and the other over the Azores (subtropical high). The high
 179 latitudes of the North Atlantic Ocean near Greenland and Iceland generally experience lower
 180 air pressure than surrounding regions. Whereas in the south, air pressure over the central
 181 North Atlantic Ocean is generally higher than surrounding regions (Dahlman, 2009). The
 182 NAO index data was taken from the website of the NOAA's Climate Prediction Center's
 183 (CPC) (<http://www.cpc.ncep.noaa.gov>).

184 The Mediterranean Oscillation (MO) Index represents the behavior of the atmosphere in the
 185 area between the western and eastern Mediterranean Sea. Changes in temperature,
 186 precipitation, streamflow and other parameters are highly related to the MO. There are
 187 different versions of the MO: i) MO.1 (Conte et al., 1989; Palutikof et al., 1996) is defined as
 188 the normalized pressure difference between Algiers (36.4°N, 3.1°E) and Cairo (30.1°N, 31.4°E);
 189 ii) the second version of the index, MO.2 (Palutikof, 2003), can be calculated from the

190 difference on sea level pressure between Gibraltar's Northern Frontier (36.1°N, 5.3°W) and
191 Lod Airport in Israel (32.0°N, 34.5°E). The MO data, both MO.1 and MO.2 time series data,
192 was taken from the website of the Climatic Research Unit of the University of East Anglia in
193 Norwich, UK (<http://www.cru.uea.ac.uk>). The analysis was conducted for both versions.
194 However, due to the similar obtained results we only show findings linked to the MO.2, which
195 displayed strongest impact on the study area.

196 The Greenland Blocking (GB) is the mean 500-hPa geopotential height over the Greenland
197 region, from 20° to 80°W and 60° to 80°N. GB occurs when there is a breaking of synoptic-
198 scale Rossby waves resulting in a quasi-stationary high pressure system that blocks circulation
199 (Barrett et al., 2020), typically resulting in a large-scale reversal of the meridional geopotential
200 height gradient (Pelly and Hoskins, 2003) and causing cold temperatures and snow over
201 Europe. The daily index is available in <https://www.esrl.noaa.gov/>.

202 The Arctic Oscillation (AO) is defined as the first Empirical Orthogonal Function (EOF) of the
203 mean sea level pressure field in the Northern Hemisphere (Ambaum et al., 2001). It is an
204 annular-like mode in the northern extratropical circulation which has an equivalent
205 barotropic structure from the surface to the lower stratosphere (Thompson and Wallace, 1998).
206 This mode exists in both hemispheres (Gong and Wang, 1999; Thompson and Wallace, 2000)
207 and it has two same-signed centers of action over the Pacific and Atlantic Ocean. Fluctuations
208 in the AO create a see-saw pattern in which atmospheric pressure at northern polar and
209 middle latitudes alternates between positive and negative phase (Gong et al., 2001). The AO
210 data was taken from the website of the NOAAs Climate Prediction Center's (CPC)
211 (<http://www.cpc.noaa.gov>).

212 **3. Methods**

213 The Continuous Wavelet Transform (CWT) and Wavelet Coherence (WTC) among the
214 indexes was conducted to have a complete understanding of the periodicities and patterns
215 that govern their behavior at long temporal scales. The WTC was computed between
216 streamflow and climate indexes time series and used to elaborate the classification based on
217 individual climate indexes and all indexes.

218 3.1. Continuous Wavelet Transform (CWT)

219 The CWT is used to determine if periodicities are present in a signal and to detect at which
220 scales and time period they are dominant. The CWT of a discrete sequence x_n , with constant
221 time spacing δt , is defined as the convolution of x_n with a scaled and translated version
222 of $\psi_0(\eta)$:

$$W_n(s) = \sum_{n'=0}^{N-1} x_{n'} \psi^* \left[\frac{(n' - n)\delta t}{s} \right] \quad (1)$$

223 where the (*) designates the complex conjugate, n is the localized time index, n' is the time
224 variable, s is the wavelet scale and N is the number of points in the time series. To resolve
225 localized signals, Morlet wavelet is chosen as the mother wavelet, since it is good for feature
226 extraction and it provides a good compromise between the time and frequency resolution
227 (Grinsted et al., 2004). Only periodicity different from red noise within 95% confidence
228 intervals estimated by Monte Carlo simulations are taken into consideration and therefore the
229 significance level of each scale is evaluated using the values outside the cone of influence
230 (COI), where the edge effects could become significant and may affect the results reliability
231 (Torrence and Compo, 1998).

232 3.2. Wavelet Coherence (WTC)

233 The wavelet coherence between two time series can be interpreted as a localized squared
 234 correlation coefficient in time-frequency space (Torrence and Webster, 1999). Coherence
 235 varies between 0 (uncorrelated) to 1 (fully correlated) and it is defined as follows (Torrence
 236 and Webster, 1999):

$$R_n^2(s) = \frac{|S[s^{-1}W_n^{XY}(s)]|^2}{S[s^{-1}|W_n^X(s)|^2] S[s^{-1}|W_n^Y(s)|^2]} \quad (2)$$

237 where S is a smoothing operator, given by $S(W) = S_{scale}\{S_{time}[W_n(s)]\}$, while S_{scale} denotes
 238 smoothing with respect to scales s and S_{time} smoothing in time.

239 Cause-effect relationships can be assessed by evaluating the wavelet phase angle that ranges
 240 between 0 and 360°. The relative phase relationship between two variables is represented by
 241 arrows. Horizontal arrows pointing to the right represent 0° phase difference (overlapping
 242 sine waves). Horizontal arrows pointing to the left reveal a 180° phase difference, which
 243 indicates counter-phase behavior. Regions of high coherence with a consistent phase
 244 relationship, which might change progressively, suggest causality between the time series
 245 (Grinsted et al., 2004; Schuler et al., 2021).

246 3.3. Clustering process and streamflow response assessment

247 From the coherence between streamflow time series and climatic oscillation indexes, we
 248 cluster the gauging stations behavior for each individual climatic index and elaborate the
 249 corresponding maps.

250 To quantitatively evaluate if two gauging stations (e.g.: gauging stations A and B) present the
 251 same patterns with an individual index, we compare coherence results by computing a metric
 252 based on the mean absolute difference (MD) for each time-frequency output.

$$MD_{index,A,B} = \frac{\sum_{x=1}^n \sum_{y=1}^m |R_{A\ x,y} - R_{B\ x,y}|}{n\ x\ m} \quad (3)$$

253 R (ranging from 0 to 1) represents the coherence value for a specific time (x) and frequency
 254 (y), m is the largest frequency considered and n is the length of the shortest between the two
 255 considered time series. We consider that two stations belong to the same cluster if MD is lower
 256 than 10%. This threshold could be dependent on the dataset. In this case, a 10% threshold
 257 empirically allows a coherent discrepancy between the different gauging stations. Thus, if the
 258 wavelet coherence results of a gauging station (e.g.: gauging station C) with a specific climatic
 259 index (e.g.: Arctic Oscillation Index) do not present MD lower than 10% with any other
 260 analyzed gauging stations, then the abovementioned gauging station (i.e.: gauging station C)
 261 is considered “not classified” for this specific index.

262 The classifications are finally merged to consider the behavior of each specific gauging station
 263 with all indexes. The merging procedure consists in overlapping the classification results
 264 obtained for individual indexes. Each specific combination (e.g., gauging stations classified
 265 as NAO1, MO1, GB1 and AO1) will be designated as a specific cluster (e.g., cluster A) of the
 266 classification based on all indexes. Only stations that are considered “not classified” for all
 267 indexes, are denominated “not classified” in the classification based on all indexes. When this
 268 is not the case, and the gauging station belongs to a specific class for at least one of the assessed
 269 indexes, then we classify it as “singular behavior”.

270 We evaluate the similarity of our classification based on all indexes with the classification
 271 based on streamflow dynamics presented in Pérez Ciria and Chiogna (2020), which was an
 272 inter-comparison of streamflow time series at multiple temporal scales. It showed the
 273 distribution of stations characterized by snow dynamics, rain-fed basins and how contrasting
 274 streamflow patterns emerged at large temporal scales, especially from the 1980s. The

275 similarity is therefore assessed by computing the Adjusted Rand Index (ARI). Given a set of
 276 n elements, and two classifications of these elements, namely $X = \{X_1, X_2, \dots, X_i\}$ and $Y = \{Y_1,$
 277 $Y_2, \dots, Y_j\}$, the overlap between X and Y can be computed as follows:

$$ARI = \frac{\sum_{ij} \binom{n_{ij}}{2} - \left[\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right] / \binom{n}{2}}{\frac{1}{2} \left[\sum_i \binom{a_i}{2} + \sum_j \binom{b_j}{2} \right] - \left[\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right] / \binom{n}{2}} \quad (4)$$

278 n_{ij} denotes the number of objects in common between the clusters. a_i and b_j denote the number
 279 of objects per cluster X_i and Y_j , respectively.

280 From this comparison we investigate the level of agreement of our results. We are able to
 281 attribute discrepancies, if present, to specific gauging stations by means of an approach based
 282 on evidence of “total agreement”, “partial agreement”, or “strong disagreement”:

- 283 - “Total agreement” implies that there is a complete overlap of the stations
- 284 - “Partial agreement (larger streamflow variability)”. This implies that there are
 285 discrepancies in hydrological behavior that cannot be linked to the coherence analysis
 286 with the selected climate indexes.
- 287 - “Partial agreement (unique hydrological behavior)”, indicates that these gauging
 288 stations belong to a specific cluster when analyzing climate indexes impacts, but
 289 showed a unique hydrological regime.
- 290 - “Partial agreement (larger climatic variability)”, in this case represents gauging
 291 stations that show a more heterogenous response while analyzing their coherence
 292 with climate indexes, but belonged to the same cluster for streamflow behavior.
- 293 - “Strong disagreement” represents stations that were classified in a completely
 294 different cluster (no overlap).

295 A step-wise description of the clustering process and streamflow response assessment is
296 provided in Fig. 2.

297 **Figure 2**

298 **4. Results**

299 **4.1. Wavelet analysis of climate oscillation indexes**

300 CWT results of the selected climate oscillation indexes are shown in Fig. 3. The ordered axis
301 presents the time in years and the analyzed periods are represented in the abscissa axis. The
302 normalized time series used for the wavelet analysis are included in Fig. S1. As we observe
303 in Fig. 3a, NAO index does not show a clear intra-annual variability and therefore we do not
304 observe a constant statistically significant pattern at the yearly scale. We detected however
305 that high-power values are present in 1990 and from 2010. The multi-year scales display
306 higher power than the yearly scale in general. We can observe high wavelet power bands
307 associated to 2-4 years and also a continuous high-power band at 8 years-scale. In Fig. 3b the
308 CWT of the Mediterranean Oscillation Index (MO) presents high power at the yearly scale,
309 which implies a very strong intra-annual variability. We observe this strong periodicity from
310 the beginning of the analyzed period. Nevertheless, this pattern seems to fade in 1980 and it
311 becomes intermittent. Thus, gauging stations that present high coherence with MO during
312 the whole analyzed period are actually characterized by an intermittent loss of the yearly
313 periodicity from the 1980s. Additionally, we observe high power bands during the analyzed
314 period at 5 years and 10 years scales. For the Greenland Blocking CWT (Fig. 3c) the strongest
315 yearly pattern is detected. No significant high-power patterns are detected however at multi-
316 year scales. From this, we are able to anticipate that the identified clusters will be mainly
317 driven by the correlation found at the yearly scale. The Arctic Oscillation Index CWT (Fig. 3d)

318 does not show a clear intra-annual variability. Similar to NAO, the multi-year scales display
319 high power. We can observe a high wavelet power bands associated to 2-4 years and 8 years-
320 scale.

321 **Figure 3**

322 WTC among considered climate indexes at long temporal scales is shown in Fig.4. We can
323 observe high coherence values in phase: at yearly scale between MO and GB (Fig. 4d), and
324 with intermittent presence at 2-4 years scale between NAO and AO (Fig.4e). High coherence
325 values in counterphase are also present: at 2-4 years scale between NAO and GB (Fig. 4c), and
326 at multiannual scales between AO and GB (Fig. 4f). Additionally, we observe low coherence
327 values or only sporadic high coherence spots: from yearly to 8 years scale between NAO and
328 MO (Fig. 4a) and between MO and AO (Fig. 4b); at yearly scale between NAO and GB (Fig.
329 4c) and also at yearly scale between AO and GB (Fig. 4f); at 2-8 years scale between MO and
330 GB (Fig. 4d); at 4-8 years scale between NAO and AO (Fig. 4e). Even if the high correlation of
331 some indexes, such as NAO and AO (Ambaum et al., 2001; Hamouda et al., 2021), is
332 confirmed by the coherence analysis, the coherence among indexes displays a variety of
333 patterns depending on the targeted temporal scale. This implies that each selected oscillation
334 index carries different information that might contribute to understand patterns of
335 hydrometeorological variables.

336 **Figure 4**

337

338 **4.2. Wavelet coherence between streamflow and climate oscillation indexes**

339 Fig. 5 shows an illustrative example of the coherence outcome considering three different
340 gauging stations and the four selected climatic indexes. Fig. S2 contains the entire analysis (50
341 coherence plots per climatic index). From the comparison of Fig. 5a (wavelet coherence

342 between NAO index and Innsbruck streamflow time series) with Fig. 5b (wavelet coherence
343 between NAO index and Kirchbichl streamflow time series), we can observe that the same
344 patterns are present during the analyzed time span. Focusing on the yearly scale, intermittent
345 patterns in phase (arrows pointing right) are present till 1980. From this year intermittent
346 patterns characterized by high coherence values are observed, but presenting a counter-phase
347 behavior (arrows pointing left). At longer temporal scales only sporadic high coherence spots
348 associated to 2 years scale are detected in 1960 and 1980. These two gauging stations present
349 resembling coherence patterns with NAO index with a mean absolute difference (MD) of
350 0.0499 (Table 2). They belong therefore to the same class, in this case NAO1-2 (see Fig.6 and
351 Table 3). Analogously, when comparing Fig. 5 left panel (Innsbruck streamflow time series)
352 with Fig. 5 middle panel (Kirchbichl streamflow time series) we observe that the coherence
353 results present identical patterns along the analyzed time span with MD lower than 10%
354 (Table 2). In particular, for the WTC with MO, both plots (Fig. 5d and Fig. 5e) present high
355 coherence at the yearly scale and a pattern associated to the 4-8 years scale emerges in the
356 1980s. The WTC with GB shows for Fig. 5g and Fig. 5h a very strong coherence at yearly scale,
357 which is due to the intra-annual variability characteristic of snow dominated regions. The
358 WTC with the AO index shows in both Fig. 5j and Fig. 5k that a high coherence pattern
359 associated to the 4-6 years scale stops in 1980. Thus, for the classification based on all indexes,
360 we conclude that Innsbruck and Kirchbichl belong both to class D (see Table 3 and Fig. 7).
361 The comparison of Fig. 5 left panel (Innsbruck streamflow time series) and Fig.5 right panel
362 (Anger streamflow time series) illustrates contrasting results with MD values larger than 20%
363 (Table 2), exceeding the established threshold of 10%. Fig. 5f does not show a constant yearly
364 periodicity as it is observed in Fig. 5d (and Fig. 5e), but only intermittent high coherence
365 patterns. Additionally, the in-phase pattern observed at the 4-8 years scale from the 1980s in

366 Fig. 5d (and Fig. 5e) is not present in Fig. 5f. Thus, the gauging station located in Anger
367 belongs to a different class (class K based on all indexes) (see Table 3 and Fig. 7).

368 **Figure 5**

369

370 **Table 2.** Mean absolute difference (MD) among coherence results shown in Fig. 5.

Climate oscillation index	Innsbruck - Kirchbichl	Innsbruck - Anger	Anger - Kirchbichl
NAO	0.0499	0.2102	0.1987
MO	0.0522	0.2482	0.2367
GB	0.0518	0.2805	0.2648
AO	0.0535	0.2065	0.1861

371

372 **4.3. Classification results**

373 The classifications based on individual indexes are presented in Fig. 6 and Table 3. Fig. 6
374 contains four maps, each of them with the geographical distribution of the clusters detected
375 for the individual climatic index. In Fig. 6 stations that displayed the same coherence results
376 at yearly scale with the indicated index are represented with the same color. Additionally, if
377 those stations presented any different behavior at longer temporal scales, the different clusters
378 maintain the same color but are represented by different symbols. The sub-class at multi-
379 annual scales is represented by the sub-class number; while grey crosses represent “not
380 classified” stations (mean absolute difference values higher than 10% with all analyzed
381 stations).

382 **Figure 6**

383 We merge the obtained clusters for each individual index to obtain the classification based on
384 all indexes (Fig. 7a). The overlay of clusters highlights the heterogeneous response of the
385 catchments and the difficulty to attribute a unique trigger to a particular alteration. Fig. 7b

386 displays the level of agreement of the classification based on all indexes with the classification
387 based on streamflow dynamics at multiple temporal scales (Fig.1b).

388 Table 4 displays the matching matrix between both classifications needed for the Adjusted
389 Rand Index (ARI) computation. The 50 gauging stations are in this work the set of n elements
390 mentioned in Eq. 4 description. Each element of Table 4 (n_{ij}) denotes the number of objects in
391 common between the clusters (i.e., number of gauging stations in common). The values of the
392 last column and the last row (a_i and b_j) denote the total number of gauging stations per cluster
393 (e.g., 5 gauging stations belong to cluster A). By computing ARI (Eq. 4) we can therefore assess
394 the overlap between two classifications of these elements, namely “classification based on all
395 indexes” and “classification based on streamflow dynamics” presented in Pérez Ciria and
396 Chiogna (2020).

397 ARI for both classifications is 0.4, which shows a relatively high level of agreement
398 considering the heterogeneity of the stations with singular behavior (classification based on
399 all indexes) and the not classified stations (classification based on streamflow dynamics).

400 From the comparison of the two different classification approaches we can highlight there is
401 a total agreement of the cluster for 58% of the stations. Moreover, consistent results are found
402 for 90% of the stations. This includes gauging stations that displayed total agreement and
403 partial agreement with a more homogeneous cluster distribution than the classification based
404 on streamflow dynamics.

405 Only 2% of the analyzed gauging stations show disagreement in Fig.7b. However, 40% of the
406 gauging stations show partial agreement. From the partial agreement we observe that 24% of
407 the gauging stations were classified in a different cluster when considering streamflow
408 variability, but displayed common patterns with a larger group of gauging stations in the

409 classification based on all indexes. 8 % of the gauging stations belong to a specific class based
410 on all indexes, but were identified as not classified based on streamflow dynamics. These two
411 groups highlight the presence of additional triggers as cause of the detected streamflow
412 variability (e.g.: geomorphological characteristics, surface-groundwater interaction, water
413 uses). On the other hand, 8% of the analyzed gauging stations are classified in an additional
414 cluster for the classification based on all indexes. This discrepancy is originated by the
415 classification performed while analyzing the coherence at long temporal scales with the AO
416 index. Thus, Fig. 7 points out regions of interest that deserve further study. For example,
417 stations that belong to Class B and C, which showed homogeneous behavior based on
418 streamflow dynamics but larger climatic variability or gauging stations with singular
419 behavior.

420 In the following sections we provide an in-depth assessment of the clusters detected based on
421 coherence results with each individual climatic index and we explore the reasons behind
422 changes in streamflow periodicities. Localized particular behaviors, such as isolated
423 discontinuities at yearly scale, have been verified with the information gathered in a previous
424 study. For detailed information regarding anthropogenic impacts in the case study region,
425 please see Pérez Ciria et al. (2019).

426 **Table 3.** Classification obtained from the WTC analysis of 50 gauging stations along the Inn River and
427 its tributaries according to their response to climate oscillation indexes (NAO, MO, GB, and AO
428 indexes). The gauging stations are clustered based on the observed patterns at i) the yearly scale
429 (represented by the first number that follows the climate index acronym), and ii) longer temporal
430 scales, which are only represented by a second number indicating a sub-class for gauging stations that
431 showing the same yearly patterns display a different behavior when analyzing longer temporal scales.
432 Gauging stations that presented a peculiar behavior are categorized as “not classified” (NC). The last

433 two columns include a summary of the class identified for each climate index and the class based on
 434 all indexes. Basins which were not classified for a specific index are categorized as basins with “singular
 435 behavior”.

444

445 5. Discussion

446 5.1. Classification based on individual indexes

447 5.1.1. NAO index

448 Firstly, focusing on the yearly scale, we determined an evident pattern that is present in all
 449 the analyzed stations that belong to cluster NAO1 (80% of the stations). The detected pattern
 450 consists of occasional yearly high coherence values in phase till 1980, followed by a shift to
 451 counter phase and more frequent high coherence values starting from the 1980s. NAO1 is
 452 characterized by nested catchments including all station located in the main Inn river, while
 453 NAO2 and NAO3 stations are located at tributaries of the Inn. NAO2 cluster displays medium
 454 to high coherence values from the 1980s but with a 90° phase shift. The coherence is
 455 particularly strong in the late 1980s and in 2000. The NAO3 cluster presents a different yearly

456 pattern, showing intermittent high coherence from 1965 till 1980 and a loss of coherence from
457 the 1980s with an isolated spot of high coherence in phase in 2000.

458 At longer temporal scales we observe in NAO1 high coherence in counter-phase around 1980
459 at the 2 years scale and a strong signal associated to 4-8 years scales starting from 2000. For
460 the stations within the Sanna River Basin (NAO1-1) intermittent high coherence values at the
461 2-4 years scale are spotted in the late 1980s (counter-phase), around 2000 (in phase) and from
462 2010 (counter-phase). NAO2 presents at 2-4 years scale statistically significant high coherence
463 from the late 1970s till 1990 (counter-phase). High coherence between NAO and this second
464 cluster returns at the 2-4 years scale from 2005. For NAO3 stations, which already presented
465 a strong difference in WTC behavior at the yearly scale, at multi-temporal scales we can
466 recognize medium to high coherence values within the 1980s, but with lower power, and
467 during a shorter period than the patterns observed for the cluster NAO2. Gauging stations
468 belonging to cluster NAO3 present therefore the weakest coherence signals with NAO and
469 are characterized by mean catchment elevations lower than 1000 m a.s.l. (Fig. S3). These
470 findings agree with previous studies (Beniston et al., 2018; Beniston and Jungo, 2002) that
471 reveal that at low elevations the NAO impact is rather weak or even absent in the Alpine
472 region, while higher elevation sites are sensitive to changes in NAO patterns.

473 During negative significant NAO index phases (e.g.: 1962, 1968), high coherence in phase at
474 the yearly scale is found with most of the stations within the Inn river basin. In contrast, when
475 the index is positive and high (e.g.: episodes from 1980 to 2010), we observe a 180° phase shift
476 of high coherence patterns. These findings suggest that positive and high NAO leads to a time
477 lagged impact on high altitude Alpine rivers. This is evident for the subclasses within cluster
478 NAO1, particularly after the 1980s, period when NAO starts to be significantly positive (Rossi

479 et al., 2011). On the other hand, streamflow time series display high coherence during
480 considerably negative NAO. The NAO extends its influence to the Alps when the index is
481 either significantly low or high. Mild NAO phases do not seem to have a significant impact
482 on streamflow variability.

483 When the NAO index is high, alpine climate tends to respond through lower-than-average
484 precipitation and higher-than-average temperatures (Beniston, 2006; Beniston and Jungo,
485 2002). This could be linked to a decrease in streamflow associated to the anti-correlated high
486 coherence episodes at yearly scale. The opposite climate behavior is found for negative NAO
487 phases (Casty et al., 2005). In the European Alps, relationships between the NAO and hydro-
488 meteorological variables (e.g.: glacier surface mass balance) have proved to be not stable over
489 time and not always significant (Marzeion and Nesje, 2012; Vincent et al., 2017). This is
490 because the Alps can be considered a pivotal zone between southern and northern Europe,
491 where the correlations between the NAO index and temperature or precipitation tend to be
492 typically strong (i.e., in the Mediterranean zone and in Scandinavia) (Beniston et al., 2018).
493 From this analysis we can highlight that due to the Alpine region location, between the main
494 poles of enhanced NAO-relationships (Hurrell and Van Loon, 1997; Quadrelli et al., 2001;
495 Schmidli et al., 2002), impacts on streamflow although generally present are complex and
496 present intermittent patterns. Thus, we can conclude that the heterogeneous catchment
497 dynamic observed cannot be attributed to the influence of NAO only.

498 **5.1.2.MO index**

499 In this case, different behavior is found at the yearly scale, which leads to four clusters (MO
500 1- MO 4). Firstly, we identify a large cluster (MO1-1) with 64% of the stations (Table 3). At the
501 yearly scale it presents very high, in-phase, and continuous coherence values during the

502 whole analyzed period. At multi-annual scales we found repeatedly a significant high-
503 coherence pattern from 1970 to 1980 associated to the 2-4 years scale. At 4-8 years scale a
504 pattern showing very high coherence values from around 1980 till the 1990s is detected. This
505 pattern is prolonged in some cases with medium to high coherence values till the end of the
506 analyzed period. We detected a particular case of two gauging stations (MOI1-2), that
507 presented high coherence at yearly scale, but no coherence at larger scales. These two
508 locations present a unique streamflow behavior.

509 At the yearly scale stations belonging to MO2 shift in the 1980s from continuous high
510 coherence to no coherence with only sporadic high coherence spots. Stations belonging to
511 cluster MO3 do not present continuous high coherence at yearly scale, but rather an
512 intermittent pattern that vanishes from the 1980s. From this intermittency and no coherence
513 patterns we can derive that MO cease its influence in the Northern region of the basin. Even
514 a weaker yearly pattern can be recognized for MO4. In a similar manner, the yearly coherence
515 recurs for MO2 and MO3 clusters in 2005, but the absence of coherence persists for MO4. At
516 longer temporal scales MO2-MO4 stations behave similarly till the 1980s. In fact, significant
517 high coherence at 4-8 years scale is present from the 1970s in all stations. The extension in
518 time of this pattern varies however depending on the cluster. For MO2 and MO3 this pattern
519 is prolonged till mid-1990s with less power till the present, while for MO4 this pattern is
520 shorter and vanishes already in the early 1980s.

521 By applying continuous wavelet analysis, we analyzed the periodicities that characterize the
522 MO and we observed a discontinuity from the 1980s at the yearly scale. The high-power
523 pattern associated to the yearly scale is interrupted and Fig. 3 shows intermittent high power
524 from the 1980s onwards. The fact that WTC shows a complete coherence at the yearly scale

525 means that these specific gauging stations (classified in MO1) are following a similar
526 alteration in the periodicity. MO positive phase produces a sea level pressure anomaly field
527 that is associated to dry periods in the central Mediterranean region, whereas the negative
528 phase is linked to intense cyclogenesis over the central Mediterranean that produces wet
529 conditions (Criado-Aldeanueva and Soto-Navarro, 2013). On the other hand, the stations that
530 lose this strong coherence after the 1980s are seemingly not strongly influenced by MO (i.e.,
531 MO2, MO3 and MO4).

532 The annual correlations between the MO index and streamflow time series provide very high
533 values even after the detected anomaly in the 1980s. This MO index anomaly has also been
534 recognized as an influencing factor in neighboring regions (Martic-Bursac et al., 2017). This
535 points out that MO variability is a valuable tool to measure atmospheric forcing in the Alps.
536 From these insights we could conclude that MO has notable impacts on gauging stations
537 within the Eastern Alps. However, relatively little influence is found in regions located north
538 of the Bavarian Alps particularly from the 1980s.

539 **5.1.3. GB index**

540 Greenland Blocking index presents a very strong yearly periodicity, which leads to four
541 clusters (GB1- GB4, Fig. 6c). Only GB1 presents two sub-classes (GB1-1 and GB1-2). The strong
542 seasonality that characterizes alpine river basins is easily detectable with very high coherence
543 values for GB1 stations, which have a mean catchment elevation above 1250 m a.s.l. (Fig. S4).
544 Multi-temporal analysis shows diverse patterns, particularly for the cluster GB1. Stations
545 belonging to cluster GB1 present a high coherence period between 1970 and 1980 associated
546 to 4 years scale (although it extends in 1980 from the 2 years scale). Additional patterns
547 emerge at the 2-4 years scale around 1990 (in-phase), 2000 (counter-phase) and 2010 (in-phase)

548 for several gauging stations classified in GB1-1. In contrast, GB1-2 stations do not present any
549 high coherence spots at multi-temporal scales after 1980. Furthermore, we capture a new
550 pattern emerging from the mid-2000s associated to the 4 years scale. These mid-2000s (2003–
551 2006) extreme high GB episodes have been related to the recent rapid loss of sea-ice to the
552 west of Greenland (starting in 1980). A delayed response (high coherence counter-phase
553 episodes) of the streamflow can be spotted during this specific period, while positive
554 coherence is found during the late 1980s and early 1990s and from 2010. These findings are
555 consistent with observed extreme negative GB events (Hanna et al., 2016). Recently, links
556 between NAO and GB have been investigated (Hanna et al., 2015; Hanna et al., 2018). GB has
557 reached a minimum during the 1980s and 1990s and therefore the eastward shift of the NAO
558 during this period has been related to the GB variability (Davini et al., 2012). This implies that
559 although the information provided by the indexes is complementary, the indexes' patterns
560 might be interlinked for specific anomalies.

561 At the yearly scale, discontinuities from the 1980s are present for several catchments located
562 within the lower Inn river basin (gauging stations belonging to GB2) with mean elevation
563 between 1000 and 1250 m a.s.l. This change in behavior is evolving from a continuous high
564 coherence at yearly scale to an intermittent presence of both high coherence and very low
565 coherence values. This finding alone highlights the evolution of the seasonality in basins with
566 the lowest mean catchment elevation and serves as indicative of the current climatic trend
567 (i.e., global warming that might affect specific river basins by changing their seasonality
568 periodicities from patterns linked to snow dominated catchments to hydrological behavior
569 associated to rain dominated basins or a combination of both).

570 **5.1.4. AO index**

571 Fig. 6d presents the spatial distribution of the clusters obtained from the WTC results between
572 streamflow time series and the Arctic Oscillation index. The AO CWT (Fig. 3d) shows that
573 AO is not characterized by a strong yearly periodicity, but it rather presents high wavelet
574 power bands at larger scales (from 2 years to 8 years scales). Thus, the clusters present several
575 subclasses, which means that several gauging stations behave similarly at the yearly scale,
576 but their coherence patterns with AO differ at longer temporal scales. We detected three
577 groups that present contrasting behaviors at yearly scale (AO1, AO2 and AO3), but additional
578 sub-classes were found for AO1 (AO1-1 to AO1-5) and AO2 (AO2-1, AO2-2) that account for
579 the larger scale variability in the coherence results.

580 At the yearly scale cluster AO1 is characterized by in phase intermittent significant high
581 coherence till 1970 and sporadic high coherence values after 1980. AO2 intermittent
582 significant high coherence is present till 1980 and it is followed by a complete loss of
583 coherence. AO3 displays similar patterns till 1980, but differs from AO2, since a counter-phase
584 significant high coherence pattern associated to the 1-2 years scale occurs in 2005.

585 When we focus on larger scales the behavior seems to have a common pattern for AO1
586 (particularly AO1-1, AO 1-3, AO1-4 and AO1-5) gauging stations till 1980. High coherence is
587 present at 4 years scale that extends from 1965 to late 1970s, followed by significant high
588 coherence at 2-4 years scales around 1980. Only AO1-2 does not present high coherence at the
589 4 years scale. Indeed, cluster AO1-2 does not show any high coherence patterns at scales larger
590 than 2 years. Besides cluster AO1-2, the remaining stations belonging to AO1 only start to
591 show different coherence patterns from the 1980s. Thus, we can distinguish different
592 behaviors after 1980 linked to larger scales. After this year at large scales AO1-1 displays two
593 main patterns: counter-phase pattern associated to 2-4 years scale till 1990 and significant high

594 coherence in phase around 2000. AO1-3 and AO1-4 clusters behave similarly till 2000. What
595 characterizes AO1-3 is the reappearance of a pattern associated to 2 years scale from 2000 till
596 2010. In contrast, AO1-5 displays a high coherence pattern associated to the 4 years scale (in
597 counter-phase) from the early 1980s till the 1990s. Indeed, this pattern associated to the 4 years
598 scale seems to continue the pattern found before 1980 and is slightly migrating to even larger
599 scales.

600 At larger scales, cluster AO2 presents high coherence from 1965 to late 1970s associated to the
601 4-6 years. Linked to 2 years scale significant coherence values in counter-phase are present
602 only in an isolated point around 1990. For this cluster AO2 we can distinguish two different
603 behaviors after 1980 linked to multi-annual scales. In the case of cluster AO2-1 a segment that
604 entails from 2 to 6 years scales shows significant high coherence in counter-phase and with a
605 90° phase shift from 1980 till the 1990s. In contrast, AO2-2 shows significant coherence
606 exclusively at 4 years scale with 90° phase shift. Regions of high coherence with a consistent
607 phase relationship (e.g., 90° phase shift) imply causality between the analyzed variables
608 (Grinsted et al., 2004; Schuler et al., 2021). Finally, AO3 does not present any coherence with
609 AO after 1980 at 4 years scale. Different clusters show indeed a different coherence with
610 climatic indexes from the 1980s, which highlight the increased heterogeneity of alpine rivers
611 behavior from the 1980s. The results show that despite the correlation found between AO and
612 NAO in past studies (Ambaum et al., 2001; Hamouda et al., 2021), different patterns are
613 detected when analyzing multiple temporal scales.

614 Seven basins (Table 3) present singular behavior. These basins are representative of the
615 smallest catchments selected for this study with catchment area not larger than 300 km^2
616 (minimum catchment area 100 km^2) with 70% of these basins smaller than 140 km^2 . This

617 implies that small basins display a more complex variability that might be driven by
618 particular geographical factors. The complexity observed in the Alps for the AO coherence
619 with streamflow has been also found for other variables, such as snowmelt (Schaefer et al.,
620 2004).

621 **5.2. Classification based on all indexes and link to detected variability**

622 The complex analysis of the coherence results points out that several gauging stations display
623 different behaviors from the 1980s. Cold winters and significant amounts of snow, which led
624 to high intra-annual streamflow variability, were characteristic of the Alpine region till the
625 1980s. From this decade, several mild winters with little snow occurred and have been linked
626 to the presence of very persistent NAO high pressure periods (particularly in fall and winter)
627 (Beniston and Jungo, 2002; Hurrell and Van Loon, 1997; Marty, 2008; Terzago et al., 2022).
628 Thus, the occurrence and persistence of NAO high pressure episodes has been proved to affect
629 the streamflow variability, decreasing it during the following years. Interestingly, with the
630 CWT analysis we detected that for the MO the yearly pattern is also altered from then.
631 Consequently, stations that show high coherence values with the MO during the whole
632 analyzed time span are actually following a similar behavior at the yearly pattern. Stations
633 located in the southern region of the Inn basin, which present higher mean elevation, are
634 characterized by high coherence during the whole analyzed time span. In contrast, those
635 which cease to have a strong coherence from the 1980s might not be as influenced by this
636 climatic pattern as the abovementioned regions. This is the case for the stations located in the
637 lower Inn basin (MO3 and MO4). We could observe therefore that the MO exhibits strong
638 correlation with the gauging stations located in the southern region of the basin, closer to the
639 Mediterranean Sea.

640 Atmospheric blocking has been associated with extreme episodes, such as cold winters and
641 droughts and heat waves in summer, with a recent increase in frequency (Barrett et al., 2020).
642 Thus, periods of high GB allow us to anticipate a more extreme seasonality. GB variability
643 trends have been connected to alternating years characterized by cold winters with large
644 snow contribution and mild winters with more unpredictable precipitation patterns
645 (Ballinger et al., 2018; McLeod and Mote, 2015). This behavior is present in basins with mean
646 elevation ranging from 800 to 1000 m a.s.l. (GB3).

647 The results presented for the AO analysis are the most complex. AO is not characterized by a
648 strong yearly periodicity, but the multi-year scales coherence reveals interesting patterns. In
649 fact, a similar distribution of coherence values is detected for several stations till 1980, but
650 they start differing from this decade as has been observed with other indexes. Interestingly,
651 the AO coherence results are the ones able to capture the particularities of some gauging
652 stations that were considered as not classified based on streamflow dynamics. We observe
653 that very low coherence values are found for several gauging stations. This could imply a
654 reduced sensitivity of these gauging stations to the AO. This is particularly true for either low
655 elevation sites in the Alps or for very high altitudes.

656 Negative phases of AO have been related to higher snowfall and longer persistence of winter
657 snow cover at low-middle elevation in the Alps. On the contrary, positive phases of AO lead
658 to unfavorable conditions for solid precipitation, since they imply dry-air advection and mild
659 temperatures over Mediterranean regions (Terzago et al., 2022). Positive AO is present during
660 1979–2008 and consequently changes in the 1980s have been attributed to the interdecadal
661 strengthening of winter AO (He et al., 2017). Similar to the NAO, Bartolini et al. (2009) stated
662 that AO displays a rather weak correlation with winter alpine precipitation. However, it has

663 been proven that the influence of large scale forcing (e.g.: NAO, AO) on the Alps is not
664 uniform in space (Terzago et al., 2022). Thus, the investigation of the correlation at multiple
665 spatial scales becomes valuable and these results highlight that one single index does not
666 explain entirely the observed variability.

667 **5.3. Characterization of the clusters**

668 We analyze the mean catchment elevation (which can be used as in this case study as a proxy
669 for snow processes) and the glacier coverage for classes based on all indexes. Fig. 8 displays
670 the comparison of the characteristics of each cluster by representing the mean, maximum and
671 minimum values of glacierized area (%) and mean catchment elevation (m a.s.l.) for each class
672 based on all indexes. Figures S3-S6 show these features for clusters based on each individual
673 index. The mean catchment elevation seems to differentiate two groups: i) classes A-F (snow-
674 dominated basins and mean catchment elevation higher than 1300 m a.s.l. for all stations), ii)
675 classes G-K (rain dominated catchments with no presence of glaciers within the basins and
676 mean catchment elevation lower than 1300 m a.s.l.). In Fig. 8b, classes B and C present the
677 highest mean catchment elevation with mean values higher than 2250 m a.s.l.. For classes A,
678 E and F mean values of mean catchment elevation range from 2000 to 2250 m a.s.l.. Class D
679 however displays a lower mean catchment elevation (1900 m a.s.l.), but with a higher
680 variability within the class (from 1330 m a.s.l. to over 2100 m a.s.l.). In contrast, within group
681 ii) we observe that classes are also linked to a differentiated range of mean catchment
682 elevation: for class G the range is from 1000 to 1300 m a.s.l., for class H and I from 900 to 1000
683 m a.s.l., for J between 800 and 900 m a.s.l., and finally for class K stations present mean
684 catchment elevation lower than 550 m a.s.l.. These elevation intervals can be associated to the
685 relevance of the snow processes in the basins. Additionally, the variability at yearly and multi-
686 annual scales of singular behavior gauging stations displayed unique patterns that were

687 commonly attributed to the catchment size. The singular behavior stations are small basins
688 (<300 km²) with an elevation range between 1500 and 2400 m a.s.l..

689 These findings could be linked to previous studies that state that above the altitudinal range
690 1500–2000 m, the snowpack is much less sensitive to the shifts in large-scale forcing. The snow
691 will likely accumulate at these altitudes on any occasion that there is precipitation, and even
692 anomalous temperatures induced by high-pressure subsidence are unlikely to be sufficient to
693 initiate melting (Beniston, 1997). In contrast, small changes in temperature or pressure could
694 indeed link to alteration in the snowpack at mid altitudes close to the melting level height.
695 The altitude where falling precipitation begins to melt has been increasing with a rapid rate
696 since the 1980s and this trend has been observed not only in the Alps but globally (Prein and
697 Heymsfield, 2020).

698 **Figure 8**

699 **5. Conclusions**

700 The present study has investigated the impact of selected oscillation indexes on streamflow
701 of representative sites of the Inn river catchment, with an additional focus on the overlap of
702 these impacts to explore streamflow variability changes detected from the 1980s. We
703 investigate the interplay of selected climate indexes and how they present heterogeneous
704 coherence patterns with the analyzed gauging stations. This study has confirmed the
705 complexity in the long-term streamflow variability of the Alps and the existence of long-term
706 cycles in streamflow behavior that are partly governed by shifts in large-scale climate indexes.
707 We observe that a shift from constant to intermittent periodicities of the MO index from the
708 1980s can be associated to changes detected in the streamflow behavior. NAO and GB extreme

709 phases are connected with cold winters and hot summers, while AO results are able to capture
710 singular hydrologic behaviors. The obtained classifications have been compared with
711 previous studies (Bartolini et al., 2009; Schaepli et al., 2007; Pérez Ciria et al., 2019; Pérez Ciria
712 and Chiogna, 2020) and we can conclude that the presented methodology gives us a quite
713 accurate representation of the heterogeneous response of streamflow in Alpine catchments.

714 The Alps can be considered a pivotal zone between southern and northern Europe and the
715 mountain range represents a transition between Mediterranean and continental domains.
716 Therefore, within a few kilometers we pass from sub-Mediterranean to glacial and
717 continental-dry climates. Moreover, several factors contribute to create different
718 microclimates, which might be more important than large scale factors. The mountainous
719 complex topography and shading effects are additional factors that have weight on the
720 catchment hydrological behavior and consequently are reflected on the streamflow time series
721 analysis. From the cluster analysis we can therefore derive how mean catchment elevation
722 and geographical location can contribute to the explanation of the influence and
723 teleconnection to the oscillation indexes, while glacierized area is not identified as a dominant
724 characteristic.

725 Following the suggested multi-temporal analysis by applying wavelet techniques, we
726 observed the existence of strong links between the temporal development of streamflow
727 variability in the Eastern Alps and specific atmospheric modes of variability. The novel
728 suggested method quantifies the similarity of climate indexes impacts on streamflow in the
729 time-frequency space. The clustering process is highly useful to better understand the
730 streamflow dynamics and to detect any recent changes in variability at specific temporal
731 scales. The approach could be applied to assess the effects and interplay of other

732 hydrometeorological variables. Moreover, the presented findings confirm that a fraction of
733 the observed shifts can be attributed to decadal-scale atmospheric circulation changes. We
734 reached a better understanding of the impacts and interplay of several climate oscillation
735 indexes on the Eastern Alps and the resultant heterogeneity of streamflow variability. This
736 work could be used to provide a first order prediction of the evolution of water resources in
737 the Alpine region considering climate scenarios of atmospheric circulation and sea surface
738 temperature conditions, along the line of recent global research in this direction (Feng et al.,
739 2020; Ham et al., 2019; Maher et al., 2021).

Figure captions

Fig. 1. a) Overview of the study domain showing the elevation and location of the selected streamflow gauging stations along the Inn River and its tributaries (identified by gauging station IDs described in Table 1); b) Inn river basin with the classification of the gauging stations based on streamflow dynamics after Pérez Ciria and Chiogna (2020). Plot b shows the classes considering the different streamflow behaviors detected at multiple temporal scales. Each cluster represents stations with correlation coefficient higher than 0.85 for all analyzed temporal scales.

Fig. 2. Methodological flowchart of the wavelet analysis, clustering process to obtain the classification based on each individual index, based on all indexes and comparison with catchment classification based on streamflow dynamics of the Inn River basin.

Fig. 3. Continuous Wavelet Transform (CWT) of a) NAO, b) MO, c) GB, and d) AO indexes time series. The x axis displays the analyzed time span (years) and the y axis the different investigated periods (temporal scales). The shadowed area indicates regions inside the COI, where edge effects can occur. Colors range from red (high wavelet power associated to periodicities in the signal) to blue (low wavelet power). The black contour lines indicate 95% confidence level.

Fig. 4. Wavelet Transform Coherence among considered climate indexes (NAO, MO, GB, and AO). The focus is on long temporal scales (i.e. yearly, 2–8 years scales). The x axis displays the analyzed time span (years) and the y axis the different investigated periods (temporal scales). The color of the plot ranges from blue, which means no coherence between the variables (value equal to 0), to red, which means total coherence (value equal to 1). The black contour lines indicate 95% confidence level. The relative phase relationship between variables is represented by arrows: arrows pointing right represent in-phase coherence and pointing left a counter-phase behavior.

Fig. 5. WTC between climatic indexes (NAO, MO, AO, and GB) and three different gauging stations representing different coherence results. Plots a-d) show the results of the WTC with the gauging station Innsbruck (ID 16), plots e-h) show the gauging station Kirchbichl (ID 20). These two gauging stations present very similar coherence patterns with the four climatic indexes and belong therefore to the same class. In contrast, plots i-l) show the gauging station Anger (ID 1), which belongs to a different class. The x axis displays the analyzed time span (years) and the y axis the different investigated periods (temporal scales). The focus is on long temporal scales (i.e. yearly, 2–8 years scales). The color of the plot and the arrows description is analogous to Fig. 4.

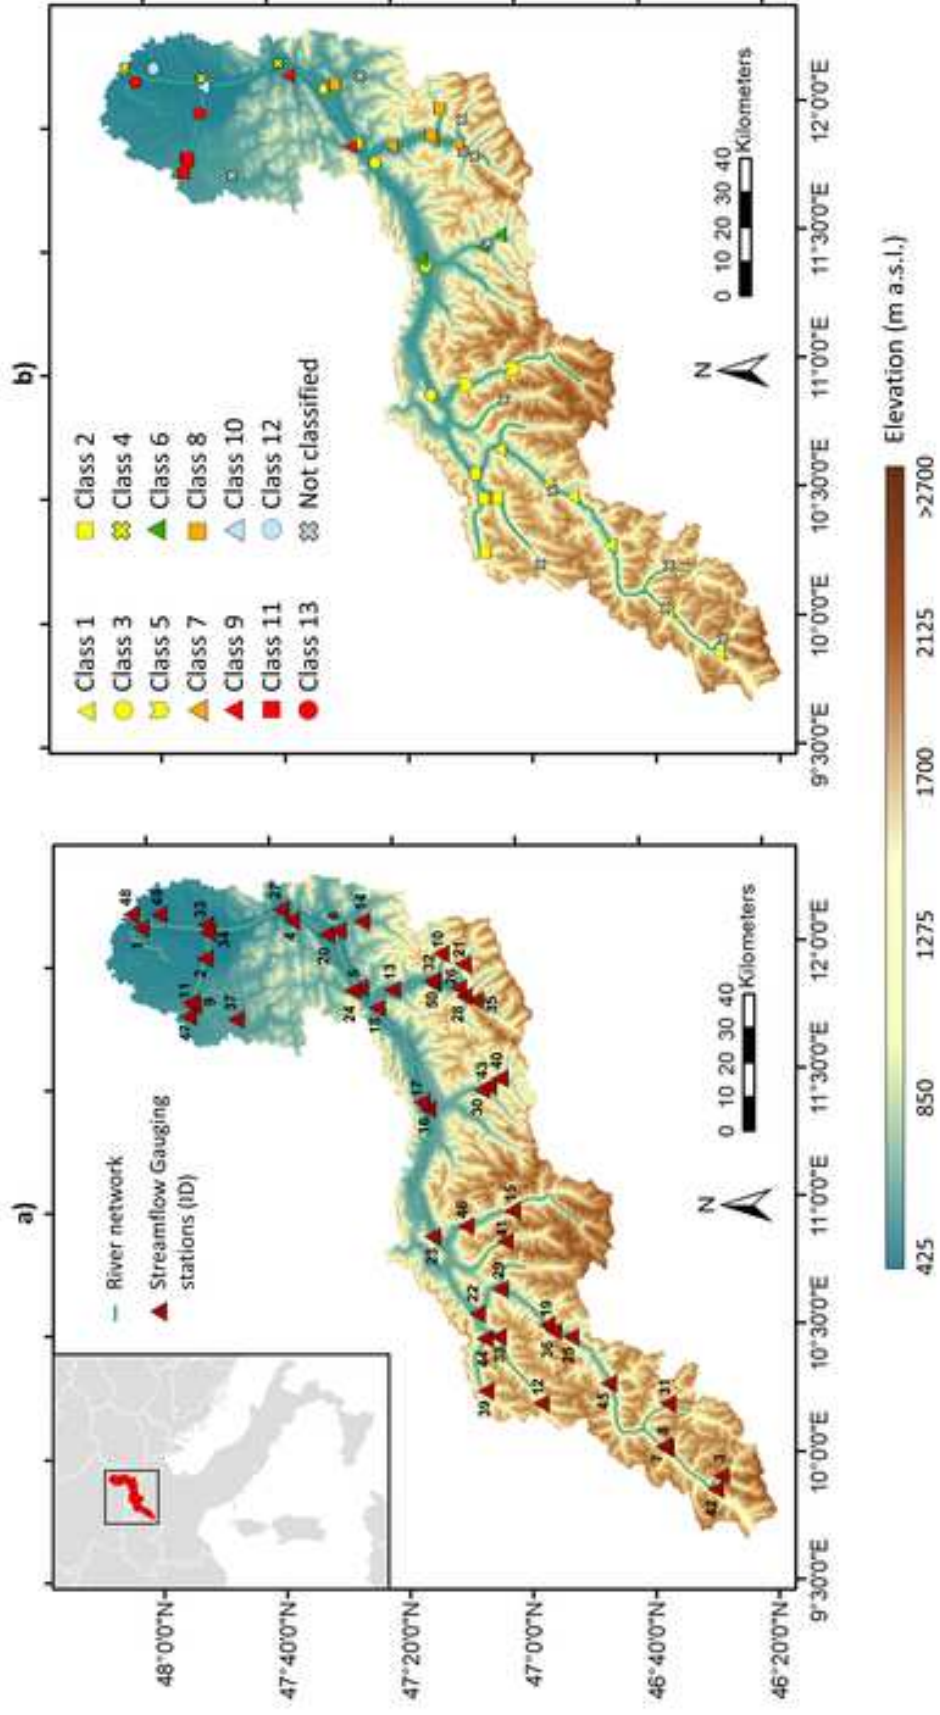

Fig. 6. Geographical distribution of the different classes obtained from the WTC analysis of 50 gauging stations along the Inn River and its tributaries with climate oscillation indexes: a) , b) MO, c) GB, and d) AO indexes. The maps show the heterogeneous response of gauging stations, which are clustered based on the observed patterns at i) the yearly scale (represented by the first number that follows the climate index acronym), and ii) longer scales (only represented by a second number indicating a sub-class for gauging station that even showing the same yearly patterns display a different behavior when analyzing longer temporal scales). Gauging stations that display a similar behavior at the yearly scale share the same symbol color (e.g.: green for NAO1). Sub-classes derived from groups of gauging station with the same patterns at yearly scale, but different behavior at longer temporal scales are represented with different symbols (e.g.: cross for NAO1-1 and triangle for NAO1-2). In addition, gauging stations categorized as having singular behavior are represented with a grey cross.

Fig. 7. Overlay of clusters showing the heterogeneous response of gauging stations of the Inn catchment to climatic indices. Plot a) presents the classification based on all indexes (classes A-K) and gauging stations with singular behavior (i.e., basins which were not classified for a specific index). The detailed explanation of the definition of each class is presented in Table 3. Plot b) displays the level of agreement (described in detail in section 3.3) between the classification based on all indexes showed in plot a) and the classification based on streamflow dynamics presented in Pérez Ciria and Chiogna (2020) (Fig. 1b).

Fig. 8. Comparison of the characteristics of each cluster by representing the mean (symbolized with a circle), maximum and minimum values (symbolized with "+") of glacierized area (%) and mean catchment elevation (m a.s.l.) for each group of gauging stations that belong to the same class for the conducted analysis with the different climate oscillation indexes (classification based on all indexes in Table 3). Please note that classes F, H and J only have one gauging station and therefore only one value is shown (symbolized with a circle as the mean for other classes). The number of gauging stations attributed to each class is shown in Table 4.
